Our design principles. In this work, we explore a trade-off in the design space between the usage of dedicated and shared resources to accelerate stateful packet processing. Our observation from Sect. 2 is that any stateful packet processing should support *i)* high-speed insertions into per-flow state data

	Operations			Communication overhead (per packet)	
	Header processing	Payload store	Split & merge	NF server [bits, # pkts]	Shared server [bits, # pkts]

RIBOSOME	NF server	RDMA server	switch	pkt.header, 1	pkt.payload, 2

Table 1: Qualitative comparison among existing systems in the design space and RIBOSOME.

structures (in the order of tens of millions per second) and *ii*) more complex stateful logic (*e.g.*, batch-based processing) when deployed on a multi terabits per second switch. Our design is inspired by the following principles:

- **Offload complex logic to dedicated devices.** As ASIC switches support a limited number of flow-table updates per second and provide limited memory space, we argue that non-trivial network functions, whether for inserting high volumes of per-flow entries into the per-flow data structures or processing packets in a batch (*e.g.*, for scheduling), should be realized on dedicated general-purpose servers.
- **Process only relevant bits.** Our design targets network functions (*e.g.*, load balancers, NATs, rate limiters, packet schedulers) that do not require inspecting the entire packet, but rather just a few bytes such as a flow identifier. We therefore propose to only send the relevant bits to the dedicated general-purpose servers and store the payloads on shared servers while the headers are being processed. Splitting headers is not a new idea *per-se* (see [13, 35]), however we leverage it in such a way that the large gains materialize in practice, as shown in our evaluation section. Notice that our design also provides the possibility to disable the packet splitting for specific traffic classes. This allows the coexistence between RIBOSOME and NFs that require fully inspecting packets.
- **A programmable buffer on shared resources.** ASIC switches (including programmable ones) do not provide an interface for buffering packets in a programmatic manner. Packets are stored either while their headers are processed through the pipeline or in port queues. We argue that a network function system should be able to buffer packets in a programmatic manner, operate on batches of packets and schedule their transmission (to a certain degree of granularity, see Sect. 4). We rely on RDMA to bypass CPU and avoid wasting CPU cycles on shared machines. Note that our approach does not rule out the possibility of accessing

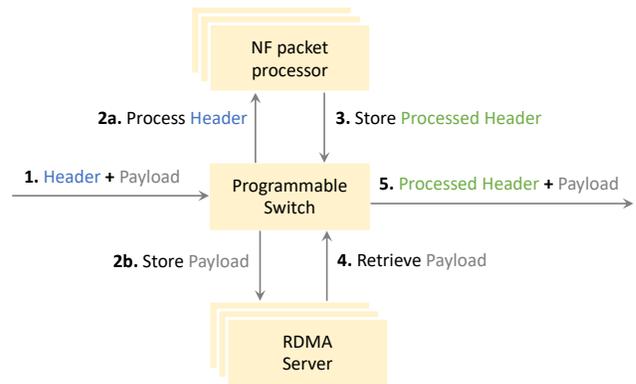

Figure 3: RIBOSOME overview.

other types of memory for storing payloads. We embrace disaggregation paradigms where the storage of payloads is performed on any shared memory resources in the network. As an example, switches could potentially support a programmable interface to store and fetch packets in an internal DRAM or HBM.

To summarize, the main benefits of RIBOSOME are that it relies on dedicated devices only for realizing the NF processing logic and delegates the storage of the payload on external RDMA servers. RIBOSOME does not use any CPU cores on these RDMA servers. It only shares memory and NIC bandwidth with applications running on these servers. The benefits of RIBOSOME come with a cost: doubling the number of packets in a network since each packet will be split into a header and a payload packet.

System overview. RIBOSOME consists of a high-speed programmable switch, a set of *dedicated* external NF packet processors (*e.g.*, CPUs, FPGAs) and a set of *shared* servers. We leverage recent advancements in high-speed ASIC programmable switches [19], CPU-bypass memory storage (*i.e.*, RDMA [17]), and NF-specific CPU compiler optimiza-

tions [10] to design a system where dedicated packet processors only process the *relevant* portions of a packet while their payloads are stored on RDMA servers. We show a diagram of the high-level RIBOSOME architecture in Fig. 3. The programmable switch receives incoming packets (step 1) and splits each packet whose size is above a predefined threshold into a small header and a larger payload chunks. The programmable switch assigns an ID to both the header and the payload chunks. The switch assigns increasing IDs to each received packet within a predefined range (in a modulo manner). The switch forwards the header of the packet to one of the external NF packet processors (step 2a) and the payload to one of the shared servers (chosen hashing the flow 5-tuple) using RDMA (step 2b). The NF packet processors store the per-flow state needed to process any incoming packets. The NF uses this state to transform each incoming header into a new *processed header*, which is sent back to the programmable switch where it is stored on its small memory using the header ID as an index into an array in the switch SRAM memory (step 3). After storing a packet header, the programmable switch retrieves the corresponding payload from the RDMA servers (step 4). The programmable switch *combines* then the payload with the stored header using the ID and outputs the transformed packet (step 5).

We now discuss the different relevant operations and components of RIBOSOME, focusing on the main design challenges and our proposed solutions.

3.1 Splitting and Merging Packets

Deciding *i)* how many bits of a packet should be sent to the NF processor, *ii)* when a packets should be split into a header and payload, and *iii)* how to store the headers before the payloads are recollected are all questions that affect the overall performance of the system.

Challenges. Splitting a packet into a header and payload bring several benefits: it reduces both bandwidth overheads and cache pollution on the dedicated resources. However, splitting a packet also comes with some overheads: when we split a packet, *i)* we need to process a higher number of packets on the switch and *ii)* we need to use the switch memory to store the headers before recombining them with their corresponding payloads. More specifically, a single incoming packet arriving at a switch requires two packet processing if the packet is not split (*i.e.*, forwarding the packet to the NF and forwarding the modified packet from the NF to the output port) whereas a packet that is split results in 4 packet processing operations (*i.e.*, forwarding the header to the NF, forwarding the payload to the RDMA server, forwarding the NF response to the RDMA server to retrieve the payload, forwarding the recombined payload on the output port). Moreover, RDMA comes with limits on the number of operations per second that it can perform, which means transmitting small payloads may overload the server NICs without bringing any meaningful

performance improvement.

Our approach. We devise a mechanism in RIBOSOME that splits a packet based on a threshold. There are two key thresholds in RIBOSOME: one threshold to specify when a packet should be split and one threshold to specify how many bits should be sent to the NF. We split packets at 72 bytes, considering the minimum Ethernet frame size of 64 bytes plus 8 bytes of additional custom RIBOSOME headers. Notice that the split threshold is configurable depending on the use case.⁹

RIBOSOME does not need to store any information on the switch when the packet has been split. Our system stores an header received from the NF on an array in the switch SRAM memory. Every time we split a packet, the switch increases the array index by one (modulo size of the array). This information is carried over in the header and the payload. When the header comes back to the NF, it is stored in the switch memory, and it also issues an RDMA Read Request to retrieve the corresponding payload.

The headers are stored until either *i)* the payload comes back to the RDMA server or *ii)* a new packet header is stored at the same array index, *i.e.*, the index pointer looped over the array size. We micro-benchmark the RDMA Read Request time (see Appendix F), finding that the maximum latency is at 4 μ s (with a 4096B payload). At 1.6 Tbps with an average packet size of 1 KB, this means we only need to store less than 800 headers in the array without risking to overwrite any header and combining it with the wrong payload. We configure the array with a size of 2K entries, which is large enough to guarantee that when the payloads come back, the header has not been replaced by a different header. By storing only 72 B of the packet header, RIBOSOME requires less than 60 KB of SRAM to store all the headers.

Our approach brings a significant advantage compared to alternative switch-based approaches like PayloadPark [13]. RIBOSOME only stores headers while retrieving payloads using RDMA, while PayloadPark must store payloads while waiting for the NF to process the headers. We observe that RDMA has more deterministic and lower response time than arbitrary NF processors. For instance, Batchy [25] reports processing times ranging from 100s of μ s to few milliseconds to process a packet even for NFs that only look at packet headers (no heavy intrusion detection systems). At 1.6 Tbps with an average packet size of 1 KB and a response time of 1 ms, PayloadPark would need to store 185 MB of payloads, almost 10 \times the available memory on a 3.2 Tbps pipe.

Avoiding RDMA memory collisions. Packet payloads are stored contiguously in the external memory and are retrieved with the information contained in custom headers, hence there is no chance that two packets close in time read the same memory chunk. RIBOSOME conceptually uses the RDMA

⁹Ideally, the switch would only extract the bits relevant for a specific NF and batch the bits extracted from different packets into a single packet that is sent to the NF. Unfortunately, creating such batches is not supported by today's ASIC switches. We leave such optimizations as future work.

memory as a circular ring buffer, with a size provisioned large enough to prevent collisions.

Exploiting spare bandwidth on the RDMA servers. RIBOSOME leverages shared servers as remote buffers and it is therefore critical to use only the spare bandwidth of the server links without affecting the hosted services. Thus, RIBOSOME includes a control-plane mechanism that monitors the link bandwidth. When a link carries above a user-configured *back-off RDMA threshold*, the system stops sending payloads to the overloaded server.

Packets-per-second overhead. As RIBOSOME split packets, it also doubles the number of packets-per-second to be processed on both the switch (where we split the packets) and across the NF and RDMA-enabled devices when compared to a traditional approach. This is an inherent cost of splitting packets that is part of the RIBOSOME architecture. Table 2 compares per-packet processing overheads on each single component of three different NF approaches: *i*) Traditional NF processing where a switch sends the entire packet to an external NF processor, *ii*) a Payload-on-Switch (PoS) approach in which the payload is entirely stored on the switch (*e.g.*, PayloadPark), and *iii*) RIBOSOME. As it can be seen, RIBOSOME has the highest overhead. We first discuss the overhead on the switch. We note that several ASIC switches today support line-rate forwarding for small packets (*e.g.*, 300-Byte packets on general switches [18]). This means that RIBOSOME would support line-rate for packets with doubled size (*e.g.*, 600-Byte packets). This seems a reasonable trade-off in RIBOSOME as splitting a packet brings substantial benefits only when the packet is large-sized. As for the dedicated NF and shared RDMA-enabled servers, the number of PPS handled by the set of all these servers is twice as in a traditional approach. More specifically, the number of PPS handled by the NF servers is equal to that of the shared RDMA-enabled servers.

	Trad.	PoS	RIBOSOME
Switch	2/2	2/2	3/4
NF Server	1/1	1/1	1/1
RDMA Server	-	-	1/1

Table 2: Number of RX/TX packets for each approach (traditional, store payload on the switch, and RIBOSOME) in each component for each processed input packet.

3.2 High-Speed Reliable RDMA

To obtain a high-speed reliable RDMA implementation from the programmable switch, RIBOSOME has to overcome two main technical challenges. To support both RDMA Write and Read operations, Queue-Pairs (QPs) (virtual queues always composed of a *send* and a *receive* queue used to manage connections) must use the Reliable Connection transport mode. In this mode, the QP sends an acknowledgement for each

packet received correctly, or a Nak in case of transmission problems. Detecting and recovering an RDMA Nak from a programmable switch is complex. For instance, receiving a *PSN Error Nak* would require transmitting the Nak-ed packet, and it is infeasible to store pending requests on the switch memory (especially RDMA Write operations that could contain a payload up to 4096 B). It is even more complex to recover from an *Invalid Request Nak*, triggered when the maximum number of outstanding RDMA Read Requests limit is reached. In fact, Infiniband specifications [42] limit the maximum number of outstanding Read Requests targeting a responder QP at any one time to a fixed amount (that is 16 with Nvidia Mellanox ConnectX-5 NICs [33]). To recover from this error, the QP state must be entirely reset.

We present a mechanism for recovering from the aforementioned failures with a minimal drop of packets in Appendix C. Moreover, we show in Sect. 5 how it is possible to handle multiple QPs, incrementing the maximum number of outstanding Read Requests, using a lower level API available within InfiniBand verbs [28].

4 Supporting Advanced Network Functions

Several common per-flow stateful operations require either batching a set of incoming packets (*e.g.*, [11, 25]), or keeping track of highly frequently arriving connections (*e.g.*, load balancers, NATs). In the following, we discuss three use cases for RIBOSOME that leverage advanced NFs whose logic would be difficult to realize on today’s ASIC switches with large amounts of flows.

Stateful Load Balancers and NATs. Stateless load balancers suffer from high load imbalance [3] while software load balancers such as Maglev [8] must rely on many servers to remember which servers are taking care of every new selection. In RIBOSOME, we support stateful load balancers by storing the per-flow state on the NF processors and sending the headers of all packets to these processors. The main challenge is to support both high-throughput with millions of connections (which may not fit in the CPU caches) and forwarding rule insertions in the order of millions per second. In RIBOSOME, we use per-core Cuckoo++ [41] hash-tables, which have demonstrated superior performance [12]. The state management is using the recent FastClick’s flow system, which finds a minimal per-flow state layout and handle state allocations and releases [2]. We support NATs similarly to load balancers.

Advanced per-packet software telemetry. Network telemetry is an indispensable component of today’s networks, for both traffic optimization and security. Traditional monitoring tools such as NetFlow [16] rely on packet sampling and aggregation to perform off-path monitoring of the traffic, where “off-path” refers to the fact that network events are not detected on the data-path. Per-packet software monitoring has been proposed in *Flow [44], which however is also off-path,

thus cannot support advanced NFs. Emerging data-plane approaches such as ElasticSketch [45] detects network events directly in the ASIC data-plane using approximate data structures. However, ASIC switches have constrained memory for storing information about all flows. Through RIBOSOME, an operator leverages the large server memory to monitor in software and *on-path* all the packets processed by other advanced network functions, including load balancers and packets schedulers, which we discuss next.

Packet Schedulers. Packet schedulers are an example of network functions that determines the rate at which a flow or a traffic class should transmit traffic on a port or a destination server. Most importantly, they only need to inspect the packet headers and *buffer* packets for a limited amount of time (*e.g.*, on RDMA servers), which fits well within the RIBOSOME design. Realizing a per-flow packet scheduler on a hardware switch is hard for a number of reasons. Switches typically offer basic packet scheduler policies that scale to few traffic classes (up to 32 in general [43]). Realizing packet schedulers at the per-flow granularity or for more than 32 traffic classes is therefore hard to realize entirely in hardware.

RIBOSOME supports packet schedulers at the per-flow granularity, for instance, it support a per-flow leaky bucket rate limiter and the advanced Reframer [11] scheduler. RIBOSOME guarantees that packets belonging to the same traffic class leave the switch in the desired order. The main challenge in building a packet scheduler on RIBOSOME is that even if the NF processor reorders packets, there is no guarantee those packets will be output in the correct order from the RDMA servers. In fact, an RDMA Queue-Pair guarantees RDMA Read Request are served sequentially but Read Requests spread over different Queue-Pairs are not. Our key intuition is to guarantee that payloads of packets belonging to the same traffic class are read from the same RDMA Queue-Pair. The maximum throughput at which RIBOSOME guarantees an ordering of packets in a traffic class is limited by the hardware throughput of an RDMA Queue-Pair.

Example with a Reframer packet scheduler. We show an example of our approach implementing the Reframer packet scheduler [11]. Reframer is a NF that buffers packets for tens of microseconds and reorders them so that packets belonging to the same flow are transmitted back-to-back. We show that this functionality can be implemented on top of RIBOSOME.

Consider Fig. 4, where the RIBOSOME switch receives 8 packets from four ports belonging to four flows called *A* (black squares), *B* (yellow squares), *C* (blue squares), and *D* (green squares). Assume flows *A* and *B* are mapped to core 1 of the NF and they should be forwarded on port 1 of the switch while flows *C* and *D* are mapped to core 2 and they will end up on port 2. The switch is connected to one RDMA server which has 2 active Queue-Pairs; hence, all the payload data will be written on the same RDMA server. We use dashed orange (green solid) arrows to denote packets moving from the switch to external entities (from external entities to the

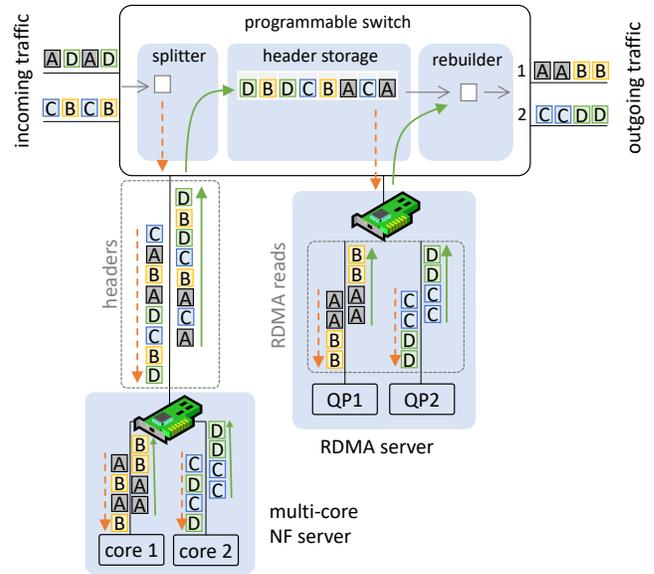

Figure 4: Supporting packet schedulers with RIBOSOME.

switch). The packets are initially split into a header that is forwarded to the NF server and a payload that is stored on the RDMA server (this RDMA Write operation is not shown in the figure). The headers will traverse the NF link in any extension of the partial order in which they arrived at the 4 ports. The switch tags headers with information about which RDMA server is used to store packets content (in this case, we have only one RDMA server and all packets have the same tag)¹⁰. On the NF side, core 1 (core 2) receives a sequence of packets $\langle B, A, B, A \rangle$ ($\langle D, C, D, C \rangle$) and reorders it into $\langle B, B, A, A \rangle$ ($\langle D, D, C, C \rangle$). To avoid Queue-Pairs overloading and to preserve packets ordering, the NF is enabled to add a new tag to packets determining the preferred Queue-Pair index for reading the content from the RDMA server. In this scenario, core 1 tags packets with QP1 and core 2 tags packets with QP2. Finally, the NIC forwards these headers back to the switch, possibly interleaving packets from the two cores. When packets arrive at the switch, the headers are stored in the order in which they are received and the corresponding RDMA Read Request are generated according to tags added by the NF cores. As a result, the RDMA server receives the Read Requests in two Queue-Pairs exactly in the order in which the corresponding NF cores have generated them. The payloads also return in the same order of the Read Requests.

5 Implementation

We implemented RIBOSOME's data plane in P4_16 language and compiled it to a Intel Tofino ASIC [19]. The server pro-

¹⁰We encode this tag in the MAC destination address which gives the flexibility to users to dispatch packets among cores based on corresponding RDMA servers if it is needed.

cess that manages RDMA connections and remote buffers is written in C++, using Infiniband Verbs [28].

Server Connection Establishment. For initializing a connection with the switch, the server agent takes as input the Infiniband interface name and the Server ID (an incremental index that starts from 0). It allocates a memory buffer enabled for remote write/read access. The process sends to the switch all the information to identify the connection using several different custom Ethernet frames (described in Appendix E).

The switch saves this information in different registers (`base_addr`, `rkey`, `mac`, and `ip`), using the Server ID as index.

After this initial setup, the process creates a user-defined number N_{qp} of Queue-Pairs. Each QP q_i ($i = 0, \dots, N_{qp}$) is created using the Reliable Connection transport mode. A unique local Queue-Pair ID L_{q_i} is assigned by the NIC. Instead of pairing q_i with a remote QP, RIBOSOME fakes the connection to a remote endpoint, avoiding the need of a second Infiniband-capable device. A fake remote Queue-Pair ID R_{q_i} is computed using the formula $R_{q_i} = i + (Server_ID * N_{qp})$. The remote and local initial PSNs are set to 0. At this point, the server sends the Queue-Pair information to the switch with a Server Queue-Pair Info frame, containing L_{q_i} and R_{q_i} . The switch stores L_{q_i} in the `qp` register at index R_{q_i} , it writes the `enabled_qp` register at index R_{q_i} , enabling the QP, and it also sets the register `psn` to 0 at the same index R_{q_i} .

RIBOSOME Headers. RIBOSOME uses two custom headers, that contain information needed to retrieve a payload and merge it with its correct headers. We provide a description of the headers and their fields in Appendix E.

Splitter. When a packet is received on a RIBOSOME enabled port, the switch checks that the length of the packet is higher than a definable threshold. If it is under the threshold, the packet is not split and sent to the NF. Otherwise, the switch applies a hash function (on a 4-tuple composed of `SrcIP`, `DstIP`, `SrcPort`, `DstPort`) to index a Match-Action Table to select the server and the index i of the QP q_i that will store the relative payload. This ensures that payloads of the same flow will be managed by the same server and QP, and avoids reordering packets belonging to the same flow. The switch reads the `enabled_qp` register: if the QP is not enabled (equal to 0), the packet is sent to the NF without splitting it. Else, the switch retrieves (using i) the server data from `mac`, `ip`, `base_addr` and `rkey` registers. The packet is then transformed into a RoCEv2 RDMA Write. The `PSN` field of the BTH header is set by reading and incrementing the register `psn` at index i . The switch also appends the Header Info, selecting an index h where the header will be stored after being processed by the NF. It also appends the exact padding bytes to align the payload to a 4-byte boundary. The packet is mirrored to the Egress pipeline, where it is truncated to the header size. The switch appends both Payload Info and Header Info, that will be used for reconstructing the packet after the NF processing.

We show a high level overview of the flow in Appendix D.

Rebuilder. When the switch receives a processed header from the NF, if it contains the Payload Split header, it means that the packet must be reconstructed, else the packet is normally routed. Before reconstructing the packet, the switch saves the processed header into several registers `hdrs` at the index h specified by the Header IDX field in Header Info. The packet is then transformed into a RoCEv2 RDMA Read Request. The switch reads the Payload Info header and retrieves the index i to read the information of the server that contains the payload (`mac`, `ip`, and `rkey` registers). The `PSN` field of the BTH header is set by reading and incrementing the register `psn` at index i . The switch fills RETH header with the Payload Address and Payload Length fields stored in Payload Info.

The RDMA Read Request is sent to the corresponding server, which answers with an RDMA Read Response containing Header Info and the payload. The switch parses the response, reads h from the Header IDX field of Header Info and uses it to load the right header from registers `hdrs`. It removes the additional padding and prepends the processed header, reconstructing the entire packet that is normally routed. The reconstructed packet is 4 bytes longer than the original one as the switch cannot remove the ICRC appended by RoCEv2.

We show a high level overview of the flow in Appendix D.

Spare Bandwidth Exploitation. To ensure that RIBOSOME uses only the spare bandwidth of the shared servers without affecting hosted services, we implement a control plane mechanism that monitors the actual usage of the links. If the per-port bandwidth usage is under a configured *back-off RDMA threshold*, RIBOSOME uses the link for storing payloads in the remote memory of the server. Instead, if the port usage is above the threshold, the switch stops using that link for payloads, preserving the bandwidth for services. In this case, RIBOSOME remaps the Match-Action Table that selects QPs and servers, equally redistributing the entries of the overloaded server among the others. When the port bandwidth usage goes below the threshold, RIBOSOME restores the original mapping of the table, re-enabling the server.

6 Evaluation

RIBOSOME is the first programmable buffer abstraction that is suitable for Tbps advanced NF packet processing. It performs stateful packet processing, carefully splitting operations between dedicated and shared resources, dedicated servers process headers and servers hosting customers' services store payloads without CPU interference. In this section, we demonstrate the performance gains achievable by RIBOSOME. All scripts, including documentation for full reproducibility, are available [39]. We aim to answer five main questions:

- “How much RIBOSOME improves the per-packet throughput and latency gain on the NF server?”
- “How does the packet size impact the throughput gains?”
- “Can we build advanced NFs on top of RIBOSOME?”
- “What are the overheads on the RDMA servers?”
- “How many ASIC resources does RIBOSOME require?”

RIBOSOME’s data plane is deployed on a 64×100 Gbps Stordis BF6064X with Intel Tofino ASIC [19]. Four of its ports are connected to a 32×100 Gbps Edgecore Wedge100BF-32X with Intel Tofino ASIC. Four commodity servers run the server agent and are equipped with Intel®Xeon®Gold 6140 CPU @ 2.30GHz and Nvidia Mellanox ConnectX-5 NICs [33]. All CPUs are set at their nominal frequency. The testbed is wired with 100Gbps links. The experimental setup is depicted in Appendix A.

Workload generation. To generate different loads, we use an additional server equipped with Intel®Xeon®Gold 6140 CPU @ 2.30GHz, and Nvidia Mellanox ConnectX-5 NICs [33], connected to the 32-port switch. The switch multicasts the incoming traffic to three ports unless stated differently. We inject both synthetic and real-world traffic traces using FastClick [1]. Another server with the same hardware runs different NFs, also implemented in FastClick. All the experiments are repeated 3 times.

6.1 Throughput and Latency Gains

RIBOSOME enables multi-100G packet processing. Fig. 5 shows the throughput of the NF (in pps) and the output throughput of the system (in Gbps) for three systems: a baseline where the NF receives the entire packet (dashed-dotted orange line), a PayloadPark-like system that removes 160 bytes of a payload when transmitting a packet to the NF server (dashed light blue line), and RIBOSOME (solid dark blue line). The average packet size is 1KB. The x-axis is the packet rate injected by the traffic generator (in Mpps). The baseline rapidly saturates the available 100 Gbps link bandwidth, consequently capping the NF throughput to this rate. The PayloadPark-like performance shows that only a limited increase in throughput can be achieved as the switch can store just a small part of the payload. RIBOSOME achieves higher throughput by sending only the headers to the NF, showing the system can keep up the processing of the 300 Gbps input traffic. We note that only ~75 Gbps of payloads can be handled by the RDMA NICs in our testbed due to RDMA overheads. Therefore, the 300 Gbps of generated traffic is limited by the 4 RDMA servers. So in order to process 1.6 Tbps of traffic, RIBOSOME would need to be connected to 22 shared RDMA-enabled servers. The gains for this simple forwarding NF could potentially be even higher by deploying more RDMA servers, which we could not do in our testbed.

RIBOSOME improves latency. While one would expect delaying packets to recover the payload through RDMA takes time, the advantage of reducing the queue sizes and the transmission rate at the NF compensates. In Fig. 6, we show the median latency (y-axis) with respect to the input rate (x-axis). Even at a medium input rate, the latency of the baseline system (which does not split packets) increases, while the latency of RIBOSOME is kept constant, achieving a $4\times$ gain. We also verified that tail latency follows a similar trend: the baseline

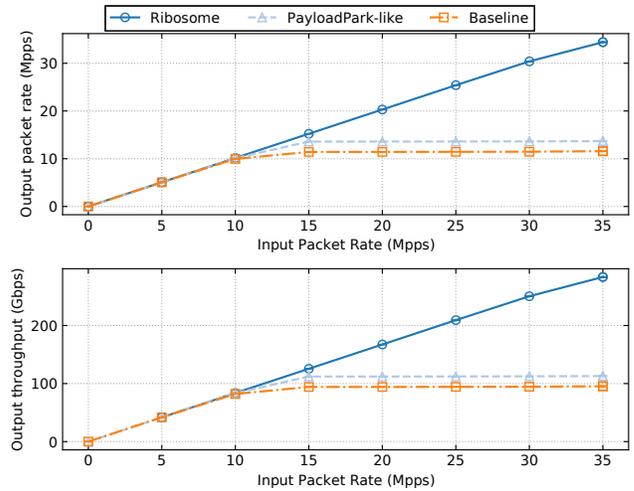

Figure 5: Bandwidth advantage of sending only headers to a forwarding NF, 1024 B packets.

reaches up to $\sim 500\mu\text{s}$ tail latency because of the queuing happening on the NF server, while Ribosome maintains a constant $\sim 60\mu\text{s}$ latency.¹¹

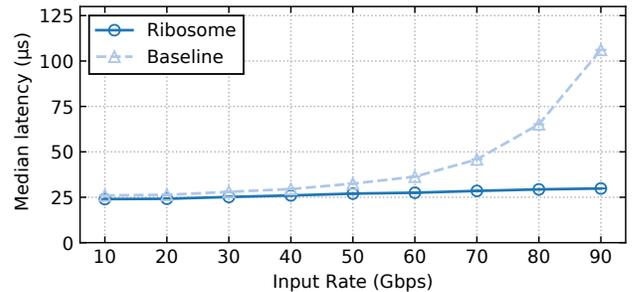

Figure 6: Median RTT latency for 1024 B packets sent by the generator to a forwarding NF under varying input rate.

RIBOSOME retains high performance regardless of the input packet size. Fig. 7 shows the output throughput (y-axis) of our baseline forwarding NF that does not split packets (dashed line) and RIBOSOME (blue line). The x-axis is the packet length in bytes. The split threshold is set to 64 bytes. Varying the packet size does not affect the overall throughput as the NF is still capable of processing 300 Gbps. Moreover, this also demonstrates that RIBOSOME is highly effective for the relevant real-world scenarios, where the average packet size ranges between 500 and 1K bytes [6]. We reach 300 Gbps of throughput already with 400 B packets (*i.e.*, 93Mpps). This graph demonstrates that the bottleneck with 1KB packets is not the CPU but rather the limited number of RDMA servers. We hypothesize that RIBOSOME could potentially operate

¹¹Fig. 11 in Appendix B shows 99th percentile tail latency.

above 600Gbps (75Mpps) with a simple NF forwarder.

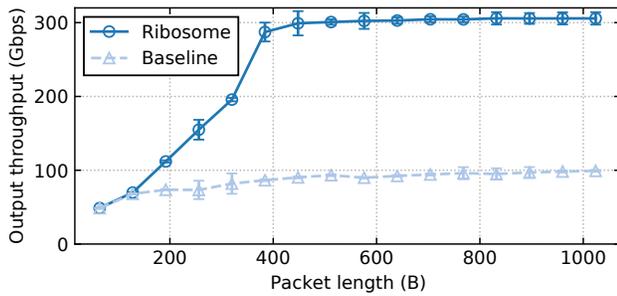

Figure 7: Bandwidth gain according to packet length.

6.2 Advanced Network Functions

We have successfully integrated and evaluated the three applications presented in Sect. 4 within RIBOSOME. Fig. 8 shows the RIBOSOME output throughput (in Gbps, y-axis) for the Reframer [11] advanced packet scheduler (blue solid line), a per-flow rate limiter (light blue dashed line), and a Layer-4 load balancer (orange dashed-dotted line). We vary the number of CPU cores used on the NF (x-axis). We replay a CAIDA trace that runs for 3.7s and contains 13.4 M flows.

RIBOSOME supports the Reframer packet scheduler at about 150 Gbps with 4 CPU cores and about 220 Gbps with 8 CPU cores (hyperthreading enabled). To put things into perspective, this level of throughput is almost $2.2\times$ higher than the one achieved in the original paper on a single server (*i.e.*, 100 Gbps) [11]. We observe that a single Queue-Pair has a throughput limitations of 2.5 Gbps. This means that currently RIBOSOME, combined with Reframer, can only guarantee packet ordering for traffic classes whose throughput is at most 2.5 Gbps. We expect such limitations to ease in future generations of RDMA.

Similarly, Fig. 8 shows the performance of the per-flow rate limiter that independently tracks the rate of each individual micro-flow going through the switch and limits them using a per-flow token bucket. The rate-limiter NF achieves close to 300 Gbps similarly to the load balancer function. Both these NFs require keeping track of individual Layer-4 connections. In both cases, the NF server handles 3 M new flows per second, whereas an ASIC switch can only support ~ 100 K flow-table entry modifications [46].

RIBOSOME preserves the order of packets. As discussed in Sect. 4, there is a possibility that packets from different Queue-Pairs got interleaved during RDMA Reads. We investigate the amount of unordered packets by measuring the average Spatial Locality Factor (SLF) of the traffic on the RIBOSOME output and comparing it with the SLF value right after Reframer instances on the NF. It is the parameter used in [11] to measure the ordering level of the traffic. We observe that using

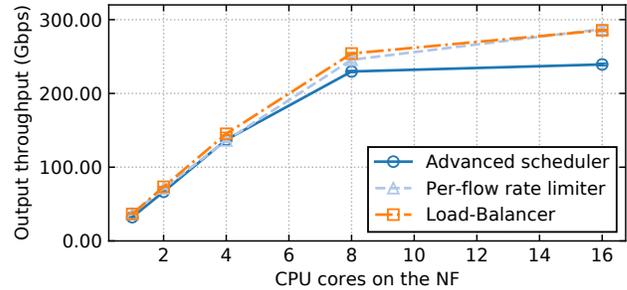

Figure 8: Throughput of three advanced Network Functions.

our trace file, the SLF value on the NF server is 1.31 while it only drops slightly to 1.29 on the output of RIBOSOME, which demonstrates its ability to primarily preserve the order of packets according to the advanced scheduler.

6.3 RDMA Interference Analysis

Storing payloads on RDMA servers may impact applications running on those servers, and specifically, their available network and memory bandwidth.

Little impact of RDMA on memory bandwidth and CPU. We generate RDMA operations that fill the NIC capacity (nearly 100 Gbps) and verify that the CPU load is 0% as RDMA traffic bypasses the CPU. We then use STREAM [30] to benchmark the CPU-to-memory bandwidth. We see that the available CPU-to-memory bandwidth decreases by $\sim 25\%$ when using 100% of the NIC for RDMA operations. Despite such bandwidth decrease, RIBOSOME leaves plenty of memory spare bandwidth on the RDMA servers.

RIBOSOME reactively releases network bandwidth resources from RDMA servers. We craft a synthetic trace where RIBOSOME does not split a specific traffic class and forwards it directly to the RDMA Server 1. This “unsplit” traffic gradually increases over time simulating an increased bandwidth demand on Server 1. We run this experiment without $3\times$ multicasting enabled and we set the back-off RDMA threshold at 40 Gbps. Fig. 9 shows the input throughput of the “unsplit” traffic (violet line) and that of the four RDMA servers. We see that the RDMA throughput on each RDMA servers is around 7 Gbps at time 15s. When the “unsplit” traffic reaches roughly 33Gbps (at time 16s), this event triggers RIBOSOME’s control mechanism, which stops sending payloads to Server 1 and redistributes the load on the other three servers. In future work, we will design an adaptive algorithm (instead of an on/off control mechanism) to share the NIC bandwidth in a fine-grained manner. This will also decrease the CPU memory controller utilization of RIBOSOME when the server is used for a network workload.

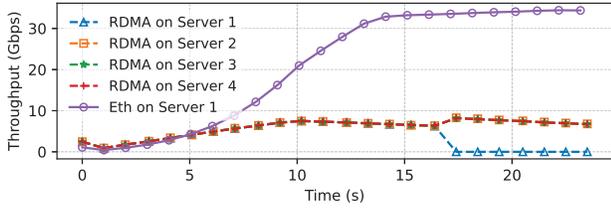

Figure 9: RIBOSOME stops sending payloads to Server 1 when it becomes overloaded.

6.4 ASIC Resource Usage

Table 3 shows the additional ASIC resources consumed by RIBOSOME based on the Tofino compiler’s output. Overall, RIBOSOME consumes a similar amount of VLIW Instructions and Match Crossbar than TEA [21] and occupies a negligible amount of TCAM. For SRAM memory usage, we allocate $1.5K \times 15 \times 4B$ register entries to store headers while fetching the payloads with RDMA, which suffice to sustain the $4\mu s$ RDMA maximum response time. Moreover, RIBOSOME also relies on several registers to store RDMA connections data, which justifies the additional memory usage.

Resource	Additional Usage
SRAM	7.84%
TCAM	1.14%
VLIW Instruction	13.82%
Exact Match Crossbar	13.92%
Ternary Match Crossbar	0.69%

Table 3: Additional ASIC resources used by RIBOSOME.

7 Discussion

How many NF-dedicated ports to achieve full-throughput on a high-speed ASIC switch? Similarly to Tiara, RIBOSOME only achieves half of the switch throughput as half of the ports store payloads. One RIBOSOME server processes up to 80 Mpps for a forwarding NF. We need to use three ports of the switch exclusively for NF processing to process the equivalent of 1.6 Tbps of 1 KB packets. With advanced NFs, we must reserve 6-7 ports on the switch whereas Tiara requires 8 ports to connect its FPGAs. Replacing our NF servers with FPGAs may lower the number of dedicated ports to our lower bound of 3 ports, which is future work.

Can RIBOSOME offload heavy-hitter entries to the switch after an insertion? Yes, this is doable (whenever the NF function is realizable on a programmable switch) and similar to what TEA or CRAB [22] do. We believe this optimization is orthogonal to our approach and we leave it as future work.

8 Related Work

We discuss related work that we have not already mentioned.

Dedicated external devices. Several systems require sending the entire packet to the NF processor [8, 15, 20, 26, 34–36, 46, 49]. Gallium [48] enables offloading a part of the NF processing on the switch, but complex processing still needs to be executed on the NFs servers. In contrast, we minimize the amount of dedicated resources needed to run complex NFs by relying on shared resources to store and retrieve payloads, thus minimizing the number of ports on the switch connected to dedicated devices. Moreover, we present a novel programmable buffer that supports packet schedulers or batch-based NFs.

RDMA on a high-speed ASIC switch. TEA [21], SwitchML [38], and Dart [24] all propose to use RDMA directly on the Intel Tofino switch. TEA (SwitchML) implements reliable (unreliable) RDMA transport. TEA code is not publicly available. Unreliable RDMA does not support RDMA Reads. Dart sketches an implementation without providing code. We implement reliable RDMA, evaluate bottlenecks, and make all our code public.

9 Conclusion

We presented RIBOSOME, a high-speed stateful packet processor that reduces the amount of dedicated NF processors by carefully sending only headers to the external NFs. We showed in our testbed that RIBOSOME scales throughput by up to a factor of $3\times$ with a single NF processor (potentially up to $10\times$ with additional RDMA servers for storing payloads). We believe that RIBOSOME aligns with the current trends towards disaggregating architecture in which resources are shared for different purposes. We leave as future work the fundamental problem of further improving the performance of CPU-based NF processors given the observed high cost of retrieving the flow state from memory (especially when it resides outside the cache). Also, we will further investigate optimizations for reducing packet-per-second overheads introduced when splitting packets.

A Experimental Setup

Fig. 10 depicts the experimental setup. The Traffic Generator is connected to the Multicast Tofino with a 100-Gbps link. The Multicast Tofino has four of its 100-Gbps ports connected to the RIBOSOME Tofino, and it multiplexes the incoming traffic from the Generator. It modifies each packet to have two additional copies with different 4-tuple values before sending them to the RIBOSOME Tofino. RIBOSOME Tofino is attached to four commodity servers running the RDMA server, and one server that implements the NF, all with 100 Gbps links. When a packet is reconstructed after the NF processing, the RIBOSOME Tofino sends it back to the Multicast Tofino. If

the packet is an original one (with no flow modifications), it is sent back to the Traffic Generator.

B RIBOSOME Tail Latency Impacts

Fig. 11 demonstrates the impact of RIBOSOME on packets 99th percentile tail latency when the NF server is running a simple forwarder.

C Recovering RDMA Queue-Pairs

We illustrate the implementation of the QP Recover mechanism discussed in Sect. 3.

For supporting both RDMA Write and Read operations, Queue-Pairs are created using the Reliable Connection transport mode. This mode expects that packets are received in the correct order, by checking their PSN. If a packet is out of order, the QP sends back a *PSN Error Nak*, requesting the retransmission. RIBOSOME’s implementation does not store RDMA Write or Read Request packets in the switch (it only keeps the current PSN). Hence, it is not able to retransmit a Nak-ed packet. Additionally, Infiniband specifications limit the maximum number of outstanding RDMA Read Requests on each QP. If there are more of such requests, the QP transits into an invalid state, sending an *Invalid Request Nak*.

To overcome these limitations, RIBOSOME exploits several QPs on each server, and it also implements a QP recovery mechanism, that allows to reset a QP in case of errors.

When the programmable switch receives a Nak, it puts the corresponding Queue-Pair q_i in a disabled state writing the `enabled_qp` register to 0. The index i to access the register is the `DestQP` field of the BTH header, that is the value $R_{q_i} = i + (Server_ID * N_{qp})$. The `enabled_qp` register is periodically checked by a control plane script, that takes all the entries with a value of 0 and, for each index j , reads register `qp` at index j . If the Queue-Pair ID is set, the switch writes another register (called `qp_to_restore`) at index j with a value 1.

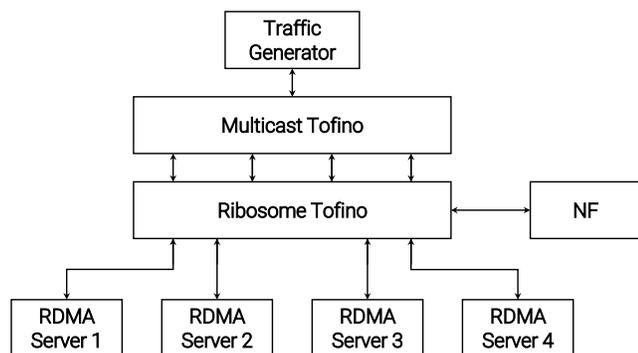

Figure 10: RIBOSOME testbed.

When receiving a packet in the Splitter component, if the Queue-Pair q_i is selected, and the value of `enabled_qp` register at index i is 0, and the value of `qp_to_restore` register at index i is 1, the packet is sent to the NF without splitting it. Also, the packet is mirrored to the Egress pipeline, and transformed into a simple Ethernet frame with `EtherType = 0x4321`, containing the index of the Queue-Pair to restore. The server agent has a raw L2 socket listening on the interface used to open the connection. When the aforementioned frame is received, the associated QP is reset and re-initialized. At this point, a Server Queue-Pair Info packet is sent to the switch, that re-enables the QP.

D Splitter and Rebuilder Components

We illustrate a high level overview of the two main RIBOSOME’s components. Fig. 12 depicts the *Splitter* component, while Fig. 13 shows the *Rebuilder* component.

E Custom Ethernet Frames and Headers

RIBOSOME leverages on several custom Ethernet frames to identify a server connection, depicted in Fig. 14.

Also, the system uses two custom headers (showed in Fig. 15), that contain information needed to retrieve a payload and merge it with its correct headers:

- Payload Info:** appended to truncated headers when the packet is split. The Marker field is used by the switch to identify the header. The Payload Address indicates the starting address of the payload in the remote RDMA buffer. The Length field is the length of the payload in the buffer. The Index is used by the switch to request the payload on the same Queue-Pair used when sending the RDMA Write request.
- Header Info:** appended to the Payload Info when the packet is split. It is also prepended to the payload before sending it to the remote buffer. The Pad Count field stores the number of bytes of the Additional Padding field to align the payload to a 4-byte boundary as per Infiniband

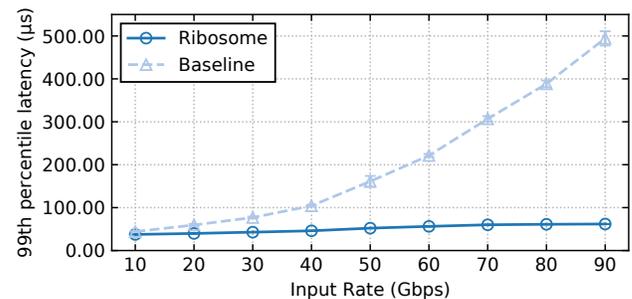

Figure 11: RIBOSOME 99th percentile latency of packets w/w/o existence of Ribosome.

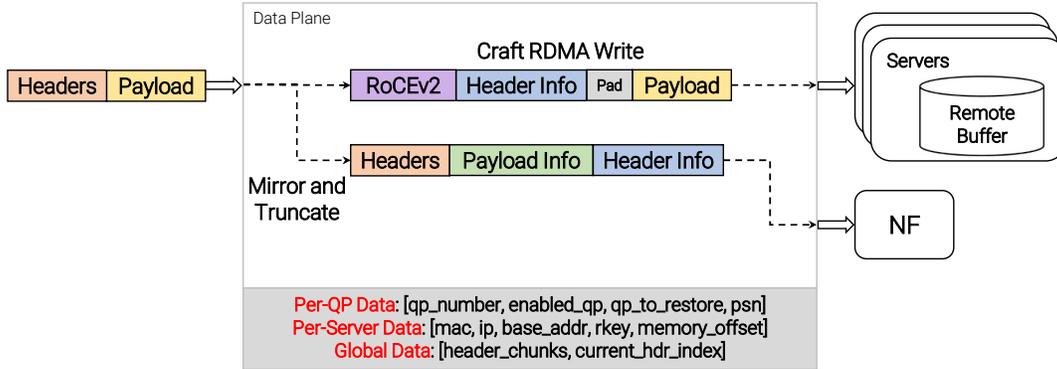

Figure 12: RIBOSOME's *Splitter* Component Overview.

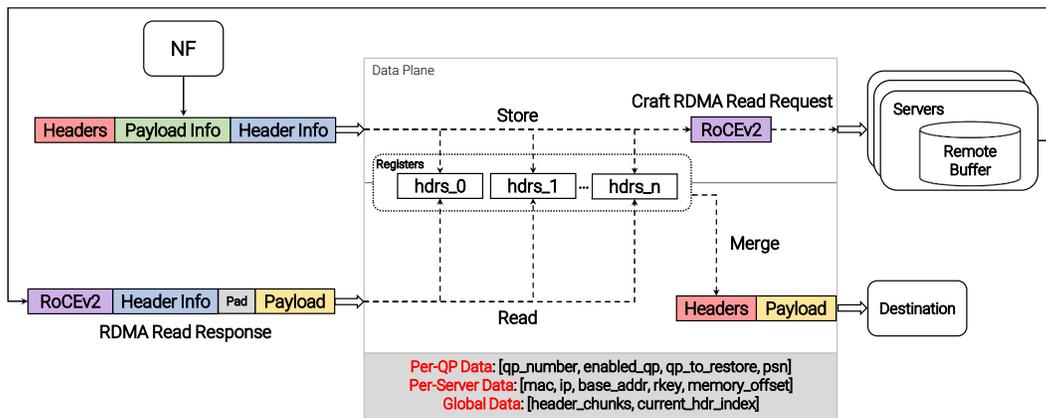

Figure 13: RIBOSOME's *Rebuilder* Component Overview.

specifications [42]. The Header IDX indicates the index of the register where the header processed by the NF is saved while the switch is fetching the payload from the remote buffer.

