MAINSTREAM DESKTOP and server machines increasingly require explicitly concurrent programs to achieve full performance, owing to the increasing prevalence of both single-chip multiprocessors and hardware support for multiple threads.

Currently a common way to write such programs is to program in C or C++, with the aid of a threads library, such as an implementation of the POSIX pthreads interfaces, to provide concurrency. This is also an established technique for handling multiple concurrent event streams, even on single-threaded single-processor machines.

Unfortunately, this approach has turned out not to be completely sound, primarily because reliable multithreaded execution requires certain guarantees about the language and compiler that cannot easily be provided by a library or library specification [1]. Some of the associated issues have been understood for many years. The second half of this paper briefly outlines a symptom of this issue that appears to not have been well recognized.

As a result, several of us have started an effort to address these problems by directly defining the meaning of multithreaded programs in the underlying programming language. Initially this is being done in the context of C++, building on some earlier work in the context of Java [2, 3].

There appears to be consensus that these issues should be addressed in the current ongoing revision of the C++ standard. In that context, we are addressing three somewhat separable issues:

1. Defining the meaning of existing programs in the presence of threads. Our current approach largely follows pthreads and leaves the semantics undefined if there is a data race, i.e., if a program modifies a location while another thread is accessing it. This approach appears to be the only plausible one for C and C++. However, it can only succeed if the definition of a data race is made precise enough for programmers, compiler writers, and hardware to know when data races occur and how to avoid them. Currently, it is not defined at all. Among other consequences, unexpected compiler transformations regularly break multithreaded programs (as illustrated in the example that follows).

2. Defining an atomic operations library to allow the construction of correct multithreaded programs without locks. This does not directly affect most existing application-level programs, though a significant number of them should be modified to use this library in order to ensure correctness. Such a library is necessary for development of portable core libraries and infrastructure code that increasingly use lock-free techniques to implement high-performance synchronization support. Defining an atomic operations library relies critically on the semantics of memory operations and data races.

3. Designing a threads API that meshes better with the rest of the C++ language.

We expect that the first two issues and their solutions also apply, with minor modifications, to C. And compatibility would be greatly desirable. We expect the last issue is mostly C++ specific,
though there are likely to be exceptions, such as support for thread-local storage.

As a result, we would like to encourage members of the C committee to follow our discussions and to provide input, particularly if they see aspects of our approach that would make it less palatable to the C committee, and hence lead to unnecessary divergence between C and C++.

A Simplified Example

We illustrate some of the problems addressed by this work with a simple case in which the current language specifications for C and C++ are clearly inadequate for multithreaded programs. This is only one among many possible examples. It helps demonstrate that the problems are in fact profound and must be addressed by the language specification and compilers. It also points out that the expected impact on compilers is likely to be nontrivial.

Consider the following declarations and function definition:

```c
int global_positives = 0;
typedef struct list {
  struct list *next;
  double val;
} * list;

void count_positives(list l)
{
  list p;
  register int r;
  r = global_positives;
  for (p = l; p; p = p -> next)
    if (p -> val > 0.0) ++r;
  global_positives = r;
}
```

This transformation is clearly consistent with the C language specification, which addresses only single-threaded execution. In a single-threaded environment, it is indistinguishable from the original.

The pthread specification also contains no clear prohibition against this kind of transformation. And since it is a library and not a language specification, it is not clear that it could.

However, in a multithreaded environment, the transformed version is quite different, in that it assigns to global_positives, even if the list contains only negative elements. Our original program is now broken, because the update of global_positives by thread B may be lost, as a result of thread A writing back an earlier value of global_positives. By pthread rules, a thread-unaware compiler has turned a perfectly legitimate program into one with undefined semantics.

This is a contrived example, but similar issues have been encountered in practice, and these are discussed in more detail in Boehm [1]. We hope this has served as a brief introduction to the kind of problems we are trying to address and will encourage others to follow the discussion.