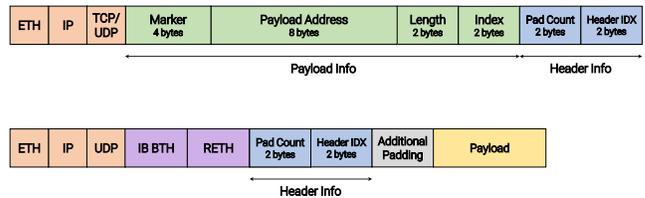

Figure 15: RIBOSOME Headers.

ExoPlane: An Operating System for On-Rack Switch Resource Augmentation

Daehyeok Kim^{†‡} Vyas Sekar[§] Srinivasan Seshan[§]
[†]Microsoft [‡]University of Texas at Austin [§]Carnegie Mellon University

Abstract

The promise of in-network computing continues to be unrealized in realistic deployments (e.g., clouds and ISPs) as serving concurrent stateful applications on a programmable switch is challenging today due to limited switch’s on-chip resources. In this paper, we argue that an on-rack switch resource augmentation architecture that augments a programmable switch with other programmable network hardware, such as smart NICs, on the same rack can be a pragmatic and incrementally scalable solution. To realize this vision, we design and implement ExoPlane, an operating system for on-rack switch resource augmentation to support multiple concurrent applications. In designing ExoPlane, we propose a practical runtime operating model and state abstraction to address challenges in managing application states correctly across multiple devices with minimal performance and resource overheads. Our evaluation with various P4 applications shows that ExoPlane can provide applications with low latency, scalable throughput, and fast failover while achieving these with small resource overheads and no or little modifications on applications.

1 Introduction

While recent efforts have demonstrated the feasibility of using programmable switches to implement network functions, such as NATs, firewalls, and load balancers (e.g., [4, 38, 46]) and to accelerate distributed systems (e.g., [43, 44, 52, 55]), there is still significant apprehension from practitioners whether in-network computing is ready for prime time. In many ways, this apprehension is justified as serving concurrent stateful applications in production-scale clouds and cellular networks is not possible today or in the foreseeable future. The fundamental issue is that due to limited on-chip resources (e.g., 10s MB of SRAM), these switches cannot keep up with the increasing number of stateful applications [33, 39] which operators want to run on a switch and the demand to handle heavier workloads in terms of traffic volume and flows [8, 26].

Instead of arguing for beefing up the switch ASICs or creating hyper-optimized applications, we explore a pragmatic alternative and make a case for *on-rack switch resource augmentation* architecture. We envision a deployment that consists of a programmable switch, other data plane devices (e.g., smart NICs [7, 11, 14, 18], and software switches running on servers [19, 56]) connected to the switch on the same rack. These external devices offer more resources to offload stateful packet processing, albeit with some performance penalty.

Perhaps more significantly, they offer a path to affordably and incrementally scale the effective capacity of a programmable network to handle future workload demands.

To effectively realize this vision of on-rack switch resource augmentation, we argue that we need an *operating system* (OS) to manage resources spread across multiple on-rack devices. To borrow from Anderson and Dahlin [21], we can draw a first-principles analogy to the three roles that any OS serves: (1) a “glue” to provide a set of common services that facilitate the sharing of resources among applications; (2) an “illusionist” to provide an abstraction of physical hardware to simplify application design; and (3) a “referee” for managing resources shared between multiple applications. While there is some recent work on mapping a single switch application to heterogeneous devices or to augment memory (e.g., [30, 40, 42, 54]), these fundamentally do not tackle multiple concurrent applications or provide these capabilities.

However, realizing such components in our context is uniquely challenging because of hardware and workload characteristics. More specifically, we observe that managing states correctly while minimizing the performance and resource overhead is difficult, especially under high packet processing speed and dynamically changing workloads. In our setting, application states can be placed, and workloads (i.e., packets) can be executed on multiple devices. Thus, state management becomes critical for application correctness (e.g., accessing incorrect state), performance (e.g., high packet processing latency due to inter-device communications), and resource overhead (e.g., additional switch resources).

In designing ExoPlane,¹ an OS for switch resource augmentation, we address these challenges as follows:

- Runtime service (the glue): To avoid frequent inter-device communications during packet processing, we propose a *packet-pinning* operating model that guarantees that a packet is processed entirely on a single device.
- State abstraction (the illusionist): To enable correct stateful processing of packets even under dynamically changing workloads, we design a *two-phase state management* that places application states correctly on different devices as the workload changes. We also design appropriate levels of consistency for different types of stateful objects that appear in applications.

¹The name denotes an external (exo-) data plane.

Applications	States
Per-tenant VPN gateway + Packet counter	Ext.-to-int. tunnel mapping and processed packet counter for each tenant.
Per-tenant NAT	Per-flow address mapping for each tenant. Per-flow address mapping for each tenant.
Per-tenant ACL + Filtered packet counter	Per-flow ACL and dropped packet counter for each tenant.
Sketch-based monitor	UnivMon [45] for remaining traffic classes.

Table 1: P4 applications deployed in a gateway switch of the data center in our motivating scenario.

- Resource allocation (the referee): To achieve performance and policy goals specified by developers and operators, we formulate and solve an optimal resource allocation problem that accommodates heterogeneity across applications and data plane device capabilities.

ExoPlane consists of two key components: the planner and runtime environment. The planner takes multiple P4 [25] applications written for a switch with no or little modifications and optimally allocates resources to each application based on inputs from a network operator and developers. It requires developers to add application-specific logic using our APIs *only if* the program contains an object that can be updated in the data plane. Then, the ExoPlane runtime environment executes workloads across the switch and external devices by correctly managing state, balancing loads across devices, and handling device failures.

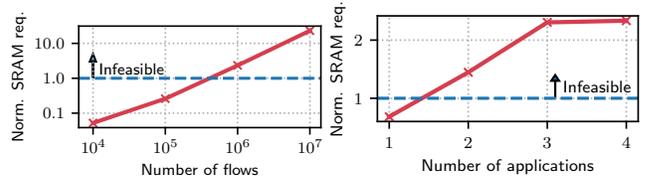

We implement the planner in C++, the data plane of the runtime environment in P4, and the control plane of the runtime environment in Python and C++. We evaluate it using various P4 programs in our testbed consisting of a Tofino-based programmable switch [9] and servers equipped with Netronome Agilio CX smart NICs [7]. Our evaluations show that ExoPlane achieves low latency (e.g., ≈ 300 ns at the switch and $5.5 \mu\text{s}$ at an external device in steady-state) and scalable throughput with more external devices (e.g., up to 394 Gbps, the maximum rate in our testbed). In case of an external device failure, ExoPlane can recover an end-to-end TCP throughput within 200 ms. ExoPlane achieves these with small control plane (a few tens MB) and switch ASIC resource overheads (less 4.5% of ASIC resources).

2 Motivation and related work

In this section, we motivate the need for supporting multiple concurrent stateful applications in the network, provide a primer on in-switch stateful applications, and discuss why prior work falls short.

2.1 Motivating example

We observe two key trends in in-network computing that increase demands on switch resources. First, the number of applications that need to run concurrently will likely in-

(a) Four applications with varying numbers of flows (log-scaled). (b) Varying number of applications with 1 million flows.

Figure 1: SRAM requirements (normalized to the total amount of SRAM on a switch) with varying workload sizes and numbers of applications. If the requirement > 1 , it is infeasible.

crease [33, 39]. Second, the per-app workload size in terms of traffic volume and the number of flows keeps growing [8, 26].

As a concrete example, suppose a cloud or cellular operator wants to deploy four applications in Table 1 on the edge router (e.g., [47, 49]) processing traffic entering/leaving the network. Each application maintains per-flow states for each tenant to enable virtual private networks (*VPN gateway*), route traffic from tenants' on-premise networks to VMs running services (*NAT*), or control access to services running on tenants' VMs (*ACL*). The *sketch-based monitor* collects statistics for the remaining traffic classes using an UnivMon sketch [45]. To see if/how these applications can coexist, we implement them in P4 or use source code from the original authors, compose them into a single P4 program using our merger (described in §6) and compile the result using the Tofino P4 compiler.

Unfortunately, we find that enabling these applications concurrently in a switch is infeasible for typical workloads, which requires the support of at least 1M concurrent flows [28, 46, 47], as shown in Fig 1. We consider two scenarios: (a) running all four applications but varying numbers of concurrent flows per application and (b) fixing the number of flows to 1M but adding applications incrementally. Here, we use SRAM requirements from each application, normalized (due to vendor NDAs) to the total amount of SRAM on a switch, which is the bottleneck resource in our scenario. In Fig 1a, we see that as the workload increases, it becomes infeasible to run all the applications. Similarly, in Fig 1b, we see that the switch can support only a single application.²

2.2 Stateful switch applications

Before we discuss why prior work cannot tackle the above problem, we provide a brief primer on *stateful* in-switch applications, where a state on the switch determines how to process packets. A typical program (p) contains one or more *stateful objects* (o_i), each of which can be represented as a P4 construct [25] such as a match-action table and a register.³ Each object contains *state data* in the form of key-value pairs ((K_{o_i}, V_{o_i})) and *actions*. For example, a register in P4 consists

²In Fig 1b, adding the 4th app does not increase the SRAM usage much because the sketch's SRAM usage is independent of the number of flows.

³While our focus of this paper is on P4, other programming languages for programmable switches such as NPL [15] provide similar constructs.

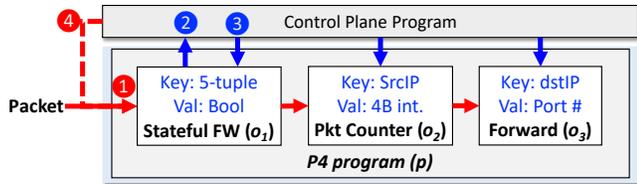

Figure 2: An abstract P4 application and runtime model. An application consists of multiple stateful objects (white boxes) and the control plane logic (blue arrows).

of a data array and actions that access the array. Fig 2 shows an example stateful P4 program (p) with three objects (o_1 – o_3). Each object requires some amount of memory (e.g., SRAM) for state data and compute resources (e.g., stateful ALUs (SALUs)) for actions. The vendor-provided compiler (e.g., Tofino P4 compiler) allocates resources to each object using proprietary heuristics; if it cannot find a feasible allocation, the compilation will fail.

Once the program is successfully compiled and loaded to a pipeline, it can process incoming packets using its stateful objects; e.g., the firewall application in Fig 2 tracks active connections and drops unwanted packets from the Internet that do not belong to active connections. At runtime, the control plane logic can access the objects in the data plane (e.g., inserting a new entry to the stateful FW object). Note that in the current switch architecture, inserting and deleting entries from a match-action table can be done only via the control plane. From the data plane, a packet only can look up an entry from the table. Registers can be read and updated by both the data and control plane. For example, in Fig 2, when a packet from an internal network comes in and if a state miss occurs at the stateful FW (1), it reports the packet to the control plane program (2) that inserts new entries for the packet (or flow) (3). Optionally, it sends the packet back to the data plane (4) so that it can be processed with the inserted entries.

2.3 Prior work and limitations

At a high level, our work is related to prior efforts in switch program composition (e.g., [32, 53, 58, 59]), recent efforts to tackle switch resource constraints (e.g., [30, 40, 54]), and prior work in the software stateful NF literature (e.g., [31, 36, 37, 50, 57]). While these efforts are valuable, they do not tackle the problem our motivating scenario poses—*multiple concurrent switch applications with demanding workloads*.

Language and framework for application composition.

Some prior works attempt to support multiple data plane programs or modules in a single device [32, 53, 58, 59]. For example, software-based virtualization approaches such as Hyper4 [32] and HyperV [58] allow composing multiple P4 programs with a constrained programming model. P4Visor [59] merges different versions of a program resource-efficiently. However, they fail to work when the amount of resources

required by the composed program exceeds the available resources in the switch.

Leveraging external resources. TEA [40] provides a virtual table abstraction for a single switch application to access remote DRAM for a large lookup table. While TEA can be extended for an application with multiple tables, it requires multiple remote memory accesses, affecting application’s performance. Flightplan [54] takes a single application written with custom annotations and disaggregates it to multiple devices. Developers need to manually partition the application so that each device runs only a particular portion of the application. Lyra [30] proposes a custom language for writing a single application split across multiple heterogeneous switches. None of these considers multiple applications.

Server-based network functions. In the context of server-based NFs, previous work augments servers’ resources by leveraging remote compute and storage resources, especially to manage NF state [31, 36, 37, 50, 57]. However, they are not directly applicable in our setting due to the workload characteristics of switch applications and hardware constraints.

3 Overview

In this section, we make a case for on-rack switch resource augmentation and discuss the challenges in realizing it.

3.1 Case for on-rack augmentation

Given the above trends and limitations of prior work, one can consider several candidate approaches; e.g., optimizing applications to reduce resource footprint or adding more resources to switch ASIC. While these are valid, they have limitations; e.g., applications, even if optimized, may have high resource usage, especially with changing workloads, and extending switch hardware is expensive.

We explore a practical alternative and envision an *on-rack switch resource augmentation* architecture consisting of a programmable switch connected to a few other programmable external devices on the same rack. For example, we can allocate 2U of rack space, where a programmable switch is located, to install a server equipped with four 100 Gbps NPU, DPU, or FPGA-based smart NICs [6, 18, 34] connected to the switch. While these NICs provide a lower packet processing rate (up to a few 100s Gbps), compared to hardware switches (a few tens Tbps), they have more resources (e.g., a few GB of DRAM vs. a few 10s MB of SRAM) to support demanding workloads. This architecture provides a practical deployment solution as it takes up limited space and does not require changes to other parts of the network.

Deployment assumptions. In this context, we assume the following deployment capabilities: (1) A switch and external devices located on the same rack are programmable with the same set of P4-16 [10] constructs (e.g., tables and registers), and we have blackbox access to vendor P4 compilers; (2) External devices have enough memory (e.g., a few GB) to

store all states for multiple applications;⁴ (3) Each application handles its own non-overlapping subset of traffic, called a traffic class, with no inter-app dependencies (i.e., a given packet is processed by only a single application). This simplifies our design for merging programs, but it is also a limitation of our current design;⁵ (4) The number of switch pipeline stages is not a bottleneck resource; and (5) Stateful objects that can be updated in the data plane, which we call data plane-updatable objects, only maintain *mergeable* statistical data (e.g., packet counter) that do not impact the control flow.

3.2 ExoPlane architecture

While the vision of on-rack switch resource augmentation is promising, to realize it in practice, we need to effectively share resources available on multiple devices across multiple applications. Drawing an analogy from traditional computing [21], ideally, we need an OS to provide an *infinite switch resource abstraction*. That is, application developers and network operators can express their programs and requirements at a higher level of abstraction without worrying about the complexities of managing and multiplexing the resources on heterogeneous devices. While some early efforts have leveraged resources on heterogeneous devices for individual in-switch applications [30, 40, 54], they do not provide the OS-like capabilities and abstractions for multiple concurrent applications.

A classical OS multiplexes multiple applications on the limited CPU/memory by choosing when, and what processes, to swap in/out. Our workload is a set of incoming packets mapped to various in-switch applications. In this setting, state management becomes especially critical to system performance and resource overheads. To see why, let us consider two seemingly natural strawman solutions:

- In an *app-pinning* model, an application is pinned to a single device by placing the entire application states only on that device, and thus a packet is entirely processed on the device without requiring additional logic. In this model, there is no additional processing latency due to inter-device rerouting and resource overhead. However, since the application can only run on that particular device, its throughput and available resources are limited.
- Alternatively, we can consider a *full-disaggregation* model where an application can run on multiple devices, and a packet also can be processed on multiple devices. Since application states can be placed on any device, it has more available resources. However, depending on the availability of the state, a packet needs to be routed between the switch and the external device multiple times. Such frequent inter-device routing increases packet processing latency and

⁴We acknowledge that not every P4-programmable device supports all the features used by a switch application. According to our conversations with vendors, they plan to add such missing features, so this is not a fundamental limitation. Nonetheless, our design adapts such devices as well by considering app-to-device compatibility.

⁵One possible approach for this is to apply offline preprocessing steps to convert overlapping subsets into an equivalent non-overlapping set [48].

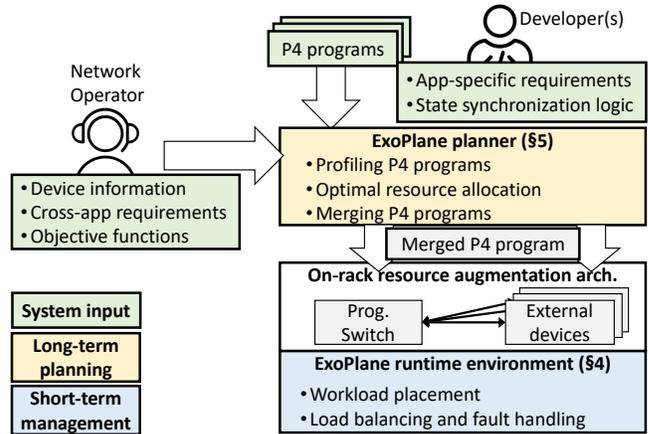

Figure 3: ExoPlane Overview: Green boxes represent inputs and yellow and blue boxes indicate key modules.

makes it unpredictable. This approach incurs high resource overhead due to per-object inter-device processing logic to route packets to a particular device and resume processing at that object on the device. Furthermore, this approach consumes significant link and device bandwidth.

Building on the above insights, we adopt a *packet-pinning* model that pins a given packet to one device (i.e., the switch or an external device) where it is processed entirely while providing flexibility in placing an application and its flows on any device. First, it can avoid frequent per-packet inter-device routing with much lower complexity. Second, our observation from real network traces shows that only a small fraction of popular flows serve the majority of traffic for a given application (e.g., 6% of flows takes more than $\approx 80\%$ of an Internet backbone traffic [20]). By placing these popular flows on the switch, we can process the majority of the packets at the switch, while the rest are processed at the external device.

ExoPlane implements the packet-pinning operating model via two key components (Fig 3):

- **The ExoPlane planner** takes inputs from developers and the network operator and allocates resources on the switch and external devices to each application.
- **The ExoPlane runtime environment** places workloads on devices, manages app states, and handles external device failures. In particular, at runtime, it tracks workload changes (i.e., new flows arrive or flow popularity changes) and updates the application’s objects at the switch and external devices according to the changes.

As illustrated in Fig 3, to run applications on ExoPlane, developers provide P4 program codes and app-specific requirements (e.g., affinity to the switch). Note that ExoPlane requires application modifications only if it contains a data plane-updatable object whose copies can exist on multiple devices. The operator provides information on devices (e.g., resource types), cross-app workload (e.g., traffic distribution), and an objective function. The ExoPlane planner profiles the

applications to determine compatibility with each device and estimated resource usage, and performance. It then computes an optimal resource allocation and generates a merged P4 program. It compiles the merged program using vendor-provided P4 compilers (e.g., Tofino compiler) and loads the binaries to the switch and external devices. At runtime, the ExoPlane runtime environment executes the workload (i.e., packets) across the switch and external devices.

3.3 Design challenges

While the packet-pinning model for concurrent applications seems promising, managing resources and application states correctly in practical settings present three challenges:

C-1. Correctness under new flow arrivals and popularity changes. When the traffic workload changes, we need to update the application’s objects at the switch. We find that this can lead to incorrect packet processing due to the slow control plane operations. Also, when there are multiple copies of a data plane-updatable object across devices, those copies can be updated simultaneously. Unfortunately, it is infeasible to adopt shared object synchronization schemes used in server-based systems [31, 50, 57] due to hardware constraints.

C-2. Handling multiple devices and device failures. While one can add more external devices to extend resources or processing capacity, we find that just adding more devices would not be effective due to possible access load imbalance across the external devices. Also, when an external device fails, we need to detect and react to the failure rapidly.

C-3. Meeting objectives across applications. Given multiple applications, we have to share resources among them properly while considering per-app and cross-app objectives provided by an operator and developers.

4 ExoPlane runtime environment

In this section, we discuss the design of the ExoPlane runtime environment. For clarity, we start with a few simplifying assumptions—a single instance of an external device, steady state traffic with no workload changes, no data plane-updatable state, no device failure, and a single application. We relax these assumptions subsequently.

4.1 Packet-pinning operating model

Recall from §3.2 that the packet-pinning model ensures that each packet is processed at a single device only (i.e., requires at most a single round-trip between the switch and an external device). Here, we load an application binary and all the state entries on an external device with a subset of entries loaded along with the application on the switch. As mentioned in §3.1, an external device has a few GB of DRAM, which is enough to store all the state entries (requiring up to a few hundred MB for a few million entries). If there is no entry for an incoming packet at the switch, the packet is routed to an external device as all the state entries needed to process the packet will be available.

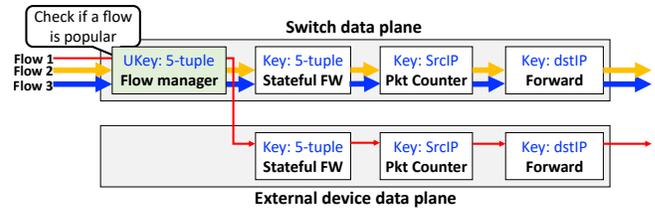

Figure 4: Our runtime environment processes most traffic at the switch and the rest at the external device. The green box is a per-app flow manager, and *UKey* indicates the app’s union key.

However, naïvely implementing the packet-pinning model has two potential problems. First, if we do not carefully choose which entries to place on the switch, a high volume of traffic will be routed to the external device, and it becomes overloaded, limiting the throughput. Second, since an entry miss can happen for an arbitrary object, per-object inter-device processing logic is needed to handle such cases. Such additional logic incurs switch data plane resource overheads.

To tackle this, we propose a *union-key based* state management to process a majority of traffic for an application at the switch and the remaining at the external device (Fig 4). We define a union key type (*UK*) for an application as the union of key types of its constituent objects ($UK = \cup_i K_{O_i}$). A flow is a set of packets with the same union key value. For example, in the figure, an IP 5-tuple is the union key type, and packets with the same IP 5-tuple form a flow.

Having defined the union key, we can use traffic workload characteristics to enable the switch to serve the majority of traffic for the application. Specifically, we build on the observation that the distribution of flow keys (including the union key) is skewed in typical networks. For example, we measure the distribution of IP 5-tuple which is the union key of our example application, by analyzing packet traces collected from an Internet backbone [20] and a university data center [22] (Fig 15 in Appendix C illustrates the distributions). For both cases, we see that a small fraction of the keys contribute to the majority of the traffic; $\approx 6\%$ of keys in the backbone and $\approx 10\%$ of keys in the data center take more than $\approx 80\%$ of traffic. The skew persists across measurement epochs (5 mins and 1 min for the backbone and data center, respectively). We also confirm the skew exists for other coarse-grained keys such as the source IP. This suggests that we can serve most of the traffic at the switch by placing a few popular union keys (e.g., 516 entries for 80% in the data center trace).

Based on this, we employ a per-app *flow manager* (the green box in Fig 4 and denoted as *OFM*) at the switch, which maintains a list of popular union keys for an application and checks if the key of an incoming packet exists in the list when it arrives. If the key exists (i.e., the packet is from a popular flow), the packet is processed at the switch. Otherwise, it is routed and processed at the external device. This allows for low overhead by avoiding per-object inter-device process-

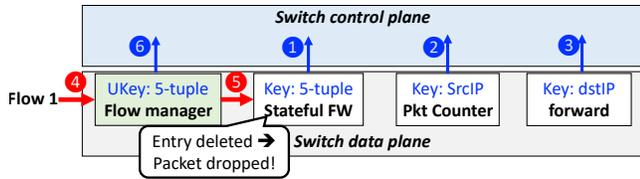

Figure 5: Incorrect state eviction: application’s state has been removed while there is a packet being processed.

ing. Taken together, our packet-pinning model and data plane design provide the following correctness property:

Invariant 1 (Packet-pinning model) For each application, if the flow manager (o_{FM}) has the packet’s union key ($UK(pkt)$), the constituent objects (o_i) must have entries ($K_{o_i}(pkt)$) for the packet. Formally,

$$\forall pkt : UK(pkt) \in o_{FM} \implies \forall i : K_{o_i}(pkt) \in o_i.$$

4.2 Handling workload changes

So far we assumed a steady state—(1) no new flows and (2) no changes in flow popularity. Next, we discuss how we handle new flows and popularity churn.

Handling new flows. When a packet belonging to the new flow arrives at the switch, and if a miss occurs in the flow manager, it routes the packet to the external device. There are two cases for the miss: (1) the first packet of the new flow or (2) a packet of an existing flow for which the flow state is not at the switch. Since these two cases are indistinguishable from the view of the flow manager, it always routes packets with misses to the external device. When a packet of the new flow arrives at the external device, it must first be processed by the application’s control logic for handling new flow arrivals. In our example, the stateful FW table reports the packet to the control logic that inserts entries for the flow to three objects. The control logic also asks the control logic running on the switch to initialize the flow state at the switch data plane, which can succeed only when there is a space on every object. Depending on the application logic, the packet can be sent back to the data plane and processed with the new entries. If the flow state has been initialized both at the switch and the external device, the switch will process subsequent packets in the flow. Otherwise, the external device will process them.

Promoting popular flows. In practice, the popularity of flows can change, and we need to promote and demote flow states as needed. Suppose we know which flow keys become popular (i.e., their entries are currently not on the switch) and unpopular (i.e., their entries are currently on the switch). We discuss how we track this in §6.

When promoting a new popular flow (i.e., installing state at the switch), there are two possibilities: (1) there is spare space in the flow manager and application’s other objects for new entries vs. (2) there is no room in the objects. For (1), we can simply insert new entries to the objects. For (2), however, we need to evict some unpopular flow to make room.

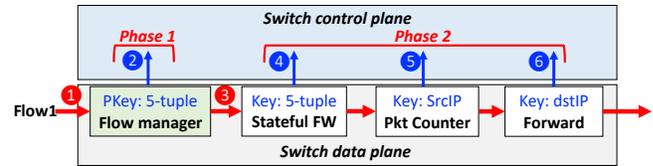

Figure 6: Correct two-phase state eviction.

Doing so correctly is challenging. Fig 5 illustrates why via a naïve mechanism can violate Invariant 1. Suppose that flow 2 becomes popular while flow 1 becomes unpopular, and there is no room for inserting new entries. Thus, the switch control plane tries to replace the entries for flow 1 with the flow 2’s. It first evicts entries for flow 1 from application objects (FW, Counter, and Forward) as well as the flow manager (blue arrows in Fig 5). However, in the current switch architecture, a set of eviction operations (blue arrows) cannot be executed atomically. Thus, there could be cases where state entries have been removed while packets are being processed in the data plane (5), violating Invariant 1. Even if eviction is correct, insertion can be incorrect. That is, during the time the switch control plane tries to insert entries for a flow, packets for the flow arrive and are looked up the flow manager. If the entry exists, the packet must be processed completely at the switch. However, since entries in other objects may not be available, the packet cannot be processed and will get dropped.

Two-phase state update. To address the issues, we adopt a *two-phase state update* mechanism, inspired by classical two-phase update or commit protocols [23, 51]. As illustrated in Fig 6, when evicting entries for flow 1, in the first phase, the switch control plane evicts an entry from the flow manager. Since there can be some packets being processed in the switch data plane, it waits for a certain period (T_{flush}) to flush out the packets. Then, in the second phase, it evicts entries from the application’s objects. This mechanism ensures that all packets that arrive at the switch before the entry of the flow manager has been evicted are correctly processed in the switch. When it evicts entries from the application’s objects, it ensures that entries for other non-victim flows will remain. The insertion works similarly. To insert entries for a flow, in the first phase, the switch control plane inserts entries to the objects, and then in the second phase, it inserts an entry to the flow manager.

4.3 Synchronizing shared stateful objects

The previous discussion considers scenarios with no cross-flow objects that can be updated at runtime, which meant there was no need for objects on an external device and the switch to be synchronized. In practice, applications may have such objects; e.g., per-SrcIP packet counter in our example is shared across flows. Next, we extend the basic ExoPlane protocol to handle such objects.

Consistency modes. P4 programs can have two types of stateful objects: (1) *control plane-updatable object* can be updated *only* from the control plane, such as a match-action

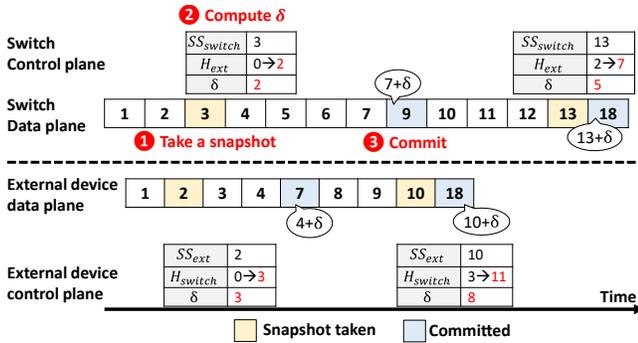

Figure 7: Our state synchronization protocol synchronizes two copies of an entry in the packet counter. The switch and external device’s control plane maintain the history (H) of entry updates.

table and (2) *data plane-updatable object* can be updated from the data plane, such as a register. Correspondingly, ExoPlane provides two levels of consistency. Control plane-updatable objects are rarely updated (e.g., a stateful firewall table entry is inserted only for the first packet of each flow generated from an internal network) and an exact value is critical for correct behavior (e.g., allowing packets for an established TCP connection). Thus, for this type, we provide a *strong consistency*. In contrast, data plane-updatable objects can be updated more frequently (e.g., per-*SrcIP* packet counter is updated for every packet) in the data plane and typically do not require strong consistency since they maintain approximate or statistical information (e.g., packet counters and sketches). Thus, for data plane-updatable objects, we provide *bounded inconsistency* within a configurable time bound T_e (e.g., 1 s in our prototype). As mentioned in §3.2, we consider bounded inconsistency only for mergeable statistical stateful objects.

Supporting strong consistency for control plane-updatable objects is straightforward; when the external device’s control plane receives a request for updating (or inserting) an entry to an object with a key (e.g., a *SrcIP*), it updates (or inserts) all entries corresponding to the key existing at the external device and the switch.

Bounded inconsistency for data plane-updatable objects is more challenging. Consider the per-*SrcIP* packet counter implemented using a P4 register array. Suppose that for a given *SrcIP*, there are two copies placed on the switch and the external device that can be updated simultaneously. To achieve bounded inconsistency, the ExoPlane runtime needs to periodically *merge* values of the copies. Traditional techniques for state merging in server-based network functions (e.g., [31, 50, 57]) are impractical in our context since they rely on buffering incoming packets and pausing processing while synchronizing copies. This is expensive and even infeasible in the switch because packet rates are much higher, and we cannot buffer arbitrary packets during synchronization.

Our approach for bounded inconsistency. We devise a state synchronization protocol that achieves bounded inconsistency without needing packet buffering. We do so by combining the capabilities of both the switch and the external device’s

control and data plane. We use the control plane’s memory to track the history of periodic synchronizations while executing the merge operation in the data plane.

Let us revisit our packet-counter example from Fig 7. The control plane of each device maintains per-entry metadata including the current snapshot (SS) and a history (H) of an entry value on the other side (i.e., the switch tracks the history of the external device and vice versa). When there are multiple objects that need to be synchronized, the control plane maintains metadata for each object. We discuss the overhead of maintaining the metadata in §7.5. For every T_e seconds, the switch control plane initiates synchronization by sending its SS and the H , and the external device’s control plane replies it with its snapshot and history; in Fig 7, the switch control plane takes the snapshot of the packet counter (1) and sends $\langle SS=3, H=0 \rangle$ to the external device, and the external device sends $\langle SS=2, H=0 \rangle$ back. Then, each side computes the changes that have been made on the other side (δ) after the previous synchronization round by subtracting two history values from the received snapshot value (2). This prevents a potential under or double-counting issue. Lastly, the control plane of both sides injects a special control packet containing δ to the data plane to merge the changes to the latest state value (3). Note that our protocol synchronizes the copies of states correctly even when the external device fails and recovers. This is because the switch maintains the progress that the external device had made until the failure happened (H) and provides this information to the recovered device to resume the synchronization from the state when it failed.

Generally, our protocol supports mergeable key-value pair states for most stateful objects implemented using P4 registers. We provide a developer with an interface to specify object-specific *merge operators* consisting of an addition (\circ^+) that merges two values and an optional subtraction (\circ^-) operator that subtracts one value from the other, which are used by our protocol to compute δ and commit the update. For example, a Bloom filter [24] can be expressed as (Key: an integer, Value: $\{0, 1\}$) pairs with the binary OR as \circ^+ (no subtraction operator is needed). We provide a detailed pseudo-code in Appendix B.

4.4 Scaling to multiple devices

Thus far, we have assumed that there is a single external device. However, in practice, a single device instance may not provide enough processing capacity or resources. To use multiple devices, ExoPlane shards entries in objects across the devices based on the union key. When an entry miss occurs at the flow manager, it routes a packet based on the union key to a specific external device that has state for the key. However, the skewness in the union-key space (§4.1) could result in load imbalance across the devices (i.e., a subset of devices can be overloaded). Fortunately, the small fraction of popular entries we already have at the switch is helpful for load balancing. Prior analysis in storage systems shows that caching at least $O(N \log N)$ popular entries where N is the number of backend

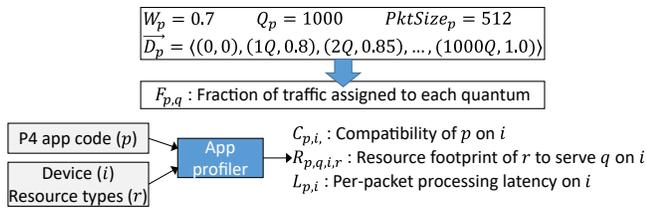

Figure 8: Example inputs for an application p .

servers (in our context, external devices), guarantees uniform load balancing across the servers regardless of the skew [29]. Thus, by placing $\geq O(N \log N)$ popular union keys at the switch, we can provide the cache effect for load balancing.

4.5 Handling external device failures

Application state loss due to failures can affect the performance or correctness of applications [41]. Specifically, we consider the failure model where an external device (or its hosting machine) fails or a network link between the switch and the device fails.⁶ To deal with state loss due to such failures, the ExoPlane runtime environment replicates each flow state to at least one additional external device when initiating flow entries, and when the primary device fails, it falls back to a replica. It does so by managing the logical to physical external device ID mapping at the switch, where the primary and replicas share the same logical ID. However, even if there is a replica, if we cannot detect failures and route packets to the replica quickly, the application performance can be degraded (e.g., due to packet drops). To enable rapid failure detection and reaction, we repurpose the packet generation engine of the switch ASIC (which is typically used for diagnosis), similar to previous work [40]. We configure the engine to generate a packet when ports go down. By processing the generated packet, the runtime environment updates the external device ID table in the data plane. Using the table, it can route subsequent packets to the replica.

5 ExoPlane planner

Next, we tackle the issue of sharing resources across multiple applications while meeting the performance objectives given by developers and operators. The resulting ExoPlane planner consists of a resource allocator and an application merger. The resource allocator finds an optimal resource allocation using inputs from the developers and the network operator. The application merger generates a merged P4 program based on the optimal allocation decision. Fig 8 illustrates example inputs for an ensemble of applications.

Inputs. Developers provide a set of P4 programs (p), each of which consists of a set of stateful objects. For each object, developers specify the required size (e.g., the number of entries in a table or register). Optionally, they can also specify

⁶We do not consider the failure of the switch itself since in that case, packets cannot be processed in our deployment model (§3.1) where the switch is the single entry point of the architecture.

a high, medium or low affinity to the switch for each app. If the affinity of an application is set to high (or low), the application will run entirely at the switch (or at external devices). The network operator provides cross-app and per-app traffic information, which includes the fraction of all traffic served by each application out of the entire traffic arriving at the switch (W_p) and the cumulative traffic distribution (D_p) over the union key space. While using a fraction of traffic served by *each key* provides the most fine-grained information, we find that it could make the search space for resource allocation too large. Instead, we use the distribution discretized into a larger quantum size denoted as Q_p . Based on D_p , we compute the estimated fraction of traffic served by each quantum q ($F_{p,q}$). The operator also provides resource information (r) for devices (i). This includes SRAM, TCAM, hash units, and SALUs for a Tofino-based switch and compute units, SRAM, and DRAM for NPU-based NICs.⁷

Profiler. Based on the inputs, our profiler generates per-app profiles consisting of a resource footprint, per-packet processing latency, and compatibility matrix for each device type. The profiler estimates a resource footprint of r for p serving q on i denoted as $R_{p,q,i,r}$. Since blackbox compilers determine the resource usage using proprietary heuristics, our preprocessor compiles p to determine $R_{p,q,i,r}$. For each q , it updates the size of each object specified in the application code and compiles it using vendor-provided compilers. Then it extracts the resource usage from compiler outputs. If the compilation fails due to insufficient resources, it sets the resource usage to infinite. We use constants $Cap_{i,r}$ to represent the total amount of r available on i . The profiler also estimates a per-packet processing latency of p on i , $L_{p,i}$. Specifically, it instruments the switch to record two timestamps on a custom packet header field when a packet enters and leaves the rack. Then it injects $PktSize_p$ -sized packets to the rack and estimates the latency based on the timestamps in returned packets.

Finally, some vendor-provided P4 compilers for external devices may not support certain features or P4 constructs⁸ used by applications. Because of this, if an application uses a feature that is not supported by an external device, it cannot run the application. To consider the compatibility of the application on devices, our profiler generates a compatibility matrix ($C_{p,i}$) that indicates whether p can be run on device i based on a set of features supported by i and a set of features used by p . The first set can be typically obtained from vendor’s compiler manual. For the second set, the profiler analyzes the application code to extract used features.

Resource Allocation. Given these inputs, we can formulate the problem of finding an optimal resource allocation satisfying per-app and cross-app requirements. In our formulation, we assume that the resource usage of multiple applications can be estimated by accumulating the resource usage of each app.

⁷The operator can easily extend this to other resource types.

⁸e.g., Packet recirculation and P4 registers.

We use binary decision variables $d_{p,q,i}$ to indicate whether q for p is assigned to i . There are four constraints imposed:

$$\forall p, q : \sum_i d_{p,q,i} = 1 \quad (1)$$

$$\forall p, q, i : d_{p,q,i} \leq C_{p,i} \quad (2)$$

$$\forall i, r : \sum_p \sum_q d_{p,q,i} \times R_{p,q,i,r} \leq Cap_{i,r} \quad (3)$$

$$\forall p : lat_p = \sum_q \sum_i d_{p,q,i} \times F_{p,q} \times L_{p,i} \quad (4)$$

First, q must be assigned to a unique i (Eq. 1). Second, q can be assigned to i if and only if p is compatible with i (Eq. 2). Third, the amount of r consumed by q on i must be less than or equal to the total amount of r on i (Eq. 3). Last, the expected latency of p is the sum of per-packet processing latency of p on i weighted by $F_{p,q}$ (Eq. 4).

The network operator provides an objective to share resources across multiple application fairly. One possible fairness metric would be minimizing the weighted sum of the expected processing latency of each application:

$$\text{Minimize } \sum_p W_p \times lat_p \quad (5)$$

Other commonly used fairness metrics such as maximizing the minimum expected throughput can be used as well. By solving the ILP, the ExoPlane resource allocator finds an optimal assignment of q to i for p , and the size of each object and flow manager for p accordingly, which are used as input for the application merger, as we describe next.

Application Merger. Given a set of P4 programs and the optimal resource allocation decision, our application merger combines the programs into a single P4 program, following our deployment model for multiple applications, described in §3.2. Our merger supports programs written in P4-16 [10] (Fig 16 in Appendix C illustrates how the merger works). First, for each app, the merger renames the main control block [10] to avoid naming conflicts between applications. Second, it specifies the size of each object (e.g., number of entries in a table) based on the decision made by our resource allocator. Third, it inserts a flow manager. Finally, in the merged P4 code, it instantiates an instance of each application and inserts execution logic. The merged P4 code is compiled using the vendor-provided compiler and loaded on the switch and external devices. Sometimes, the compilation process fails due to its proprietary heuristics for resource allocation. If so, we repeat the process with a tighter resource constraint.

In summary, ExoPlane planner allocates resources across applications based on inputs from developers and the operator and produces a merged P4 program. This process needs to be re-run when a set of applications or workloads changes, which we do not expect to happen frequently (e.g., once every hour). While this module is not on the critical path, performance results are available in Appendix D.

6 Implementation

Data plane. The data plane components of the runtime environment implemented in P4-16 consists of: (1) the flow manager implemented using a match-action table and (2) the global logical-to-physical external device ID mapping implemented using a register array (on the switch).

Tracking flow popularity. We implement a flow popularity tracker on external devices using the count-min sketch [27] that tracks the frequently accessed flow keys. When it detects a new popular key, it reports the key to the external device’s control plane that has a list of flow keys and corresponding entries, and they are reported to the switch control plane. We enable the *aging* supported by the switch ASIC for the flow manager. If a certain key has not been accessed for a timeout period (T_{idle}), a callback function registered at the switch control plane is triggered, and it evicts the entry corresponding to the idle key. In our prototype, we set T_{idle} to 2 s.

Control plane. We implement the control plane of the runtime environment in Python and C++. The main capability is to initialize new flow entries and promote new popular flows’ entries on the switch. On the switch side, we use Barefoot Runtime APIs to access the stateful object in the switch data plane. On the NIC side, we use Netronome Thrift APIs [12] to interact with the NIC data plane. The switch and the external device control planes are communicated via an out-of-band TCP session over the 1 Gbps management network.

Resource allocator. We implement the resource allocator in C++ based on the Gurobi C++ API [13] to encode and solve our resource allocation ILP.

Application profiler and merger. We extend the open-source P4 compiler [17] to analyze input P4 programs. Using its frontend, we extract information from each program including the entry size of each object. We implement the application merger in C++, which takes an IR generated by the compiler frontend, and produces a merged P4 program.

Supporting other hardware platforms. While our prototype uses a Tofino-based programmable switch and Netronome smart NICs, ExoPlane can be extended to other platforms. For example, ExoPlane can be applied to other types of programmable switches (e.g., Nvidia Spectrum-2 [16]) and FPGA or ASIC-based smart NICs (e.g., Xilinx and Intel FPGA NICs [1, 6]) as external devices.

7 Evaluation

We evaluate ExoPlane on a testbed consisting of a programmable switch and servers equipped with a Netronome smart NIC using various workloads. Our key findings are:

- In steady-state, ExoPlane provides predictable per-packet latency (e.g., 273—384 ns at the switch) and scalable throughput with more external devices while the app-pinning model achieves a limited throughput (§7.1).

Applications	States
Per-VM NAT	Per-flow address mapping for each VM.
Per-VM Stateful FW + Packet counter	Active TCP connection list.
Per-VM SYN proxy	Per-flow sequence number translation table.
NetCache [35]	Key-value store cache.

Table 2: Switch programs written in P4 used in the evaluation in addition to ones introduced in Table 1.

- Even under dynamic workloads, ExoPlane can process packets with the correct state and sustain high throughput with multiple devices (§7.2).
- In case of an external device failure, ExoPlane can recover an end-to-end TCP throughput within 200 ms (§7.4).
- ExoPlane provides the above benefits with small control plane (e.g., a few tens MB) and switch ASIC resource overheads (e.g., less than 4.5% of ASIC resources) (§7.5).

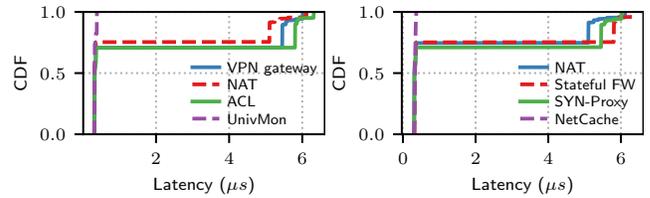

Testbed setup. We build an on-rack resource augmentation architecture consisting of Wedge100BF-32X Tofino-based programmable switches [9] and four servers equipped with Netronome Agilio 40 Gbps smart NICs [7]. We use four additional servers with 100 Gbps regular NICs to generate traffic workloads. All servers are equipped with an Intel Xeon Silver 4110 CPU and 128 GB DRAM, running Ubuntu 18.04. We repeat each experiment 100 times unless otherwise noted.

Traffic workloads. We use packet traces from a real data center [2], the Internet backbone [20], and synthetic ones. The packet sizes vary (64–1500 B) in the real trace. We generate traces with the flow key distribution in terms of the number of packets per flow that follows a Zipf distribution with the skewness parameters ($\alpha=0.9, 0.95, 0.99$). We use a keyspace of 1M randomly generated IP 5-tuples when creating packet traces. We generate packet traces with different packet sizes and skewness parameters. We replay the traces using DPDK-pktgen [3] or run iperf [5] for TCP workloads.

Deployment scenarios. We use two scenarios with multiple P4 applications: (1) at the data center gateway, four applications in Table 1 and (2) at the leaf of the network, four applications from Table 2. Given packet traces, we synthesize inputs for the ExoPlane planner (e.g., per-app affinity and a flow key distribution). For example, we set the affinity level for the UnivMon [45] and NetCache [35] to high so that workloads for these are always processed at the switch.

7.1 Performance in steady state

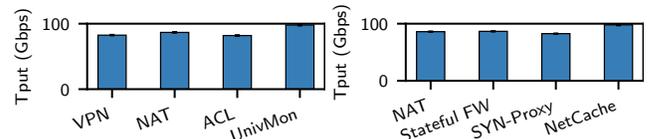

First, we evaluate the per-packet processing latency and throughput of applications running on ExoPlane in steady state (i.e., no new flows, no changes in flow popularity, and no device failures). Here, we pre-populate popular flow entries at the switch and assume that the traffic is equally distributed across the applications (i.e., $W_p = 0.25$ for all applications).

(a) Data center gateway.

(b) Data center leaf.

Figure 9: Per-packet processing latency distribution of applications concurrently running on ExoPlane in steady state.

(a) Data center gateway.

(b) Data center leaf.

Figure 10: Throughput of each application running on ExoPlane in steady-state with a single external device. Applications are running concurrently.

Per-packet processing latency. We define per-packet processing latency as the time difference between when a packet first arrives at the switch from a sender and when it is sent to a receiver after processing. We instrument the P4 program running on the switch to record two timestamps (48-bits each) to our custom packet header fields of each packet so that the receiver can compute the processing latency for a packet. From the sender, we replay the backbone packet traces, each of which contains more than 6M flows.

Fig 9 shows the CDF of the per-packet latency distribution for each application. For the applications that are assigned to the *high* affinity (UnivMon and NetCache), every packet is processed at the switch in 273–384 ns, depending on packet sizes. For other applications, the distributions vary depending on packet sizes and how much traffic is processed at the switch and the external device. The higher the affinity level assigned to an application, the more traffic is processed at the switch. For example, in the gateway scenario (Fig 9a), at the switch, the ACL processes $\approx 70\%$ of its traffic whereas the NAT processes $\approx 75\%$ of its traffic. When packets are forwarded to the external device, their processing latency becomes 5.1–6.1 μ s, depending on the application (the top-right corner in Fig 9). The external device takes 3.2–4.1 μ s to process each packet, while several overheads constitute the overall processing latency, including the switching latency and the propagation and transmission latency. While there is a latency gap between two cases (processing at the switch vs. external device), on each device, per-packet processing latency is predictable.

Application throughput. To measure the throughput, we replay the synthetic trace that consists of 1500 B packets at line rate (98.6 Gbps in our testbed). We use four sender nodes, each of which generates traffic for each of the four applications. We start with a single external device to demonstrate the impact of the number of external devices on the throughput.

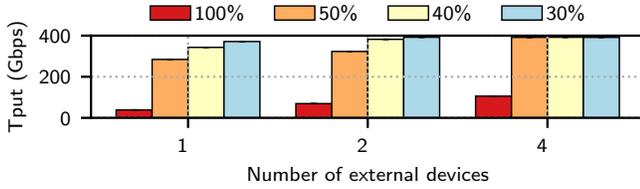

Figure 11: Scalable throughput with multiple devices with varying fractions of traffic offloaded to external devices.

Ensemble of apps	App-pinning	ExoPlane
VPN	98.6 Gbps	98.6 Gbps
VPN+NAT	137.1 Gbps	197.2 Gbps
VPN+NAT+ACL	174.6 Gbps	295.6 Gbps
VPN+NAT+ACL+UnivMon	271.3 Gbps	394.1 Gbps

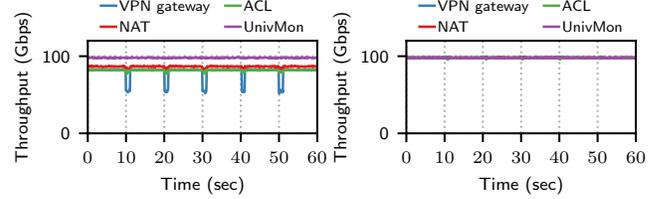

Table 3: Aggregate throughput of four applications running on the app-pinning model and ExoPlane with four external devices.

Fig 10 shows the throughput of each application. The applications that run entirely on the switch (UnivMon and Net-Cache) process traffic at line rate without dropping any packets. However, we observe that the others cannot process their traffic at line rate. This is because the aggregate amount of traffic across the applications, which needs to be processed at the external device (≈ 81 Gbps in the gateway case) exceeds the processing capacity of the single device (≈ 39 Gbps).

Scaling throughput with multiple devices. By adding more devices, ExoPlane can support higher throughput. To demonstrate this, we measure the aggregate throughput of the four applications in the gateway scenario (max. traffic rate in our testbed is ≈ 394 Gbps) while varying the fraction of traffic offloaded to an external device(s)⁹ and the number of external devices. Fig 11 shows the results. In the case of 30, 40, 50% of the traffic being offloaded to external devices, we see the throughput effectively increases with more devices. In contrast, when 100% of traffic is offloaded, adding more devices is not effective due to load imbalance. This result shows the load balancing effect of serving popular flows at the switch, described in §4.4.

Comparison with the app-pinning model. We evaluate the benefit of ExoPlane over the app-pinning model (described in §3.2) while running four applications from Table 1. In this model, we place an application along with its entire state at the switch if there is room. Otherwise, we place it on one of the external devices, which has the largest remaining capacity. Table 3 compares the aggregate throughput when running an ensemble of applications. While ExoPlane provides the maximum throughput for each ensemble, the app-pinning model achieves up to 69.3% lower throughput. This is because while ExoPlane allows an application to effectively utilize available resources across different devices, the app-pinning model fixes an application to a device.

⁹In this experiment, we control the fraction of traffic offloaded to external devices by manually assigning the affinity of each application. UnivMon is still pinned to the switch.

(a) With a single external device. (b) With 4 external devices.

Figure 12: Throughput changes due to workload changes.

7.2 Performance under dynamic workload

Per-packet processing latency. As mentioned in §4.2, workload changes happen due to new flows arriving or changes in flow popularity. Handling new flows in ExoPlane can increase processing latency because the first packet of a new flow can be processed only after initiating the necessary state for both the flow manager and application objects. In contrast, packets in the flow that becomes popular can be processed either at the switch or an external device with the same latency shown in §7.1. Thus, for each app, we measure the processing latency of the first packet of each flow. We observe that the median latency for the first packet of a new flow is 32 ms, which is an order of magnitude higher than that of an external device in a steady state. There are two factors here. First, the Netronome Thrift API takes a few tens of ms to insert new entries to objects, which is not an ExoPlane-specific overhead. Second, since ExoPlane replicates entries for new flows to one another external device, it incurs additional latency when handling new flows. Note that as described in §4.2, ExoPlane tries to initiate state for new flows both at the switch (if there is room) and at the external device, so even for short-lived flows, the subsequent packets can be processed at the switch with lower latency. However, some short-lived flows can be entirely processed at the external device, which can incur higher latency if there is no room at the switch during its lifetime.

Application throughput. The changes in flow popularity can impact the throughput. To measure the throughput changes, we use the same setup as the previous measurement in steady state, but for every 10 s, we alter the most popular top 10 flows for the VPN gateway of the gateway scenario. Fig 12 shows the throughput changes over time. Again, we first use a single external device. As shown in Fig 12a, when the popularity changes, there is a sharp drop in the throughput of the VPN gateway. Also, the throughput of other applications slightly decreases as well. This is because until the state entries for the new set of popular flows are installed at the switch (i.e., a transient period), a high volume of traffic for the flows is routed to the external device, exceeding its processing capacity. On the other hand, as shown in Fig 12b, with four external devices, there is no such performance drop because there is enough processing capacity at the external devices to handle the traffic during the transient period. Although we assume that the traffic pattern can change at an hour or day-timescale,

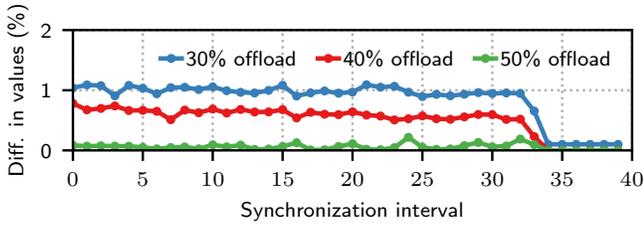

Figure 13: Difference in shared object values on the switch and external devices; the trace ends at epoch 32.

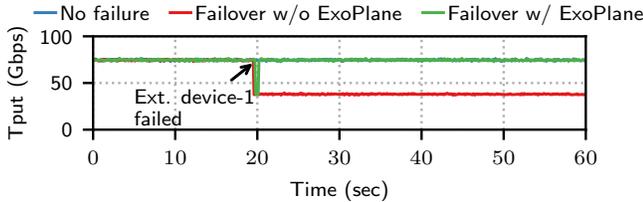

Figure 14: TCP throughput during failover and recovery.

if ExoPlane cannot detect such changes, it could suffer from severe performance degradation due to outdated resource allocation. Rapidly detecting the changes and reconfiguring the resource allocation accordingly is our future work.

7.3 Shared stateful object synchronization

Next, we evaluate the effectiveness of our state synchronization protocol (§4.3) using the per-SrcIP packet counter in the stateful FW. The metric of interest is the difference between the shared counter entries maintained by each device at each synchronization interval ($T_{\epsilon}=1$ s). We measure this by recording the values at each device right after executing the merge operation in the data plane while injecting 1500 B packets for 60 s at 98.6 Gbps. We vary the fraction of traffic offloaded to external devices. In our setting, there are 1000 entries shared between the switch and at least one of the external devices, and we get the median of the differences. Fig 13 shows the result with three different fractions of offloaded traffic. When the switch and external devices process the same amount of traffic (i.e., 50% offload), there is almost no difference. When there is a gap between the amounts of traffic (i.e., 30% or 40% offload), there are differences because incoming packets keep updating the counter at each device during the synchronization, affecting the measured values. However, we see that the variance of the difference is small across the synchronization intervals regardless of the gap, showing that our mechanism synchronizes the values. We also confirm that after the packet transmission is done, copies at each device are synchronized with the same value as the total number of packets.

7.4 Failover

In Fig 14, we use a NAT as an example and run iperf to measure TCP throughput changes. There are four TCP connections, and we configure two of them to be processed at the switch while the remaining is processed at an external device. There are two external devices enabled, and we compare changes in TCP throughput when (1) there is no failure and (2)

one of the external devices fails with and without ExoPlane. We emulate the failure by disabling a port connected to the external device. At around 20 s, when the external device-1 goes down, our failover mechanism generates a control packet that modifies the logical to physical device ID mapping in the switch data plane without involving the control plane. Then, subsequent packets are routed to the replica device. We see that the TCP throughput is recovered to its original rate within a 200 ms whereas, without ExoPlane, it cannot be recovered.

7.5 Runtime resource overheads

Control plane resource overhead. The control plane component of ExoPlane runtime environment maintains metadata for application states, including a mapping between union keys and devices and a history of each shared object entry on other devices. Each of them consumes the control plane memory. In our scenarios, the union keys-to-device mapping consumes 12.5 MB per application and the history metadata consumes 1.5 MB per shared object. Our state synchronization protocol consumes management network bandwidth as it periodically exchanges information between devices, which contains a snapshot and history of each entry. In our setting, the bandwidth consumption is 24.4 Mbps per shared object, which increases in proportion to the number of devices, the sync interval, and the number of entries.

Switch ASIC resource usage. The data plane component of ExoPlane runtime environment consumes some switch ASIC resources. Since we implement it using an exact-match table with the aging feature and a register array, it consumes SRAM, SALUs, hash bits, MAP RAM, and match crossbar,¹⁰ whose usage increases proportionally to the number of popular flows maintained (except for SALUs). In our setting where 10240 popular flow entries are managed, it consumes 4.4% of the SRAM, 2.1% of SALUs, 3.5% of the hash bits, 3.8% of the MAP RAM, and 3.6% of the match crossbar, leaving ample resources for application logics.

8 Conclusions

Limited on-chip resources today block the deployment of concurrent stateful apps on programmable switches, limiting the adoption of in-network computing. In this paper, we argue that on-rack switch resource augmentation can be a pragmatic and incrementally expandable solution to this dilemma. To realize this vision, we present ExoPlane, which provides OS-like abstractions for the new architecture by addressing challenges in managing application states and resources across multiple devices. Our evaluation shows that ExoPlane provides low latency, scalable throughput, and fast failover, and achieves these with a small resource footprint and few/no modifications to applications. Thus, ExoPlane can be a practical basis for enabling in-network computing for future applications, workloads, and emerging data plane hardware.

¹⁰MAP RAMs are used for the aging feature and match crossbars are used for implementing the ‘matching’ part of match-action tables.

Acknowledgments

We would like to thank the anonymous reviewers and our shepherd, Michio Honda, for their insightful comments and constructive feedback. This work was supported in part by the CONIX Research Center, one of six centers in JUMP, a Semiconductor Research Corporation (SRC) program sponsored by DARPA, by the NSF award 1700521, and by Intel Corporation and by VMWare under the Crossroads 3D FPGA Research Center.

A Skewness of traffic traces

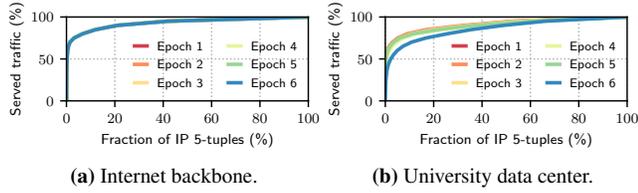

Figure 15: Skewness in flow key (IP 5-tuple): For both Internet backbone and data center case, a few popular keys serve the most of the traffic. This is consistent across measurement epochs.

We measure the distribution of IP 5-tuple as the union key by analyzing packet traces collected from an Internet backbone [20] and a university data center [22]. Fig 15 shows the union key distributions of the two data sets.

B State synchronization algorithm

Algorithm 1: State synchronization – Switch

```

1  $S_{switch}$  : The current state of the value on the switch
2  $Ext$ : a set of external device IDs
3  $SS_{switch}$  : The latest snapshot of the value on the switch
4  $H_{ext}[1 \dots N]$  : The latest information received from each external device
5 Upon the snapshot timer expires:
6 foreach  $ext_i \in Ext$  do
7     /* Send an initiate message to  $ext_i$  */
8     send ( $Snap_{switch}, I_{switch}[ext_i]$ );
9     /* Receive a response from  $ext_i$  */
10    ( $Snap_{ext_i}, I_{ext_i}$ ) = recv ();
11 foreach  $ext_i \in Ext$  do
12    /* Adjust snapshot values and merge them */
13     $\delta = Snap_{ext_i} \circ^- (I_{switch}[ext_i] \circ^+ I_{ext_i})$ ;
14    /* Update the information for  $ext_i$  */
15     $I_{switch}[ext_i] = Snap_{ext_i} \circ^- I_{ext_i}$ 
16    /* Merge ( $\circ^+$ ) the adjusted value with the current state in the data plane */
17     $S_{switch} = S_{switch} \circ^+ \delta$ 

```

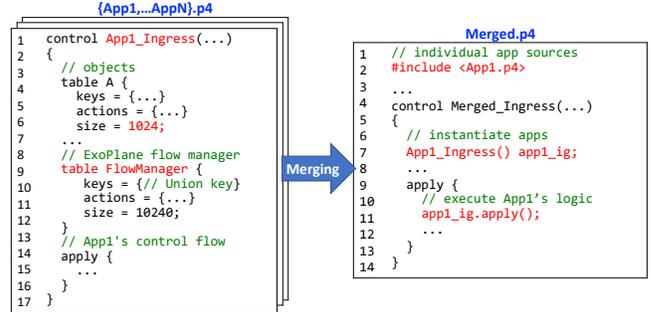

Algorithm 2: State synchronization – External device

```

C Details of Application Merger

Fig 16 illustrates how our application merger works for a set of P4 applications as described in §5.

D Performance of ExoPlane Planner

We evaluate the performance of the ExoPlane planner. In this experiment, we measure the elapsed time for finding optimal resource allocations and generating a merged P4 program on a server in our testbed. For the two sets of apps and the hardware configuration used in our evaluations, our resource allocation takes 54.5 ms and merging the program takes 642 ms, which is reasonable since the orchestrator needs to run this process on the hours or days timescale. To further understand the impact of different parameter values including the number of apps and traffic workload sizes, we synthesize inputs for the resource allocator and measure the elapsed time. First, we fix the number of external devices to 16 (to support a large number of apps) and the number of union key-based flow entries to 1M for each app. Then, we vary the number of flow entries while fixing the number of apps to four and the number of devices same as the above. As illustrated in Fig 17a, the resource allocation time grows linearly up to 712 ms as the number of app increases. Also, as shown in Fig 17b, as the number of flow entries increases, the elapsed time also increases up to 4.1 second when each app needs to handle 10M flow entries. This experiment illustrates the ExoPlane orchestrator takes a longer time as we add more apps and increases the workload size, which can be up to a few seconds, it is still within the reasonable timescale under our deployment model (§3.1).

Sketchovsky: Enabling Ensembles of Sketches on Programmable Switches

Abstract

Network operators need to run diverse measurement tasks on programmable switches to support management decisions (e.g., traffic engineering or anomaly detection). While prior work has shown the viability of running a single sketch instance, they largely ignore the problem of running *an ensemble of sketch instances* for a collection of measurement tasks. As such, existing efforts fall short of efficiently supporting a general ensemble of sketch instances. In this work, we present the design and implementation of Sketchovsky, a novel *cross-sketch optimization and composition* framework. We identify five new *cross-sketch* optimization building blocks to reduce critical switch hardware resources. We design efficient heuristics to select and apply these building blocks for arbitrary ensembles. To simplify developer effort, Sketchovsky automatically generates the composed code to be input to the hardware compiler. Our evaluation shows that Sketchovsky makes ensembles with up to 18 sketch instances become feasible and can reduce up to 45% of the critical hardware resources.

1 Introduction

Network operators need to concurrently run diverse measurement tasks for network management tasks such as traffic engineering, anomaly detection, load balancing, and resource provisioning [6, 10, 24, 35, 46]. A flow-level measurement task computes a desired statistic (e.g., heavy flow size or the distinct number of flows) based on the definition of a flowkey (e.g., srcIP or 5-tuple), a flow size (e.g., packet counts or bytes), and a measurement epoch (e.g., 1 minute).

Given resource constraints, *sketching algorithms* or *sketches* appear as a promising avenue to support measurement tasks on data collected from programmable switches (e.g., [4, 5, 7, 17, 21, 32, 40, 45, 49]). To support one measurement task, a sketch instance on a programmable switch is instantiated based on a sketching algorithm with configuration on parameters (e.g., flowkey or resource allocation). In practice, supporting the collection of measurement and management tasks will require simultaneously running an ensemble of sketch instances on the programmable switches.

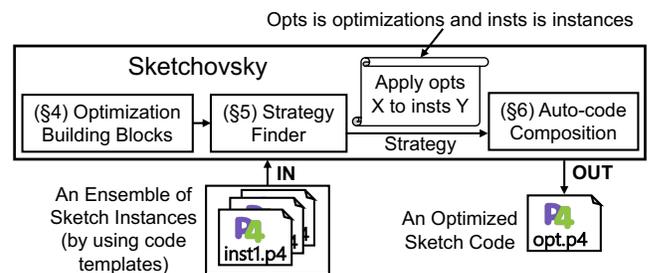

Figure 1: Sketchovsky Overview.

However, existing sketch-based telemetry efforts largely focus on running a *single* sketch instance on programmable switches and they cannot effectively support *an ensemble of sketch instances*. Naively extending a single sketch instance to support an ensemble of measurement tasks will require at least a *linear* increase in hardware resources (e.g., counters, hash units, pipeline stages), which is intractable as more measurement tasks are needed. While there have been some recent efforts on improving per-sketch efficiency (e.g., [4]), supporting P4 code composition [22, 23, 30, 42, 51], elastically trading of resource vs. accuracy (e.g., [3, 36]), and on improving the generality of sketches (e.g., [9, 15, 32, 49]), we find that these fundamentally fall short of efficiently supporting a general ensemble of sketch instances without sacrificing accuracy.

Given the limitations of current methods for running sketch ensembles, we present Sketchovsky (Sketch + Tchaikovsky), a composition framework that takes the input of sketch codes for the ensemble and outputs an optimized sketch code by leveraging cross-sketch optimizations (Fig. 1). Sketchovsky is complementary to the earlier work on implementing single-sketch algorithm more efficiently, developing more general-purpose sketches, and research that explicitly trades off accuracy reduction for resource reduction (§2). Indeed, using Sketchovsky can amplify their benefits by running expressive sketches (e.g., [32]) or extending per-sketch optimizations (e.g., [4]).

The design of Sketchovsky makes three key contributions:

```

1 packetStream
2 .map(p => (p.sIP, p.pktlen))
3 .reduce(keys=(sIP, ), f=sum)
4 .filter((sIP, count) => count > Th)

```

Query 1: Heavy hitters detection of srcIP written in Sonata [25].

```

1 packetStream
2 .map(p => (p.sIP, p.dIP, p.sPort, p.dPort, p.Proto))
3 .distinct()

```

Query 2: Distinct number of 5-tuple flows written in Sonata [25].

Optimization building blocks (§4): We observe that sketching algorithms have three common workflow steps: hash computations, counter updates, and heavy flowkey storage. We identify and formalize five novel cross-sketch optimization building blocks to *reuse* key hardware resources *across* sketch instances in each step. For *hash computations*, we show how and when (1) hash results can be reused across sketch instances or (2) can be reconstructed by cheap XOR operations. In the *counter updates* step, we discuss how (3) counter arrays can be reused or (4) can be co-located to reduce memory accesses. In *heavy flowkey storage*, we discuss (5) a novel mechanism to reuse the heavy flowkey storage by using the union of all flowkeys for sketch instances in the ensemble. Each optimization guarantees no accuracy loss.

Strategy finder (§5): Given an arbitrary sketch ensemble, there are many possible ways to use and combine the above building blocks. Naively solving this problem is intractable due to the challenges in modeling resource usage, identifying conflicts for combining optimizations, and the combinatorially large search space (e.g., it takes more than a day to solve). We identify practical relaxations to the problem and a greedy heuristic to make the problem tractable to solve. We show that our approach can quickly identify (e.g., in less than 1 second) an effective strategy that yields significant benefits.

Auto-code composition (§6): To simplify developer and operator effort, we design a simple-yet-effective switch-code generation process that realizes the selected strategy obtained above. We provide code templates of sketching algorithms to create sketch codes for an ensemble of sketch instances (Fig. 1) to enable this automatic code composition.¹

We demonstrate the utility and benefits of Sketchovsky over a wide range of settings and a library of sketching algorithms that measure various statistics of interest [11, 14, 17, 19, 20, 21, 27, 28, 29, 32, 44]. Given this basic library, we built an ensemble generator that can create diverse ensembles using a wide range of parameters. We then used the generator to generate tens of thousands of ensembles that we used to measure the resource reduction benefits of Sketchovsky. We measure accuracy results by running four representative ensembles on the Tofino switch processing various inter-ISP packet traces [2]. Compared to the baseline of SketchLib, Sketchovsky reduces the use of hash units by 7~40%, SALUs by 9~45%,

¹Sketchovsky is publicly available at <https://github.com/Sketchovsky>.

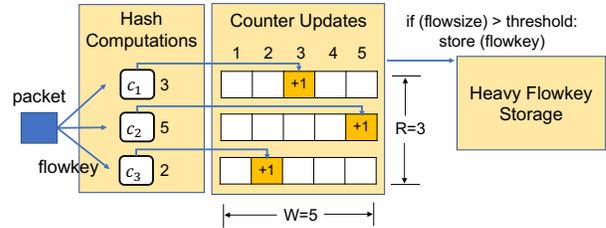

Figure 2: Sketching algorithms have three common workflow steps; hash computations, counter updates, and heavy flowkey storage.

and SRAM by 0~7% for the ensembles that have the same flowkey for all sketch instances. Even for the ensembles with randomly picked sketching algorithms and parameters, resource reduction is 3~21% for the hash units, 4~26% for SALUs, and 0~0.4% for SRAM. For the accuracy experiment, we report no accuracy loss for any sketch instances.

2 Background and Related Work

We begin with background on sketches and their hardware footprints. Then we motivate the need for running an ensemble in practice. We end by explaining why state-of-the-art solutions fall short of effectively supporting an ensemble.

2.1 Sketches and Programmable Switches

Sketches or sketching algorithms on programmable switches are promising to support diverse measurement tasks due to resource efficiency and high accuracy. Sketching algorithms are randomized approximation algorithms designed to measure different statistics with a theoretical guarantee of high accuracy and sub-linear memory space in relation to the number of flows. Thus, sketching algorithms fit well for programmable switches with tight resource constraints. There are sketching algorithms to support diverse statistics for measurement tasks. For example, count-min sketch (CM) [17] can identify heavy hitters, and it can be configured with flowkey definition of srcIP to run Query. 1. HyperLogLog (HLL) [21] can estimate the distinct number of flows, and it can answer Query. 2 with flowkey definition of 5-tuple. There are other sketching algorithms, such as K-ary sketch (KARY) [27] for heavy change detection or UnivMon (UM) [32] for multiple statistics.

Sketching algorithms follow three common steps. We explain these steps with a canonical sketching algorithm count-min sketch [17] (Fig. 2). First, sketching algorithms perform *hash computations*. As each packet arrives, the count-min sketch extracts a flowkey (e.g., 5-tuple) from the packet header. On this key, the count-min sketch computes independent hash functions c_i . Second, using these hash results, sketching algorithms perform *counter updates*. They typically maintain 2D counter arrays, R independent counter arrays with the size of W , thus $R \times W$ counters in total. The hash result of c_i selects a specific column for counter update per row. The count-min sketch is a single-level sketching algorithm meaning that it maintains 2D counter arrays. There is a notion of a multi-level sketching algorithm, which uses multiple levels of 2D counter

arrays. Third, sketching algorithms need to maintain *heavy flowkey storage*. Sketching algorithms use threshold values to compare against flow size estimates to detect and store heavy flowkeys. While these steps run on the data plane, the control plane periodically reads and resets counter arrays and heavy flowkey storage to compute desired metrics [37].

While the ideas of Sketchovsky can be applied to other programmable switch architectures (as stated in §9), we showcase the effectiveness and benefits of Sketchovsky using Intel’s Tofino switch [1]. Tofino is a commercially available programmable switch built on the RMT architecture [13] and the P4 language [12]. Its pipeline stage architecture is equipped with equal resources per stage, and running sketching algorithms on programmable switches requires the use of four key hardware resources. **Hash units** execute hash functions and there are a certain number of hash units per pipeline stage. The hash results of hash units can be used to select a specific column for counter updates or other purposes (§A.1). Each pipeline stage has a fixed amount of **SRAM** that can be used to maintain the state. SRAM is used by counter arrays and heavy flowkey storage. **Stateful ALU (SALU)** is the essential hardware resource that allows one read and one write operation to a register array in SRAM. A counter array for a sketch instance is mapped to a register array. Thus, a sketch instance using R counter arrays requires R SALUs. Storing heavy flowkey also requires SALUs. More **pipeline stages** are needed for more usage of the above three hardware resources. In addition, the notion of dependencies among workflow steps (e.g., *counter updates* must be executed earlier than *heavy flowkey storage*) can contribute to even more pipeline stage usage due to the imbalanced resource allocation.

2.2 Need for Ensemble of Sketch Instances

Network operators need to concurrently run diverse flow-level measurement tasks on programmable switches because the more information operators can get about the network, the more they can make the right management decisions [15, 25, 34, 38, 47, 48, 49, 52]. As concrete examples of measurement tasks, we show two network queries written by Sonata [25], a state-of-the-art query language on programmable switches. [Query 1](#) can detect heavy hitters based on the sum of packet length in bytes aggregated on flowkey of srcIP. [Query 2](#) measures the distinct number of 5-tuple flows. Network operators want to concurrently run these measurement tasks as many as possible.

Each such measurement task would entail creating a sketch instance based on a base sketching algorithm (SA) with four configurable parameters (Table 1): (1) **Flowkey** is any combination of packet header fields (e.g., srcIP or 5-tuple); (2) **Flowsize** defines whether the sketch instance keeps track of packet counts or packet bytes; (3) **Epoch** is the measurement time interval; and (4) **Resource Parameters** configure the memory size (e.g., W and R of 2D counter arrays). The net-

SI	Base SA	Configurable Parameters			
		Flowkey	Flowsize	Epoch	Res. Param.
s_1	CM	(srcIP)	counts	10s	(3, 1024)
s_2	CM	(dstIP)	bytes	10s	(5, 2048)
s_3	KARY	(srcIP, dstIP)	counts	10s	(4, 4096)
s_4	HLL	(srcIP, srcPort)	-	5min	(1, 2048)
s_5	UM	(5-tuple)	counts	5min	(3, 2048, 16)

Table 1: An example of an ensemble of sketch instances. For resource parameters, (R, W) for single-level and $(R, W, level)$ for multi-level sketching algorithms.

Solution	General	Resource	Accuracy
P4 Composition [22, 23, 30, 42, 51]	✓	X	✓
Per-sketch optimizations [4]	✓	X	✓
Expressive sketches [9, 15, 32, 49]	X	✓	✓
Dynamic resource allocation [3, 36, 50]	✓	✓	X
Sketchovsky (Our system)	✓	✓	✓

Table 2: Existing efforts cannot support a general ensemble of measurement tasks with low resource footprint and high accuracy.

work operator should choose resource parameters carefully due to a trade-off between resource use and accuracy.

For instance, given [Query 1](#) above, we can use a count-min sketch instance on the srcIP as flowkey and for [Query 2](#) we may use HyperLogLog on the 5-tuple. More generally, given the collection of measurement tasks with different configurable parameters (flowkey, flowsize, epoch) and statistics, we will need to concurrently run *an ensemble of sketch instances* in practice. For our work, we assume that the ensemble of sketch instances is given as input; the problem of finding the best ensemble of sketch instances given a collection of measurement tasks is outside the scope of this paper (§9).

2.3 Prior Work and Limitations

We discuss some existing efforts in sketch-based telemetry on programmable switches and why they are insufficient to tackle the ensemble of sketch instances problem (Table 2).

Composing P4 programs. Many P4 code composition works have been recently published for resource optimizations [22, 23, 30, 42, 51]. However, none of them can optimize the sketch ensemble because they did not consider stateful processing, which is at the core functionality of sketching algorithms (e.g., *counter update* step). P4visor [51], Lyra [22], and Cetus [30] focus on optimizations for match-action tables, but they did not consider optimizations for stateful processing, including MicroP4 [42]. Thus, they cannot be used to optimize an ensemble of sketch instances.

Chipmunk [23] seems to be a promising candidate for providing cross-sketch optimizations at first glance because it compiles a program written by Domino language into optimized P4 code with stateful processing optimizations. However, Chipmunk can not compile a full single sketch implementation due to its limited scope. It only supports the update part of the stateful value but does not include the addressing part (e.g., computing hash functions to address the column

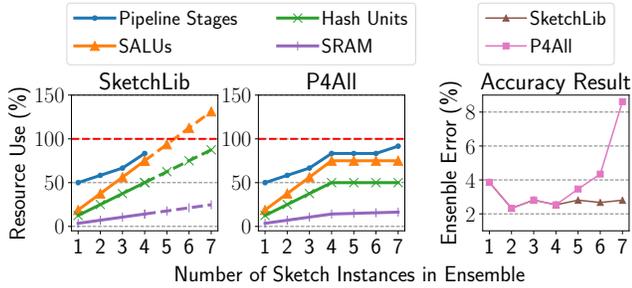

Figure 3: Existing efforts cannot efficiently run the ensemble.

index of counter arrays), which is critical for sketch implementations.

Per-sketch optimizations [4] can be used to implement the sketch ensemble. However, this approach cannot achieve low resource footprints due to *linearly* increasing resource consumption as we run multiple sketch instances.

More expressive sketches. To make improvements, recent advances in sketching theory empower a single sketch instance to support multiple measurement tasks [9, 15, 32, 49]. However, their coverage of the measurement tasks is still far from general (e.g., none of them can support the entropy estimation tasks for two different flowkey definitions).

Dynamic resource allocation. Earlier work has reduced resource use for the ensemble of sketch instances [3, 36, 50]. SCREAM [36] dynamically reduces resource parameters of sketch instances to meet specified minimum accuracy when there are variations in traffic. P4All [3] can be used to reduce the resource parameters of some sketch instances in the ensemble by identifying lower-prioritized sketch instances. FlyMon [50] enables dynamic parameter configuration at runtime (e.g., flowkeys and resource parameters). It essentially offers a time-sharing capability to run a sketch ensemble by switching out active sketch instances. However, all these techniques reduce resource use at the expense of accuracy. In contrast, our work proposes optimizations that reduce resources while maintaining accuracy for all sketch instances in the ensemble.

Quantitative results for existing efforts. We quantitatively show why existing efforts are insufficient. Fig. 3 shows the resource footprint and accuracy results for two approaches, per-sketch optimization (SketchLib) and dynamic resource allocation (P4All). To create the ensembles, we only use the count-min sketch with $(R, W) = (5, 8K)$, flowkey of 4-tuple, different measurement epochs, and different flowsize definitions. We use CAIDA traces [2]. For the P4All experiment, we fix the width of counter arrays and reduce the number of rows if necessary to fit the maximum number of SALUs on the Tofino switch. We treat all sketch instances equally in the objective function.

The results in Fig. 3 show that SketchLib cannot support more than four sketch instances. While P4All can support more than four sketch instances by reducing hardware re-

sources, this also reduces the accuracy. In summary, we find that existing techniques cannot achieve both low resource footprint and high accuracy.

3 Sketchovsky Overview

Given that prior work is insufficient, we explore a *complementary* approach to identify and exploit *cross-sketch* optimizations to run an ensemble of sketch instances $\mathcal{S} = \{s_i\}_{i=1}^N$. To this end, we present Sketchovsky (Fig. 1), a novel cross-sketch optimization and composition framework. Sketchovsky identifies five cross-sketch optimization building blocks so that resource consumption increases *sub-linearly* in the number of sketch instances with guarantees of no accuracy loss. Sketchovsky uses efficient heuristics to find an effective strategy to combine these building blocks for a given ensemble and implements a module to automatically generates an optimized switch code.

Optimization building blocks (§4). We find that key hardware resources used in each workflow step of sketching algorithms can be *reused across* multiple sketch instances. We identify five optimization building blocks to reduce resource footprint while maintaining accuracy. O_{Hash1} and O_{Hash2} optimize the first step of hash computations; O_{Ctr1} and O_{Ctr2} optimize the second step of counter updates, and O_{Key} optimizes the third step of heavy flowkey storage. Note that optimizations can be generalized to other hardware (§9). Each O_j has applicable conditions to determine whether O_j can be applied to a subset of sketch instances $\mathbf{S} \subset \mathcal{S}$. Applicable conditions are expressed by *configurable parameters* introduced in (§2.2) (e.g., all $s_i \in \mathbf{S}$ have the same flowkey) and *sketch features*. The notion of sketch features captures the differences among different sketching algorithms in algorithm designs or data structures (e.g., counter array type, counter update type, or whether maintaining heavy flowkeys or not).

Strategy finder (§5). Among many valid strategies for applying five optimization building blocks to different subsets of sketch instances in the ensemble, it is challenging to quickly find the most effective strategy due to the intractably large search space. To solve this problem, we formulate an optimization problem by defining the objective function to minimize hardware resources. Next, we propose an idea of problem decomposition. We show that one large problem can be decomposed into small sub-problems, and separate solutions for sub-problems together produce the overall solution. To detect the validity of a strategy, the strategy finder takes inputs of sketch features (e.g., base sketching algorithm) and configurable parameters (e.g., flowkey and flowsize) for \mathcal{S} as in Table 1. Optimization building blocks can be applied to a subset $\mathbf{S} \subset \mathcal{S}$ only if \mathbf{S} satisfies the applicable conditions.

Auto-code composition (§6). Manually translating a strategy into an optimized code is challenging because the strategy contains information about the complicated interplay among multiple optimization building blocks and a set of sketch

Workflow Step	Optimizations	Reduction	Overhead

instances. We build an auto-code composition that automatically translates a given strategy into optimized sketch code. This relieves the burden of manual work of network operators. Given the output of the strategy finder and a set of sketch P4 codes for \mathcal{S} , we generate a unified and optimized P4 program.

4 Optimization Building Blocks

Given $\mathcal{S} = \{s_i\}_{i=1}^N$, we identify five cross-sketch optimization building blocks (two for hash, two for counters, and one for flowkey storage) that can apply to a given set of sketch instances $\mathbf{S} = \{s_i\}_{i=1}^n \subset \mathcal{S}$. Table 3 summarizes relationships among workflow steps, optimizations and resource reductions. For each optimization, we explain the key idea, the conditions under which it applies, and its implications for resource use and accuracy. Table 4 summarizes applicable conditions to validate whether each optimization can be applied to $\mathbf{S} \subset \mathcal{S}$.

4.1 Hash Computations

To optimize the workflow step of *hash computations* (§2.1), we have two optimizations HASHREUSE (O_{Hash1}) and HASHXOR (O_{Hash2}). Hash unit refers to the hardware resource on programmable switches to execute hash functions. Hash result is the outcome hash value of the hash unit.

HASHREUSE (O_{Hash1}) Reusing hash results. If a set of sketch instances use the same definition of flowkey (e.g., srcIP), we can reuse hash results to reduce the usage of hash units. We explain this optimization using an example in Fig. 4. Assume we have a set of sketch instances $\mathbf{S} = \{s_i\}_{i=1}^n$ with a required set of independent hash results $\mathbf{E} = \{e_i\}_{i=1}^n$ and flowkey definition $\mathbf{F} = \{f_i\}_{i=1}^n$, which means that a sketch instance s_i needs e_i number of hash results based on flowkey f_i . Without optimization, $\sum_i e_i$ hash units are used. However,

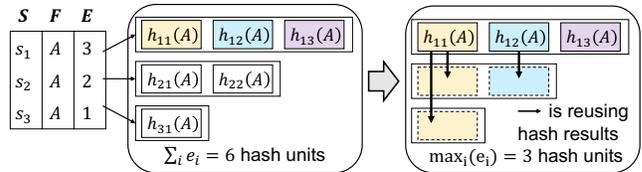

Figure 4: HASHREUSE (O_{Hash1}) reduces hash units by reusing hash results. A small box with $h_{seed}(\text{flowkey})$ indicates one hash unit allocation.

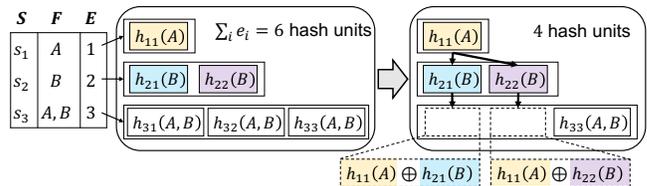

Figure 5: HASHXOR (O_{Hash2}) reduces hash units by using XOR.

we can reuse hash results, and we can reduce the allocation of hash units to $\max_i(e_i)$ on the hardware as in Fig. 4.

Applicability: Regardless of any sketching algorithms, we can apply this optimization as long as \mathbf{S} uses the same flowkeys. We denote this as (C4) in Table 4.

Implication: Allocation of $\max_i(e_i)$ hash units is sufficient to preserve the accuracy of $\mathbf{S} = \{s_i\}_{i=1}^n$. The accuracy of sketch instances is closely related to hash independence among hash results. To implement hash independence in practice, randomly picked hash seeds are used; $h_{seed1}(A)$ and $h_{seed2}(A)$ are independent if $seed1 \neq seed2$. For a single sketch instance, hash independence among hash results is required. A key insight here is that hash independence is not required *across* sketch instances. Thus we can reuse $\max_i(e_i)$ hash results across sketch instances in a way that all hash results within any single sketch instance s_i are independent (e.g., in Fig. 4).

HASHXOR (O_{Hash2}) Less hashing, same performance with XOR-based reconstruction. We can reduce hash units even for a set of sketch instances with different flowkeys by leveraging XOR operations. We explain this optimization using an example in Fig. 5 where $\mathbf{S} = \{s_1, s_2, s_3\}$ and $\mathbf{F} = \{\{A\}, \{B\}, \{A, B\}\}$ and $\mathbf{E} = \{1, 2, 3\}$. A and B are different packet headers, such as $A = \text{srcIP}$ and $B = \text{dstIP}$. We can reduce allocation of hash units by reconstructing independent hash results for s_3 as follows because $\{A, B\} = \{A\} \cup \{B\}$.

$$h_{31}(A, B) = h_{11}(A) \oplus h_{21}(B) \quad (1)$$

$$h_{32}(A, B) = h_{11}(A) \oplus h_{22}(B) \quad (2)$$

Note that XOR-based reconstructed hash results $h_{31}(A, B)$ and $h_{32}(A, B)$ are independent because $h_{21}(B)$ and $h_{22}(B)$ are independent. For arbitrary e_1 and e_2 , we can reconstruct $e_1 \times e_2$ independent hash results for s_3 .

Applicability: This optimization HASHXOR (O_{Hash2}) can be applied if \mathbf{S} and \mathbf{F} meet the following condition.

$$\text{For } \mathbf{S} \in \mathcal{S}, |\mathbf{S}| = 3 \text{ and } f_1 \cup f_2 = f_3 \quad (3)$$

This optimization can be applied as long as a set of sketch instances satisfies (3). Thus, we mark (*) at (C4) in Table 4 for O_{Hash2} .

Implications: This idea of XOR-based hash reconstruction is proven pairwise independent and has already been used in other contexts [26, 43]. Thus, accuracy will not be compromised, and our evaluation result confirms this. As a minor side effect, more pipeline stages might be needed by adding XOR operations in the sketch workflow. However, we will see in the evaluation that the impact of this overhead is small.

4.2 Counter Update

To optimize the second workflow step of *counter updates*, we have SALUREUSE (O_{Ctr1}) and SALUMERGE (O_{Ctr2}).

SALUREUSE (O_{Ctr1}) Reusing counter arrays (rows) across sketch instances. If all sketch instances in \mathbf{S} meet certain applicable conditions, we can reuse counter arrays to reduce both SALUs and SRAM. We first see how this optimization works by looking at an example in Fig. 6, and we will describe applicable conditions later. Suppose $\mathbf{S} = \{s_1, s_2, s_3\}$ satisfies applicable conditions of O_{Ctr1} and $\mathbf{C} = \{(r_i, w_i)\}_{i=1}^n$ represent that s_i has r_i number of counter arrays with width w_i . Then, instead of updating three different sets of counter arrays for three sketch instances in the data plane, we can update only one set of counter arrays. Then, in the control plane, one set of counter arrays can be used to compute statistics for all three sketch instances. The way we compute the row and width of counter arrays for reuse is represented by \mathbf{W} :

$$\mathbf{W} = \{w_j^*\}_{j=1}^{\max_i(r_i)} \text{ where } w_j^* = \max_i \{w_i | r_i \geq j\} \quad (4)$$

\mathbf{W} represents width w_j^* per j -th counter array for reuse. Note that \mathbf{W} can have different widths across counter arrays, and it does not affect the functionality of sketching algorithms. We can see that \mathbf{W} has $\max_i(r_i)$ rows. Thus, we can reduce SALUs from $\sum_i r_i$ to $\max_i(r_i)$. Moreover, SRAM usage is reduced from $\sum_i r_i w_i$ to $\sum_j w_j^*$ and we show $\sum_i r_i w_i - \sum_j w_j^* \geq 0$ in §B.1. While the discussion focused on single-level sketch instances, the same idea also applies to multi-level sketch instances.

Implication: If we compare resource parameters (r_i, w_i) of any sketch instance s_i to counter arrays for reusing \mathbf{W} , \mathbf{W} has the same or larger width. As a result, all sketch instances are guaranteed to achieve the same or improved accuracy.

Applicability: Applicable conditions for this optimization use two sketch features. The first sketch feature is **counter array type**. Sketching algorithms have different types of counter arrays; the single-level (SL) type has 2D counter arrays, and the multi-level (ML) type has multiple levels of 2D counter arrays. The second sketch feature is **counter update type**. Sketching algorithms have different ways of updating counters. It can be bitmaps (BITMAP) or integer counters that only add values (COUNTER). Refer §A.1 for a full list of five

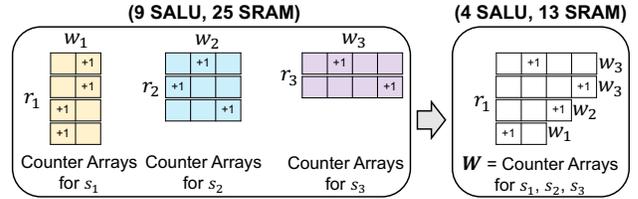

Figure 6: SALUREUSE (O_{Ctr1}) reuses counter arrays.

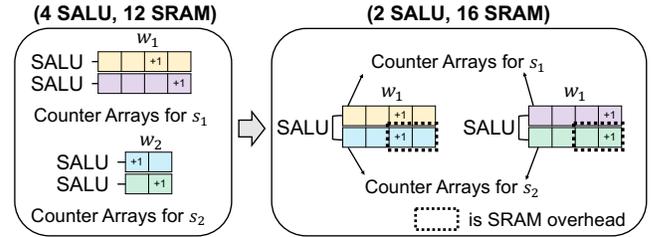

Figure 7: SALUMERGE (O_{Ctr2}) reduces SALUs by making SALUs update two counter arrays simultaneously.

counter update types. $\mathbf{S} \subset \mathcal{S}$ must satisfy five conditions to apply this optimization (Table 4): the same counter array type, the same counter update type, the same flowkey, the same flowsize, and the same epoch (C1, C2, C4, C5, C6).

SALUMERGE (O_{Ctr2}). Combining two counter updates into one SALU allocation. Leveraging the full capability of the underlying hardware resources can help resource reduction of \mathbf{S} . We observe that SALU can update two registers addressed in the same index and we can leverage this feature to update two counter arrays simultaneously. As a result, we can reduce SALUs by up to 2x. We explain this optimization by using an example in Fig. 7. We have two sketch instances with two counter arrays each, and we originally needed four SALUs. Then, we can make SALUs update two counter arrays simultaneously and reduce SALUs from 4 to 2.

We find two rules in the Tofino switch for a SALU to update two counter arrays. (R1) derives applicable conditions, and (R2) incurs SRAM overhead.

- (R1) Column indexes for counter updates are the same
- (R2) Two counter arrays have the same width

Applicability: (R1) derives two applicable conditions (C1, C4). If sketch instances use the same counter array type (C1) (e.g., sketch instances are either all single-level or all multi-level) and use the same definition of flowkey (C4), we can apply this optimization. Because flowkeys are the same, we can leverage HASHREUSE (O_{Hash1}), and SALU can update two counter arrays using the reused hash result for the column index. If flowkeys are different, then column indexes for the counter update can not be the same, which will violate (R1). Note that we should not let SALU update two counter arrays within a sketch instance because updating the same column index will lose hash independence and degrade accuracy.

Implication: This optimization can incur the additional SRAM overhead due to (R2). Suppose we have two sketch

instances $\{s_1, s_2\}$ with two counter arrays each as in Fig. 7 with width of $\{w_1, w_2\}$ s.t. $w_1 > w_2$. Suppose we can apply the optimization to $\{s_1, s_2\}$. Then, we should pick the longer width w_1 for counter arrays to preserve the accuracy of both $\{s_1, s_2\}$. As a result, the accuracy will be maintained (e.g., for s_1) or improved (e.g., for s_2). However, this will incur an SRAM overhead of $w_2 - w_1$ for s_2 , as marked in Fig. 7. Despite the SRAM overhead, we argue that this optimization is still effective and practical for three reasons. First, increased SRAM is not wasted but will improve accuracy. Second, the overall SRAM overhead is bounded by $2x$ ($\frac{2 \max(w_1, w_2)}{w_1 + w_2} \leq 2$). Third, SRAM is not the imminent bottleneck as we will see in the evaluation.

4.3 Heavy Flowkey Storage

To optimize the third workflow step of *heavy flowkey storage*, we have one optimization HFSREUSE (O_{Key}).

HFSREUSE (O_{Key}). Reusing heavy flowkey storage across sketch instances. A large portion of sketching algorithms store heavy flowkeys in the switch data plane [9, 14, 16, 17, 27, 32, 41]. We can reduce the usage of SALUs (the hardware used for memory accesses) by reusing heavy flowkey storage across sketch instances. If multiple sketch instances have the same definition of flowkey (e.g., srcIP), we can store heavy flowkey in one heavy flowkey storage to save SALUs. We can generalize this idea to sketch instances with different definitions of flowkey using the notion of *union-key*. Suppose we have two sketch instances $\mathbf{S} = \{s_1, s_2\}$ with two different flowkey definitions $\mathbf{F} = \{\{\text{srcIP}\}, \{\text{dstIP}\}\}$. Then, instead of maintaining two heavy flowkey storage, we use one flowkey storage using union-key of $\{\text{srcIP}, \text{dstIP}\}$ where union-key can be computed by $(UK = \cup_i f_i)$. Then, for a given packet, if *either* $\{\text{srcIP}\}$ is identified as a heavy flowkey for s_1 or $\{\text{dstIP}\}$ is identified as a heavy flowkey for s_2 . We store $\{\text{srcIP}, \text{dstIP}\}$ of the given packet in the heavy flowkey storage.

We can do a further optimization to reduce memory usage of heavy flowkey storage. Suppose $\mathbf{S} = \{s_1, s_2\}$ and $\mathbf{F} = \{\{\text{srcIP}\}, \{\text{dstIP}\}\}$. For a given packet, if $\{\text{srcIP}\}$ is identified as a heavy flowkey whereas $\{\text{dstIP}\}$ is not, we store $\{\text{srcIP}, 0\}$ so that the control plane knows this flowkey is only for s_1 . To generalize this idea to multiple sketch instances, we can compute a *conditional union-key* $UK_C = \cup_j f_j$ where (flow size estimate) $_j > \text{threshold}_j$ and set 0 to $(UK - UK_C)$ when we store heavy flowkey into the storage.

Applicability: We can apply this optimization to a set of sketch instances \mathbf{S} if all sketch instances in \mathbf{S} tracks heavy flowkeys (C3) as in Table 4. For different measurement epochs, we can compute the greatest common denominator (GCD) among all epochs, and the control plane can retrieve heavy flowkeys every time period of GCD. For example, if there are sketch instances with 10s, 20s, and 30s measurement epochs, the control plane retrieves heavy flowkeys for

every 10s, and we can reconstruct heavy flowkeys for sketch instances of 20s and 30s.

Implication: By storing fine-grained heavy flowkeys by union-key, the control plane can retrieve heavy flowkeys for individual sketch instances by aggregation without missing any heavy flowkeys. This optimization incurs small additional computations on the switch control plane. However, this overhead does not affect the overall performance because this control plane computation is not on the critical path to provide measurement results. While the switch data plane updates the counter arrays, the switch control plane can independently execute heavy flowkey aggregation on the CPU. Another small overhead of the pipeline stage can occur, but we will see in the evaluation that the impact is small.

5 Strategy Finder

In the previous section, we proposed five optimizations $\{O_j\}_{j \in \{\text{Hash1}, \text{Hash2}, \text{Ctr1}, \text{Ctr2}, \text{Key}\}}$ and their applicable conditions to a subset of sketch instances $\mathbf{S} = \{s_i\}_{i=1}^n \subset \mathcal{S}$. In this section, we aim to develop a strategy finder that partitions \mathcal{S} into the best applicable subsets so that five optimization building blocks can produce the maximum benefit for any given ensemble \mathcal{S} .

5.1 Problem Formulation

We formulate an optimization problem to find the optimal strategy. We consider partitions of \mathcal{S} because each optimization O_j is applied to disjoint subsets of \mathcal{S} . Suppose $\mathcal{P}_{\mathcal{S}} = \{P_k | P_k \text{ is } k^{\text{th}} \text{ partition of the set } \mathcal{S}\}$ is a set containing all partitions of the set \mathcal{S} where $P_k = \{\mathcal{S}_l \subset \mathcal{S} | \cup_l \mathcal{S}_l = \mathcal{S}\}$. The goal is to find the optimal strategy X^* , which minimizes hardware resources while satisfying the applicable conditions:

$$\min_X HwResource(X) \quad (5)$$

$$\text{s.t. } \sum_{k=1}^{|\mathcal{P}_{\mathcal{S}}|} x_{jk} = 1, \forall j \in \{\text{Hash1}, \text{Hash2}, \text{Ctr1}, \text{Ctr2}, \text{Key}\} \quad (6)$$

$$Valid(X) = 1 \quad (7)$$

The decision variable is $X = \{X_j\}_{j \in \{\text{Hash1}, \text{Hash2}, \text{Ctr1}, \text{Ctr2}, \text{Key}\}}$. X_j selects a partition $P_k \in \mathcal{P}_{\mathcal{S}}$ for O_j so that O_j is applied to all subsets $\in P_k$. To express this, we define $X_j = \{x_{jk} | x_{jk} \in \{0, 1\}\}_{k \in \{1, \dots, |\mathcal{P}_{\mathcal{S}}|\}}$ and $x_{jk} = 1$ if P_k is selected. Note that (6) makes X_j pick only one partition P_k for O_j . About constraint (7), we use $Valid(X) \in \{0, 1\}$ to denote whether strategy X is *valid* or not. X is valid if all subsets $\in P_k$ satisfy the applicable conditions of O_j for $\forall j$. It is assumed that applicable conditions are met for the subset $\mathbf{S} \subset \mathcal{S}$ containing a single sketch instance s.t. $|\mathbf{S}| = 1$. For objective function (5), we aim to find a strategy X^* that minimizes hardware resource among all valid strategies X . To model this objective function $HwResource(X)$, we use the linear combination of four key

resource usage:

$$LinearComb(X, R) = \sum_{r \in R} a_r \cdot resource_r(X) \quad (8)$$

$$R = \{SALU, HashUnit, SRAM, PipelineStage\} \quad (9)$$

Network operators can use (8) and customize the objective function by choosing different coefficient sets $\{a_r\}_{r \in R}$ for their preference. For example, suppose network operators desire to reduce SRAM more than other resources to run the ensemble with memory-intensive applications, they can increase the weight for a_{SRAM} in (8).

5.2 Challenges

We face three challenges in formulating and solving the optimization problem.

C-1. Large search space. We have a large search space for enumeration because the number of possible partition $|\mathcal{P}_S|$ increases exponentially as the number of sketch instances $|\mathcal{S}|$ increases [8]. Even after we consider constraint (6), the decision variable X has $|\mathcal{P}_S|^5$ combinations because X selects five partitions among \mathcal{P}_S . This large search space makes finding the optimal solution X^* become intractable. In practice, operators often need to reconfigure sketch ensembles, and waiting for the optimization to complete may end up being on the critical path [50].

C-2. Modeling the valid function. It is hard to define $Valid(X)$ due to the dependencies among optimizations. Specifically, there exist dependencies between O_{w1} and O_{w2} for $w \in \{Hash, Ctr\}$ because they are applied to the same workflow steps. Thus, it is unclear whether a sketch instance s_i can be benefited from O_{w1} and O_{w2} at the same time. Further, if they can, then it is also unclear how to figure out the relationship between X_{w1} and X_{w2} to detect the validity of X to define $Valid(X)$.

C-3. Modeling the objective function. We find that computing $LinearComb(X, R)$ takes a long time because accurately measuring pipeline stage usage requires the compilation of an optimized P4 code by applying strategy X . The execution time for $resource_{pipeline_stage}(X)$ takes several minutes. This delay will significantly impede the search process, and finding a solution X^* can become even more intractable.

5.3 Our Approach

Next, we reformulate the problem and show that finding the optimal strategies for each O_j will create the overall solution X^* . This reduces search space significantly and makes the problem tractable.

Excluding pipeline stage from the objective function. To handle (C-3), we make a pragmatic choice of excluding the pipeline stage from the objective function. We use $LinearComb(X, R')$ as objective function where $R' = \{SALU, HashUnit, SRAM\}$. $resource_r(X)$ for $r \in R'$ can be quickly

computed because X contains information about the number of reused or XOR-reconstructed hash units, reused or co-located counter arrays, and reused heavy flowkey storage. The impact of this decision cannot be measured because the optimal objective function is unknown and difficult to define. However, we can still identify effective solutions that can yield significant benefits in practice because there is a correlation between the resource reduction on R' and the pipeline stage reduction (§8).

Search space decomposition across workflow steps. To overcome the challenge of large search space (C-1), we can decompose the optimization problem into three sub-problems, and solution X^* can be achieved by solving sub-problems separately. Specifically, we decompose the decision variable X into three groups corresponding to three workflow steps:

$$X_{Hash} = \{X_{Hash1}, X_{Hash2}\}, X_{Ctr} = \{X_{Ctr1}, X_{Ctr2}\}, X_{KEY} = \{X_{KEY}\}$$

Then, we can also decompose the valid function and the objective function as follows:

$$X = \cup_{w \in \{Hash, Ctr, KEY\}} X_w \quad (10)$$

$$Valid(X) = \prod_{w \in \{Hash, Ctr, KEY\}} Valid(X_w) \quad (11)$$

$$HwResource(X) = \sum_{w \in \{Hash, Ctr, KEY\}} HwResource(X_w) \quad (12)$$

This problem decomposition is possible for two reasons. First, although there are dependencies in terms of applicability within X_w , there are no dependencies *across* X_w because optimizations are independently applied to different workflow steps. Thus, $Valid(X)$ can be achieved by multiplication of decomposed $Valid(X_w)$ as in (11). Second, $HwResource(X)$ can be achieved by summation of decomposed $HwResource(X_w)$ as in (12). Without the idea of excluding pipeline stage usage, this linearity property (12) does not hold because measuring pipeline stage usage must consider the overall table dependency graph (TDG) among workflow steps (X_w). As a result, a solution X^* can be achieved by $X^* = \{X_{Hash}^*, X_{Ctr}^*, X_{KEY}^*\}$ where X_w^* is a solution of each sub-problem for $w \in \{Hash, Ctr, KEY\}$ as follows:

$$\min_{X_w} HwResource(X_w) \text{ s.t. } Valid(X_w) = 1 \quad (13)$$

Two-step enumeration for X_{Hash} and X_{Ctr} . Although we can decompose $Valid(X)$ into three $Valid(X_w)$ as in (11), it is still unclear how to realize $Valid(X_w)$ for $w \in \{Hash, Ctr\}$ because there exist dependencies between O_{w1} and O_{w2} . We can solve this problem using an enumeration technique that efficiently explores the search space. Suppose the enumeration does not miss out on *valid* X_w (s.t. $Valid(X_w) = 1$) while efficiently skips *invalid* X_w . In that case, it will help to solve not only the challenge (C-2) of modeling a valid function but also the challenge (C-1) by reducing search space. To achieve this, we develop a two-step enumeration technique as in Alg. 1.

Algorithm 1 TwoStepEnumeration

```

1: procedure TWOSTEPENUMERATION( $\mathcal{S}, w$ )
2:    $\mathcal{P}_{\mathcal{S}} = \{P_k | P_k \text{ is } k^{\text{th}} \text{ partition of the set } \mathcal{S}\}$ 
3:    $min \leftarrow INTMAX$ 
4:   for  $X_{w1}$  s.t. selected  $P_{w1} \in \mathcal{P}_{\mathcal{S}}$  is valid do
5:     for  $X_{w2}$  s.t.  $P_{w1} \leq P_{w2} \in \mathcal{P}_{\mathcal{S}}$  do
6:        $X_w \leftarrow \{X_{w1}, X_{w2}\}$ 
7:        $P_{w12} = NESTEDPARTITION(P_{w1}, P_{w2})$ 
8:       if  $P_{w12}$  is valid then
9:         if  $min > HwResource(X_w)$  then
10:            $min \leftarrow HwResource(X_w)$ 
11:            $X_w^* \leftarrow X_w$ 
12:   return  $X_w^*$ 

```

We explain this algorithm by both cases of $w \in \{\text{Hash}, \text{Ctr}\}$. Let's first see an example for $w = \text{Hash}$, HASHREUSE (O_{Hash1}) and HASHXOR (O_{Hash2}). Suppose we have five sketch instances $\mathcal{S} = \{s_i\}_{i=1}^5$ with flowkey definition $\mathbf{F} = \{\{\text{srcIP}\}, \{\text{srcIP}\}, \{\text{dstIP}\}, \{\text{srcIP}, \text{dstIP}\}, \{\text{srcPort}\}\}$. Then the algorithm enumerates all valid P_{w1} at line 4 in Alg. 1. $P_{w1} = \{\{s_1, s_2\}, \{s_3\}, \{s_4\}, \{s_5\}\}$ can be picked because $\{s_1, s_2\}$ have the same flowkey so that we can reuse hash results to reduce hash units. Next, given picked P_{w1} , it enumerates P_{w2} s.t. $P_{w1} \leq P_{w2}$ ² to create *nested partition* P_{w12} using P_{w1} and P_{w2} . If $P_{w2} = \{\{s_1, s_2, s_3, s_4\}, \{s_5\}\}$ is picked, then the nested partition is $P_{w12} = \{\{\{s_1, s_2\}, \{s_3\}, \{s_4\}\}, \{\{s_5\}\}\}$. To see the validity of P_{w12} , check whether all subsets in P_{w12} satisfy applicable conditions of O_{Hash2} at line 8. Picked P_{w12} is valid because subset $\mathbf{S} = \{\{s_1, s_2\}, \{s_3\}, \{s_4\}\} \in P_{w12}$ satisfies applicable conditions of $|\mathbf{S}| = 3$ and $\{\text{srcIP}\} \cup \{\text{dstIP}\} = \{\text{srcIP}, \text{dstIP}\}$ as in (3) at §4.1. Note that $\{s_1, s_2\}$ is handled as if it is a single sketch instance with a flowkey of $\{\text{srcIP}\}$.

Interestingly, the same algorithm works for $w = \text{Ctr}$, SALUREUSE (O_{Ctr1}) and SALUMERGE (O_{Ctr2}). First, the algorithm enumerates P_{w1} where all subsets in P_{w1} satisfy applicable conditions (C1, C2, C4, C5, C6) of O_{Ctr1} . For picked P_{w1} , O_{Ctr1} is applied to all subsets $\in P_{w1}$, meaning that each subset has one set of counter arrays for reuse \mathbf{W} as discussed as in (3) at §4.2. Then each subset can be handled as if it is a single sketch instance with counter arrays configured with \mathbf{W} . Next, we can detect the validity of nested partition P_{w12} using the applicable conditions (C1, C4) of O_{Ctr2} at line 8 in Alg. 1.

HFSREUSE (O_{Key}) does not need this two-step enumeration. The solution for O_{Key} is one subset \mathbf{S} containing all sketch instances that track heavy flowkey because this will minimize the hardware resource usage.

Search space decomposition within workflow steps. Although two-step enumeration reduces search space by picking P_{w1} first and then P_{w2} such that $P_{w1} \leq P_{w2}$, this enumeration technique still takes a long time to finish (e.g., more than a day). To this end, we come up with an idea to decompose

²If every element of partition P_{w1} is a subset of some element of partition P_{w2} , then $P_{w1} \leq P_{w2}$. In other words, P_{w1} is finer and P_{w2} is coarser.

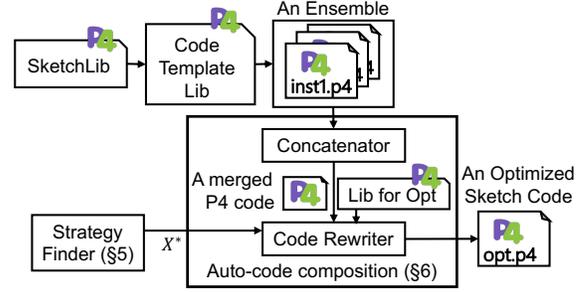

Figure 8: Overview of auto-code composition.

```

07: /* 3. heavy flowkey storage step - no code */

```

Figure 9: Code template example for PCSA.

X_{w1} and X_{w2} by using a greedy heuristic algorithm. Instead of running a nested loop (lines 4-5 in Alg. 1) for finding P_{w1} and P_{w2} , we can first find the optimal P_{w1}^* given \mathcal{S} and then finds P_{w2}^* based on already fixed P_{w1}^* . This greedy heuristic algorithm decomposes the search space of $\{X_{w1}, X_{w2}\}$ into separate $\{X_{w1}\}$ and $\{X_{w2}\}$.

The insight behind this greedy heuristic algorithm comes from the applicability-benefit trade-off between O_{w1} and O_{w2} . O_{w1} is more difficult to apply but has a high resource reduction benefit. O_{w2} is easier to apply but has a low resource benefit. Thus, it makes sense that the algorithm first applies O_{w1} as much as possible, then next applies O_{w2} . We can not prove whether this greedy heuristic algorithm can find the same or close solution compared to the two-step enumeration. However, we empirically show that the overhead of objective function increase is small (e.g., less than 2%) while solving time of the greedy heuristic algorithm is more than three orders of magnitude faster (§D.3).

6 Auto-Code Composition

Using solution X^* from the strategy finder, we need two steps to generate an optimized P4 code for \mathcal{S} as in Fig. 8.

6.1 Sketch P4 Codes and Concatenation

The first step requires network operators to provide N sketch P4 codes that should match with sketch features and configurable parameters for the ensemble $\mathcal{S} = \{s_i\}_{i=1}^N$ (e.g., Table 1).

Code template library. Writing N sketch P4 codes from scratch is a cumbersome task for network operators. An effective way is to provide code templates of the sketching algorithm with which P4 code for a sketch instance can be created. We build code templates for sketching algorithms so that network operators can configure the template with tunable parameters. Fig. 9 shows a code template example of

one sketching algorithm PCSA [20]. Network operators can fill out placeholders using configurable parameters.

SketchLib. To further simplify the code template, we consider using a common library to write codes for sketch instances, such as SketchLib [4]. The idea of using API calls makes code templates simple and concise. We extend SketchLib to enable the flexible configuration of various sketch features and configurable parameters. For example, API call CounterUpdate() in Fig. 9 at line 5 gets any definition of flowkey and any counter update type (e.g., PCSA type is used in this example). A full list of extended API calls of SketchLib is in §C.1.

Code concatenation. Finally, the concatenator in Fig. 8 gets the input of N sketch P4 codes created from code templates and concatenates N sketch P4 codes into one merged P4 code.

6.2 Code Rewriting

The second step is code rewriting to translate the selected strategy X^* into optimized code. Code rewriter in Fig. 8 gets three inputs; a merged P4 code from the first step, strategy X^* from the strategy finder, and Library for Optimization (Lib for Opt) that is used to apply SALUMERGE (O_{Ctr2}). Using $X^* = \{X_{Hash}^*, X_{Ctr}^*, X_{KEY}^*\}$, the code rewriter sequentially translates X_w^* to each workflow step in a merged P4 code by rewriting short lines of code. Leveraging the code templates makes the code rewriting process a lot easier. First, a merged sketch P4 code is structured in a way that the code rewriter can easily parse and apply optimizations. Second, the amount of code rewrite is minimized because sketch code templates are concise by using API calls in SketchLib and Lib for Opt.

7 Implementation

Auto-code composition. We use two examples, O_{Hash1} and O_{Hash2} to illustrate how we auto-generate an optimized code. Fig. 10 is the code snippet without optimization and we call it before code. Fig. 11 is the code snippet after applying X_{Hash}^* and we call it after code. We have $\mathcal{S} = \{s_i\}_{i=1}^4$, $\mathbf{F} = \{\{\text{srcIP}\}, \{\text{srcIP}\}, \{\text{dstIP}\}, \{\text{srcIP}, \text{dstIP}\}\}$. The before code allocates hash units to generate hash results for each flowkey (lines 3, 7, 10, 13 in Fig. 10). To emulate different logical hash seeds for independence, we configure the hash units with different CRC polynomials in practice. Then, we apply optimizations using a given solution $X_{Hash}^* = \{\{\{s_1, s_2\}, \{s_3\}, \{s_4\}\}\}$, which means the code should reuse $\{\text{srcIP}\}$ for $\{s_1, s_2\}$ and use XOR operation to create a hash result for $\{\text{srcIP}, \text{dstIP}\} = \{\text{srcIP}\} \oplus \{\text{dstIP}\}$. If we look at line 4 in Fig. 11, the hash result of s_2 reuses the hash result of s_1 . Line 6 in Fig. 11 shows XOR-based hash result reconstruction. As a result, the usage of the hash unit is reduced from 4 to 2.

Applying SALUMERGE (O_{Ctr2}) requires new codes for implementing two counter arrays to share one SALU that the before code does not have. Thus, we build a new library (Lib for Opt) shown in Fig. 8 to implement O_{Ctr2} and the

```

01: // code for s1
02: /* 1. hash computation step */
03: s1_h = HashUnit(seed1, srcIP);

code rewriter can use this library for applying O_{Ctr2} . The definition of the API call for Lib for Opt is in §C.1. For other optimizations $\{O_j\}_{j \in \{\text{Hash1}, \text{Hash2}, \text{Ctr1}, \text{Key}\}}$, we do not need new API calls because a simple rewrite is enough for implementing reusing resources (O_{Hash1} , O_{Hash2} , O_{Ctr1}) or XOR operation (O_{Hash2}) (e.g., at line 6 in Fig. 11). As a result, the code rewriter can translate all five optimizations into an optimized code. We show examples of before and after code snippets for O_{Hash1} , O_{Ctr1} , O_{Key} in §C.2.

Strategy finder. One minor issue here is that while implementing SALUMERGE (O_{Ctr2}) on the Tofino switch, we face a known problem of sketch inaccuracy caused by the counter read and reset delays [37]. To address this, we add one more applicable condition of the same epoch (C6) to O_{Ctr2} .

8 Evaluation

Our extensive set of experiments shows that Sketchovsky can achieve both a low resource footprint and high accuracy simultaneously.

8.1 Experimental Setup

Testbed. We evaluate Sketchovsky on a local testbed with an Edgecore Wedge 100BF Tofino-based programmable switch and a server equipped with dual Intel Xeon Silver 4110 CPUs, 128GB RAM, and a 100Gbps Mellanox CX-4 NIC connected to the switch. We use the P4-16 version with the Tofino SDE version of 9.5.1.

Sketching algorithms. We use eleven sketch algorithms that measure six different statistics.³ Although Bloom filter (BF) is not a sketching algorithm, we include BF because it also follows the workflow steps of sketching algorithms, and Sketchovsky can optimize it.

Four ensemble types. We use four types of ensembles that network operators would practically consider using. In ensembles of (Type 1. Same Sketch), (Type 2. Same Flowkey), and (Type 3. Same Epoch), all sketch instances in the ensemble use the same sketching algorithm, flowkey, and epoch, respectively. For (Type 4. Random), sketch instances in an ensemble are picked randomly.

Ensemble Generator. To create four types of ensembles, we build an ensemble generator that takes two inputs; (1) the ensemble type and (2) the number of sketch instances for the ensemble. Using these two inputs, the ensemble generator randomly picks sketching algorithms and assigns configurable parameters from a large pool of candidates. A full list of candidates for parameters is in §D.1. The ensemble generator does not allow any two sketch instances in an ensemble to have the same statistic, flowkey, flowsize, and epoch.

Metrics. We use three metrics for accuracy: (1) Relative Error (RE): $\frac{|True-Estimate|}{True}$, where *True* is the ground truth value and *Estimate* is the estimated value. We use this metric for sketching algorithms for cardinality and entropy. (2) Average Relative Error (ARE): $\frac{1}{k} \sum_{i=1}^k \frac{|f_i - \hat{f}_i|}{f_i}$, where *k* means the top *k* heavy flows. *f_i* is the actual flow size for flow *i*, and *ŷ_i* is the estimated flow size from the sketch instances. This metric is used to evaluate the accuracy of the heavy hitter and heavy change detection. We use *k*=50. (3) Weighted Mean Relative Difference (WMRD) is used for MRAC [28].

For resource reduction, we use two metrics: (1) Resource Usage (RU): $\frac{Used}{Available}$, where *Used* is the amount of resource used for the ensemble and *Available* is the total amount of available resource on the switch; and (2) Resource Reduction (RR): $\frac{RU(before) - RU(after)}{RU(before)}$, where *RU (before)* is the amount of used resource before applying optimizations of Sketchovsky and *RU (after)* is the amount of used resource after optimization.

8.2 Accuracy

We show that Sketchovsky does not degrade accuracy and sometimes improves accuracy. For this experiment, we picked four ensembles from each ensemble type. A full list of base sketch algorithms and configurable parameters for picked ensembles is in §D.2. Given each ensemble as input, we generate

³Linear counting (LC) [44], HyperLogLog (HLL) [21], PCSA [20], multi-resolution bitmap (MRB) [19] measure cardinality. Count-sketch (CS) [14], count-min sketch (CM) [17] can detect heavy hitters, and K-ary sketch (KARY) [27] can detect heavy change. Entropy sketch (ENT) [29] measures entropy, MRAC [28] measures flow size distribution (FSD). UnivMon (UM) [32] can measure general statistics. Bloom filter (BF) [11] can do the membership test. A full list of sketching algorithms that we used for our experiments with sketch features is in §D.1.

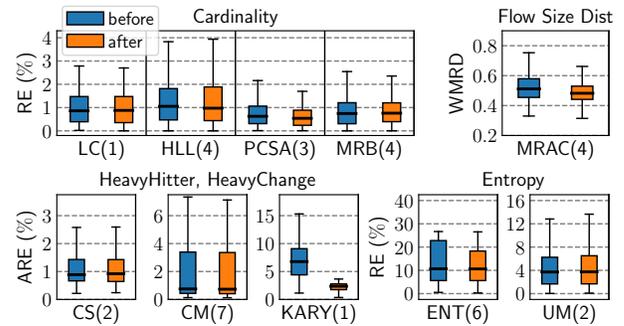

Figure 12: Overall accuracy evaluation.

sketch P4 codes for the Tofino switch both before and after we use Sketchovsky for optimization. All five optimizations are enabled. We then run sketch P4 codes for (four picked ensembles) × (before and after optimizations) on the Tofino switch and compare the accuracy of the sketch instances. We use five traffic workloads of inter-ISP packet traces collected on different dates.⁴ For each traffic workload, we send ten 60s packet traces from a directly connected server to the Tofino switch using tcpreplay at full speed.

Fig. 12 shows the overall accuracy results. We grouped sketch instances into four different statistics based on the sketching algorithm used. The X-axis in Fig. 12 shows the number of sketch instances with the same sketching algorithm (e.g., HLL(4) means there are four sketch instances using the sketching algorithm of HLL). The Y-axis shows the quartiles of errors for sketch instances. We see that none of the sketch instances lose accuracy after optimization. In fact, we observe some accuracy improvements. Thanks to *O_{Ctrl1}*, counter arrays of KARY are increased from 1 to 3, and the error is reduced. In addition, we do not miss any heavy flowkeys both before and after optimization. Because BF does not produce measurement results, the accuracy result for two BF sketch instances is not shown.

8.3 Resource Reduction

Sketchovsky makes infeasible ensembles feasible. We show the resource reduction benefits of using Sketchovsky. For this experiment, we generate a total of 400 ensembles of sketch instances; (four ensemble types) × (10 different numbers of sketch instances from 2, 4, ..., 20) × (10 different ensembles). Then, we run Sketchovsky to produce 400 sketch P4 codes both before and after optimization.⁵ Next, we compile the codes using the Tofino compiler to check the feasibility. To make the experiment more realistic, we append codes for L2 switching, L3 routing, and access control list (ACL) to all of the before and after optimization codes. L2 and ACL consume 55% of on-switch SRAM in total, and L3 uses 63% of TCAM.

⁴We use five CAIDA backbone traces captured in 3/20/14 Sanjose, 6/19/14 Sanjose, 1/21/16 Chicago, 5/17/18 NYC, and 8/16/18 NYC [2]

⁵We use count-min sketches to create ensembles for (Ensemble Type 1) because it is one of the most popular and widely-used sketching algorithms.

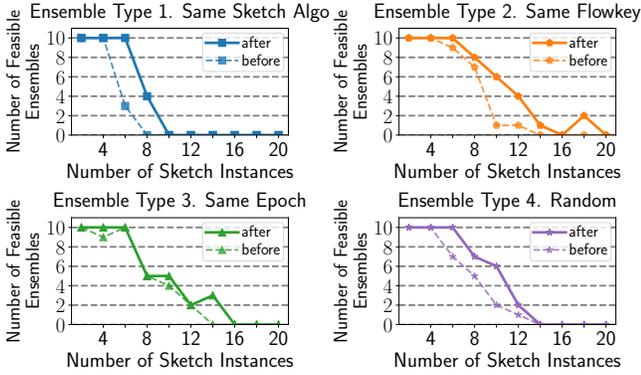

Figure 13: Feasibility comparison of ensembles before vs after.

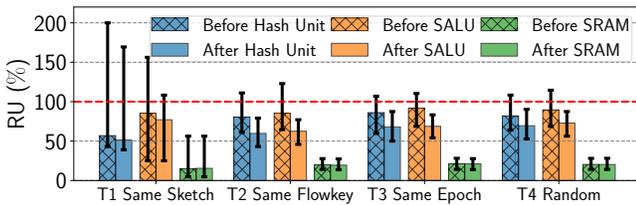

Figure 14: Resource usage comparison before vs after for the number of sketch instances = 12.

The X-axis in Fig. 13 is the number of sketch instances in the ensemble. The Y-axis is the number of feasible ensembles among ten ensembles per different number of sketch instances. The result shows that 42 ensembles that were previously infeasible become feasible with Sketchovsky. For example, if we look at "Ensemble Type 1" and "6 sketch instances", only 3 out of 10 ensembles were feasible before optimization. However, all ten ensembles become feasible after optimization. Note that the pipeline stage overhead of O_{Hash2} and O_{Key} does not negatively impact feasibility after applying them.

Resource usage before and after optimization. Fig. 14 shows the use of individual resources before and after optimization. Using the ensemble generator, we generated 1200 ensembles; (four ensemble types) \times (300 different ensembles). Each ensemble has 12 sketch instances. Because some ensembles are not feasible on the Tofino switch because of the limited number of stages, we calculated resource use using the strategy finder so we are not limited by, and do not show, pipeline stages. We cross-checked the resource use between the strategy finder and the Tofino compiler for feasible ensembles. Each bar in Fig. 14 shows the median value, and the error line shows the 10% and 90% percentile among 300 ensembles. The red-dotted line shows the total available resources on the switch, so values above the red line represent infeasible ensembles. Fig. 14 visually shows how previously infeasible ensembles become feasible. SRAM usage of heavy flowkey storage before and after optimization is similar because heavy flowkeys overlap across sketch instances.

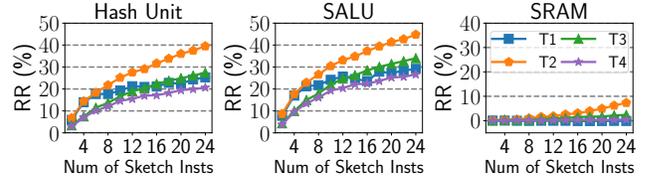

Figure 15: Resource reduction result.

Resources		Total	O_{Hash1}	O_{Hash2}	O_{Ctrl1}	O_{Ctrl2}	O_{Key}
Type 1	Hash Unit	21.3	3.1	0.1			18.1
	Same SALU	25.7			-	0.8	24.9
	Sketch SRAM	-0.02			-	-0.02	
Type 2	Hash Unit	27.6	10.4	-			17.2
	Same SALU	33.1			3.8	5.9	23.4
	Flowkey SRAM	1.8			2.3	-0.5	
Type 3	Hash Unit	18.9	5.5	0.04			13.4
	Same SALU	24.7			2.2	3.7	18.8
	Epoch SRAM	0.9			1.3	-0.4	
Type 4	Hash Unit	15.5	1.9	0.04			13.6
	Random SALU	20.4			0.5	1.0	18.9
	SRAM	0.2			0.3	-0.1	

Table 5: Breakdown of resource reduction by each optimization for the number of sketch instances = 12.

Sensitivity analysis on the number of sketch instances. We show a more detailed view of resource reduction by looking at ensembles with different numbers of sketch instances. We generate (four ensemble types) \times (12 different numbers of sketch instances from 2, 4, ..., 24) \times (300 different ensembles). The X-axis of Fig. 15 is the number of sketch instances, and the Y-axis is the average reduction for the three resource types of 300 ensembles between before and after optimization. We can see that hash unit reduction is up to 40%, SALU reduction is up to 45%, and SRAM reduction is up to 7%. As the ensemble has more sketch instances, we have more opportunities to apply optimizations, and resource reduction benefits increase. SRAM reduction is more limited, but we do observe SRAM reduction for type 2 due to O_{Ctrl1} because reusing counter arrays can reduce SRAM.

Fig. 15 also shows that the resource reduction depends on the ensemble type. Ensemble type 2 has sketch instances with the same flowkey, which makes many optimizations easier to apply. Thus, ensemble type 2 has the highest resource reduction. On the other hand, type 4 has random sketch instances, so optimizations are the least likely to be applied, resulting in the smallest resource reduction. However, even for random ensemble type, the reduction of the hash unit is up to 20% and SALU is up to 26% because Sketchovsky offers five multiple building blocks for optimization.

Breakdown on individual optimizations. We zoom into ensembles with 12 sketch instances and show the breakdown of resource reduction in Table 5. HFSREUSE (O_{Key}) shows consistently high resource reduction for all four ensemble types (18% to 25% SALU reduction). Note that O_{Key} can also reduce hash units. This is because of the specific

hardware architecture of Tofino; one hash unit must be allocated for one SALU (now we call this HashUnit-SALU coupling). HASHREUSE (O_{Hash1}) is the next impactful optimization. For type 2, O_{Hash1} reduces hash units by up to 10.4%. SALUREUSE (O_{Ctr1}) reduces both SALU and SRAM and SALUMERGE (O_{Ctr2}) reduces SALUs but increases small SRAM overhead (negative values such as -0.5%). Finally, HASHXOR (O_{Hash2}) has the least impact on Tofino because of HashUnit-SALU coupling. Note that the application of O_{Ctr1} and O_{Ctr2} enables O_{Hash1} automatically. Thus the impact of O_{Ctr1} and O_{Ctr2} is bigger than shown in Table 5.

9 Discussion

Measurement-sketch mapping. We currently assume the ensemble of sketch instances is given as input. An interesting direction for future work is to automatically generate the most efficient ensemble of sketch instances for a given set of measurement tasks. We posit that explicitly considering the characteristic of input workload and the resource-accuracy trade-off in an ensemble setting using Sketchovsky could be an interesting direction for future work [33, 47].

Generalizing to other hardware. While our prototype uses Tofino due to its open-source development API, we posit that our research contributions, such as optimization building blocks, strategy finder, and auto-code composition framework, can be adapted to other programmable switches and platforms as they have similar resource bottlenecks [31, 40].

Generalizing to other sketching algorithms. Today, some sketching algorithms are still infeasible in the data plane due to their complex data structures [39, 40]. We envision Sketchovsky to be useful for implementing other feasible sketching algorithms on programmable switches than the eleven sketching algorithms we demonstrated in §8. In this section, we elaborate on the applicability of Sketchovsky’s main components, including optimization building blocks, strategy finder, and auto-code composition framework, to other sketches.

First, the optimization building blocks proposed in Sketchovsky are based on common compute and memory operations in sketching algorithms (e.g., hash computations, arithmetic counter updates, heavy flowkey storage). Since all sketching algorithms perform *hash computations*, O_{Hash1} and O_{Hash2} are generally applicable to current and future sketching algorithms. For *counter updates*, some sketching algorithms may have complicated counter update operations (e.g., threshold-based counter updates in ElasticSketch [45]). Sketchovsky cannot directly support these complicated counter updates and requires a case study to determine whether resource savings are possible. It is also possible that these complicated counter operations are fundamentally excluded from further optimizations. For *heavy flowkey storage*, the sketching algorithms that require storing heavy flowkeys [9, 16, 41] can benefit from O_{Key} . In summary, the individual

optimizations introduced in Sketchovsky are broadly applicable to sketching algorithms.

Second, the strategy finder is a general optimizer to maximize resource saving. As long as the specifications of sketching algorithms such as counter array type and counter update type are given as input, the strategy finder will output an optimized strategy. For example, a user may define single-level (SL) or multi-level (ML) as the counter array type and COUNTER or SIGNCOUNTER as the counter update type. When optimizing counting bloom filters [11] as part of an ensemble, the user can define the same counter array and counter update types as the count-min sketch [17], and exclude the heavy flowkey storage part.

Finally, the auto-code composition framework can accommodate new sketching algorithms as long as their sketch templates are properly defined based on the specification of Sketchovsky. A sketch template follows three main steps, i.e., hash computation, counter updates, and flowkey storage. For the auto-code composition framework to work, the user needs to ensure that if several sketches share a common operation (e.g., signed counter update), the code provided for implementing the operation must be the same across the sketch templates. For example, implementing a counting bloom filter should reuse codes from a count-min sketch for the hash computation and counter update operations. In summary, Sketchovsky can be generalized to other sketching algorithms.

10 Conclusions

In this paper, we tackle an often ignored problem of running an ensemble of sketch instances to support a given portfolio of measurement tasks. To the best of our knowledge, Sketchovsky is the first end-to-end system that explores cross-sketch optimizations in practice. We showed that our novel cross-sketch optimization building blocks and efficient strategy finder make previously infeasible ensembles of sketch instances feasible on modern hardware.

A Supplement to Background

A.1 Counter Update Type

We introduce five counter update types as in [Alg. 2](#).

- BITMAP** is just a bitmap.
- COUNTER** receives index and size for the counter update, then increase the counter depending on packet counts or packet bytes.
- SIGNCOUNTER** receives one additional input of 1-bit hash result. Depending on this hash value, it will either increase or decrease the counter. The 1-bit hash value is computed by using flowkey.
- HLL** type can be used for loglog-variant sketches [18, 21]. It receives index and value as inputs and updates the counter if it is less than the value. Value can be computed by a function $\rho(\text{hash})$ where $\text{hash} \in \{0, 1\}^{32}$, $\rho(\text{hash})$ is the position of the leftmost 1-bit (e.g., $\rho(0001\dots) = 4$) and hash is computed using flowkey [21]. This ρ function can be implemented efficiently by using TCAM in the switch data plane [4].
- PCSA** receives index and bitmask as inputs. Then it uses the bit-OR operation to update the counter using the

bitmask. Bitmask value can be computed by shift operation ($1 \ll \rho(\text{hash})$).

Algorithm 2 Five Counter Update Types

```

1: function BITMAP(index)
2:   A[index] = 1
3: function COUNTER(index, size)
4:   A[index] = A[index] + size
5: function SIGNCOUNTER(hash, index, size)
6:   if hash == 0 then
7:     A[index] = A[index] + size
8:   else if hash == 1 then
9:     A[index] = A[index] - size
10: function HLL(index, value)
11:   if A[index] < value then
12:     A[index] = value
13: function PCSA(index, bitmask)
14:   A[index] = A[index] | bitmask

```

B Supplement to Optimizations

B.1 SRAM reduction of SALUREUSE (O_{Ctrl})

SALUREUSE (O_{Ctrl}) reduces not only SALUs but also SRAM. Suppose $\mathbf{S} = \{s_i\}_{i=1}^n$ is a set of sketch instances and $\mathbf{C} = \{(r_i, w_i)\}_{i=1}^n$ represent that s_i has r_i number of counter arrays with width w_i . \mathbf{W} represents row and width of counter arrays for reuse after applying O_{Ctrl} .

$$\mathbf{W} = \{w_j^*\}_{j=1}^{\max_i(r_i)} \text{ where } w_j^* = \max_i \{w_i | r_i \geq j\} \quad (14)$$

Then, SRAM usage changes from $\sum_{i=1}^n r_i w_i$ to $\sum_{j=1}^{\max_i(r_i)} w_j^*$. O_{Ctrl} will always maintain or reduce SRAM usage because $\sum_{i=1}^n r_i w_i - \sum_{j=1}^{\max_i(r_i)} w_j^* \geq 0$. Suppose $\text{comp}(x, y) \in \{0, 1\}$ where $x, y \in \mathbb{N}$. If $x \leq y \rightarrow \text{comp}(x, y) = 1$, otherwise $\rightarrow \text{comp}(x, y) = 0$.

$$\sum_{i=1}^n r_i w_i - \sum_{j=1}^{\max_i(r_i)} w_j^* = \sum_{j=1}^{\max_i(r_i)} \left(\left(\sum_{i=1}^n w_i \cdot \text{comp}(r_i, j) \right) - w_j^* \right)$$

$\left(\sum_{i=1}^n w_i \cdot \text{comp}(r_i, j) \right) - w_j^* \geq 0$ for $1 \leq j \leq \max_i(r_i)$ due to (14)

Thus, $\sum_{i=1}^n r_i w_i - \sum_{j=1}^{\max_i(r_i)} w_j^* \geq 0$

C Supplement to Auto-code Composition

C.1 SketchLib and Lib for Optimization

SketchLib. We extended API calls from SketchLib as in [Table 6](#) for the easier code-rewrite process.

- TCAM_LPM (hash_result) uses TCAM for the longest prefix match to compute the leftmost position of 1-bit in the

```

01: /* 1. hash computation step - no code */
02: /* 2. counter update step */
03: s#_est1 = CounterUpdate(seed1, FLOWKEY, WIDTH,
04:                          SL, Counter, FLOWSIZE);
05: s#_est2 = CounterUpdate(seed2, FLOWKEY, WIDTH,
06:                          SL, Counter, FLOWSIZE);
07: s#_est3 = CounterUpdate(seed3, FLOWKEY, WIDTH,
08:                          SL, Counter, FLOWSIZE);
09: s#_th = AboveThreshold(s#_est1, s#_est2, s#_est3,
10:                       THRESHOLD);
11: /* 3. counter update step */
12: if (s#_th) { HFS(FLOWKEY); }

```

Figure 16: Code template example for count-min sketch.

hash result, which is used in many sketching algorithms. This API call is the same as `tcam_optimization()` in SketchLib.

- CounterUpdate (seed, flowkey, width, CA_type, CU_type, ...) does one counter update for configured flowkey, counter array type (CA_type) of whether single-level (SL) or multi-level (ML), counter update type (CU_type), width of counter array (width). seed is used for the hash unit to generate column index for the counter update. Depending on the different CU_type, it takes more parameters (e.g., packet length for COUNTER type or value out of TCAM_LPM for HLL/PCSA type). We extended `consolidate_update()` in SketchLib to build this API call.
- AboveThreshold (LIST(estimate), threshold) gets the threshold and a list of flow size estimates (these are return values after each counter update). This API call returns whether the overall flow size estimate is above the threshold or not⁶. This logic was part of `heavy_flowkey_storage()` in SketchLib and we separate the API call for the code rewrite process.
- HFS (flowkey) stores heavy flowkey. This API extends `heavy_flowkey_threshold()` in SketchLib by supporting any definition of flowkey.

You can see how these API calls are used in [Fig. 16](#), which is a code template example for count-min sketch. Network operators can put {srcIP, dstIP} to `FLOWKEY`, `hdr.ipv4.total_len` to `FLOWSIZE`, and `1024` to `WIDTH`. For different numbers of counter arrays (e.g., 3 counter arrays), network operators should write multiple lines of code for counter updates (e.g., lines 3-8 in [Fig. 16](#)).

Lib for Opt. Lib for Opt is used to implement SALUMERGE (O_{Ctrl2}) as in [Table 6](#).

- CounterUpdate_2 (seed, flowkey, width, CA_type, CU_type1, CU_type2, ...) This API looks similar to CounterUpdate() but the difference is that this API does two counter updates by using one SALU. Thus, parameters include two counter update types

⁶For count-min sketch, overall flow size estimate is min of List (estimate). For count-sketch, overall flow size estimate is median of List (estimate).

Two Libs	API Name	API Parameters	Explanation
SketchLib	TCAM_LPM()	hash_result	Same as tcam_optimization() in SketchLib
	CounterUpdate()	seed, flowkey, width, CA_type, CU_type, ...	Extends consolidate_update() in SketchLib
	AboveThreshold()	LIST(estimate), threshold	Extends heavy_flowkey_storage() in SketchLib
	HFS()	flowkey	Extends heavy_flowkey_storage() in SketchLib
Lib for Opt	CounterUpdate_2()	seed, flowkey, width, CA_type, CU_type1, CU_type2, ...	New API for SALUMERGE (O _{Ctrl2})

Table 6: API calls in extended SketchLib and Lib for optimization.

```

01: // code for s1
02: ... /* 1. hash computation step */
03: /* 2. counter update step */
04: s1_est1 = CounterUpdate(seed1, srcIP, 2K, SL,
05:                          Counter, pktlen);
06: s1_est2 = CounterUpdate(seed2, srcIP, 2K, SL,
07:                          Counter, pktlen);
08: s1_est3 = CounterUpdate(seed3, srcIP, 2K, SL,
09:                          Counter, pktlen);
10: s1_th = AboveThreshold(s1_est1, s1_est2, s1_est3,
11:                       100);
12: ... /* 3. heavy flowkey storage step */
13:
14: // code for s2
15: ... /* 1. hash computation step */
16: /* 2. counter update step */
17: s2_est1 = CounterUpdate(seed4, srcIP, 4K, SL,
18:                          Counter, pktlen);
19: s2_est2 = CounterUpdate(seed5, srcIP, 4K, SL,
20:                          Counter, pktlen);
21: s2_th = AboveThreshold(s2_est1, s2_est2, 100);
22: ... /* 3. heavy flowkey storage step */
23:
24: // code for s3
25: ... /* 1. hash computation step */
26: /* 2. counter update step */
27: CounterUpdate(seed6, srcIP, 4K, SL, Counter,
28:               pktlen);
29: ... /* 3. heavy flowkey storage step */

```

Figure 17: [Before] SALUREUSE (O_{Ctrl1}).

CU_type1 and CU_type2. There are one flowkey, one width, and one counter array type because they should be the same due to applicable conditions of O_{Ctrl2}.

C.2 Before and After Code Snippets for O_{Ctrl1}, O_{Ctrl2}, and O_{Key}

Code rewrite for counter update. Code rewriter uses $\{X_{Ctrl1}^*, X_{Ctrl2}^*\}$ to apply SALUREUSE (O_{Ctrl1}) and SALUMERGE (O_{Ctrl2}) to counter update step. Although O_{Ctrl1} and O_{Ctrl2} can be applied simultaneously, we explain code rewrite logic separately for better readability. Code rewrite for O_{Ctrl1} to \mathcal{S} requires code changes with lines using CounterUpdate() in the extended SketchLib. Code rewrite for O_{Ctrl2} uses a new API call, CounterUpdate_2().

We first look at how to apply O_{Ctrl1} using X_{Ctrl1}^* by looking at the before (Fig. 17) and after (Fig. 18) code snippets. Three sketch instances $\{s_1, s_2, s_3\}$ in Fig. 17 are count-min sketch, K-ary sketch, and entropy sketch respectively and they have different resource parameters $\mathbf{C} = \{(r_i, w_i)\}_{i=1}^3 =$

```

01: // optimized code for s1, s2, s3
02: ... /* 1. hash computation step */
03: /* 2. counter update step */
04: s_est1 = CounterUpdate(seed1, srcIP, 8K, SL,
05:                          Counter, pktlen);
06: s_est2 = CounterUpdate(seed2, srcIP, 4K, SL,
07:                          Counter, pktlen);
08: s_est3 = CounterUpdate(seed3, srcIP, 2K, SL,
09:                          Counter, pktlen);
10: s1_th = AboveThreshold(s_est1, s_est2, s_est3,
11:                       100);
12: s2_th = AboveThreshold(s_est1, s_est2, s_est3,
13:                       200);
14: ... /* 3. counter update step */

```

Figure 18: [After] SALUREUSE (O_{Ctrl1}) to $\{s_1, s_2, s_3\}$.

$\{(3, 2K), (2, 4K), (1, 8K)\}$. $\{s_1, s_2\}$ tracks heavy flowkey and they check whether flow size estimate is above threshold at line 10 and 21 in Fig. 17. X_{Ctrl1}^* specifies that code rewriter should apply O_{Ctrl1} to $\{s_1, s_2, s_3\}$, meaning that they satisfy applicable conditions for O_{Ctrl1}. Then, the code rewriter computes row and width of counter arrays for reuse \mathbf{W} as discussed as in (3), §4.2. As a result, $\mathbf{W} = \{8K, 4K, 2K\}$ is computed in this example and the code rewriter applies this as in lines 4-9 in code snippet Fig. 18.

Next, we look at how the code rewriter applies O_{Ctrl2} by using X_{Ctrl2}^* . Fig. 19 is the before code snippet and Fig. 20 is the after code snippet. $\{s_1, s_2, s_3\}$ in Fig. 19 are count-min sketch, entropy sketch, and PCSA sketch respectively and $\mathbf{C} = \{(3, 2K), (2, 4K), (1, 8K)\}$. We cannot apply O_{Ctrl1} to $\{s_1, s_2, s_3\}$ for this example because flowsize definitions are different between s_1 and s_2 (s_1 tracks packet bytes if we look at lines 5, 7, 9 in Fig. 19 whereas s_2 tracks packet counts at lines 17-18 in Fig. 19). Counter update types are also different between $\{s_1, s_2\}$ and $\{s_3\}$. $\{s_1, s_2\}$ uses COUNTER type whereas $\{s_3\}$ uses PCSA type.

Instead of O_{Ctrl1}, we can apply O_{Ctrl2} and X_{Ctrl2}^* specifies that the code rewriter can apply O_{Ctrl2} to $\{s_1, s_2, s_3\}$. Using the information in X_{Ctrl2}^* , the code rewriter knows that the first two counter arrays of s_1 can share SALUs with s_2 , and the last counter array of s_1 can share a SALU with s_3 . We use the new API call CounterUpdate_2() to apply this optimization at lines 4-9 in Fig. 20. For the first two counter arrays (lines 4-7), both counter update types are COUNTER type. Thus, the API call takes two additional parameters of flowsize definitions of packet bytes and packet counts. For the third counter array (lines 8-9), counter update types are COUNTER and PCSA.

```

01: // code for s1
02: ... /* 1. hash computation step */
03: /* 2. counter update step */
04: s1_est1 = CounterUpdate(seed1, srcIP, 2K, SL,
05:                          Counter, pktlen);
06: s1_est2 = CounterUpdate(seed2, srcIP, 2K, SL,
07:                          Counter, pktlen);
08: s1_est3 = CounterUpdate(seed3, srcIP, 2K, SL,
09:                          Counter, pktlen);
10: s1_th = AboveThreshold(s1_est1, s1_est2, s1_est3,
11:                       100);
12: ... /* 3. heavy flowkey storage step */
13:
14: // code for s2
15: ... /* 1. hash computation step */
16: /* 2. counter update step */
17: CounterUpdate(seed4, srcIP, 4K, SL, Counter, 1);
18: CounterUpdate(seed5, srcIP, 4K, SL, Counter, 1);
19: ... /* 3. heavy flowkey storage step */
20:
21: // code for s3
22: ... /* 1. hash computation step */
23: /* 2. counter update step */
24: CounterUpdate(seed6, srcIP, 8K, SL, PCSA,
25:               s3_value);
26: ... /* 3. heavy flowkey storage step */

```

Figure 19: [Before] SALUMERGE (O_{Ctr2}).

```

01: // optimized code for s1, s2, s3
02: ... /* 1. hash computation step */
03: /* 2. counter update step */
04: s_est1 = CounterUpdate_2(seed1, srcIP, 8K, SL,
05:                          Counter, Counter, pktlen, 1);
06: s_est2 = CounterUpdate_2(seed2, srcIP, 4K, SL,
07:                          Counter, Counter, pktlen, 1);
08: s_est3 = CounterUpdate(seed3, srcIP, 2K, SL,
09:                          Counter, PCSA, pktlen, s3_value);
10: s1_th = AboveThreshold(s_est1, s_est2, s_est3,
11:                       100);
12: ... /* 3. counter update step */

```

Figure 20: [After] SALUMERGE (O_{Ctr2}) to $\{s_1, s_2, s_3\}$.

Thus, two additional parameters are flowsize definition of packet bytes and an output value of TCAM_LPM written as s_3_value at line 9 in Fig. 20.

Code rewrite for heavy flowkey storage. Code rewriter uses X_{Key}^* to apply HFSREUSE (O_{Key}) to the heavy flowkey storage step. Fig. 21 is the before code snippet and Fig. 22 is the after code snippet. We have four sketch instances $\{s_1, s_2, s_3, s_4\}$ with different flowkeys $F = \{\{srcIP\}, \{srcIP, dstIP\}, \{srcIP, srcPort\}, \{srcIP, dstIP, srcPort, dstPort\}\}$ and all sketch instances track heavy flowkey. O_{Key} uses union key $UK = \cup_i f_i$ for the heavy flowkey storage for reuse. In this example, $UK = \{srcIP, dstIP, srcPort, dstPort\}$ is written at line 14 in Fig. 22. Recall that we have further optimization using conditional union-key $UK_C = \cup_j f_j$ where $(flow\ size\ estimate)_j > threshold_j$ and set 0 to $(UK - UK_C)$. This optimization is written in the code at lines 6-11 in Fig. 22. For

```

01: // code for s1
02: ... /* 1. hash computation step */
03: ... /* 2. counter update step */
04: /* 3. heavy flowkey storage step */
05: if (s1_th) { HFS(srcIP); }
06:
07: // code for s2
08: ...
09: /* 3. heavy flowkey storage step */
10: if (s2_th) { HFS(srcIP, dstIP); }
11:
12: // code for s3
13: ...
14: /* 3. heavy flowkey storage step */
15: if (s3_th) { HFS(srcIP, srcPort); }
16:
17: // code for s4
18: ...
19: /* 3. heavy flowkey storage step */
20: if (s4_th) { HFS(srcIP, dstIP, srcPort, dstPort); }

```

Figure 21: [Before] HFSREUSE (O_{Key}).

```

01: // code for s1, s2, s3, s4
02: ... /* 1. hash computation step */
03: ... /* 2. counter update step */
04: /* 3. heavy flowkey storage step */
05: hf_srcIP = hf_dstIP = hf_srcPort = hf_dstPort = 0
06: if (s1_th || s2_th || s3_th || s4_th) {
07:   hf_srcIP = srcIP;
08: }
09: if (s2_th || s4_th) { hf_dstIP = dstIP; }
10: if (s3_th) { hf_srcPort = srcPort; }
11: if (s4_th) { hf_dstPort = dstPort; }
12:
13: if (s1_th || s2_th || s3_th || s4_th) {
14:   HFS(hf_srcIP, hf_dstIP, hf_srcPort, hf_dstPort);
15: }

```

Figure 22: [After] HFSREUSE (O_{Key}) to $\{s_1, s_2, s_3, s_4\}$.

each packet header field (e.g., $dstIP$), it detects which sketch instances have this header field (e.g., s_2 and s_4 because f_2 and f_4 have $dstIP$). Then if any of those sketch instances is above the threshold (at line 9), those header fields are included in UK_C . If not, this header field is set to zero (at line 5). As a result, we can reduce 4 heavy flowkey storages to 1 heavy flowkey storage.

D Supplement to Evaluation

D.1 Eleven Sketch Algorithms for Evaluation

We use eleven sketching algorithms for our evaluation as in Table 7. They have different sketch features. Counter array type can be single-level (SL) or multi-level (ML). We also show a pool of candidate configurable parameters per each sketching algorithm in Table 7. For entropy sketch, counter update type SIGNCOUNTER guarantees theoretically better accuracy due to F2 estimation. However, we found that the COUNTER type produces better accuracy in practice. Thus, we use this COUNTER type for entropy sketch in our evaluation.

Sketch Algorithms		Sketch Features			Configurable Parameters Candidates						
Statistic	Name	Counter Array	Counter Update	Heavy Flowkey	Flowkey	Flowsize	Epoch	Row	Width	Level	
Membership	BF [11]	SL	BITMAP	N	{(srcIP), (dstIP), (srcIP, dstIP), (srcIP, srcPort), (dstIP, dstPort), (4-tuple), (5-tuple)}	{counts}	{10s, 20s, 30s, 40s}	{1}	{128K, 256K, 512K}	-	
Cardinality	LC [44]	SL	BITMAP	N					{counts, bytes}	{1, 2, 3, 4, 5}	{16K, 32K}

Table 7: Eleven sketch algorithms with sketch features and possible configurable parameters. (4-tuple) = (srcIP, dstIP, srcPort, dstPort). (5-tuple) = (srcIP, dstIP, srcPort, dstPort, proto).

D.2 Four Ensembles for Accuracy Evaluation

Table 8 - Table 11 shows four picked ensembles for four ensemble types. All five optimizations are found in four picked ensembles.

Ensemble Type 1.

- HASHREUSE (O_{Hash1}): none
- HASHXOR (O_{Hash2}): none
- SALUREUSE (O_{Ctr1}): none
- SALUMERGE (O_{Ctr2}): none
- HFSREUSE (O_{Key}): $\{s_1, s_2, s_3, s_4, s_5, s_6\}$

Ensemble Type 2.

- HASHREUSE (O_{Hash1}): $\{s_3, s_4, s_6, s_{10}\}$
- HASHXOR (O_{Hash2}): none
- SALUREUSE (O_{Ctr1}): $\{s_8, s_9\}$
- SALUMERGE (O_{Ctr2}): $\{\{s_1\}, \{s_2\}\}, \{s_7, \{s_8, s_9\}\}$
- HFSREUSE (O_{Key}): $\{s_2, s_8, s_9\}$

Ensemble Type 3.

- HASHREUSE (O_{Hash1}): $\{s_3, s_4\}$
- HASHXOR (O_{Hash2}): none
- SALUREUSE (O_{Ctr1}): $\{s_8, s_9\}$
- SALUMERGE (O_{Ctr2}): $\{\{s_3\}, \{s_4\}\}, \{\{s_6\}, \{s_7\}\}$
- HFSREUSE (O_{Key}): $\{s_4, s_5\}$

Ensemble Type 4.

- HASHREUSE (O_{Hash1}): none
- HASHXOR (O_{Hash2}): $\{\{s_1\}, \{s_2\}, \{s_3\}\}, \{\{s_4\}, \{s_5\}, \{s_9\}\}$
- SALUREUSE (O_{Ctr1}): none
- SALUMERGE (O_{Ctr2}): $\{\{s_7\}, \{s_8\}\}$
- HFSREUSE (O_{Key}): none

SI	Base SA (*)	Configurable Parameters			
		Flowkey	Flowsize	Epoch	Resource
s_1	CM	(srcIP)	counts	40s	(1, 16K)

D.3 Experiment for Greedy Heuristic Algorithm

In the strategy finder section (§5), we propose the greedy heuristic algorithm to tackle the problem of large search space. Here we show that the performance loss of the greedy heuristic algorithm is small while solving time is three orders of magnitude faster.

Metric. We introduce two metrics for this experiment.

- Solving Time: time to find the solution.
- Objective Function Increase: $\frac{HwResource(X_G)}{HwResource(X_T)}$ where X_T is a found solution using the two-step enumeration and X_G is from the greedy heuristic algorithm.

We can see in Fig. 23a that the greedy heuristic algorithm is three orders of magnitude faster than two-step enumeration. However, the objective function increase is less than 2% (Fig. 23b). For solving time, we measure time for 300 ensembles per data point in Fig. 23a and show the worst solving time. Data points that take more than 24 hours are not shown.

RingLeader: Efficiently Offloading Intra-Server Orchestration to NICs

Abstract

Careful orchestration of requests at a datacenter server is crucial to meet tight tail latency requirements and ensure high throughput and optimal CPU utilization. Orchestration is multi-pronged and involves load balancing and scheduling requests belonging to different services across CPU resources, and adapting CPU allocation to request bursts. Centralized intra-server orchestration offers ideal load balancing performance, scheduling precision, and burst-tolerant CPU re-allocation. However, existing software-only approaches fail to achieve ideal orchestration because they have limited scalability and waste CPU resources. We argue for a new approach that offloads intra-server orchestration entirely to the NIC. We present RingLeader, a new programmable NIC with novel hardware units for software-informed request load balancing and programmable scheduling and a new light-weight OS-NIC interface that enables close NIC-CPU coordination and supports NIC-assisted CPU scheduling. Detailed experiments with a 100 Gbps FPGA-based prototype show that we obtain better scalability, efficiency, latency, and throughput than state-of-the-art software-only orchestrators including Shinjuku and Caladan.

1 Introduction

Modern cloud services generate thousands of RPCs in response to a single external request [35]. The services often need to provide microsecond-scale tail latencies for these RPCs to meet service level objectives (SLOs) [4]. What makes this challenging is that each server in a distributed system running multiple services receives many RPC requests of varying importance, and *intra-server orchestration*, which is necessary to provide low tail latencies and high CPU efficiency, itself incurs substantial latency and wastes CPU cycles.

Intra-server orchestration entails three aspects (Figure 1a): request scheduling, load balancing, and core assignment [6, 13, 14, 19, 24, 31, 33]. These tasks play an indispensable role in maintaining microsecond-scale tail latency, achieving high

(a) Intra-server orchestration

(b) Ringleader

Figure 1: Intra-server orchestration: today vs. Ringleader.

CPU efficiency and high throughput, and enforcing appropriate request prioritization. Request scheduling and load balancing determine, within and across services, in what **order** requests are processed and by **which** worker core [6, 14, 19, 33]. Load balancing reduces tail latencies by reducing worker queue lengths and improves CPU efficiency as fewer cores in the system are left idle when they could instead be processing requests. When requests or services have different SLOs or priorities, scheduling can eliminate head-of-line (HoL) blocking and guarantee tail latencies for critical workloads. Core re-allocation decides how cores process requests belonging to different services [13, 24, 31]. Fast re-allocation maintains low tail latency and improves CPU efficiency and throughput, as it can repurpose cores that are not needed by a latency-sensitive service toward batch services during periods of low load.

Coordinating orchestration tasks is a vision shared by other recent systems that have either on-loaded orchestration onto dedicated CPU cores [6, 14, 16, 19, 31, 33] or offloaded some aspects to SmartNICs [15]. Unfortunately, both sets of approaches have key limitations (Sections 2 and 8). On-loading has high latencies, poor scalability, and wastes CPU cycles. Using a dedicated centralized orchestrator core does not scale with increasing network line rates and worker core counts. Offloading orchestration to SmartNICs using on-NIC CPU cores has similar issues: the wimpy on-NIC cores have high latency overheads and scalability limitations.

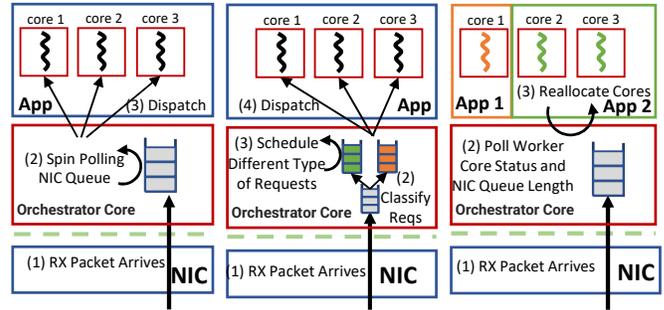

We argue that effective orchestration requires a fundamentally different division of labor than onloading or SmartNIC-based approaches: Given recent advances in programmable

network hardware, we start with an approach that offloads as many of the different aspects of orchestration as possible onto NIC hardware while systematically onloading onto host cores minimal functionality for precise scheduling and high performance. As NICs already process all incoming packets, offloading orchestration tasks can reduce request processing latency and save CPU cycles. We realize this division-of-labor in RingLeader, a system for offloading and executing intra-server orchestration on 100+Gbps NICs (Figure 1b).

In RingLeader, software running on CPUs uses a new OS-NIC interface to provide the NIC with per-core updates on request completions and relative priorities across arriving requests. Custom-built load balancing and scheduling units on the NIC interface with each other and leverage software-provided information to schedule precisely and enqueue requests within/across services at cores. By tracking NIC-local queues of requests waiting to be scheduled, the RingLeader NIC detects load changes and provides fine-grained reallocation hints to host cores via the same OS-NIC interface.

Several challenges arise in making this division-of-labor effective (Sec. 2.3): (1) carefully distributing packet buffering across the NIC and CPU cores to avoid core idling while tightly controlling request dispatch from the NIC to CPU cores; (2) coordinating request dispatching among per-core buffers and the on-NIC load balancing and scheduling engines to meet various load targets and scheduling policies; (3) developing hardware support to combine load balancing and scheduling decisions at line-rate; and (4) developing an efficient OS-NIC interface to enable low overhead coordination between the NIC and host cores. We make several innovations (Secs. 4 and 5) to overcome these challenges:

1. We leverage *shallow per-core request priority queues* alongside limited on-NIC buffering to overcome the challenges caused by PCIe latency and ensure requests dispatched by the NIC are processed quickly and with suitable prioritization.
2. We develop a novel load balancing algorithm, Join-Bounded-Shortest-Ranked-Queue (JBSRQ), which accounts for multi-service isolation/priorities *and* ensures good load balance across the per-core buffers. We build a new first-eligible-out (FEO) line-rate request scheduler that coordinates with the request load balancer.
3. We develop new NIC hardware that uses a reduction tree to calculate which core should process the current highest priority request at the line rate.
4. We introduce an OS-NIC interface with low CPU overheads and avoid generating extra PCIe messages. This provides an API for services to benefit from on-NIC orchestration, and achieves $\sim 50\text{M}$ messages-per-second for OS-NIC communication.
5. We develop simple NIC-assisted algorithms that support burst-sensitive core re-allocation across high/low priority requests by leveraging re-allocation hints provided by a

(a) Load Balancing (b) Scheduling (c) Core Allocation
Figure 2: Illustrations of existing intra-server orchestration.

new on-NIC load monitoring module.

We present a full evaluation of RingLeader’s feasibility and effectiveness. From experiments performed on a 100 Gbps FPGA-based prototype, we find RingLeader is high-performance, scalable and CPU-efficient, and RingLeader provides better latency and throughput than existing state-of-the-art intra-server orchestrators, including Shinjuku [19] and Caladan [13]. For example, in an experiment with 30 worker hyperthreads, RingLeader was able to service $3\times$ as many requests within a P99 SLO of $45\mu\text{s}$ as Shinjuku and RSS. We compare RingLeader’s core allocation with Caladan running both a latency-sensitive service and a batch service, and RingLeader achieves up to 50% less latency for the latency-sensitive service and $1.3\times$ throughput for the batch service.

2 Background and Motivation

Online cloud services such as search, distributed model serving pipelines, and key-value caches are deployed today across thousands of physical machines. User requests to these services are composed of sequences of RPCs. Each RPC is processed using a two-layer scheduling framework: first, RPCs are assigned to servers, and then RPCs are dispatched to a service instance running on one of the server cores [43]. The latter, i.e., intra-server orchestration, which consists of load balancing requests and scheduling (ordering) them across service instances, and reallocating cores across services based on demand, play a crucial role in the ultimate performance experienced by requests.

2.1 Intra-server Orchestration Today

State-of-the-art (SOTA) intra-server orchestration relies on a centralized software-based approach running in user-space [6, 10, 13, 19, 31, 33]. This approach addresses the unpredictable/high tail latency issues of conventional in-kernel approaches [4, 14, 18]. It also addresses both the load imbalance, poor tail latencies, and poor request scheduling issues of decentralized randomized RSS (receive-side steering) approaches such as IX and ZygOS [6, 33] and the imbalance and

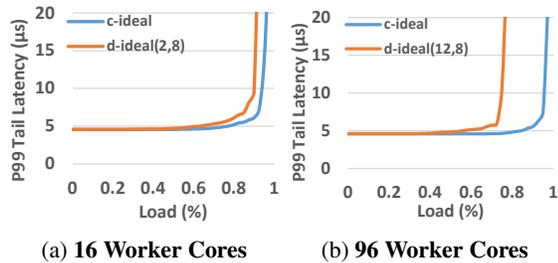

Figure 3: Simulation results comparing centralized and decentralized scheduling. **C-ideal** uses the ideal centralized scheduling policy. **D-ideal(X,Y)** uses X decentralized orchestrator cores to schedule Y worker cores per orchestrator core.

imprecision that results from the asynchrony of reactively programming aRFS (accelerated Receive Flow Steering) rules.

Figure 2 shows how existing orchestration mechanisms work: **(1) Request Load Balancing** (Figure 2a): For each service, one orchestrator core is dedicated to: 1) polling a centralized receive queue and 2) dispatching packets to worker cores according to their load. Packets are delivered from the NIC to the orchestrator core in a centralized, First Come First Serve manner. **(2) Request Scheduling** (Figure 2b): The orchestrator core identifies different request types and schedules competing requests, *e.g.*, by suitably prioritizing them. Request scheduling reduces HoL blocking and ensures RPCs with higher priority receive service first. **(3) CPU Allocation** (Figure 2c): When there are multiple services running on the host, the orchestrator core detects when services would benefit from more cores, and reallocates cores to ensure low latency and high CPU utilization under fast-changing load.

Multiple dedicated busy-polling orchestration cores may be needed to support demanding service workloads running across many cores, or when multiple services run on a server.

Limitations: A core that is used as an orchestrator incurs overhead and is unable to perform service-specific processing; this is problematic because the CPU is the key bottleneck in today’s network-intensive workloads. Further, a single orchestrator core’s maximum throughput determines scalability w.r.t request processing rates. Shinjuku’s “dispatcher” that performs request scheduling and load balancing only achieves 5M RPS (Requests-Per-Second) with a single core [15, 19]. With μ s-scale requests, one orchestrator core can saturate ~ 5 worker cores. However, servers today may be equipped with 100s of cores and serve 100+Gbps demand.

The overheads of performing reallocations over a large pool of worker cores are not negligible either, limiting reallocation speed and precision. For example, with 16 worker cores (hyperthreads), Shenango’s core allocator can only support packet rates of up to 6.5 Mpps, and this can only saturate a 10 Gbps NIC with 128B packets [31].

To achieve higher throughput, multiple orchestrator cores could be used. Each orchestrator core handles a set of worker cores, and the server relies on NIC RSS (Receive-Side Scaling) to spread requests across orchestrator cores. However,

because orchestrator cores operate independently, it is not possible to simultaneously enforce request scheduling policies and ensure even load and high core utilization.¹

We built a discrete-event simulator to quantify the impact of using multiple orchestrator cores on a given service. For simplicity, we focus here on comparing the load balancing performance between an ideal centralized approach (c-ideal), and an ideal decentralized approach (that ignores the costs of using many orchestrator cores). We generate requests with service times following an exponential distribution with a mean of 1μ s ($\text{Exp}(1)$).

Figure 3 shows the results for 16-core and 96-core systems. The saturation point of the d-ideal is much earlier than the c-ideal, especially when the worker core count is high. This is because the processing time for each request is unpredictable, and using RSS to partition requests between orchestrator cores leads to severe load imbalance. This imbalance causes CPU underutilization, unnecessary queuing, and increased latency.

Recent work improves on RSS by enabling work-stealing between cores to avoid load imbalance [24]. However, work-stealing incurs CPU overheads; it is hard to enforce request weights or priorities under work-stealing; and, as recent work has shown, centralized orchestration still significantly outperforms work-stealing (Fig. 3 in [24]).

2.2 A Case for NIC-Offloaded Orchestration

Using the NIC to perform orchestration has the potential to solve the key limitations associated with software-based approaches. Because all incoming requests necessarily pass through the NIC, the NIC could be an ideal location to perform *request scheduling* and *load balancing*; the NIC can buffer incoming requests and, in theory, make centralized scheduling and load balancing decisions without added latency. In contrast with software-only approaches that must sacrifice performance and efficiency to operate at scale, high-performance on-NIC accelerators can be designed to operate at the hyperscale required by today’s line rates and core counts. Additionally, offloading orchestration tasks onto NIC hardware can further improve host CPU efficiency by freeing up host cores, removing inter-thread communication overheads, and improving the accuracy of scheduling and load balancing decisions. The NIC is also a good vantage point for fine-grained network load profiling and queuing delay monitoring, so the NIC can assist with CPU scheduling by providing hints regarding incipient load arriving over the network.

We further argue that once a decision has been made to offload load balancing to the NIC, it is necessary to *also* offload scheduling and load monitoring. To achieve the c-ideal line in Figure 3, it is necessary to perform centralized buffering and

¹aRFS allows the orchestrator cores to program flow steering rules on the NIC [8], this cannot prevent load imbalance at short time scales because rules must be installed reactively and is imprecise because rules are installed asynchronously.

load balancing. However, once requests are buffered on the NIC, it is not possible to prevent a high priority request from being blocked inside the on-NIC buffer, and centralized on-NIC buffering hides information about buffered requests from a CPU-based scheduler, precluding informed scheduling.

2.3 On-NIC Orchestration Challenges

Achieving on-NIC orchestration is challenging:

C1: To Buffer at cores or not: On-NIC orchestration requires tight coordination between the NIC and the host. A NIC-only approach where: (1) all incoming packets are buffered on the NIC, (2) the NIC computes which core and in what order to process incoming requests, and (3) cores pull "ready" requests from the NIC to process can, in theory, yield good load balance and adhere to scheduling policies perfectly, but can experience poor throughput and fallow cores due to PCIe latency. To improve throughput and utilization, we need to unload some amount of buffering onto the cores by allowing the NIC to send new packet descriptors to a core that is not yet finished processing its current request. But it is unclear how deep these per-core buffers should be and what queuing discipline they should implement. Deep FIFO buffers can improve utilization but impose HoL blocking with high-priority requests stuck behind low priority ones at a core.

C2: Coordination across cores, load balancing, and scheduling: Per-core buffering also needs to be coordinated with the load balancing and scheduling algorithms running at the NIC. For example, a NIC-based load balancer agnostic of the priorities of requests enqueued at per-core buffers - e.g., "enqueueing a request at the shortest queue" - can easily lead to HoL blocking. Likewise, a NIC-based scheduler that simply dequeues highest priority requests buffered at the NIC and tries to enqueue them at per-core buffers may inadvertently stall both high and low-priority requests and lead to non-work-conserving behavior when the buffers at the cores serving high-priority requests are all full (Section 4).

C3: Lack of existing hardware: Existing hardware architectures are insufficient for precise on-NIC load balancing and scheduling. For example, modern hardware priority queues, notably PIFO [39], can only be used to provide programmable packet scheduling; we cannot support both programmable scheduling and load balancing with just the PIFO abstraction.

C4: Host and NIC Communication Overheads: To efficiently offload request load balancing to the NIC, the CPU needs to provide load feedback to the NIC at a fine granularity (e.g., per-packet). Furthermore, with 100+ Gbps NICs, PCIe throughput can become the performance bottleneck even in combination with optimized software stacks [29]. Thus, it is necessary to ensure that the CPU and PCIe overheads of CPU-NIC communication are low.

Overall, for effective orchestration, we need new NIC architectures for offloading load balancing and scheduling, coupled with new algorithms, and new OS-NIC interfaces.

3 RingLeader Overview

RingLeader is a new NIC architecture and OS-NIC interface that enables efficient and precise orchestration. In RingLeader, scheduling and load balancing are performed in tandem by an efficient and precise novel hardware offload on the NIC, and core allocation is performed by a host datapath OS with information from a new OS-NIC interface. We aim our discussion at servers equipped with a single NIC; we discuss multi-NIC support in Sections 9 and 12.2.

3.1 System Assumptions

In RingLeader, we assume that an application runs multiple services, where each service processes a specific type of request (e.g., latency-sensitive reads vs. throughput sensitive scans). A service can be replicated using multiple instances running across cores to handle load (e.g., deploying many read-oriented instances to serve heavy read traffic). We assume that distinct services can share a core; but our system also applies to cases where services need to be isolated across cores.

In RingLeader, the host uses a Demikernel-like single address space datapath OS [42]. The datapath OS achieves 1) fast multiplexing between OS tasks (e.g., buffer management, I/O processing, core allocation, coroutine scheduling) and application-specific work, and 2) fast context switching between different services' computations. We have chosen to use a datapath OS to manage host services instead of a kernel-based OS, as the traditional kernel-based OS abstractions (such as threads or processes) impose high overhead in multiplexing and context switching [42]. Figure 4 shows the system running multiple services. Each service launches multiple coroutines² on multiple cores; the coroutines are scheduled and managed by the datapath OS. We assume that each service is designed to run well on multiple cores.

The datapath OS uses cooperative scheduling: a long-running coroutine will *yield* voluntarily after a few microseconds of running. The datapath OS schedules the highest priority runnable coroutine once a running coroutine yields. The policy for yielding and scheduling depends on cross-service priorities.

The RingLeader NIC *buffers* received packets. This is reasonable because commercial NICs have a large amount of memory (tens of MBs of SRAM and 4–16 GBs of DRAM) [2, 7, 25–27]. If additional buffer capacity is needed, host DRAM can be used to buffer packet data with the RingLeader NIC only buffering packet descriptors.

RingLeader is designed to operate regardless of whether the transport layer is implemented in the NIC or on the CPU. On-NIC transport enables RingLeader to easily load balance

²As defined in Demikernel, coroutines are light-weight user-level threads that encapsulate the OS or application computation.

and schedule at the RPC granularity, while on-CPU transport necessitates load balancing at the flow or flowlet granularity.

3.2 Key Ideas and Design Overview

RingLeader can schedule and load balance requests from different services in a given application; to this end, inter-service policies can be specified in RingLeader. We discuss how RingLeader can support policies *across* applications in Section 9. Furthermore, each service provides input to the RingLeader NIC to assist with scaling up/down the per-service allocated cores.

Ideas: RingLeader approximates an ideal centralized orchestration approach using the following ideas that address the challenges in Sec.2.3: (1) We employ *shallow priority queues* on each core (Sec. 4.2). The per-core coroutine scheduler prioritizes dequeuing certain requests from these queues to avoid HoL blocking inside the buffer. (2) The NIC uses a new Join-Bounded-Shortest-Ranked-Queue (JBSRQ) load balancing algorithm that utilizes the per-core priority queue behavior to inform load balancing decisions (Sec. 4.2). In addition, we develop a new priority-based on-NIC request scheduler called first-eligible-out (FEO) and a simple interface between the scheduler and the load balancer (Sec. 4.3); this helps coordinate the scheduler’s dequeue actions with the load balancer by exposing available room at per-core buffers to the scheduler. (3) We present a novel NIC hardware architecture that uses a reduction tree to combine scheduling and load balancing decisions at line rate (Sec. 5). (4) We use memory-mapped IO and inlining metadata in packet descriptors to develop an efficient OS-NIC communication interface (Sec. 4.1).

Example: Figure 4 illustrates how RingLeader operates when network packets are received. For simplicity, we only focus on load balancing and scheduling. Here, two services are running on a host. When a request packet enters RingLeader, it is processed by a programmable match+action (RMT) pipeline, which parses the packet’s L3-L7 packet headers as necessary to identify the service that the packet belongs to and compute appropriate ranks. Then the packet is enqueued into the per-service packet buffer queue waiting to be scheduled.

The on-NIC request scheduler uses the FEO queue to schedule different services’ requests according to a programmable policy. FEO schedules the highest priority service for which there is available room at a core where the service can run (this "eligibility" is provided via a mask). The on-NIC load balancer then steers this highest priority service’s request to an eligible core that has the lowest rank (akin to queuing time) as computed by JBSRQ.

On each host core, the coroutine scheduler launches the runnable coroutine corresponding to the highest priority request. After the request finishes processing, the datapath OS provides load feedback to the NIC through the TX packet’s descriptor or a separate MMIO register write.

We conclude the overview with a few more details.

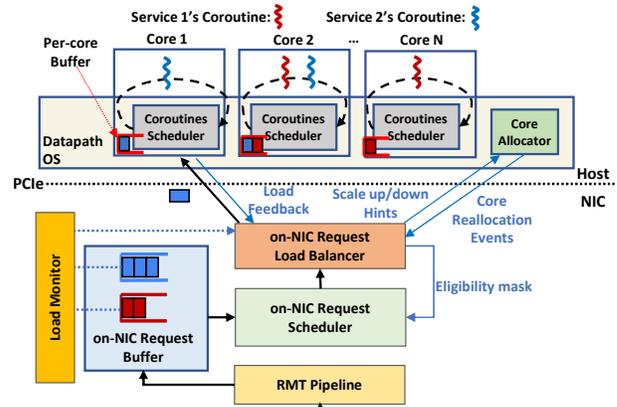

Figure 4: RingLeader Design.

Policies: RingLeader’s load balancer, scheduler, and core allocator cooperate from top to bottom to enforce a given inter-service policy. Scheduling policies in RingLeader are expressed as a hierarchy of functions that compute the rank, rate, and/or transmission time for a packet [38–40]. Having a hierarchy of functions enables policies where multiple services can be grouped together, *e.g.*, two latency-sensitive services can be given equal priority over another service but different weights when competing with each other.

Core assignment: An on-NIC load monitor tracks the queuing condition for each service/request type. Each service can configure its trigger condition; when the scale-up/down threshold is met, the NIC sends a scaling hint to the least loaded core which runs this service/request type. The core allocator runs inside the datapath OS in a distributed fashion, *e.g.*, it can run on any core depending on which core receives the NIC hint.

4 RingLeader Design

We now discuss the design of the individual components of RingLeader. In Sec 4.1, we introduce the interface and mechanism that the NIC uses to communicate with the OS. In Sec 4.2, we introduce RingLeader’s on-NIC request load balancer and our JBSRQ algorithm. In Sec 4.3, we describe the design of our FEO request scheduler and the non-blocking interface between the request scheduler and the load balancer. In Sec 4.4, we describe our NIC-assisted CPU re-allocation.

4.1 OS-NIC Interface

The OS-NIC interface in RingLeader (Table 1) is designed to minimize both HoL blocking latency and the CPU overheads of communicating orchestration metadata. We focus on the mechanisms here and outline the metadata exchanged over the interface at relevant places in later subsections.

CPU-to-NIC metadata: The datapath OS communicates with the NIC by writing to the NIC control registers via memory-mapped IO (MMIO) and via metadata in descriptors.

OS-to-NIC Interface	Description
RegisterService(s_id: X, ip: I, port: P, prio: O)	Register a new service X with the NIC.
EnableService(s_id: X, core_id: Y)	Notify the NIC that core Y is running service X.
DisableService(s_id: X, core_id: Y)	Notify the NIC that core Y is no longer running service X.
LoadFeedback(s_id: X, core_id: Y, count: C)	Notify the NIC that service X finishes C packets on core Y.
EnableLoadMonitor(s_id: X, trigger: T)	Enable load monitor for service X, with trigger condition T.
RearmLoadMonitor(s_id: X)	Notify the NIC that the host is ready to receive the next load hint for service X.
NIC-to-OS Interface	Description
LoadHint(s_id: X, hint: H)	Notify the host that service X's load has triggered the scale-up/down condition.

Table 1: RingLeader OS-NIC Interface

Each core accesses a different set of cache-aligned NIC registers to increase MMIO write performance. Our microbenchmarks in Section 7.4 show the throughput for OS-to-NIC communication is roughly 50M messages per second.

NIC-to-CPU metadata: The NIC communicates with the OS through packet descriptors. The NIC-generated reallocation hint is inlined into the packet descriptor and sent to the per-core NIC queue.³ The datapath OS polls the NIC queue and parses the NIC hint. To avoid HoL blocking, the NIC limits the number of outstanding unACKed hints per core.

Our interface allows the NIC to monitor and control the length of each per-core queue despite the inherent asynchrony caused by PCIe latency. This design also overcomes PCIe throughput limitations by avoiding generating new PCIe messages in the common case.

4.2 On-NIC Load Balancing with JBSRQ

RingLeader performs hardware-based request load balancing for each service using a Join-Bounded-Shortest-Rank-Queue (JBSRQ) algorithm to decide **when** and **where** to send a packet. JBSRQ is an extension of the Join-Bounded-Shortest-Queue (JBSQ) algorithm [21] that considers inter-service inference and priorities.

As defined in R2P2 [21], JBSQ(n) approximates an ideal, work-conserving single queue policy using a combination of an on-NIC centralized queue and short, bounded queues at each worker. Each worker queue has a maximum depth of n messages. JBSQ(1) is equivalent to a single-centralized-queue model, whereas JBSQ(∞) is equivalent to JSQ.

Per-core shallow priority queues: JBSRQ approximates centralized pull-based load balancing (which achieves ideal load distribution) using a combination of an on-NIC buffer and *shallow* bounded-size (e.g., 4 requests) per-core queues.

When multiple services with different priorities co-exist in the same core, the per-core buffers (no matter how small) can cause undesirable HoL blocking. To avoid this HoL blocking, we implement the per-core buffers as *software priority queues*; a core's coroutine scheduler uses the priority queue to enforce lightweight prioritized scheduling. The enqueue overhead of this priority queue is minimal given that the queue depth is ≤ 4 , and priority calculation overhead is eliminated by the fact that the NIC scheduler computes priorities (Section 4.3)

³If there is no active packet descriptor being sent from the NIC to the host, RingLeader will generate a new packet descriptor (for scaling down).

and simply carried along with packet descriptors. Further, the currently running lower priority request will yield to the highest priority request, which further reduces HoL blocking. **JBSRQ:** Before describing our approach, we outline the sub-optimality of the classical join-bounded-shortest-queue (JBSQ) approach.

The main issue is that JBSQ does not consider the behavior of the host's priority queue.

Figures 5 (a), (b) show this limitation for two types of JBSQ algorithms: global-JBSQ and per-service-JBSQ. In global-JBSQ, which is used in RackSched [43], the NIC tracks per-core NIC queue lengths and always steers new requests to the core with smallest queue length. In per-service-JBSQ, which is used in nanoPU [17], the NIC tracks per-service queue length on each core and implements a JBSQ per service.

Given two services running on core 1 and core 2 where service A's priority is higher than service B, the example in Figure 5 (a) shows how global-JBSQ prevents new arriving high priority requests from preempting the on-host low priority requests. Since core 1's queue length is larger than core 2, global-JBSQ would dispatch the newly arrived service A's request to core 2. However, the optimal decision is to steer the request to core 1 as A's request would be served before B's request; the low priority request's queue length has little impact on the high priority request's completion time.

Similarly, Figure 5 (b) shows that per-service-JBSQ leads to sub-optimal performance for low priority requests.

To overcome JBSQ's limitations, we introduce JBSRQ. For simplicity, we assume each service has a single request type and that we are given priorities across services. In JBSRQ, the NIC tracks same-core services' queue lengths and service priorities. Then, for each service's request, the NIC selects the core that has the minimal rank, where rank is calculated as follows for a request for service A:

$$R[A].c = \sum_{P_x \geq P_A} Q[x].c + \lambda * \sum_{P_x < P_A} Q[x].c$$

Here, $R[A].c$ represents service A's rank on core c. P_A represents service A's priority, $Q[x].c$ represents service x's queue length on core c. λ is a constant factor between 0 and 1.

The underlying idea in JBSRQ is: when dispatching one service A's packet, the load balancer should consider the amount of the queue on a core that is contributed by requests of at least the same priority as A (because A's request cannot be scheduled ahead of such requests); the first term captures this. The rank calculation ignores the queue length contribution from all lower-priority requests. The factor λ and the sum-

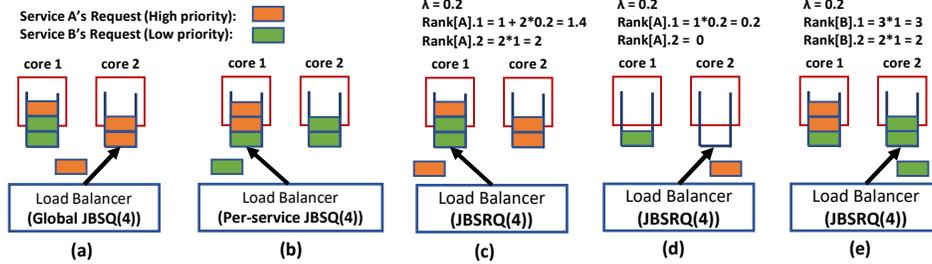

Figure 5: Comparison between JBSQ and JBSRQ. In (b): Since core 1’s low priority request queue length is smaller than core 2’s, per-service-JBSQ would dispatch the new arrived service B’s request to core 1. However, the optimal decision is to steer the request to core 2. This is because a high-priority request’s queue length would impact the low-priority request’s completion time.

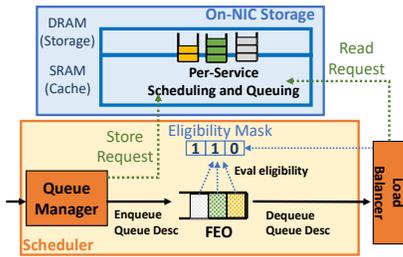

Figure 6: On-NIC Request Scheduler

mation in the second term captures the cost of waiting for a lower-priority request to yield before the higher-priority request is scheduled.

We now exemplify the benefit of using the JBSRQ policy. Figure 5 (c) shows that, when dispatching A’s request, we could mostly ignore B’s queue length. The calculated core 1’s rank is smaller than core 2. Thus the newly arriving A’s request is steered to core 1. Figure 5 (d) shows that, at low load, B’s queue length can influence the load balancing policy for A’s request; this is because we have added a small constant factor for the low priority request’s queue length, which allows B to obtain fair service at low load. In this example, selecting idle core 2 is the optimal decision. This is because the overhead of scheduling or preempting B’s request is non-negligible; thus choosing core 1 leads to a sub-optimal decision. Figure 5 (e) shows that when dispatching B’s request, we should consider A’s queue length, as a high priority request will always be served before a low priority request.

4.3 Non-blocking On-NIC Request Scheduler

We develop an FEO (First-Eligible-Out) priority scheduler that provides programmable per-cycle scheduling while supporting a non-blocking interface with the load balancer.

To understand why FEO is needed, consider PIFO [39], which assumes that, at any given time, all elements are eligible for scheduling. PIFO always schedules the smallest ranked element in the entire list of enqueued requests. However, given that we use shallow per-core buffers, we require that, for a given service, if a request’s rank at all worker cores exceeds the queue-length bound, the load balancer must hold

the request to avoid it getting dropped at a core. In this situation, the scheduler would block the rest of the lower-priority requests, which the load balancer could have dispatched to other potentially-idle cores.

FEO extends PIFO to avoid this problem by interfacing with the load balancer. As Figure 6 shows, when dequeuing elements, we first filter the set of elements eligible for dispatch and then schedule the smallest ranked element from that set. To enable this, the load balancer provides a bitmask that records the dispatching eligibility of each service.

The main difference between PIFO and FEO is the dequeue operation, which proceeds in two steps. First, we evaluate each element’s eligibility in parallel by looking up its bit in the bitmask. Second, FEO uses priority encoding to select the front-most element whose eligibility is true, pops out the selected entry, and shifts the array. This design achieves a fast and parallel evaluation of elements upon dequeue. Additionally, FEO also provides buffer isolation by ensuring that the lowest priority request is dropped when buffers overflow.

4.4 NIC-assisted CPU Assignment

In RingLeader, each service could enable its own on-NIC load monitor through the interface defined in Table 1. RingLeader’s load monitor supports rich triggers based on services’ performance goals (e.g., latency or throughput) or scheduling policies. By default, scale-up trigger uses the congestion detection policy in Caladan [13]: if any service’s request is found to be present in the on-NIC queue for two consecutive intervals, the NIC generates a scale-up hint. The scale-down policy is more conservative: within a time interval, if the maximum on-NIC queue length for a service never exceeds a threshold, the NIC generates a scale-down hint.

When a threshold is reached for a service, the load monitor generates a scale-up/down hint, inlines into the packet descriptor, and sends it to the buffer of the service’s least-loaded core; it then *disarms* hint generation for this service. If no active packets are sent from the NIC to the cores, RingLeader will generate a new packet descriptor (to aid scale down).

The datapath OS polls the per-core queue and receives NIC hints. Then, the OS calls the core allocation function to decide

whether/where to scale up/down this service.

Assignment strategies: In an ideal system with a perfect load balancing policy and no multiplexing overhead, the best core allocation policy would be **complete-share**: similar to Shinjuku [19], all services run on all the cores, and a service is immediately granted CPU when its request is dispatched. This policy can tolerate bursts well and ensure good CPU efficiency. In practice, though, multiplexing overheads (including preemption and yielding) are non-negligible. For example, even with state-of-the-art low-overhead interrupt mechanisms, multiplexing tasks in a core could incur at least 24% overhead [15, 19]. Therefore, frequent switching between services waste considerable CPU resources under complete-share.

Thus, RingLeader supports two additional core assignment strategies to balance the trade-off between burst tolerance and wasted CPU. In the **no-sharing dedicated** model (similar to Shenango [31], Caladan [13]), each service has its own dedicated core set. The core allocator reallocates cores between services at fine-granularity (e.g., 5 μ s per reallocation). A dedicated core improves cache locality and avoids multiplexing overhead. But such a system will have worse burst tolerance since even a 5 μ s reallocation interval cannot react to transient micro bursts [24].

In the **allow-sharing hybrid** model, each service has some dedicated cores, as well as cores shared with other services. The dedicated core is used to handle the long-term constant load, and the shared core is used when a burst of requests arrives. This balances multiplexing overhead and burst tolerance.

After the datapath OS successfully scales up/down a service, it calls the rearm function (Table 1) to rearm the load monitor for the service. Before being rearmed, the load monitor will not generate further hints for the service; this ensures only one in-flight hint per service and reduces the synchronization overhead inside the host’s core allocator (e.g., only one core will receive the hint for a service at a time).

5 Hardware Design

We describe the hardware design of RingLeader’s programmable load balancer and provide details on how it interfaces with FEO and with software priority queues. We end with an example to show how requests flow through the RingLeader hardware. We provide benchmarks in Sec. 7.5.

5.1 Load Balancer Hardware

The load balancer unit uses two fundamental building blocks: **Per-core rank register array:** JBSRQ needs to sum up the queue lengths of all services/request types on a core at or above a certain priority (Sec 4.2). Instead of spending cycles scanning and summing up different queue lengths, we maintain a pre-calculated rank register array for each priority level in the on-NIC SRAM. This register array stores each

priority level’s current rank on each core. When a request arrives, RingLeader directly reads out its rank according to the priority. The rank register array is updated asynchronously either when a request is dispatched or when load feedback is sent back from the worker core.

Reduction-tree-based “choose min”: We use a hierarchical tree-based circuit for computing the “choose min” operation in JBSRQ to select a core. Although PIFOs are typically used for “choose min” operations in scheduling, using the same design in our load balancer is not feasible. This is because ranks are frequently updated as requests are dispatched and completed, and it is not possible to update the ranks of entries in a PIFO. Using a new reduction-tree-based design in RingLeader overcomes this limitation and allows for ranks to be updated frequently and in parallel.

Because the “choose min” operation can also be costly when the core count is high, RingLeader uses a hierarchical tree-based circuit to compute this minimum value. This circuit lends itself to pipelining, and it can calculate a minimal ranked core at every cycle. In RingLeader, we found that with 64 cores, a 3 staged reduction tree pipeline can fit on a middle-end FPGA without any utilization or timing issues.

5.2 End-to-End Example

We now present a simple example that puts the hardware components of RingLeader all together. We have two active services running on a host with two cores; the services are prioritized as shown in the top right; all requests in service are the same priority. Figure 7 (A) shows each service’s priority, as well as how five existing requests are queued on the host. We assume the λ in JBSRQ is 0.2, and the depth of each per-core queue is 3; the scheduling policy is a strict priority.

Our example is shown via the numbered steps in Figure 7: To start with, in the PIFO unit, both services’ eligibility bit in the mask is true. Then, (1) PIFO schedules service 1’s queue descriptor, with the highest priority (see top right). (2) The request scheduler reads service 1’s request F from the request buffer. (3) Request F is sent to the load balancer, which then looks up the priority register and directly reads ranks from the register array. Priority 2’s rank on core 1 is 0.4 and on core 2, rank is 1.4. (4) The load balancer checks the core bitmask. If a given service is not running on a core, the rank for this core is set to infinite. However, in this example, both cores run service 1, so the rank is not reset or modified.

(5) Per-core ranks are then sent to the hierarchical reduction tree to identify the destination core with the minimal rank, core 1. Then, request F is dispatched to core 1. (6) We update core 1’s priority registers according to the JBSRQ algorithm (Sec 4.2). As shown in Figure 7’s (B) table and looking at core 1 queue occupancy before enqueueing F at the top right, we add one to the ranks of both priority 1 and priority 2, and we add λ to priority 3’s rank. ⁴

⁴F belonged to a service with priority 2; after enqueueing it, priority 1’s

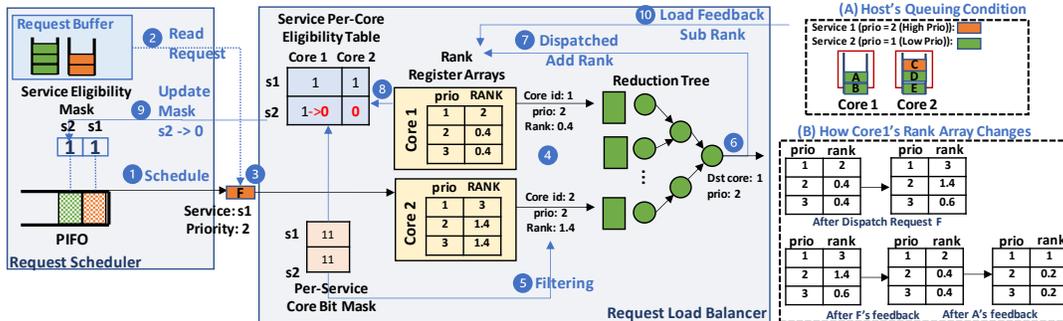

Figure 7: End-to-End Example in RingLeader NIC

(7) After the update, priority 1's rank on core 1 reaches the rank boundary (which is 3). We then update the per-core eligibility table - where we log which service on which core has reached the rank bound, meaning that buffers are exhausted at the core and requests from the service can no longer be scheduled on the core. Given service 2 is mapped to priority 1 on core 1, we change service 2's eligibility on core 1 into 0. (8) Since service 2 is now ineligible to be dispatched on all the cores (core 2's queue was already full - see top right), in the request scheduler, we set service 2's eligibility bit into 0. Therefore, PIFO will no longer schedule service 2's request. (9) Finally, Figure 7's (B) table further shows how the rank array is updated when receiving feedback from core 1 after processing requests F and A.⁵

6 Implementation

Our implementation consists of an FPGA prototype for the RingLeader NIC, a user space NIC driver, and a library operating system built over Demikernel.

FPGA-based Prototype: The FPGA prototype is implemented in 4K lines of Verilog code, and uses the DMA Engine, Ethernet MAC and PHY provided in Corundum [12] run at a 250 MHz frequency with a data width of 512 bits.

RMT pipeline: We implemented a single-stage RMT pipeline in our FPGA prototype. The datapath OS preinstalls the appropriate rules in the pipeline through the NIC-OS interface.

On-chip Request Buffer: The request buffer is implemented using high-speed BRAM, which supports concurrent reads and writes at 128 Gbps. The size of the on-chip BRAM buffer is set to 800 KB. This buffer size can be increased by utilizing on-NIC DRAM in the future.

FEO scheduler and reduction tree: In our implementation, the FEO block runs at a 125 MHz frequency with a queue size of 64. The reduction tree supports 64 worker cores with a three-stage pipeline in the dispatcher. In the rank register array, each core has 8 physical priorities.

rank will see all 3 entries in the queue; priority 2's rank will see priority 2 requests (1) + λ ($=0.2$) times priority 1 requests (2); priority 3's rank will see priority 3 requests (0) + λ ($=0.2$) times priority 1 and priority 2 requests (3).

⁵F's feedback comes before A because of the software priority scheduler.

User space NIC driver: The user space poll mode driver for the RingLeader NIC is implemented in 1.5K lines of C code and provides DPDK-like kernel-bypass access to the NIC for standard NIC functions, in addition to providing all of the functions in Table 1.

The Datapath OS: We integrated RingLeader with Demikernel's catnip libOS using 800 lines of Rust. We made the following modifications to Demikernel: (1) We extended the catnip libOS to add support for RingLeader's user space driver. (2) We added multi-core support to Demikernel, which previously only ran on a single core. (3) We extended Demikernel's coroutine scheduler to enforce prioritized scheduling between different services' coroutines. (4) RPC requests yield to the coroutine after a fixed amount of work instead of always running to completion (Section 3).

7 Evaluation

Our evaluation answers the following questions:

- (1) Does RingLeader achieve high performance for load balancing and request scheduling? How does RingLeader's tail latency and scalability compare to the state-of-the-art software-only approaches across different workloads and service time distributions? (Sections 7.2 and 7.3)
- (2) How much do the individual components of RingLeader contribute to overall improvements? (Section 7.4)
- (3) How do our NIC-assisted core assignment's resulting CPU efficiency and burst tolerance compare to the state-of-the-art software-only approaches? (Section 7.5)
- (4) What is the scalability and hardware resource usage of the RingLeader NIC? (Sections 7.6)

7.1 Methodology

Testbed: We evaluate our system on a server with two Intel Xeon Gold 6326 16-core (32-thread) CPUs and 128 GB of RAM. This server runs Ubuntu LTS 20.0.4 with the 5.4.0 Linux kernel. In addition, the server has a 100G Alveo U280 Data Center Accelerator Card [1] atop which we implemented our 100G FPGA prototype. The server also has a Mellanox ConnectX-5 Ex 100 Gb NIC, which we use to run the Caladan

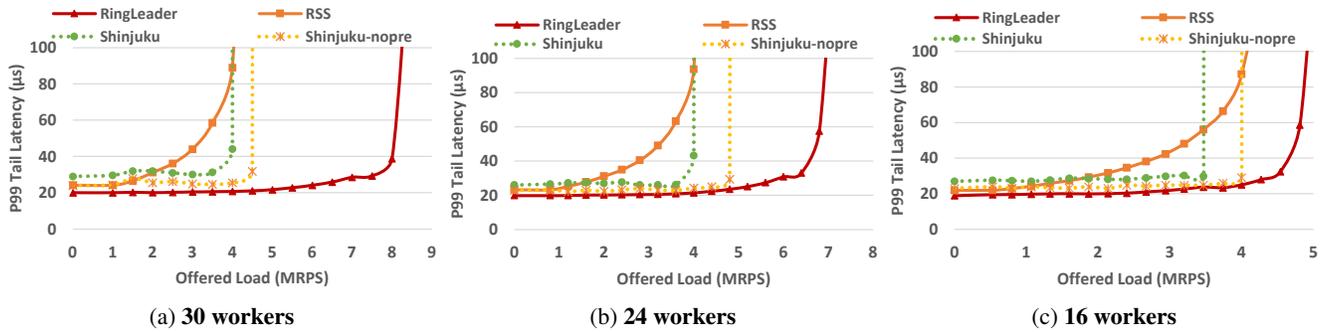

Figure 8: Load balancing performance under Exp(3) workload.

baseline (described below). We use another client machine with a Mellanox ConnectX-5 Ex 100Gb NIC to generate load using DPDK. The client has the same CPU and OS version as the server. Our experiments (RingLeader and baseline experiments) don't consider NUMA and direct all interrupts, memory allocations, and threads to the NIC-local socket.

RingLeader configuration: Software priority queue depth is set to 4, and λ (Sec. 4.2) is set to 0.2. (We study sensitivity to λ in the appendix (12.1), and find $\lambda = 0.2$ to be a good setting). The yielding interval is set to $5\mu s$.

Baselines: We compare RingLeader to three baselines:

Shinjuku [19]: Shinjuku uses centralized preemptive scheduling to achieve high-performance request load balancing and scheduling. Shinjuku only supports Intel 10G NICs and Linux kernel version 4.4.x, and it can only run on Intel cores because its fast preemption mechanism requires VT-x support. We use two Cloudlab [34] c6420 nodes (one client and one server, connected through a ToR switch) to run Shinjuku with kernel v4.4.0; each node is equipped with two 16-core (32-hyperthread) Intel Xeon Gold 6142 CPUs, and an Intel X710 10 Gigabit NIC. By default, Shinjuku uses two hyperthreads for orchestration – one for the network and another for the load balancer – collocated on the same physical core. The preemption interval is set to $5\mu s$. To ensure a fair comparison, we always assign one more physical core (two hyperthreads) to Shinjuku than RingLeader for running orchestration tasks.

Caladan [13]: Caladan reallocates cores between applications at a fine granularity to increase CPU efficiency under changing workloads. We run Caladan on the same server and the same OS and kernel version as RingLeader.

Caladan runs its IOKernel on a single dedicated core. Therefore, like Shinjuku, we always assign one more physical core to Caladan than RingLeader.

RSS: We also study a decentralized RSS-based system. In this baseline, worker hyperthreads are managed by the Demikernel datapath OS, and each worker polls its own large receiving NIC queue. Here, we use a bare metal 100G U280 FPGA NIC [1] that performs standard NIC functions.

Workloads: We employ both synthetic workloads and RocksDB.

Synthetic Workloads: (Table 2) Our synthetic workload is a server application where requests perform dummy work that

Workloads	Description
Exp(3)	Single request type, service times follows exp distribution with mean $3\mu s$.
Bimodal (95-5,5-100)	95% requests are high priority, take $5\mu s$. 5% requests are low priority, take $100\mu s$.
High Bimodal (99-3,1-100)	99% requests are high priority, take $3\mu s$. 1% requests are low priority, take $100\mu s$.

Table 2: Synthetic Workloads

we can control to emulate any target distribution of service times. This allows us to run microbenchmarks that systematically study how RingLeader and different baselines perform under different performance limits.

RocksDB Workloads: We also performed experiments with RocksDB, a popular and widely deployed in-memory key-value store developed by Facebook [11]. We use RocksDB queries that are either GET/PUT requests or range SCANS.

To generate both the synthetic and RocksDB workloads, we developed an open-loop load generator similar to Shinjuku [19] that generates requests over user space UDP. It uses 12 threads to generate requests following a Poisson arrival process and specific service-time distributions and another 12 user space threads to receive server replies. Request latency is measured through timestamps carried inside packets. We ensure that the network speed and the load generator are not bottlenecks in any experiment by checking for packet drops.

7.2 Load Balancing Performance

First, we evaluate the RingLeader load balancing unit using an Exp(3) workload that, for simplicity, only has a single type of request (with service times following an exponential distribution with a mean of $3\mu s$). We compare RingLeader against three baselines: Shinjuku, Shinjuku-nopre, and RSS. In Shinjuku-nopre, we use Shinjuku without preemption.

Figure 8 shows the load balancing results when the server runs 30, 24, and 16 workers. Each worker is a hyperthread, and all workers run on the NIC-local socket. Across all levels of load, RingLeader provides the lowest tail latency. Also, RingLeader has the highest saturating throughput for all worker counts. This shows that RingLeader has the best scalability and load balancing precision. In contrast, the dedicated orchestrator core Shinjuku uses for networking and

load balancing becomes a performance bottleneck when the offered load is > 4.8 MRPS (Million-Request-Per-Second) and preemption is disabled and when the offered load is > 4 MRPS and preemption is enabled. Figure 8 also shows that RingLeader consistently outperforms RSS, which distributes load unevenly across cores, hurting tail latency.

7.3 Scheduling Performance

Synthetic Workload: We now study RingLeader’s ability to achieve high-performance scheduling across services/request types. We use the High Bimodal workload (Table 2) with two types of requests for one service: high priority requests that follow Exp(3) and low priority requests that follow Exp(100). We turn off core assignment in these experiments, so the two types of requests run on all worker hyperthreads.

Figure 9 shows the results from this experiment. For all worker counts, RingLeader consistently outperforms Shinjuku. This is because Shinjuku’s orchestrator cores become bottlenecked when the load is larger than 3.5 MRPS. In contrast, RingLeader has better scalability and lower latency.

Also, in RingLeader, high priority requests can still maintain low tail latency even when the low priority requests’ load is saturated (*e.g.*, at load > 3.5 in Fig 9a). This is because the on-NIC scheduler provides buffer isolation (Sec. 4.3) and ensures each request type is dropped separately.

RocksDB Workload: Next, we evaluate RingLeader’s scheduling performance under the RocksDB workload. We use two request types: GET requests for a single key-value pair that execute within $5\mu\text{s}$; SCAN requests that scan 200 key-value pairs and require $60\mu\text{s}$. We also vary the yielding interval for SCAN across 40 items-per-yield (Y40), 20 items-per-yield (Y20), and 10 items-per-yield (Y10). Figure 10 shows that RingLeader’s prioritized scheduler allows GET requests to avoid long queuing times due to SCAN requests. Aggressive yielding improves tail latency performance for short requests and adds a constant overhead to scan requests. RingLeader-assisted core re-allocation is a way to get around the constant yielding overhead.

7.4 Benefits of RingLeader Components

We now study how the individual components in RingLeader’s load balancing and scheduling functionality contribute to overall performance; core assignment is turned off here (we study it later in Sec. 7.5). Figure 13 (in appendix) presents a comparison of RingLeader and reduced versions of RingLeader that remove/replace a single component. We use the bimodal workload shown in Table 2. **FEO:** Here, we turn off our scheduler eligibility bitmask (Section 4.3), causing it to be degenerate to vanilla PIFO (Blocking_PIFO). Figure 13 shows that PIFO’s performance is much worse than RingLeader when the load increases for high priority requests. This is because, in our two-request-type

setting, low priority requests prevent high priority requests from entering the load balancer at high load.

Global-JBSQ: Next, we evaluate global-JBSQ(4), a load balancing algorithm similar to RackSched [43] where the NIC tracks per-core queue lengths and always steers new requests to the core with the smallest queue length. The queue length bound for each core is set to 4. Figure 13 shows that, even with preemption and the software priority queue enabled, the high priority request’s tail latency is much worse than JBSRQ when the offered load is > 2.24 MRPS. Because global-JBSQ does not consider the behavior of the software priority queue, a burst of long requests can occupy all per-core NIC queues, and new arriving high priority requests cannot be dispatched.

Per-service-JBSQ: We evaluate per-service-JBSQ(4), a load balancing policy that is similar to nanoPU [17] where the NIC implements JBSQ(4) per service. On each worker, the queue length limit for a service is 4. Figure 13b shows that low priority requests have worse performance than RingLeader because, when dispatching a low priority request, the NIC ignores the influence of high priority requests on the queuing delay of low priority ones.

No Software Priority Queue: Figure 13a shows what happens when we disable per-core software priority queues (and cooperative yielding). High priority requests suffer a lot because a burst of low-priority requests can enqueue at currently idle cores and unduly delay later-arriving sensitive requests.

7.5 NIC-Assisted Core Assignment

We evaluate RingLeader’s ability to detect load changes and aid in fast core reallocation. We experiment with two types of services running on the host. One serves high-priority latency-sensitive RocksDB GET requests. The other runs a best-effort analytics workload that continuously scans a range of the RocksDB database and performs data comparisons over the scanned results. We increase RocksDB GET’s load gradually and measure offered load averaged over 10s intervals.

We compared RingLeader’s core reallocation performance with Caladan. In this experiment, Caladan and RingLeader have 16 worker hyperthreads, and the core assignment decision interval is $8\mu\text{s}$. Furthermore, in this experiment, RingLeader uses the same CPU assignment strategy as Caladan, which is the no-sharing dedicated model.

We evaluate the analytics service’s throughput and the GET request’s tail latency. Figure 11 shows that RingLeader keeps the tail latencies of the GET request low while also allowing for spare CPU cycles to be shared with the best-effort analytics service. Furthermore, RingLeader yields both better GET requests tail latency and higher analytics workload throughput than Caladan because load-imbalance and work-stealing in Caladan increase latency and CPU load. For example, in Figure 11b, Caladan’s latency goes up at load 1.44 Mpps since work-stealing happens most frequently at this point. In contrast, RingLeader consistently achieves near-optimal

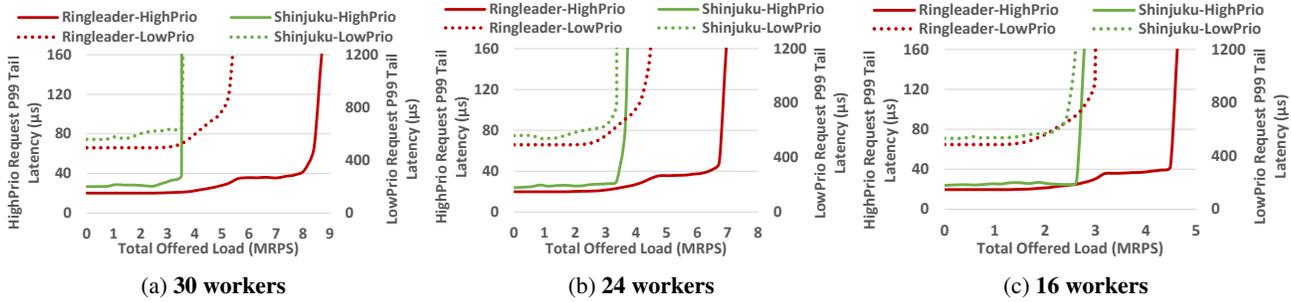

Figure 9: Load balancing and scheduling performance under High Bimodal workload.

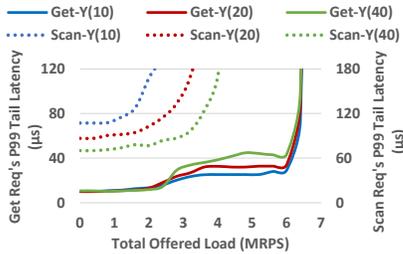

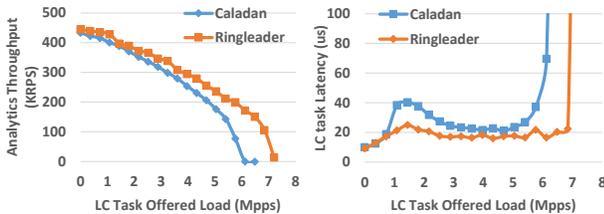

Figure 10: RocksDB performance.

(a) Analytics throughput. (b) GET's P99 tail latency.

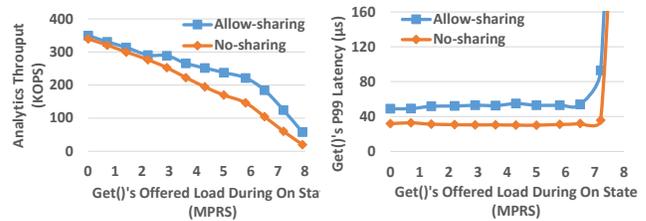

Figure 11: Comparison with Caladan.

centralized scheduling and low overhead core assignment.

Next, we use the on-off traffic pattern to compare the performance of two CPU allocation policies: allow-sharing hybrid and no-sharing dedicated (Section 4.4). During the on state, the traffic source generates GET requests; during the off state, the traffic source stops sending. The switching time between the on/off states is 0.8 ms. Under this pattern, core reallocation happens several times every 0.8 ms. Figure 12 shows that the allow-sharing policy has better analytics throughput as it allows the two services to coexist in the same core, accommodates small timescale bursts of arrivals, and minimizes CPU waste. However, the no-sharing has better tail latency for GET requests because using dedicated cores improves cache locality and avoids multiplexing overheads; nevertheless, the allow-sharing tail latency stays relatively low and flat for the most part. Given this information, an admin can configure RingLeader to pick a core assignment policy based on the relative importance of low tail latency for sensitive services versus not starving batch services.

7.6 Scalability and Resource Usage

We now study RingLeader's performance upper bound and it's hardware resource usage.

(a) Analytics throughput. (b) GET's P99 tail latency.

Figure 12: Core reallocation under different policies.

Module	Setting	LUTs(%)	BRAM(%)
Load Balancer	(16 priorities * 64 cores)	2.82	0.10
	(16 priorities * 128 cores)	2.86	0.10
	(32 priorities * 64 cores)	6.07	0.00
Scheduler	FEO = 16	0.24	0.01
	FEO = 64	1.00	0.01
Packet Buffer	800 KB	0.16	6.54

Table 3: FPGA resource usage for different components.

OS-NIC interface: Figure 16a shows the throughput for the OS-to-NIC interface. The communication throughput between a single worker hyperthread and the NIC is 6M register writes per second, and with 8 workers, the throughput can reach 50M. The result shows that RingLeader can achieve low-overhead, fast OS-to-NIC communication.

System Throughput and Latency Overhead: Figure 16b shows that RingLeader can achieve line-rate load balancing and scheduling. In this experiment, the host uses 8 worker hyperthreads, every request finishes immediately, and the rank bound is set to 16. The result shows that RingLeader achieves 100G with MTU-sized packets and 50Mpps for 64B packets.

We measure RingLeader's latency overhead by adding hardware timestamps. We find that a request can be scheduled and dispatched within 150 ns. The end-to-end host ping-pong latency is 6µs, which is close to commercial NICs.

Hardware Resource Usage: Our U280 FPGA has 1300k LUTs in total. Table 3 shows different components' resource usage under different settings. The load balancer and scheduler occupy most of RingLeader's on-chip logic. When the load balancer is configured with 16 priorities and 64 worker counts, it consumes around 2.82% of the logic area. With 32 priorities, it consumes 6.07%. Furthermore, when FEO uses 16 entries, it consumes 0.24% of the logic area, and when the size is 64, it consumes 1.00%. Overall, we find that RingLeader can easily fit on an FPGA.

8 Related Work

Software approaches: RingLeader addresses the key scalability and performance limitations of other orchestration systems like IX [6], ZygOS [33], Shenango [31], and Shinjuku [19]. ghOSt [16] and Syrup [20] use userspace CPU scheduling policies; they are complementary with RingLeader.

Hardware approaches: Shinjuku-on-SmartNIC [15] provides centralized preemptive request scheduling on an ARM-based SmartNIC, but scheduling requests on wimpy on-NIC cores has limited processing speed and introduces tens of microseconds of latency [22].

PIEO [38] extends PIFO to support efficient extraction for time-based scheduling algorithms, but it cannot simultaneously support scheduling and load balancing. This is because it only supports packet extraction as a function of time and hence cannot be used to support an eligibility mask.

Recent related works, such as nanoPU [17], RackSched [43], Shinjuku-Offload [15], and R2P2 [21], use JBSQ to offload load balancing in systems with communication latency. However, as demonstrated in Section 7.4, JBSQ is suboptimal when requests have different priorities. Our new JBSRQ algorithm can improve performance under multi-priority scenarios. Related works, such as RackSched, RPCValet [9], and nanoPU, offloads request scheduling. However, RackSched and RPCValet do not use centralized scheduling, which can cause high-priority requests to suffer more from HoL blocking. In the case of nanoPU, request scheduling requires changes to the CPU architecture by using the hardware thread scheduler. In contrast, RingLeader achieves centralized scheduling with no need for changes to the CPU architecture.

Elastic RSS [36] uses a NIC to perform both load balancing and core allocation. However, it buffers packets at CPU cores and not on the NIC, leading to load-imbalance, and it does not schedule packets, leading to HoL blocking.

Transports: Improvements in transport protocols are complementary to RingLeader. Both new transport protocols like MTP [41] and EQDS [30] and projects that offload transport protocols to SmartNICs [3, 28, 32, 37] can enable message-level load balancing and scheduling in an orchestration system, so RingLeader would benefit from their adoption.

9 Discussion

Multi-NIC support: Although our design as presented so far assumes a single NIC per server, there are a few different ways RingLeader can be configured to support multiple NICs in a single server: 1) a master/slave configuration (described below), 2) hard-partitioning workers (Section 12.2), or 3) a cooperative configuration (Section 12.2). In a master-slave configuration, each NIC will transfer data to main memory independently but not perform dispatching. Instead, each slave NIC sends descriptors about pending requests to the master NIC, which is solely responsible for orchestration.

Multiplexing Mechanism: RingLeader uses cooperative scheduling, requiring developers to insert yield statements for low priority services. However, RingLeader is also compatible with other multiplexing mechanisms, such as: 1) optimized APIC interrupts [15], and 2) compiler interrupts [5]. Optimized APIC interrupts are a low priority service that can set a timer that will deliver a low-overhead interrupt once the time slice expires. Compiler interrupts use compile-time instrumentation to allow programs to call an interrupt handler at a regular intervals with little performance impact.

Multi-process Support: RingLeader inherits a key assumption in Demikernel today [42], namely that the data path OS and services run in a single process. However, similar to recent work like Snap [23], we can extend RingLeader to support multiple processes by using Demikernel as a standalone process that multiplexes I/O across client processes through shared memory regions. Such an extension would naturally enable RingLeader to support policies across applications (as opposed to policies across services in an application).

Applicability to a general kernel: Fine-grained multiplexing between services on the same core is too expensive for μ -scale applications in a traditional kernel. This is why many previous works [13, 19, 31, 42] and RingLeader use highly specialized data path OSes. However, our system can also be applied to existing Linux kernels. With a general kernel, users may want to avoid processor sharing by isolating services across cores, and our load balancer and CPU allocator still work effectively.

10 Conclusions

Existing intra-server orchestration approaches have limited scalability, poor precision, and high overheads. We address these problems by introducing RingLeader, a new system that efficiently offloads orchestration in their entirety to a programmable NIC while minimally onloading limited functions to host cores. RingLeader introduces a novel OS/NIC interface, a new load balancing algorithm and scheduler, and a hardware element that combines the decisions of the two. Our experiments with a prototype on a 100 Gbps FPGA NIC show that RingLeader offers good tail latency, high throughput, good CPU utilization, and effective core reallocation.

12 Appendix

12.1 JBSRQ Policy parameters

We evaluate how the constant factor λ in JBSRQ influences system throughput and tail latencies under the Bimodal workload. Figure 14 shows that, for both high priority and low priority requests, a constant λ between 0 and 1 brings significant performance gain over $\lambda = 0$ or $\lambda = 1$. When $\lambda = 0$, the rank calculation does not consider preemption overheads. Under low load (load < 2.24), $\lambda = 0$ leads to unnecessary preemption, increasing tail latency for both high priority and low priority requests. When $\lambda = 1$, JBSRQ equals global-JBSQ. This prevents new arriving high priority requests from preempting the on-host low priority requests when load > 2.24 , increasing tail latencies for high priority requests. An intermediate λ is necessary to achieve good performance under both high and low load. Figures 15 shows how different λ s between 0 and 1 influence JBSRQ's performance. There is not much difference between $\lambda = 0.2$ and $\lambda = 0.4$. When λ

Figure 16: Scalability of RingLeader

grows to 0.6, performance drops because of the same issue with $\lambda = 1$.

12.2 Supporting Multiple NICs

While our design aimed at servers equipped with a single NIC, we believe that it can be extended to support multi-NIC settings as well. We discuss a few options below.

Hard-partitioning workers: The simplest approach is to partition workers across NICs. Here, for example, each NIC orchestrates its local NUMA node. This allows each NIC to perform ideal centralized scheduling independently. However, this requires all network traffic for a service to be sent to a specific NIC.

Cooperative multi-NIC orchestration: In this scenario, each worker can receive packets from multiple NICs. The control message in Table 1 is replicated across all NICs to achieve cooperative orchestration. When a request finishes, the worker sends load feedback to all NICs, so that every NIC knows up-to-date worker queue lengths. Also, when a NIC dispatches a request to a worker, the NIC notifies other NICs of this action. Replicating control messages is the primary trade-off introduced by this approach. However, this is unlikely to be a bottleneck given that control messages are small and MMIO throughput (16a) over PCIe is high.

STARRYNET: Empowering Researchers to Evaluate Futuristic Integrated Space and Terrestrial Networks

Abstract

Futuristic integrated space and terrestrial networks (ISTN) not only hold *new opportunities* for pervasive, low-latency Internet services, but also face *new challenges* caused by satellite dynamics on a global scale. It should be useful for researchers to run various experiments to systematically explore *new problems* in ISTNs. However, existing experimentation methods either attain realism but lack flexibility (*e.g.*, live satellites), or achieve flexibility but lack realism (*e.g.*, ISTN simulators).

This paper presents STARRYNET, a novel experimentation framework that enables researchers to conveniently build credible and flexible experimental network environments (ENE) mimicking satellite dynamics and network behaviors of large-scale ISTNs. STARRYNET simultaneously achieves constellation-consistency, networked system realism and flexibility, by adopting a real-data-driven, lightweight-emulation-aided approach to build a digital twin of physical ISTNs in the terrestrial virtual environment. Driven by public and real constellation-relevant information, we show STARRYNET’s acceptable fidelity and demonstrate its flexibility to support various ISTN experiments, such as evaluating different inter-networking mechanisms for space-ground integration, and assessing the network resilience of futuristic ISTNs.

1 Introduction

Thanks to the resurgence in the space industry [41, 46, 48], big competitors such as SpaceX and Amazon are actively planning and deploying hundreds or even thousands of broadband satellites in low earth orbits (LEO). Such emerging mega-constellations (*e.g.*, Starlink [34], Kuiper [9]) can be integrated into existing terrestrial Internet, *i.e.*, constructing an integrated space and terrestrial network (ISTN) to: (1) provide pervasive last-mile network access; (2) enable low-latency and high-bandwidth Internet transit [40, 52, 56]; and (3) facilitate efficient acquisition and delivery for big data from space (*e.g.*, earth observation images) [44, 74, 77, 78].

While holding great promise, several unique characteristics of LEO satellites (*e.g.*, high LEO dynamics) impose new challenges at various layers of the ISTN networking stack, and open a door to many new research problems, such as: (1) how should LEO satellites and ground facilities be interconnected to provide low-latency and continuous network services? (2) how should satellite routers be integrated into existing terrestrial Internet routing? and (3) are current constellation and protocol designs resilient enough to satellite failures in complex and harsh space environments? With many *unexplored* problems facing the “NewSpace” industry, it is thus foreseen that in the near future, there will be a surge of new ideas on the system and networking research relevant to ISTNs. But, *how can researchers build an experimental network environment (ENE) to test, evaluate and understand their new thoughts?*

Typically, existing approaches for creating an ENE can be classified into three categories: (1) live networks or platforms [7, 20, 34, 75, 81], which allow experiments in real deployments; (2) network simulation [60, 61, 76], which uses discrete events to model and replicate the behavior of a real network; and (3) network emulation [6, 55, 68, 69], which can test real applications/protocols in a virtual network. However, as will be illustrated in §3, all existing approaches have their limitations in creating a desired ENE for ISTNs: (1) the *feasibility* and *flexibility* of live satellite networks are *technically* and *economically* limited for normal researchers; (2) the abstraction level of simulation might be too high to capture low-level system effects, hiding practical issues such as the resource competition under heavy workload, energy drain or software errors; (3) existing emulators fail to characterize the high dynamicity of LEO satellites and thus are insufficient to build an experimental environment with acceptable fidelity.

The key challenge of building an expected ENE for ISTN research is: it is difficult to *simultaneously* achieve *realism* and *flexibility* in the experimental environment. First, terrestrial devices inherently lack the ability to reasonably mimic the high dynamics, system and network behaviors of realistic satellites. Second, mega-constellations typically consist of thousands of satellites. Thus the network scale required by an

*Hewu Li is the corresponding author.

ENE for mega-constellations might be far more than the extent supported by existing ENE methods (*e.g.*, [54, 55, 69]). Third, as a large number of satellites simultaneously move at a high velocity, continuously mimicking such frequent variations at scale could involve significant system overhead on the ENE.

This paper presents STARRYNET, an integrated experimentation framework that empowers researchers to conveniently build ENEs with acceptable realism, flexibility and cost (*e.g.*, requiring only a few number of local/cloud machines) to satisfy various experimental requirements of ISTNs. The design of STARRYNET is inspired by a key insight obtained from the satellite Internet ecosystem: many organizations or communities in this ecosystem have released and shared their constellation-relevant data, including regulatory information [2, 73], satellite trajectories [16, 38], ground station distribution [26, 39] and measurements from user terminals [32, 33], *etc.* Therefore, the key idea behind STARRYNET is to build an experimental *digital twin*, *i.e.*, a virtual presentation of a physical ISTN, in terrestrial environments by: (1) leveraging terrestrial machines to virtualize a large number of lightweight virtual nodes to emulate satellites in mega-constellations; and (2) exploiting a *crowdsourcing* approach to collect, combine and use realistic constellation information to drive the emulation of *spatial* and *temporal* characteristics of ISTNs.

To achieve acceptable realism, STARRYNET employs a *constellation synchronizer* based on realistic constellation-relevant information to make the virtual ENE as consistent as possible to a real ISTN, such as: (1) *constellation consistency*: the ENE is built with the same scale of a physical mega-constellation, where each node emulates a satellite, a ground station or a terrestrial host. The spatial and temporal characteristics, such as time-varying satellite locations and inter-visibility, are also configured and updated in each node based on our data-driven model-based analysis; (2) *system and networking stack consistency*: the ENE can support the run of unmodified applications as in real deployments; and (3) *capability consistency*: network and computation capabilities in the ENE are configured based on real hardware specifications. Further, to flexibly support various ISTN experiments and mimic *large-scale* and *highly-dynamic* mega-constellations, STARRYNET adopts a *constellation orchestrator* that judiciously schedules and manages system resources on multiple machines to collaboratively construct ENE on demand.

We evaluate the ability of STARRYNET based on real constellation information in two steps. First, we show the acceptable fidelity of STARRYNET by comparing the experiment results obtained by STARRYNET with live satellite networks and other state-of-the-art ISTN simulators. Second, facing futuristic ISTN scenarios, we demonstrate STARRYNET's flexibility by conducting three case studies to: (1) explore the trade-space of various space-ground inter-networking mechanisms; (2) evaluate the resilience of routing protocols in various constellation designs; and (3) perform hardware-in-the-loop tests to measure system effects under various workloads.

Summarily, this paper makes the following key contributions: (1) we design STARRYNET, a data-driven, emulation-aided ISTN experimentation framework (§4); (2) we implement STARRYNET with a collection of open APIs for creating and manipulating user-defined ENEs (§5); (3) we evaluate and analyze STARRYNET's experimentation overhead and fidelity (§6), and show STARRYNET's flexibility (§7) by conducting various case studies driven by realistic constellation information. STARRYNET is now available at: <https://github.com/SpaceNetLab/StarryNet>.

2 Preliminaries

Integrated space and terrestrial networks (ISTN). Recent satellite operators/organizations are actively developing their mega-constellations [4, 8, 9, 25, 34, 36], with hundreds to thousands of low earth orbit (LEO) satellites working together as a system. These satellites can be equipped with high-speed inter-satellite links (ISLs), and construct a LEO satellite network (LSN). An LSN can further be integrated into existing terrestrial Internet via globally distributed ground stations [3, 26, 39] and very-small-aperture terminals (VSAT) [31], constructing an *integrated space and terrestrial network (ISTN)* that promises to provide pervasive, low-latency, broadband Internet services [40, 52, 56, 57] for terrestrial users globally.

Unique characteristics of ISTNs, as well as the new challenges. Two critical characteristics differentiate LSNs from existing terrestrial networks, and involve new challenges on the integration of satellites and terrestrial Internet. First, LEO satellites are moving at a high-speed with the respect to the earth surface. An LEO satellite might be visible for a certain ground vantage point only within *a few minutes* in one pass. Such high dynamics could inevitably result in technical challenges (*e.g.*, frequent connectivity disruptions and routing re-convergence) at the networking stack of ISTNs. Second, while evolved, resources (*e.g.*, bandwidth, CPU, energy) are still limited and costly in space, as compared with terrestrial network systems. Resource-intensive technologies might not be doable for resource-constrained satellites to sustain good network performance (*e.g.*, applying sophisticated network coding techniques for packet recovery in remote space).

Call for new research for futuristic ISTNs. The above characteristics and challenges accordingly raise a series of *unexplored* research problems in ISTNs, such as: (1) **topology**: how should LEO satellites and ground facilities be interconnected under the high space-ground dynamicity? (2) **routing**: how should we integrate hundreds or thousands of LEO satellites into Internet routing and tackle the potential performance degradation due to intermittent connectivity? (3) **system effect**: how much energy would a new functionality consume in space under various workloads? It is foreseeable that in the near future, in parallel with the evolution of real mega-constellations, there would be a surge of new research focusing on emerging satellite network systems. But, how should researchers test, assess and understand their new

thoughts? The community requires a *technically* and *economically* feasible approach to construct *Experimental Network Environments (ENE)* and advance futuristic ISTN research.

3 How Can Researchers Evaluate Their New Thoughts for ISTNs?

3.1 ENE Requirements

Ideally, an ENE built for ISTN research is expected to simultaneously accomplish *acceptable* realism and flexibility. We summarize four baseline requirements as follows.

- **(1) Constellation-consistency.** The ENE is expected to be *spatially* and *temporally* consistent to the characteristics of real mega-constellations. For example, the ENE is desired to mimic a large number of network nodes at the same scale of a real mega-constellation, and can characterize the high dynamicity of LEO satellites, as well as its impact on network conditions (*e.g.*, connectivity, delay variations).
- **(2) System-level and networking stack realism.** The ENE is expected to run user-defined system codes and network functionalities like in a real system and networking stack.
- **(3) Flexible and scalable environment.** Emerging mega-constellations are evolving rapidly. As most state-of-the-art constellations are still not in their final stage, the ENE is expected to flexibly support various network topologies at different scales to meet diverse research requirements.
- **(4) Open, low-cost and easy-to-use interface.** Finally, it is expected that the ENE could be open to the community, and can provide low-cost and easy-to-use programmable interfaces for researchers to carry out various experiments.

3.2 Why Existing ENEs are Insufficient?

Existing approaches for building an ENE can be classified into three categories, differing in their realism, flexibility and cost: (1)live LSNs/platforms, (2)simulators, and (3)emulators.

Live LSNs or platforms. A straightforward approach for ISTN experimentation is to construct an ENE based on *live LSNs*, *e.g.*, recently SpaceX’s Starlink has started its initial

services in certain regions. Although this approach guarantees good realism, directly manipulating and inspecting a live LSN might be *technically* and *economically* difficult for a common research group. Current live LSNs are also limited in their *flexibility* when they face diverse, exploratory research requirements. Realistic mega-constellations are still under-constructed and evolving rapidly, and their regulatory information in practice cannot be flexibly modified for *what-if* analysis. Further, the network community has many public experimentation platforms [7,20] that can be shared among researchers. However, these platforms are originally designed for tests in terrestrial networks, not for ISTNs, and thus cannot characterize the unique network behaviors under large-scale LEO dynamics.

Simulators and orbit analysis tools for ISTNs. Numerical or discrete-event-based simulation presents another extreme as compared with live LSNs and platforms. STK [35] and GMAT [11] are representative *orbit analysis tools* that can perform complex analysis of spacecrafts as well as ground stations. However, both STK and GMAT mainly focus on orbit and spacecraft analysis and have limited support for network simulation. More recently, SNS3 [76], Hypatia [60] and StarPerf [61] are emerging simulators for ISTNs. SNS3 is an extension to the ns-3 platform, and it models a full satellite network with a geostationary (GEO) satellite and bent-pipe payload. Hypatia is a framework for simulating and visualizing the network behavior of emerging mega-constellations. Similarly, StarPerf is a simulator that enables users to characterize, estimate and understand the achievable network performance under a variety of constellation options. Although the above simulators can *flexibly* simulate various satellite characteristics as well as the impact of high dynamics on network behaviors, a fundamental limitation of those simulators is that they can not support the run of system codes/functionalities and interactive network traffic as in real deployments. The abstraction-level of simulators might be too high to capture system-level effects, and could hide other practical issues (*e.g.*, software overhead under heavy workloads) in real systems.

Network emulators, and their variations. Emulation is a hybrid approach that integrates real applications, protocols

and operating systems in a synthetic network environment. Similar to live networks, emulators can load and run real codes with interactive network traffic. Similar to simulators, emulators can support controllable and diverse topologies and their virtual hardware requires fewer resources as compared with live networks. The community has many prior efforts focusing on emulated environments, *e.g.*, VM- or container-based emulation [6, 45, 54, 55, 68–70, 72, 79–81, 84, 85].

However, existing emulators suffer from two limitations when they are applied for generating ENEs for ISTN research. First, they are not constellation-consistent, since existing emulators inherently lack the ability of mimicking planet-wide LEO dynamics and time-varying network behaviors in ISTNs. Second, the network scale for mega-constellations could be significantly larger than that in prior experimentation. For example, authors in [54] use 10 physical machines (25 VMs on each) to support a networked cluster with 250 nodes. Etalon [69] is a container-based emulator and its local testbed uses four servers to emulate 48 hosts in a data center network. Different from prior scenarios, ISTN experiments require a much larger network environment: only the first shell of Starlink Phase-I includes about 1584 LEO satellites. Since both VMs and containers can involve software overhead on the physical host machine, it is difficult for existing emulators (*e.g.*, [54, 55, 68]) to support such large-scale and dynamic emulations for mega-constellations.

Our motivation. Table 1 summarizes the landscape of existing experimentation approaches that can be used to build ENEs. Collectively, we find that none of existing approaches can simultaneously satisfy the four expected features. Limitations of existing approaches thus motivate us to seek for a constellation-consistent, credible, flexible, and low-cost methodology to advance the test and evaluation of new research for futuristic ISTNs. We present such a framework, namely STARRYNET, aiming at empowering researchers to build ENEs accomplishing the four goals as described in §3.1.

4 STARRYNET Design

4.1 System Overview

Key idea. The design of STARRYNET is inspired by an important insight obtained from the satellite Internet ecosystem: many organizations (*e.g.*, regulators and satellite operators) and end users have shared a collection of public data for the community, including constellation regulatory information [2, 73], orbital data observed from realistic satellites [16, 38], ground station distributions [3, 26, 39], and performance results measured from terrestrial user terminals [32, 33], *etc.* Based on this important fact, STARRYNET creates ISTN experimental environments on demand by judiciously combining: (1) crowd-sourced real data trace; (2) model-based orbit and network analysis; and (3) large-scale network system emulation, to construct a real-data-driven digital twin, *i.e.*, a virtual presentation synchronized to a real

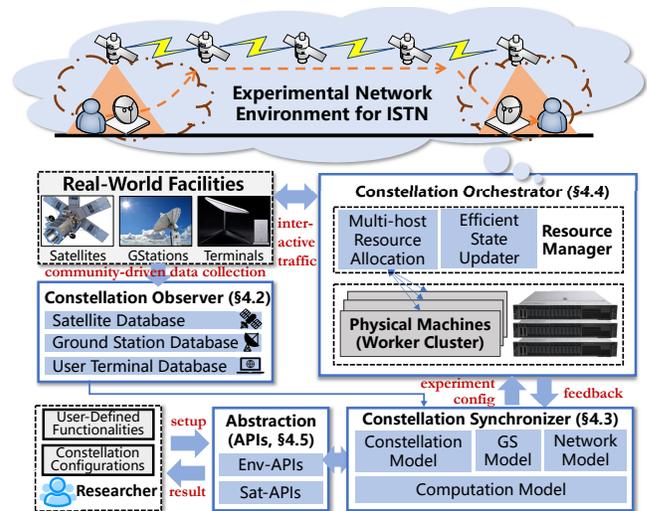

Figure 1: STARRYNET system architecture.

physical ISTN in terrestrial environments. In particular, the key idea behind our STARRYNET design can be summarized as follows: (1) leveraging a crowd-sourcing approach to collect, combine and explore realistic constellation-relevant information to calculate the *spatial* and *temporal* characteristics consistent to real mega-constellations; then (2) driven by such realistic information, exploiting a large number of networked *virtual nodes and links* to flexibly emulate a customized experimental environment, which characterizes system-level effects and network behaviors consistent to a real ISTN.

System architecture. Figure 1 depicts STARRYNET’s architecture, including four core components as described below.

- A **Constellation Observer** (§4.2) that leverages a *crowd-sourcing* approach to collect public constellation information, network performance, ground station distributions *etc.*, from the satellite ecosystem. It maintains several databases to support, guide and drive the construction of ISTN experimental environments for various research requirements.
- A **Constellation Synchronizer** (§4.3) which exploits a collection of hybrid models to calculate the *spatial and temporal characteristics* of a specific mega-constellation, based on collected data as well as user-defined configurations. Specifically, such characteristics include constellation scale, visibility, connectivity, time-varying propagation delay, *etc.*, which are further used to configure the network emulation.
- A **Constellation Orchestrator** (§4.4) for automating the management, coordination and allocation for resources used to build the experimental environment upon multiple physical machines. The orchestrator can also interact with real-world facilities (*e.g.*, real satellite hardware) to support network experiments with interactive Internet traffic.
- A **Unified Abstraction** (§4.5) offering flexible and easy-to-use *APIs* for researchers to create and manipulate the configurations of the ISTN experimental environment.

4.2 Constellation Observer

The constellation observer is designed as a collector for constellation-relevant information, and it maintains three databases related to satellite, ground station and user terminal information respectively. Specifically, the observer searches and collects the latest: (1) regulatory information (*e.g.*, from [2, 10, 73]) which describes frequency and orbital coordination of mega-constellations; (2) operating satellites information (*e.g.*, from [16, 38, 71]); (3) ground station distributions (*e.g.*, from [3, 26, 39]); (4) Internet user statistics (*e.g.*, from [59]) which can be used to generate the distribution of terrestrial users; and (5) network measurements from end users (*e.g.*, from [32, 33]). The constellation observer classifies the above information, and saves them in the databases, which then can be used to drive other components and build ENEs to flexibly support various research experiments.

4.3 Constellation Synchronizer

STARRYNET's synchronizer leverages a collection of models to calculate various constellation characteristics and network behaviors, and accordingly generate a virtual network presentation synchronized to a real ISTN. At runtime, values in these models are assigned primarily based on real ISTN information collected by the constellation observer. In addition, to improve the flexibility, STARRYNET also allows researchers to manually configure model values based on his or her customized experimental requirements.

4.3.1 Hybrid models

Constellation model. STARRYNET's synchronizer characterizes a satellite system in both *constellation-granularity* and *orbit-granularity* descriptions. First, STARRYNET uses the Walker notation [82] to describe a constellation: $N/P/p$, where N is the number of satellites per plane, P is the number of planes, and p is the number of distinct phases of planes to control spacing offsets in planes. Second, the orbit-granularity description enables a fine-grain notation for orbits in a certain constellation via specifying several primary orbital elements, including: (1) inclination, which is the angle between an orbit and the Equator as satellites move; (2) altitude, which is the height above sea level and determines the orbital velocity; (3) phase offset [56], which is a factor between $[0, 1]$, describing the relative position between two satellites in adjacent orbits.

Ground station model. STARRYNET leverages the following parameters to describe a ground station: (1) geographic location; (2) the number of available antennas for ground communication; (3) the elevation angle, which determines the light-of-insight (LoS) of the ground station and can affect the available duration of space-ground communication.

Network model. The inter-satellite or ground-satellite network connectivity is mainly affected by following factors: (1) the visibility between two communication ends; (2) the amount of available ISLs or antennas in satellites or ground stations; and (3) the connectivity policy, which decides how

to establish a connection between two communication ends. STARRYNET enables two prefabs of connectivity policies for inter-satellite connection: (1) +Grid [58], where each satellite connects to two adjacent satellites in the same orbit and to two in adjacent orbits; (2) Motif [40], which is a repetitive pattern where each satellite connects to multiple visible satellites and each satellite's local view is the same as that of any other. For ground-satellite connectivity, STARRYNET offers multiple optional schemes that control a ground station to connect to a visible satellite, *e.g.*, selecting the one with the shortest distance or the longest remaining visible time. Since the delay is typically determined by the network topology and speed of the light, STARRYNET calculates the propagation delay of each link based on the physical distance between two ends. As network capacity might be too speculative in practice, link capacity is set by user-specific configurations.

Computation model. The computation capability of satellites varies greatly in different real-world deployments. Generally, conventional space-grade processors have limited capability [53, 65] as compared with that used in terrestrial computer systems. For example, the operating frequency of spaceborne processors (*e.g.*, BAE-RAD series [21, 22]) ranges from 110 to 466MHz per core. Recently, satellite operators and researchers start to use commercial off-the-shelf (COTS) processors in space stations [14] or in LEO small satellites [23, 44] to reduce the manufacturing cost. To support various experimental requirements, STARRYNET allows researchers to manually configure the CPU capability of each satellite node through approximating the frequency and number of available cores of each emulated node, by scaling download CPU frequency and enforcing a maximum time quota for each node.

4.3.2 Constellation consistency

Spatial consistency. Based on constellation-wide information, STARRYNET first determines the amount of required containers. Each container runs realistic system environments and networking stack to emulate a satellite in the constellation, a ground station or a terrestrial user terminal. Second, using orbit-granularity information, STARRYNET calculates the latitude, longitude and height (*i.e.*, LLH information) of each satellite at any given time slot. Finally, exploiting the above LLH information and minimum elevation angles, STARRYNET calculates the visibility between arbitrary two satellites, or between satellites and ground facilities.

Temporal consistency. Since emerging LEO satellites are inherently moving at a high velocity, the locations, inter-visibility, and network conditions (*e.g.*, connectivity and propagation delay between two nodes) of an ISTN are changing over time. To achieve realism, these states should be temporally consistent to real scenarios. STARRYNET splits time into slots, calculates LLH information in each slot, and follows the hybrid models to determine time-varying network conditions in different slots. Such dynamic states will further be used for driving the dynamic emulation operated by the orchestrator.

4.4 Constellation Orchestrator

The orchestrator is designed for four goals. First, the orchestrator exploits container-based emulation to construct an emulated ISTN environment upon one or many physical machines (depending on the constellation size). Second, the orchestrator configures the computation and network capability of each emulated node, according to users' configurations and the spatial and temporal results calculated by the constellation synchronizer. For example, a space-ground connectivity should be dynamically updated based on the time-varying visibility between its two ends. Third, the orchestrator can connect the emulated ISTN to real-world network facilities (if any, *e.g.*, real satellite prototypes or terminals) and support interactive Internet traffic. Finally, at runtime the orchestrator leverages a measurement agent to monitor and report the runtime resource usage (*e.g.*, CPU/memory/bandwidth usage) to the user as a feedback of the experiment for further analysis.

4.4.1 Multi-machine support for constellation emulation

Since each emulated satellite consumes computation, network and storage resources in practice, it is challenging to support the emulation of large-scale constellations on a single machine, especially when additional user-defined payloads (*e.g.*, a new satellite routing protocol) need to be loaded for experimentation. STARRYNET addresses this limitation by integrating resources on multiple machines to support large-scale, time-varying constellation emulations. When deployed on multiple machines, STARRYNET's orchestrator divides these machines into two parts. First, one machine, selected as the *resource manager*, manages, schedules and allocates resources upon all machines to jointly create and maintain the ENE. Second, other machines, working as *worker clusters*, receive and follow commands from the resource manager. For each node in the ISTN (*e.g.*, a satellite or ground station), the orchestrator creates a container to emulate it, and creates a virtual bridge connecting two nodes to emulate a link.

Topology creation on multiple machines. One big challenge made by extending an emulated mega-constellation to multiple machines is to ensure that the emulated constellation is topologically consistent to the real constellation. Figure 2 shows an example of emulating an LEO satellite constellation including two adjacent orbits on two physical machines. Specifically, Figure 2a plots two Starlink inclined orbits, each of them having 22 satellites evenly spaced with available ISLs. Assume that we use two machines for this emulation, and each machine creates 22 containers to emulate 22 satellites. In a real constellation, each satellite connects its two neighbors in the same orbit, and to another satellite in the adjacent orbit. Ideally, an emulated topology for the constellation in Figure 2a can be easily created if each machine has more than 22 physical network interfaces. However, in practice the number of available interfaces of a machine is likely to be limited. As shown in Figure 2b, if we directly bridge the emulated network interface of each satellite to the physical

interface, due to the lack of traffic isolation, emulated satellites in two machines will establish an "all-to-all" topology which is inconsistent to the grid-like topology in Figure 2a.

STARRYNET addresses this inconsistency on multiple machines by creating multiple VLANs to emulate independent ISLs, interconnect satellites in two machines and isolate inter-satellite traffic as that in a real constellation. As plotted in Figure 2c, we build a VLAN for each ISL crossing different machines (*e.g.*, vlink A1-B1 interconnects emulated satellite A1 and B1), and thus STARRYNET obtains the correct virtual network topology consistent to the real constellation topology as illustrated in Figure 2a upon multiple machines.

Topology update on multiple machines. Due to the high dynamics of ISTN, the network topology fluctuates over time. If a connectivity change occurs on a single machine, *i.e.*, all affected nodes are located on the same machine, STARRYNET deletes the old virtual link, and creates a new link connecting corresponding nodes. Otherwise, if a connectivity change involves nodes on multiple machines, STARRYNET exploits a VLAN-based approach to limit the link update operation to a single machine. Figure 3 plots an example of the emulation of space-ground handovers upon multiple machines. Assume there are three satellites, two ground stations in two sequential time slots. In the first slot, satellite S2/S3 connects to ground station GS1/GS2 respectively. As satellites move, the space-ground connectivity changes, and S1/S2 connects to GS1/GS2 respectively in the second slot. STARRYNET emulates the ground-satellite links (GSLs) by two VLAN-based virtual links, and performs the correct handover by properly adjusting the connectivity change between S1/S2/S3 and vlink-GS1/GS2, in different slots on machine A.

4.4.2 Efficient time synchronization and state update

Another challenge made by multi-machine extension is the *time synchronization and link update overhead*. Specifically, to achieve temporal consistency, STARRYNET's constellation synchronizer assigns a sequence of update events to the orchestrator to inform each emulated satellite when an update (*e.g.*, a location/connectivity change) should happen. To trigger such events, a baseline approach is to let the centralized manager send commands to all emulated satellites in every slot, and trigger corresponding update events. However, such a real-time approach has limited scalability as the amount of emulated satellites increases, since each event requires to update the state of a certain virtual interface/container, and continuously and simultaneously performing a large number of updates can overload the manager, result in delayed update, and invalidate the temporal consistency of the emulation.

To reduce the state update overhead caused by mimicking temporal dynamics in mega-constellations, STARRYNET leverages a prediction-based *multi-thread event memorization* approach. We define the synodic period as the amount of time that it takes for the constellation to reappear at the same projection upon the earth surface. In the emulated environment,

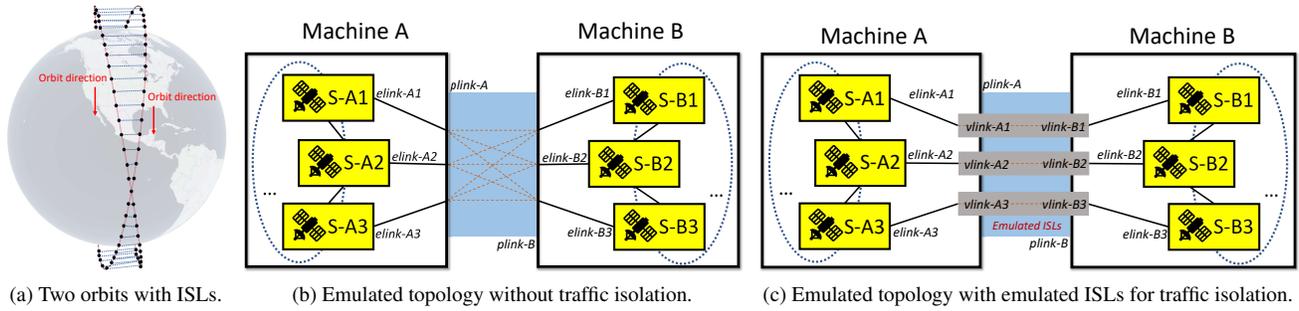

Figure 2: Multi-machine extension to support consistent topology emulation of satellite networks. Machine A and B interconnect by their physical interfaces plink-A/B (plink: physical link, elink: emulated link, vlink: virtual network link created by VLAN).

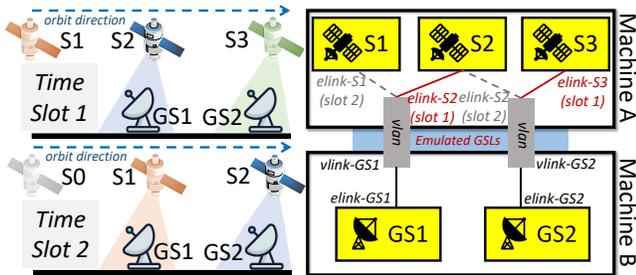

Figure 3: Emulated ground satellite links (GSLs) and space-ground handover in two time slots on multiple machines.

at the beginning of each *synodic period*, the orchestrator pre-generates an event list for each satellite that includes all its update events during the current synodic period. At runtime, each emulated satellite adopts an independent *event update thread* to read the local event list in each slot, and triggers the corresponding event scheduled in the current slot. Time clocks upon all machines are synchronized by the NTP [17].

4.5 Open APIs for ISTN Experiments

Environment APIs. STARRYNET provides the environment APIs for a researcher to load trace from the database, and create/control/run an ENE upon one or multiple machines with user-defined ISTN configurations. Once constellation and GS information are completely loaded, these configurations are delivered to the synchronizer to calculate spatial and temporal characteristics, which are further used by the orchestrator to construct the ENE. The environment APIs also allow users to configure the interval of discrete time slot to adjust the dynamicity. Note that the ENE not only maintains the runtime of emulated constellations, but also needs to run the test workload deployed by the researcher. We design a resource threshold Δ to control the percentage of CPU/memory used by the framework. In other words, at least $(100\%-\Delta)$ of the total CPU/memory should be left for the researcher's test cases.

Self-node APIs. STARRYNET's self-node APIs are designed to be called by the researcher's programs on each emulated satellite. These APIs expose underlying satellite-related information to user programs. Specifically, in each emulated satellite, user program can obtain the index of current satellite/orbit, sunlight state, time-varying geo-location informa-

tion, current satellite velocity and the index of adjacent reachable satellites, *etc.* Such satellite-specific information can be used for developing new on-board capabilities in ISTNs.

5 Implementation and Usage

We highlight the salient aspects of STARRYNET's implementation and usage in this section.

Framework implementation. STARRYNET's observer is implemented as a combination of a crawler based on Scrapy [27], together with a MySQL-based data store. We implement STARRYNET's synchronizer based on SkyField [29], an astronomy library that supports the calculation of high precision research-grade positions for satellites. STARRYNET's orchestrator is implemented upon Docker [6] and it spans the emulated constellation across multiple machines. We use OpenvSwitch [19] to emulate and configure links, and use tc [67] to dynamically set artificial network conditions according to the numeric results calculated by STARRYNET's synchronizer. Specifically, we optimized the link management module in tc to satisfy the requirement of light-weight state update. To accomplish flexibility, STARRYNET's abstraction is implemented as a combination of a lib-STARRYNET library and a collection of shell commands. Collectively, the core components of STARRYNET are implemented in about 6500 lines of Python codes and scripts.

Framework usage. We illustrate the usage of STARRYNET with a concrete example as plotted in Figure 4: a researcher wants to evaluate a novel geo-location-based routing mechanism based on [63], under the Starlink constellation. In particular, this experiment can be conducted with STARRYNET in three steps. First, leveraging STARRYNET's APIs, the researcher writes a user-defined experimental program (Figure 4a) for test. In this example, we show a geo-routing policy similar to [63], which runs on each satellite, and forwards received packets to the adjacent satellite that is the geographically closest to the destination. Second, the researcher prepares a set of manifest files describing the constellation configurations, *e.g.*, orbital information and ground station distribution (Figure 4b). Finally, the researcher runs a batch of shell commands exposed by STARRYNET to load manifest files (*e.g.*, starlink.json and gs.json), create experimental en-

```

environment (e.g., “sl_con”) on multiple machines, configure network parameters (e.g., uplink/downlink capacity), and run the user-specific program on emulated satellites (Figure 4c).

6 Framework Evaluation

In this section, we evaluate STARRYNET by exploring two important aspects related to the framework. **Q(i):** Can STARRYNET flexibly scale to various experimental requirements, with acceptable system and configuration overhead? **Q(ii):** How faithful are the results obtained by STARRYNET, as compared with other state-of-the-art simulators, and live network performance? Our framework evaluations are conducted on a typical enterprise cluster, including eight DELL R740 servers connected to a LAN. Each server is equipped with two Intel Xeon 5222 Processors (4-core, 3.8GHz for each processor), 8*32G DDR4 RAM, and Ubuntu20.04-LTS.

6.1 Ability to Satisfy Various Experimental Requirements for ISTNs

Elastic scaling to various constellation configurations. In reality, satellite operators *incrementally* deploy their satellite mega-constellations, which consist of multiple *shells*. As depicted in Table 2, STARRYNET is able to flexibly create a user-defined experiment environment for different shells, or multi-shell combinations of representative mega-constellations to satisfy various research requirements. The emulated constellation size can scale from about 300 (e.g., the T1 shell of Telesat) to 4408 (e.g., the full-scale Starlink Phase I with five shells) following different users’ configurations.

Environment setup overhead. STARRYNET’s APIs have concealed complex underlying processing for trajectory cal-

culational and resource orchestration for the emulation. Thus a researcher can easily establish each ENE listed in Table 2, by writing about a dozen lines of code based on constellation prefabs (e.g., like Figure 4b) predefined in STARRYNET’s database. The creation time of a certain ENE upon STARRYNET tightly depends on the experiment scale, and the hardware capability of these machines used for experiments. Concretely, as shown in Table 2, the total creation time, including both node and link creations, increases as the constellation size scales up, and ranges from several minutes (for small size ENE) to tens of minutes (for large size ENE) in our current STARRYNET implementation.

System overhead. Table 2 also plots the average CPU and memory overhead consumed on each machine by running various ENEs. We make several observations. First, as expected, when the constellation size increases, STARRYNET requires more worker machines, consuming more CPU/memory resources to emulate ISTN nodes, links, and their constellation-wide dynamics. Second, if STARRYNET updates satellite dynamics more frequently (i.e., with shorter update intervals), it consumes more resources to accomplish fine-granularity updates. Note that in this experiment we limit the CPU usage below $\Delta = 50\%$ in each machine. This is because in an ENE, the runtime overhead of the underlying STARRYNET should not use up all CPU/memory resources. It is reasonable to leave sufficient resources for the tested workloads and functionalities running upon the ENE.

6.2 Fidelity Analysis

Next we analyze the fidelity of STARRYNET by comparing the experiment results obtained by STARRYNET with live satellite networks and other state-of-the-art simulators.

Network performance under a live Starlink topology. We leverage STARRYNET to establish an ENE following the network topology of a recent live Starlink test conducted in Europe in 2021 [33]. Specifically, this real-world Starlink topology involves several key components as illustrated in Figure 5: (1) a user terminal together with a Starlink satellite dish located at the campus Klagenfurt Primoschgasse; (2) a SpaceX’s ground station located in Frankfurt, Germany; (3) a Point of Presence (PoP) connecting the ground station to terrestrial Internet; and (4) a Web server deployed in Vienna. This experiment publicly reports the ping and iperf results measured between user terminal and the Web server, over the ISTN integrating Starlink satellites and terrestrial Internet. We use STARRYNET, Hypatia [60] and StarPerf [61] to generate network performance under the same topology configuration. The latter two are state-of-the-art ISTN simulators. Figure 6 plots the comparison for the latency results. First, we find that existing simulators *underestimate* the latency, since their latency estimations are based on a high-level abstraction without considering system effects like packet processing overhead. Second, STARRYNET achieves acceptable fidelity, as it attains similar latency performance in each case (i.e., aver-

Constellation	Metrics	Height (km)	Constellation Size (number of satellites)	Creation Time (min)			Avg. CPU (%) Interval = 1/2/3 (s)			Avg. Memory (%) Interval = 1/2/3 (s)			Minimum # of Required Workers

age/50th/70th/90th percentile) as compared with the real measured data from live Starlink. This is because STARRYNET jointly combines model calculation, data-driven calibration and real networking stack to create the ENE.

Bandwidth is a metric that can be affected by many operational factors. Therefore, in a research experiment STARRYNET allows the researcher to manually configure the link capacity on demand. For example, we follow the realistic Starlink trace in [33] to set the uplink/downlink capacity, and run *iPerf* to measure the TCP throughput in each direction. Since Hypatia and StarPerf can not load real network traffic by *iPerf*, we compare the throughput results of live Starlink and STARRYNET. Specifically, evaluation results in Figure 7 demonstrate that STARRYNET can be tuned to accurately emulate the bandwidth of a live ISTN.

Network performance under an ISL-enabled topology. As of the date of this paper submission, most real mega-

constellations like Starlink and Kuiper are still in their early stage and under heavy construction. Although Starlink has started to deploy laser ISLs on its LEO satellites, those ISLs are still under internal test, and it is difficult to directly compare the network performance estimated by STARRYNET with a real ISL-enabled satellite network. To analyze the fidelity of STARRYNET when ISLs are activated, we compare the performance results obtained by STARRYNET with other ISTN simulators. Figure 8 plots the CDF of latency between a collection of real ground-station pairs [26] with the same constellation configuration based on the ISL-enabled Starlink network. The latency results of STARRYNET are measured by ping test in the emulated ENE, while the results of other simulators are generated by numeric or event-driven calculation. As shown in Figure 8 the latency obtained by STARRYNET is slightly higher than other simulators, because STARRYNET incorporates realistic system-level overhead (e.g., packet processing) which could be neglected in simulators.

On-demand computation capability. Researchers may need to conduct their experiments on different satellite hardware with various computation capabilities. For example, authors in [53] studied the application performance achieved by two space-grade processors RAD-5545 [21] and HPSC [13]. Recent works like [23, 44] explored new satellite functionalities running upon commercial low-power processor such as Raspberry Pi [24] and Jetson TX2 [18]. STARRYNET is able to flexibly adjusting the computation capability on each emulated satellite to satisfy various experimental requirements. To validate the computational flexibility, we use CoreMark [5],

a well-known processor benchmark to measure the performance of the real hardware and its facsimile created by STARRYNET. As plotted in Figure 9, CoreMark score is a metric that quantifies the computation capability. Higher scores indicate stronger computing capability. For various computation requirements, STARRYNET can mimic similar processor capability based on concrete experimental requirement.

7 Evaluating Futuristic ISTN Research with STARRYNET: Case Studies

Next we conduct several case studies to show how STARRYNET can be used to advance futuristic ISTN research.

7.1 Exploring the Design Space of Integrating LEO Satellites and Terrestrial Facilities

To realize the promise of low-latency and pervasive accessibility of ISTN, the first step should be interconnecting LEO satellites and terrestrial facilities (*e.g.*, ground stations and user terminals). While many existing studies have proposed different space-ground topology designs, it still lacks a systematically analysis and comparison on these integration paradigms, in terms of their network performance and corresponding cost. We leverage STARRYNET to explore how different design choices of space-ground integration (as illustrated in Figure 10) could affect the performance and cost of an ISTN.

(1) Satellite relays for last-mile accessibility (SRLA). Satellites and ground facilities can be integrated based on the classic “bent-pipe” architecture to provide last-mile network accessibility as illustrated in Figure 10a, which is the *status-quo* of many today’s satellite constellations like OneWeb. Data from the ground are first transmitted to the satellite, which then sends it right back down again like a bent pipe. The only processing performed by satellites is to retransmit the signals.

(2) Satellite relays for ground station networks (SRGS). Figure 10b depicts another “bent-pipe”-based integration paradigm originally introduced in [57], where geo-distributed ground stations work as routers to construct a network. Each satellite switches packets between two ground stations connected to the satellite. Packets from the sender are routed to the receiver by paths built upon satellites and ground stations.

(3) Ground station gateway for satellite networks (GSSN). Figure 10c shows an ISL-based internetworking approach proposed by [52]. ISL-enabled satellites can build space routes for long-haul communication, without the need of a large number of ground station relays, as well as user-side satellite dishes. Satellites and ground stations build a Layer-3 network. During an end-to-end transmission, packets from the sender are first routed to a ground station via terrestrial Internet, then to the receiver side ground station over ISL-enabled satellites, and finally to the receiver over the terrestrial Internet.

(4) Directly accessed satellite networks (DASN). Figure 10d plots a paradigm where users’ satellite dishes directly connect to ISL-enabled satellite networks, and two users can

establish long-haul communication without the assistance of geo-distributed ground stations [51, 56]. Satellites work not only as routers, but also as access points/gateways allocating addresses for different terrestrial users.

Experiment setup. We leverage STARRYNET to build an ENE for each paradigm, analyze their cost, and evaluate their network performance. Specifically, we establish an ENE based on Starlink’s first constellation shell and its ground station distribution. We randomly pick geo-distributed user-pairs and establish communication sessions between these pairs over the satellite network. On each emulated satellite, we load BIRD [37] routing software and run OSPF as the routing protocol to achieve the shortest path for data transmission.

Observations. Table 3 summarizes the average end-to-end latency and the latency breakdown of different space-ground topology designs. We observe an obvious latency reduction accomplished by laser ISLs, and DASN obtains the lowest end-to-end latency on average. Since ground stations typically can not be deployed upon oceans (70% earth surface), SRGS suffers from the highest latency as compared with other schemes due to the insufficient deployment of ground stations.

As satellites move, two main factors affect the end-to-end network reachability. First, users in certain regions may lose available satellite access due to the LEO dynamics. For example, users in high latitude areas may suffer from intermittent satellite access. Second, frequent connectivity changes can trigger *routing re-convergence*. As plotted in Table 3, SRGS suffers from the lowest reachability due to the combination of LEO dynamics and limited coverage of insufficient ground stations. GSSN obtains low reachability because frequent satellite-ground handovers result in continuous re-convergence, during which routes are fluctuating and unstable.

For SRLA, SRGS and GSSN, the IP address of user’s satellite dish is allocated by the fixed user-side ground station, and the addresses of senders or receivers do not change during the communication. However, for DASN, each satellite works not only as a router, but also as an access point/a gateway which allocates IP addresses for terrestrial dishes connect to it. Due to the LEO dynamics, terrestrial dishes have to frequently change access satellite as well as their subnet. Consequently, addresses are frequently updated, which may further disrupt high layer transport connections and application sessions.

The above four topologies have different deployment and operating costs in addition to LEO satellites. SRLA and SRGS require a large number of available ground stations near users to guarantee continuous satellite coverage. For SRGS, it also requires sufficient geo-distributed ground stations to ensure stable and low-latency routes over satellites and ground stations. GSSN and DASN require the extra deployment of ISLs. Users in SRLA, SRGS and DASN have to purchase a dedicated dish to access satellites. In GSSN, users connect to the ground station gateway via terrestrial networks, and do not need to install additional satellite dishes.

Implications. As summarized in Table 3, there is no clear win-

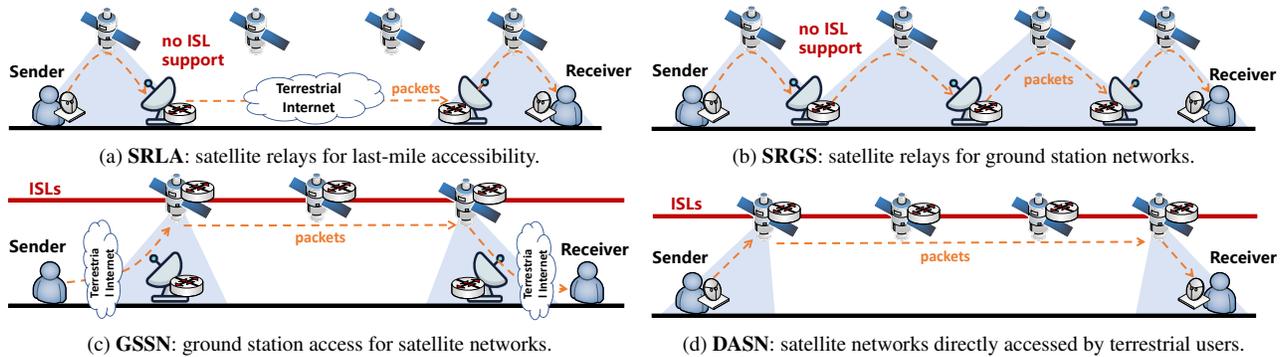

Figure 10: The design-space for various space-ground integration methodologies.

Design	Average end-to-end latency and its breakdown (ms)				Reachability	Frequent Address Update	Operating Cost		
	Inter-Satellite	Space-Ground	Ground	Total			GS	Terminal	ISLs
SRLA	0	76.25	107	183.25	97.00%	X	✓	✓	X
SRGS	0	313.39	0	313.39	51.00%	X	✓	✓	X
GSSN	48.46	38.45	20	106.91	57.40%	X	✓	X	✓
DASN	48.46	37.65	0	86.11	97.50%	✓	X	✓	✓

Table 3: Comparison for different space-ground integration methodologies.

ner for all four integration methodologies. “Bent-pipe”-based approaches achieve simplicity without ISL requirements, but they fail to fully unleash the low-latency potential of ISTNs. Approaches relying on ISLs can form near-optimal spaces routes to attain wide-area low-latency communication, but they involve extra ISL cost, and suffer from higher route instability and connection disruptions, due to the route re-convergence and address update caused by LEO dynamics. All integration approaches have their limitations, and satellite operators are suggested to choose a proper topology based on their specific performance requirements and cost budgets.

7.2 Evaluating ISTN Resilience

Satellites are operated in complex outer space environments. Small satellites deployed in emerging mega-constellations typically have a short lifetime (*e.g.*, 3-5 years [30]) due to their low manufacturing cost. Many space factors or events, such as space debris [15], geomagnetic storms [12], and single event upset [28], *etc.*, can cause immediate satellite failures. For example, in February 8, 2022, about 40 Starlink satellites are doomed by a geomagnetic storm [1]. Therefore, given the harsh and error-prone space environment, it should be important for satellite operators and researchers to evaluate and analyze how resilient an ISTN is, and what kind of system/network factors affect the resilience.

Experiment setup. We thus conduct an experiment with STARRYNET to evaluate the network resilience with different routing configurations. Specifically, we mimic the impact of a space failure (*e.g.*, due to a geomagnetic storm) which makes a fraction of satellites in the constellation inactive and can not forward network traffic. We load BIRD [37] in our ENE and

run OSPF as the routing protocol in this experiment.

Observations. Figure 11 plots the routing recovery time for a set of representative city-pairs under various failure ratios. An on-path satellite failure can cause a network disruption, and the routing recovery time increases as the constellation size and failure rate increase. Figure 12 plots the comparison for the end-to-end latency before the constellation failure and after the routing re-convergence. We observe that the latency increases slightly under low failure rate, and the latency dramatically increases when the failure rate reaches 30%.

Implications. We summarize three key implications from this experiment. First, we find the mesh-like network based on a large number of satellites can maintain low latency in case of low failure rate. This is because the mesh-like satellite network has high *path diversity*, offering backup routes for communication pairs in case of network failures. Second, the inherent high dynamicity of LEO satellites is a double-edge sword for the service restoration in an ISTN. On one hand, for terrestrial users whose access satellite above them fails, the dynamicity helps because faulty satellites will soon move out of their line-of-sight. On the other hand, the dynamicity hurts, as it spreads the failure globally, and could affect the network accessibility of other users. Finally, while improving redundancy in physical connectivity and applying robust mechanisms in protocol design are two critical directions to improve the ISTN resilience, it is challenging to attain a “win-win” integration of them in practical systems. Increasing the satellite density indeed improves the resilience of satellite accessibility in case of sudden failures, but it also involves much more nodes and links in the network, and thus imposes new challenges and requirements on the protocol scalability and recovery efficiency under various failure scenarios.

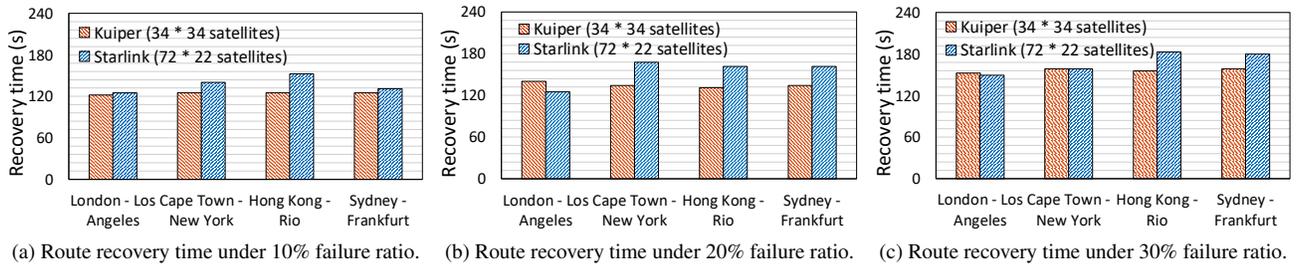

Figure 11: Route recovery time under different constellation-wide failures.

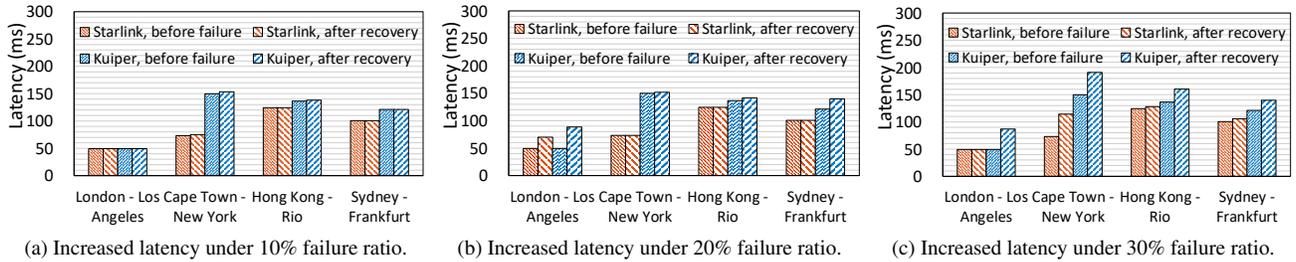

Figure 12: Increased latency after route reconvergence under various constellation-wide network failures.

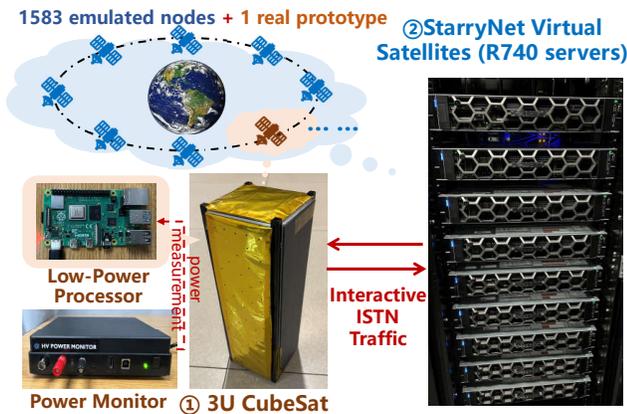

Figure 13: Hardware-in-the-loop testing with STARRYNET.

7.3 Hardware-in-the-loop Testing

In real satellite deployments, it is very important to accurately estimate how much energy a new system or network function will consume before the launch. STARRYNET enables researchers to conduct *hardware-in-the-loop* testing to accurately evaluate the low-level system effects under various workloads. As a case study to demonstrate STARRYNET’s ability, we connect a 3U CubeSat prototype, equipped with a low-power processor [23,24] running real routing protocols to the virtual satellite network emulated by STARRYNET, as illustrated in Figure 13. Collectively, the 3U CubeSat prototype together with the emulation creates a virtual constellation network with 1584 Starlink satellites. We follow the satellite traffic model proposed in [51] to inject traffic and use a power monitor to measure the satellite prototype. Table 4 summarizes the power consumption in different states (*e.g.*, calculating route convergence and forwarding traffic in various data rates). Our hardware-in-the-loop test demonstrates

State	Idle	Routing convergence	Data transmission rate (Mbps)				
			100	250	500	750	1000
Power consumption (W)	2.83	3.22	4.6	4.99	5.36	5.45	5.46

Table 4: Power consumption under various ISTN workloads.

STARRYNET’s ability to create a hybrid ENE and evaluate real system effects for user-defined functionalities.

8 Limitation and Future Work

Experimental scope and limitations. Our STARRYNET framework mainly targets at various network-level experiments for ISTNs, *e.g.*, evaluating a new routing/transport-layer protocol, or assessing the network performance of a new topology design in a highly-dynamic, resource constrained virtual ISTN environment. The scale of the experiment supported by STARRYNET is closely related to the underlying resources provided by physical machines. In its present form, the key limitation of STARRYNET can be summarized as follows. First, STARRYNET is essentially a data-driven framework combining constellation-relevant modeling and network emulation. Thus its fidelity tightly depends on the availability and accuracy of the public information shared by the satellite ecosystem. For example, in practice, public TLE data may provide inaccurate orbit information, which can have errors up to 12 km, and such errors can affect the calculation of network performance (*e.g.*, inter-satellite visibility and propagation delay). Second, some parameters are hard to obtain from a practical satellite system today, because most mega-constellations are still in their early stage with limited access. For example, it is difficult to obtain the real ISL-enabled Starlink performance right now, since Starlink’s laser ISLs are still under internal test. Thus, STARRYNET allows researchers

to manually configure the ISL parameters (*e.g.*, link capacity) and customize their experiments based on various experimental requirements. Third, our framework is primarily based on virtualization-based network-level emulation, and thus it has limited ability to emulate physical layer (PHY) characteristics that can be observed in a live network experiment, *e.g.*, spectrum adaptation and multiplexing [42], or the time consumed by a real satellite dish to detect PHY connectivity changes.

Future work. Satellite Internet mega-constellations are still evolving rapidly. New constellation designs are constantly being proposed, and existing constellation schemes are constantly being updated. In our future work, we will follow the evolution and deployment of realistic satellite Internet constellations. In particular, we will track the latest constellation information to update STARRYNET's open database, calibrate the constellation models and further improve the fidelity of the STARRYNET framework. Moreover, based on these implications obtained from our case studies in §7, we will explore new network techniques tailored for ISTNs, *e.g.*, practical and resilient satellite routing protocols in the future. Our latest research progress on STARRYNET will be updated on the website: <https://github.com/SpaceNetLab/StarryNet>.

9 Related Work

Section 3.2 has discussed most existing efforts relevant to the method of building ENEs. In this section we briefly introduce other ISTN works related to our study in this paper.

The network community has many recent efforts studying on the topology design [40, 58], routing [47, 52, 56, 57, 83], transport-layer congestion control [60, 64], new satellite applications [62] and security issues [51] for emerging ISTNs. For instance, Motif [40] is a recent topology design for LSNs, in which each satellite is dynamically connected to other visible satellites to achieve low latency under various traffic configurations. Works in [40, 56, 57] suggest the use of pre-calculated shortest-path-based routing and traffic engineering schemes for ISTNs. On one hand, these pioneering studies indeed outline the promising network potential of futuristic ISTNs. On the other hand, the above new thoughts are evaluated by simulations with a high-level abstraction. STARRYNET can stimulate new research and advance existing ISTN works by evaluating them in a more realistic ENE to obtain practical insights for further optimizations.

The rapid evolution of ISTNs also attracted the attention of the system community. Specifically, orbital edge computing (OEC) [43, 44, 66] is a new computation architecture which leverages computational satellites to pre-process earth observation (EO) data, and save the data download overhead. Studies in [49, 50] explored the feasibility of applying deep neural networks to process on-board satellite data. Since STARRYNET creates real system runtime and networking stack in an experimental ISTN environment, it can also help to evaluate system-level effects of these new algorithms, implementations and programming models designed for ISTNs.

10 Conclusion

To advance futuristic research on ISTNs, this paper presents STARRYNET, an experimentation framework that empowers researchers to conventionally and flexibly build ENEs for ISTN research. STARRYNET simultaneously achieves constellation-consistency, network realism, and flexibility, by integrating real constellation-relevant information, orbit analysis and large-scale emulations to construct ENEs. By comparing STARRYNET's results with live network performance and conducting diverse case studies, we demonstrate STARRYNET's fidelity and flexibility for various ISTN experiments. We are confident that the open-source STARRYNET can help the network and system community to flexibly conduct various ISTN evaluations with more credible results.

Acknowledgments

Abstract – Modern high-speed railway (HSR) systems offer a speed of more than 250 km/h, making on-board Internet access through track-side cellular base stations extremely challenging. We conduct extensive measurements on commercial HSR trains, and collect a massive 1.79 TB GPS-labeled TCP-LTE dataset covering a total travel distance of 28,800 km. Leveraging the new insights from the measurement, we design, implement, and evaluate POLYCORN, a first-of-its-kind networking system that can significantly boost Internet performance for HSR passengers. The core design of POLYCORN consists of a suite of composable multipath schedulerlets that intelligently determine what, when, and how to schedule user traffic over multiple highly fluctuating cellular links between HSR and track-side base stations. POLYCORN is specially designed for HSR environments through a cross-layer and data-driven proactive approach. We deploy POLYCORN on the operational LTE gateway of the popular Beijing-Shanghai HSR route at 300 km/h. Real-world experiments demonstrate that POLYCORN outperforms the state-of-the-art multipath schedulers by up to 242% in goodput, and reduces the delivery time by 45% for instant messaging applications.

1 Introduction

High-speed railway (HSR) systems, which offer a speed of 250+ km/h, revolutionize inter-city travel. Internet services on HSR are typically provided by track-side cellular base stations and an on-board proxy relaying data between WiFi APs and the cellular infrastructure [1–7]. However, the ultra-fast speed of HSR poses unprecedented challenges in bringing seamless Internet service to passengers because of the intermittent link connectivity characteristic – handover happens every less than 10 seconds [8] and the handover failure may cause a “blackout” period of up to 10 seconds [9], as reported by previous studies.

It is known that MPTCP [10] (or multipath transport in general) can leverage path diversity (with each path associated with a cellular carrier or mobile network operator) to improve link/connection robustness, as demonstrated in low mobility scenarios [11–14]. However, applying multipath transport to HSR networking is very challenging. Under such extreme mobility, the network performance fluctuates sub-second level [15], leading to 1636x higher variance in RTT

than in static or low mobility scenarios [16] – this is a sharp contrast to the common assumption that a relatively stable network condition may last for several RTTs, which is leveraged by the state-of-the-art MPTCP schedulers [17, 18] for making scheduling decisions. Indeed, as to be demonstrated in §6.2, the inaccurate link quality estimation and scheduling decision informed by inaccurate throughput and RTT observations often lead to poor performance under extreme mobility.

In this paper, we argue that in contrast to the state-of-art multipath schedulers that rely on instantaneous performance measurement for making reactive scheduling decisions, we should carefully mine the networking features specific to the extreme mobility scenario, identify the main events leading to predictable failures, and design proactive scheduling strategies accordingly. For this purpose, we conduct real-world measurements on the popular Beijing-Shanghai route in China traveling at an average speed of 300 km/h. Over 24 trips spanning three weeks, we collected 1.79 TB data covering a total travel distance of 28,800 km. Our study differs from all prior HSR networking measurement studies [8, 15, 19, 20]: through collaborating with the on-board HSR ISP, we obtain precise location (from the GPS receiver mounted on the carriage roof) for every collected network performance sample. This allows us to statistically correlate the train’s physical location with various network performance events, enabling many key analyses and henceforth the design of our system.

Leveraging our unique dataset, we identify three key aspects that guides our system design. First, handover failures, which incur several seconds of link disconnection, can be reasonably predicted from the train’s moving trajectory. Second, the multipath heterogeneity (the relative performance ranking across paths, *i.e.*, carriers) is highly dynamic, oftentimes changing on a per-RTT basis. Third, transport-layer packet retransmission is much more common than typical cellular links. We find that on HSR, 1.8% of the TCP packets experience retransmission timeout (RTO) – among them, 24% are retransmitted more than once.

Inspired by the above findings, we develop POLYCORN, a practical networking system that significantly boosts the Internet performance for HSR passengers. It is to our best knowledge the first full-fledged system that specifically optimizes for Internet services on extreme mobility ground trans-

*✉: chenren@pku.edu.cn

portation. Leveraging multipath heterogeneity, POLYCORN distributes passengers' traffic over multiple cellular carriers for bandwidth aggregation, reduced delay, and improved reliability. In its core, POLYCORN is equipped with a novel multipath scheduler called HRSRCH, which judiciously determines transmitting which data over which path(s) in real time despite the highly dynamic network conditions. HRSRCH is tailored to HSR environments through a proactive and cross-layer approach. Its design consists of four optimizations that could be either individually or jointly applied to existing "baseline" schedulers such as the minRTT shipped with MPTCP.

- **Handover-failure-aware Path Rejection** (§4.3) has an intuitive idea: once an imminent *handover failure event* is predicted, HRSRCH temporarily disables the corresponding path so packets will not be scheduled over it to avoid the black-out period (and inter-subflow out-of-order delay). To realize this idea, we apply robust and lightweight machine learning to predict handover failures. We use two features carefully derived from our measurements: location and cell ID, which lead to an overall prediction accuracy of 80.6%.

- **Tail-aware Path Rejection** (§4.4) determines whether to use path(s) when their link conditions deteriorate. Its basic idea is to avoid scheduling tail packets, which belong to the end of a flow (*i.e., upon an end-of-flow indicator*) on slow path(s). Since HSR traffic is dominated by short-lived flows (*e.g.,* web browsing, instant messaging, mini videos), this optimization can significantly accelerate short flows' completion time. We instantiate the idea by modeling the queuing and transmission process of tail packets to guide path selection.

- **Extended Reinjection** (§4.5) detects vulnerable packets when losses occur, and retransmit them early over other paths in a batched manner. The idea stems from the bursty nature of wireless losses and consequent *excessive RTO events*, which we find to be even more prominent on HSR: one single packet loss will introduce more subsequent ones. Our approach differs from MPTCP's default packet-by-packet reinjection mechanism that is far too conservative for HSR. We carefully determine the reinjection aggressiveness based on real data to avoid putting too much burden on other paths.

- **Opportunistic Redundant Traffic Injection** (§4.6) proactively leverages idle path(s) to transmit redundant data. It not only provides extra resiliency to link quality fluctuation, but also enables the transport layer to continuously probe the path for important metrics such as RTT and RTO, which are highly dynamic when probed from HSR.

We integrate the above components through a composable scheduling framework, which treats a complex multipath scheduler as a pipeline of modularized *schedulerlets* as described above. Compared to a monolithic scheduler, our schedulerlet-based approach decouples the multipath scheduling logic, and thus significantly reduces the system complexity and development overhead, through the unified interface of schedulerlets designed by us. It also makes the system exten-

sible and open to future optimizations (§4.2). The scheduling framework is then integrated with a multi-user/multi-path data transport mechanism (also developed by us), leading to the full-fledged POLYCORN system (§4.7).

Utilizing various system-level techniques including multipipe multiplexing [21, 22] and user-level packet interception, our implementation runs completely in the user space while maintaining full user/server transparency and high packet I/O performance. It is deployed as two proxy modules, one running on the HSR train and the other running on a cloud server, that schedule uplink and downlink traffic respectively over multiple cellular paths. POLYCORN requires no hardware or firmware modifications, and is orthogonal to HSR-specific PHY/MAC layer innovations [23–26] for cellular networks. Our implementation consists of 24K lines of code.

Through our three-year collaboration efforts with the HSR ISP's operational department, we managed to deploy POLYCORN on real HSR trains by instrumenting their onboard LTE gateways. We evaluate POLYCORN on the popular Beijing-Shanghai route at 300 km/h, with the key results as follows.

- On HSR, POLYCORN outperforms state-of-art multipath schedulers (*e.g.,* ECF [27], STMS [18], MuSher [17], BLEST [28] and MPTCP' default scheduler [10]) by 43% to 242% when downloading files with different sizes.

- POLYCORN consistently outperforms MPTCP by 61.5%, 30.6%, 64.2% on the three HSR route segments (Beijing-Jinan, 406 km; Jinan-Nanjing, 617 km; Nanjing-Shanghai, 301 km) respectively, in terms of the file download time. This indicates that POLYCORN could boost the networking performance under different HSR track-side environments.

- POLYCORN reduces the delivery time by 45% for an instant messaging application in a multi-user setting, compared to the current operational deployment of HSR Internet access.

Note that although the above results are obtained from LTE, POLYCORN is compatible with 5G networks that are being deployed along the HSR tracks [29]. We elaborate the applicability of POLYCORN on 5G in §7.

The Contributions of this paper is summarized as follows.

- New insights of extreme mobility networking characteristics derived from a massive, GPS-labeled TCP-LTE dataset covering 28,800 km travel distance.

- The design of cross-layer, proactive multipath scheduling algorithms tailored to extreme mobility networking, and their integration through a composable scheduling pipeline.

- The development of POLYCORN, the first-of-its-kind network system boosting the mobile Internet performance for all the HSR passengers.

- Deployment and extensive evaluations of POLYCORN on commercial HSR trains in the wild.

This work does not raise any ethical issues.

2 Networking Performance Measurement

To motivate the design of POLYCORN, we conduct real-world measurements of mobile networking performance on HSR. Our study is unique in two aspects. First, all our measured network performance samples have precise GPS coordinates, as opposed to coarse-grained cell IDs used in previous studies [8, 15]. Second, leveraging the unique GPS-labeled data, we offer new insights such as the predictability of failed LTE handovers on HSR.

2.1 Data Collection Methodology

A major challenge of collecting fine-grained location on HSR is a lack of GPS signal in the carriage due to electromagnetic shielding. To overcome it, we collaborate with the China Railway Gecent Technology operating China’s HSR WiFi platform. We next describe our data collection setup in detail.

Onboard LTE Gateway. It is deployed by China’s HSR WiFi carrier in the server room on each train. This gateway serves two purposes: in the upstream, it connects to track-side LTE base stations for Internet access; in the downstream, it connects to the WiFi access points (802.11ac APs) serving passengers in each carriage through a wired local area network (LAN). The gateway is equipped with multiple SIM cards of two major cellular carriers, as well as a 2×2 MIMO antenna mounted on top of the server room carriage. The GPS receiver is also mounted on the carriage roof, allowing precisely tracking the location and speed of the train. We are permitted to access the GPS data and use two of the LTE interfaces exclusively (*i.e.*, there is no other user traffic over these interfaces during data collection). We conduct data collection using iPerf [30], tshark [31], and Quectel LTE QLog¹ to measure the available bandwidth, capture packet traces, and record LTE control-plane messages, respectively. No prior study to our knowledge has leveraged such a unique infrastructure for HSR network measurement and optimization.

Measurement Server. We deploy two co-located servers ($4 \times$ Intel Xeon Skylake 6133 2.5 GHz CPU with 8 GB RAM) in a major cloud service provider in China. Each server serves measurement requests for one LTE carrier. The servers are located in Shanghai that is 20 to 1,300 km away from our studied HSR route. We conduct wired experiments from several hosts near the HSR route to the two servers, and the throughput (RTT) are measured to be ≥ 50 Mbps (≤ 33 ms), which is far above (below) the corresponding metric measured on HSR. This indicates that the Internet is not the performance bottleneck for the end-to-end (*i.e.*, HSR-to-server) path.

Route and Duration. We carried out experiments on the “Fuxing” high-speed trains between Beijing and Shanghai, the top-two cities in China. This 1,318 km route is one of the busiest railway routes in China, with an annual passenger volume of 215 million. The average train speed is 300 km/h.

¹A proprietary tool offered by the gateway vendor for collecting LTE log data from their LTE modems.

Over 24 trips spanning three weeks, we collected 1.79 TB data covering a total travel distance of 28,800 km. Our dataset consists of the following cross-layer records: (1) The *GPS location* of the train updated every second; (2) The *packet traces and downlink TCP Throughput* collected by a long-lived iPerf session running on the LTE gateway; the server uses the BBR congestion control [32] that is known to yield a more accurate bandwidth estimation compared to widely deployed TCP CUBIC [33]; (3) The *LTE lower-layer information* including cell ID, signal strength (RSRP), and the LTE signaling messages collected by Quectel LTE QLog and parsed by MobileInsight [34]. We made the dataset publicly available in: <https://soar.group/projects/hsrnet/dataset.html>.

2.2 Throughput & Latency Characterization

Leveraging our large dataset, we begin with basic characterizations of throughput and latency. Across the entire dataset, the 25th, 50th, and 75th-percentile downlink TCP throughput of Carrier A (B)² are measured to be 2.56 (4.60), 6.48 (10.67), and 12.42 (19.73) Mbps, respectively. Regarding the latency, the 25th, 50th, and 75th-percentile RTT of carrier A (B) are 123 (147), 185 (191), and 315 (348) ms, respectively. We observe that both throughput and latency exhibit high temporal fluctuations. To quantify them, we compute the ratio between the average throughput in the current time window $[t_0 - \Delta t, t_0]$, denoted as CT , and the average throughput in the previous window $[t_0 - 6\Delta t, t_0 - \Delta t]$, denoted as RT , where t_0 is the current time. Δt is empirically chosen as 0.2 seconds, the median RTT when HSR travels at 300 km/h. Fig. 1a plots the distribution of the throughput ratio defined above. As shown, in 26.4% (Carrier A) or 22.6% (Carrier B) of the cases, CT/RT is lower than 50% or higher than 200%, confirming the high throughput fluctuation. The latency variation is also prominent (figure not shown). This leads to frequent TCP Retransmission Timeout events (RTOs), which are experienced by 1.8% of the packets. We even observe that the transmissions of many packets experience more than one RTO, as shown in Fig. 1b (“0” indicates no RTO is triggered).

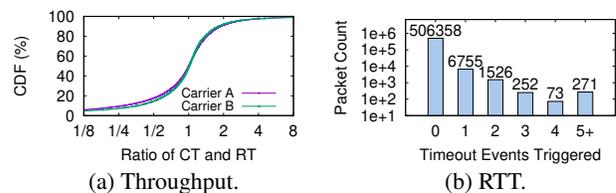

Figure 1: TCP performance temporal variation.

2.3 Predictability of Networking Performance

Since trains move along fixed rail tracks, it is anticipated that the networking performance is predictable, similar to what has been reported for lower-speed vehicles [35]. On HSR, however, the predictability may be affected by the ultra-high speed. No prior study to our knowledge has studied the predictability of HSR networking performance.

²China Mobile and China Unicom respectively.

We begin with exploring a straightforward approach of predicting the TCP throughput using the train’s trajectory. For each $\langle \text{location, direction} \rangle$ pair, we compute the average throughput near the location (± 1 km) in all trips to smooth out the temporal variation, aggregate all those samples and calculate the ratio between the 75-th and the 25-th percentile values. As shown in Fig. 2a, the median ratio is 3.21 and 3.24 for Carrier A and B, respectively, and it may reach up to 100^3 . The results indicate that, unlike low-speed transportation, throughput prediction in HSR is very challenging. The main reason is that the extreme mobility introduces complex stochastic channel fading, which can cause significant temporal variation in received signal strength and henceforth high data rate fluctuation at the same location. This is exemplified in Fig. 2b, which plots the RSRP values of Carrier A over a 40 km route measured on three different days. As shown, the link quality not only exhibits randomness across the three trips but also lacks spatial locality during the same trip. We also would to note that this unpredictable pattern is jointly determined by the highly dynamic channel condition and its complex interaction with TCP congestion control – a small difference in wireless channel condition may result in a big difference in future TCP performance. In addition, the prediction result also depends on a specific congestion control (CC) algorithm, which makes the design space for throughput prediction even more challenging.

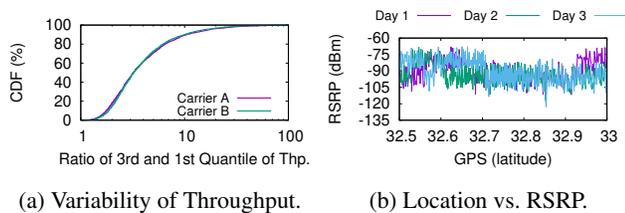

Figure 2: Measurement study of location-aware TCP throughput repeatability and predictability.

Given the difficulty of throughput prediction for HSR, POLYCORN takes a unique approach of predicting *handover failures*. Due to its high speed, HSR experiences much more frequent handovers compared to low-speed vehicles. More importantly, in HSR, handovers are more likely to fail. A *failed handover* occurs when a UE disconnects from or loses connection to the current base station but is not yet connected to the new base station. Failed handovers bring negative performance impact, including packet losses and their incurred retransmission timeout (RTO) that force TCP to enter a slow start. In our dataset, the performance impact is measured to be at least 1 second and can last as long as 10 seconds. In contrast, a successful handover usually incurs shorter than 100 ms of TCP throughput disruption.

We next explore the predictability of failed handovers given their importance. Our dataset records 32,231 and 45,656 han-

³The ratio could be even higher with finer-grained location granularity due to the bursty TCP performance on HSR.

Scenario	Carrier A	Carrier B
Distance to EHP < 200m	75.4%	83.7%
Distance to EHP \geq 200m	65.9%	71.8%
RSRP \geq -95dBm	89.2%	83.8%
RSRP < -95dBm	52.9%	67.7%

Table 1: Handover success rate.

dovers for Carrier A and B, respectively. Among them, the fraction of failed handovers is 6.22% and 5.47%, respectively, significantly higher than those experienced by low-speed vehicles. We observe that 47.33% (40.35%) of the source cells (from which the handover initiates) of Carrier A (Carrier B) experiences at least one handover failure in our three-week measurement. Fig. 3a plots the handover failure rate, defined as the ratio of failed handovers, across the cells⁴ experienced at least one handover failure. As shown, for both carriers, more than 30% of the cells have a failure rate between 20% and 80%, indicating that it is infeasible to predict failed handovers only using cell ID. Nevertheless, we identify two noticeable features that can facilitate prediction of handover failures. First, the RSRP and failure rate are found to be negatively correlated, for handover messages are more likely to be lost under lower SNR. Second, a handover that is triggered late (compared to historically recorded handovers at the same location) is more likely to fail: due to HSR’s high speed, there is simply not enough time for a late handover to complete. This is confirmed by the statistics shown in Tab. 1, which plots the successful rates across all handovers under four scenarios. (1) Handovers starting within 200 m of the Earliest Handover Positions (EHP) of their source cells. (2) Handovers starting at least 200 m beyond EHP; (3) Handovers with ≥ -95 dB RSRP when they start; (4) Handovers with < -95 dB RSRP when they start. Here the EHP of a cell s is defined as the earliest geographic location (w.r.t. the train’s moving direction) of all the handovers with a source cell s when they start. As shown in Tab. 1, handovers that start early or have high RSRP values have higher chances of success compared to late or low-RSRP handovers, respectively. We also plot some individual handovers versus signal strength and location in Fig. 3b where a dot (star) represents a successful (failed) handover, and the colors correspond to different cells.

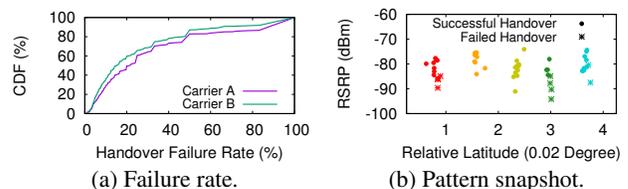

Figure 3: Handover pattern study.

⁴Unless explicitly mentioned, *cell* means $\langle \text{cell, direction} \rangle$ pair.

2.4 Multipath Heterogeneity

Recall that the on-board LTE gateway (§2.1) is equipped with SIM cards of two carriers. We next explore whether the performance of the two carriers are correlated or not. Specifically, we compute the throughput and RTT ratios between the two carriers in a synchronous manner. We find that 39.2% (16.9%) of the computed throughput (RTT) ratios are lower than 0.5, and 37.0% (23.2%) of the throughput (RTT) ratios are higher than 2.0, as plotted in Fig. 4a. This suggests that the two carriers' performance is indeed heterogeneous when accessed from HSR, and the two carriers can performance-wise complement each other. We further quantify at what time granularity one carrier can consistently outperform the other. Specifically, we define the *RTT Leading Time* as the longest consecutive period during which one carrier always has a lower RTT than the other. As shown in Fig. 4b, the median RTT leading time for Carrier A and B are 457 ms and 632 ms respectively. This indicates that the multipath heterogeneity on HSR is highly dynamic, changing every 2 to 4 RTTs (see also Fig. 4c), attributed to HSR's extreme mobility.

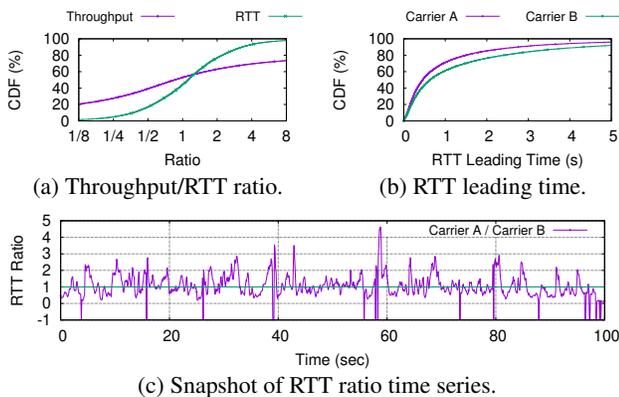

Figure 4: Measurement study of path diversity.

2.5 Implications on System Design

We summarize key findings of our measurements and their implications on system design.

- As the mobile networking performance is highly fluctuating on HSR, one needs to continuously probe the cellular link to get fresher link quality estimations and use it strategically;
- One may tackle the link dynamics by proactive reinjection, as the RTO-based retransmission is often inefficient (§2.2);
- One could leverage the predictability of handover failures to take early actions before losing the connectivity (§2.3);
- One can further leverage the path heterogeneity to mitigate the volatility on individual paths. The path selection requires judicious decisions based on traffic patterns, real-time link quality monitoring, and handover failure prediction (§2.4).

3 Handover Failure Prediction

In this section, we present how to leverage the available yet reliable information to predict handover failures, which is cru-

cial to improving networking performance in our frequently disconnected networking environment.

Handover Success/Failure Determination Methodology.

Our measurement in §2.3 provides evidence that HSR handover failures, which disrupt TCP performance for several seconds, are potentially predictable – they are more likely to fail if happened at a latter location in the overlap zone (for handover) and/or if RSRP is lower. Herein, we formulate handover success/failure determination task as a classification problem, and adopt SVM, a lightweight supervised machine learning algorithm fed with location (*i.e.*, longitude, latitude) and RSRP values when UE disconnects from the source cell as features and handover result as labels. We log all these relevant information into a database called LinkDB deployed on both mobile relay and remote proxy (see Fig. 7) and train the SVM with linear kernel function and L2 loss function for each source cell. By using location, the percentage of the linearly separable (successful and failed) handovers is 72.8% and 71.4% for carrier A and B respectively; by using RSRP, this number is reported as 73.5% and 67.1%. When jointly use location and RSRP, this number raises up to 92.6% and 89.2%. This data shows that for most cells, the handover result could be accurately inferred from the location and/or RSRP when the handover starts. Another implication is that if a fresh handover event is close to the historical handover failure data in the feature space, it is very likely to fail.

Handover Failure Prediction in POLYCORN. Although the aforementioned offline analysis shows promising results in determining whether the handover is successful or failed based on location and RSRP data, it is not straightforward to turn it into a practical online handover failure predictor. The main challenge is that the handover failure has to be predicted *in advance* so as to be useful for guiding interface scheduling, especially for downlink traffic. In other words, the time advance needs to take into account the tens or hundreds of milliseconds of delay for mobile relay to deliver the handover failure precaution signal to the remote proxy. In our data analysis, we also find that the LTE chipset can delay the RSRP log reporting to userspace for up to 200 ms. This fact together with RSRP's highly fluctuating nature (Fig. 2b) makes RSRP an error-prone feature for SVM to use for online handover failure prediction. Therefore, POLYCORN has to rely on location information only since it is truly predictable given the reliable train speed. In practice, the mobile relay sends its associated cell ID, train's speed and location, and current time to the remote proxy. On the remote proxy, LinkDB provides information about all historical handovers from this cell and calculates the predicted location of handover failure $L_{HOF}^{\hat{}}$, defined as the average location of all handover failures. Then, LinkDB predicts $t_{HOF}^{\hat{}}$, the time that train passes $L_{HOF}^{\hat{}}$. If the current moment is approaching $t_{HOF}^{\hat{}}$ (to be elaborated in §4.3), POLYCORN predicts that the handover in this cell would fail because it is too late to initiate it even from now.

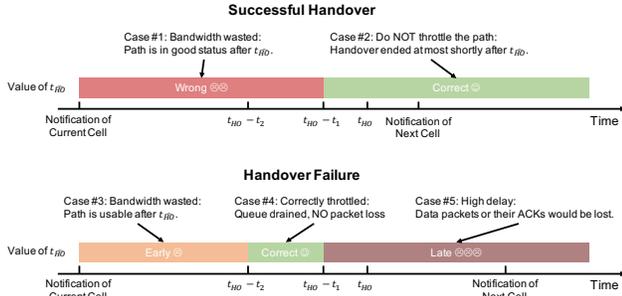

Figure 5: Types of Handover Prediction Results.

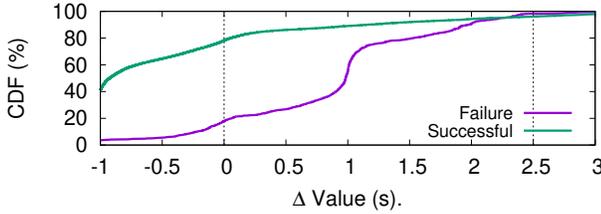

Figure 6: Handover Prediction Validation.

Prediction Validation. We consider the case where we throttle the path from t_{HOF} to the time when the UE connects to the next cell. The point is, if the handover failed, we should throttle the path right before the handover to drain the queue on it. Otherwise, we should only throttle the path for a very short period, or optimally do not throttle it. As illustrated in Fig. 5, let t_{HO} be the groundtruth value of handover time, $t_1 < t_2$ where t_1 and t_2 are two non-negative numbers, and hence there are five combinations of $\Delta = t_{HO} - t_{HOF}$ and handover results. We set t_1 to 0 seconds where t_{HOF} exactly matches t_{HO} , and set t_2 to 2.5 seconds, beyond which the side effect brought by early prediction outweighs its benefit. Fig. 6 plots the distribution of Δ , where t_{HOF} is predicted using leave-one-trip-out cross-validation over the entire dataset. For handover failure, 80.6%, 1.3%, and 18.1% of the prediction results are correct, late, and early, respectively. For successful handovers, the correct rate is 78.2%. Here we note that POLYCORN seeks for a conservative approach towards handovers prediction and path throttling decision – it prioritizes avoiding the penalty of a handover failure misprediction and considers it acceptable to waste available bandwidth in the cases that successful handover predicted as failure (Case 1) or successfully predicting the handover failure but in an earlier moment (Case 3) – in both cases the networking performance already starts to degrade when approaching the handover point anyway. As to be shown in §6.2, such coarse-grained results is adequate for our system given the high speed and the GPS system errors.

4 System Design of POLYCORN

We now present the design of POLYCORN, a software solution for high-performance Internet access for ultra-high-speed transportation. The design goals of POLYCORN include the following: (1) *Be resilient to extreme mobility environment.*

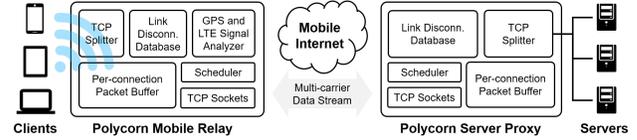

Figure 7: POLYCORN Architecture Overview.

POLYCORN should survive highly fluctuating network performance and inaccurate link quality estimations. (2) *Faster flow completion.* As opposed to bandwidth-intensive such as bulk data transfer [8], networked applications used by passengers, such as instant messaging and web browsing, typically have short or small sessions. It is therefore important to reduce the flow completion time. (3) *Effectively use multiple cellular carriers.* The multipath heterogeneity revealed in §2.4 should be leveraged for robust traffic delivery. (4) *Be practical for real-world deployment.* POLYCORN should be easy to deploy and ideally, be transparent to client and server applications and require no infrastructure modifications.

4.1 Overall Architecture

The high-level architecture of POLYCORN is illustrated in Fig. 7. As shown, POLYCORN leverages the dual-proxy architecture [22]. One proxy deployed at the on-board mobile relay (*i.e.*, cellular gateway) multiplexes passengers’ uplink traffic over the paths of multiple cellular carriers; another proxy deployed at a cloud server performs the reverse operation of demultiplexing the traffic and delivering them to the destination servers. Each in-cloud proxy is paired with one on-board mobile relay, and more pairs can be flexibly set up for scaling up the service for larger HSR network. Downlink traffic is handled in a symmetric way: the cloud-side and on-board proxy perform multiplexing and demultiplexing, transparently. The two proxies are essential for providing transparent transport-layer multipath to off-the-shelf hosts.

The dual proxies offer a centralized place for multipath scheduling, *i.e.*, deciding which traffic should be transmitted over which path(s). One path is one subflow that exclusively uses one network interface (*i.e.*, SIM card). The scheduler for uplink and downlink traffic resides on the on-board LTE gateway and the in-cloud proxy, respectively. Multipath scheduling is one of the most critical components of a multipath transport system, in particular for HSR networking where the paths’ performance is individually fluctuating and collectively heterogeneous. We are unaware of any multipath scheduler specifically designed for extreme mobility transportation, and POLYCORN’s design fills this gap.

4.2 Composable Multipath Scheduler

Our measurement study in §2.5 suggests that multipath transport for HSR networking needs to consider multiple dimensions: performance fluctuation, predictable handover failures, and path heterogeneity, *etc.* To tackle such complexity, we adopt a novel framework that treats a multipath scheduler as a pipeline of modularized *schedulerlets*. Each schedulerlet encapsulates a multipath scheduling functionality that ma-

Performance Issue	Mitigation Strategy	Schedulerlet
Disruption due to handover failure	Filter paths facing imminent handover failures based on prediction	§4.3
Suboptimal scheduling due to path heterogeneity	Filter paths that lengthen TCP flow completion due to tail packets	§4.4
Single packet experiencing multiple RTOs	Proactively reinject packet clusters facing excessive retransmissions	§4.5
Stale performance metrics on idle paths	Opportunistically deliver redundant data over unselected paths	§4.6

Table 2: Logic flow from performance issues to designs.

nipulates three sets of paths: a *selected set* \mathbb{S} containing the currently selected path(s) for data transmission, a *candidate set* \mathbb{C} containing the candidate paths that can be selected, and an *unavailable set* \mathbb{U} containing the unavailable paths that by default cannot be selected. The purpose of having \mathbb{U} is to restrict path selection to only a subset of all paths. Initially, all the paths belong to \mathbb{C} . Depending on which set(s) to manipulate, we classify the schedulers into different categories: (1) a *candidate filter* that moves path(s) from \mathbb{C} to \mathbb{U} ; (2) a *selection filter* that moves paths from \mathbb{S} to \mathbb{C} ; and (3) a *soft selector* that moves path(s) from \mathbb{C} to \mathbb{S} ; (4) a *hard selector* that moves path(s) from \mathbb{C} or \mathbb{U} back to \mathbb{S} . The purpose of having a hard selector is to provide a mechanism that can “revive” any path. This is useful when paths’ conditions are highly dynamic; it also ensures the completeness of the framework.

The schedulerlets are then strategically arranged to form the overall scheduling pipeline. Compared to a monolithic scheduler, our schedulerlet-based approach decouples the multipath scheduling logic, and thus significantly reduces the system complexity and development overhead, through the unified interface of schedulerlets (modifying \mathbb{S} , \mathbb{C} , and/or \mathbb{U}). Note that we do not claim that our design can achieve any optimality, since the “local” optimalities achieved by individual schedulerlets do not necessarily translate into a “global” optimality. Nevertheless, from a practical perspective, formulating a global optimization problem and solving it through a monolithic scheduler is extremely challenging due to the large solution space, real-time requirement, and volatile network dynamics. Therefore, we believe our “decouple-then-integrate” design achieves a right balance among practicality, simplicity, and performance, as to be thoroughly evaluated in §6.

We now consider how to instantiate the above generic framework into the concrete design of HRSCH, the multipath transport scheduler for POLYCORN. The high-level design principle is to identify scenarios where vanilla MPTCP performs poorly, based on our extensive field studies, and improve them through judiciously designed schedulerlets. Specifically, Tab. 2 lists our identified performance issues, mitigation strategies, and the corresponding schedulerlets of HRSCH, which will be detailed in the rest of §4. Here we describe the high-level scheduling pipeline. As shown in Fig. 8, the pipeline begins with a *candidate filter* schedulerlet that removes “bad” paths facing an imminent handover failure (§4.3), followed by a *soft selector* that performs initial, rough path selection. We find that the default minRTT scheduler

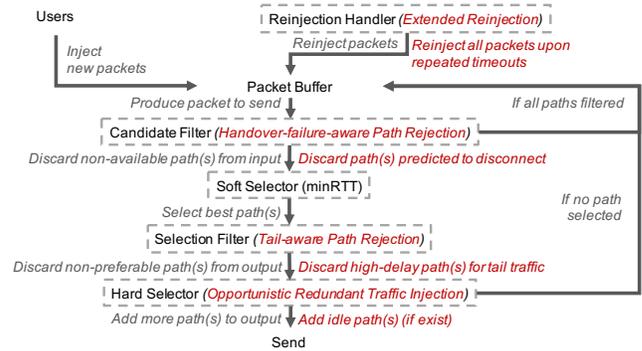

Figure 8: Composable scheduler in POLYCORN.

used by MPTCP can be properly leveraged as a soft selector, because favoring a low-latency path (when congestion window permits) is also desirable in HSR networking. Subsequently, we employ a *selection filter* to further remove certain selected paths, shortening the flow completion time (§4.4). Next, we apply a *hard selector* to make use of the remaining paths (in \mathbb{C} and \mathbb{U}) – we use them for delivering redundant data and probing the bandwidth (§4.6). Finally, due to the high network condition volatility, performance degradation or even outage may still appear on a selected path despite the above schedulerlets. To tackle this, we also introduce a *reinjection handler* that dynamically redistributes scheduled packets to other paths. This mechanism tolerates other schedulerlets’ errors and further improves the overall robustness (§4.5). Note that HRSCH is designed to be scalable, *i.e.*, they could work with any number of available paths.

The aforementioned taxonomy of schedulerlets based on which sets (\mathbb{S} , \mathbb{C} , \mathbb{U}) they manipulate also helps decide the order of the schedulerlets. For example, the candidate filter is invoked first since it does not depend on other schedulerlets; the selection filter needs to examine the output of the soft selector so the former comes after the latter in the pipeline. The hard selector tries to make use of any unselected paths; it is therefore situated at the end of the pipeline.

4.3 Handover-failure-aware Path Rejection

Recall from §2.3 that handover failures incur considerable performance impact. Our first optimization has an intuitive idea: predict imminent handover failures using LinkDB (§3), and apply a schedulerlet (candidate filter) to disable the path(s) facing handover failure(s). The rationale is that, sending traffic over a path experiencing a blackout of several seconds caused by a failed handover will significantly lengthen the flow com-

pletion time. Therefore, it should be avoided at all costs. In our design, for downlink traffic scheduling⁵, the gateway continuously sends the collected features (GPS reading and cell ID) to the in-cloud proxy where LinkDB runs. Those features are sent with top priority using a redundant scheduler to ensure that the proxy would receive the features in time. The proxy then predicts t_{HOF} , the interval between the current time and the next expected handover (§3). If t_{HOF} is predicted to be less than a threshold L , the proxy-side scheduler disables the path. The path will be re-enabled when the connectivity to the new cell is established. The threshold L incurs a tradeoff between bandwidth waste (occurs when disabling the path early) and performance degradation (occurs when disabling the path late). We configure L as: $L = RTT + \frac{E_{GPS}}{V_{HSR}}$. The first term is the estimated RTT between the in-cloud proxy and the LTE gateway. RTT is the lower bound of L because at least one round trip is needed for any in-flight data to be delivered with confirmation; if we send any data after $t + t_{HOF} - RTT$ (t is the current time), then we run into risks where the data/ACK delivery is affected by a failed handover. The second term $\frac{E_{GPS}}{V_{HSR}}$ accounts for the GPS localization inaccuracy, where E_{GPS} and V_{HSR} are the maximum GPS error (in meter) and the train’s current speed (in m/s) respectively. Due to potentially erroneous GPS reading, the train’s actual location may be ahead of the reported GPS location. Therefore, we need the second term for an additional safety margin. We conservatively set E_{GPS} to 20 m, and V_{HSR} is estimated from the recent GPS trajectory. We would also like to mention that in the corner case when all paths are predicted to experience handover failure soon, all of them would be disabled – this would effectively block all pending traffic until the mobile relay notifies the remote proxy of a new cell.

4.4 Tail-aware Path Rejection

The HSR networking performance is not only affected by handover failures, but also by the highly fluctuating channel quality due to HSR’s high speed. When a path’s quality deteriorates, HSRSCH needs to make a key decision: should the path be temporarily disabled? Here the tradeoff is bandwidth utilization vs. latency: skipping the path misses the opportunity of utilizing its (albeit low) bandwidth, while using the path can possibly lengthen the flow completion time compared to sending the data over a faster path.

To balance the above tradeoff, since our goal is to accelerate short flows dominating the traffic pattern on HSR, HSRSCH detects scenarios where a flow is about to end, and employs a schedulerlet (selection filter) that rejects sending *tail packets* over low-performance paths. Here tail packets reside at the end of a flow, whereas non-tail packets are at the beginning or in the middle of a flow. The rationale is that, sending a tail packet over a low-performance path is very likely to delay the flow completion. In contrast, transmitting a non-tail

packet over a poor-quality path usually only incurs packet out-of-order with a negligible or small impact on the flow completion time, provided that (1) all the paths are fully utilized (*i.e.*, there is no idle period), and (2) the receiver has a large enough buffer to accommodate out-of-order packets (which we can ensure as we have control over both multiplexing proxies). To transparently identify tail packets without the knowledge of flow size, HSRSCH keeps monitoring TCP FIN or RST packets. Once a TCP FIN or RST is observed, HSRSCH marks all the packets in the send buffer and all future outgoing packets of the same flow as tail packets. We leave more sophisticated tail packet identification methods (*e.g.*, based on application semantics) as future work.

To cope with highly fluctuating network conditions, HSRSCH employs a new way of deciding whether flow f has low performance over path i . Specifically, HSRSCH compares two scenarios. In the first scenario, we schedule some packets of f on path i . The packet delivery time and henceforth the flow completion time of f is *at least*:

$$T_{i,f}^- = owd_i + \frac{buf_i}{bw_i}$$

where owd_i , buf_i , and bw_i are the estimated one-way delay, the send buffer occupancy level, and the estimated bandwidth of path i , respectively. $T_{i,f}^-$ estimates the time taken to drain the FIFO send buffer of path i prior to sending any new packet belonging to f . It is therefore a *lower bound* of f ’s completion time if any of its packets are scheduled on path i . In the second scenario, we do not use path i at all to schedule f . In this scenario, the optimal flow completion time of f is *at most*:

$$T_{i,f}^+ = \min_{j \neq i} \left\{ \left(owd_j + \frac{buf_j + remain_f}{bw_j} \right) (1 + \eta_j) \right\}$$

where $remain_f$ denotes the remaining bytes of f yet to be sent, η_j is a relaxation parameter empirically defined as the ratio between path j ’s RTT variance and RTT, and j iterates over all the paths except path i . $T_{i,f}^+$ quantifies the time of transmitting all the remaining bytes of f over the best path (except i), considering the paths’ bandwidth and current send buffer occupancy levels. It is a loose *upper bound* of the optimal (single-path) completion time of f , which can in fact be further reduced (albeit difficult to quantify) by distributing f over multipath. If $T_{i,f}^- > T_{i,f}^+$, it implies that there exists a better scheduling strategy of not using path i compared to any strategy of using path i ; we thus determine that path i is too slow to schedule tail packets of f . See example in §A.

4.5 Extended Reinjection

Multipath transport needs to simultaneously manage multiple paths. To handle individual paths’ failure, MPTCP has a built-in reinjection mechanism (also known as Opportunistic Retransmission [36]): upon RTO events, the oldest unacknowledged packet on the same path will be retransmitted (reinjected) over another path as determined by performing

⁵For brevity, we only describe downlink traffic scheduling. Uplink traffic scheduling is performed at the on-board gateway in a similar manner.

the scheduling again. We find that such a reinjection policy is too conservative since it handles reinjection on the basis of *individual packets*. In contrast, in HSR networks, packet delivery failures often occur in a *bursty* manner: if a packet experiences an RTO, the probability that the subsequent packets are delayed or lost becomes much higher. Bursty losses are common in wireless networks in general. Nevertheless, on HSR, the bursty pattern of packet losses is much more prominent as the UE is frequently disconnected from base stations due to failed handovers or low signal strength.

Inspired by the above observation, we design an Extended Reinjection mechanism for HRSCH, whose basic idea is to detect scenarios where packets are undergoing multiple RTOs, and reinject packets in a *proactive and batched* manner to match the bursty packet loss pattern for HSR cellular access. Specifically, in our approach, when any packet experiences the k -th RTO, HRSCH reinjects *all* the unacknowledged (*i.e.*, in-flight) packets on the same path to other path(s). Instead of executing the reinjection(s) *immediately* by invoking the scheduling algorithm multiple times (similar to what MPTCP does when executing each single reinjection operation), HRSCH performs *lazy* reinjection: the to-be-reinjected packets are thrown back to their origin connection-level send buffers, and the actual reinjection will take place later when these packets are (re)scheduled according to their connection- and user-level priorities (at that time that destination path will also be determined⁶). The purpose of lazy reinjection is to maintain priority and fairness, *i.e.*, the reinjected packets are regarded as newly arrived so they do not bear an unfairly high priority over the reinjected path. This is particularly important when many packets belonging to the same connection are reinjected. Also note that for each reinjection, the receiver will receive at least two identical copies: the original packet and at least one reinjected packet; only the first arrived copy will be consumed by the receiver.

In the above algorithm, the parameter k incurs a trade-off: a large k provides fewer reinjection opportunities, potentially worsening the performance on the current path where losses occur, whereas a small k makes reinjection more aggressive, adding more traffic burden on other paths. We take a data-driven approach to select the appropriate k value: in our dataset, setting k to 1, 2, and 3 incurs 47%, 15%, and 0.3% more redundant traffic, respectively. We therefore set $k = 3$ in our evaluation (§6.2).

4.6 Opportunistic Redundant Traffic Injection

The soft selector along with both filters intend to find the best path for each packet, leaving the remaining unselected path(s) idle. This will cause two major issues: (1) the available bandwidth on idle paths, despite their high latency, is wasted; (2) no performance measurement can be carried out on idle paths without traffic, and previous measurement quickly becomes

⁶We use a bitmap field to ensure that the same packet is not reinjected to its previously scheduled path.

stale due to the high path dynamics. To address both issues, we design a schedulerlet (hard selector) that opportunistically schedules redundant data over idle paths. This not only allows passive measurement to be conducted, but also provides extra resiliency to channel quality fluctuation, leading to further reduced flow completion time, *i.e.*, when one path experiences unexpected performance degradation, the receiver can still receive extra copies of the data delivered over other path(s). In HRSCH, the idleness of a path is determined when no traffic has been scheduled over it for either α seconds, or β bytes worth of data, whatever occurs first. Once a path becomes idle, HRSCH duplicates the next τ scheduled packets and transmits their duplicated copies over the idle path. If multiple idle paths are available, the duplicate copies will be transmitted over all the idle paths. We empirically set $\alpha = 1$ second, $\beta = 8$ KB, and $\tau = 16$, which were found to well balance the tradeoff between the performance and bandwidth overhead based on our on-board controlled experiments.

Besides fostering reliability under performance degradation, injecting traffic over an idle path brings another benefit: it allows the transport layer to keep the path performance statistics up-to-date. As shown in Fig. 1a, on HSR, a cellular link's quality changes almost every RTT. If no packet is sent over an idle path, TCP's built-in probing mechanism, which is piggybacked with user traffic, will be paused, and TCP will thus lose track of important metrics such as RTT and RTO. Our proactive injection design addresses this issue.

4.7 Putting Everything Together

We integrate the above four schedulerlets into the composable framework introduced in §4.2. We next describe the detailed scheduling logic on both in-cloud proxy (for downlink traffic) and on-board LTE gateway (for uplink traffic).

Recall that POLYCORN is a multi-user system. In each scheduling round, HRSCH begins with selecting a user to serve, and then picking a flow belong to the selected user. Our current implementation uses the standard proportional fair (PF) scheduling [37] for user selection, and round-robin for flow selection. More sophisticated scheduling algorithms can be plugged into our framework. Once the to-be-served flow is determined, HRSCH schedules the flow's next packet, which is the untransmitted packet (including to-be-reinjected packets) with the smallest sequence number, as described in Fig. 8. Note that the reinjection handler runs in parallel with the scheduling thread that invokes the candidate/selection filters and soft/hard selectors.

5 Implementation

This section details the implementation of POLYCORN. Our high-level design goals consist of the following. First, POLYCORN should be practical. The required changes on clients' mobile devices should be minimized, or ideally none. Also, POLYCORN should be able to deploy on the HSR LTE gateway and keep its running components unmodified. Second, the data transport scheme should be able to schedule traffic

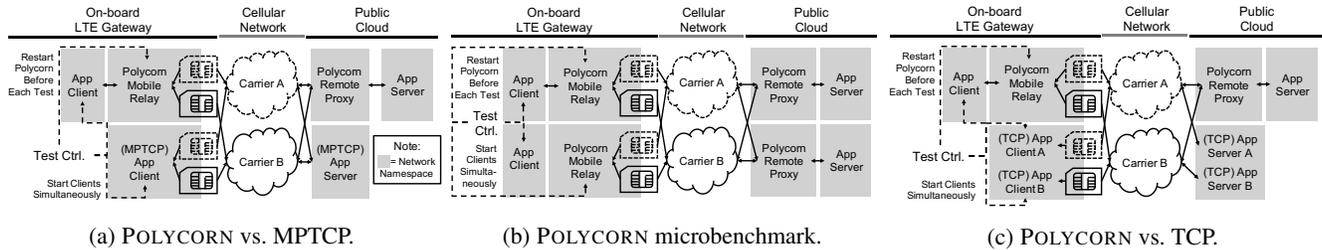

Figure 9: Experimental setup for different comparative evaluation.

with awareness of multiple users and connections.

Working with Unmodified Users and LTE Gateway.

Based on TM^3 [21] and MPFlex [22] frameworks, POLYCORN uses TCP splitting to achieve transparency towards both clients and servers. A brief summary of TCP splitting is: when communicating with servers, POLYCORN acts as a forward proxy; when communicating with clients, POLYCORN acts as a reverse proxy. To avoid kernel modification which is not allowed by the LTE gateway vendor, we use raw socket instead of `netfilter`-based [38] kernel modules (which is used by MPFlex and TM^3) or high-performance packet I/O frameworks like DPDK [39] to capture user traffic. After capturing user traffic, we drop all user packets using `iptables` [40] to prevent the kernel from forwarding them. In this way, we implement POLYCORN completely in userspace. As for the well-known performance issue of raw sockets, our experiments show that raw sockets could operate at 300 Mbps on the LTE gateway, which is significantly higher than the peak aggregated throughput of the LTE interfaces. Moreover, POLYCORN works in a separated network namespace (netns) to avoid conflicts with runtime kernel configuration used by other programs and mitigate potential security issues. For instance, POLYCORN disables reverse-path filtering in its own netns to forward packets generated by POLYCORN with any source IP. Our design allows sensitive system configurations to be preserved in the original netns, thus isolate the security risk from normal runtime programs.

Multuser Multipath Traffic Multiplexing. Similar to TM^3 and MPFlex, POLYCORN multiplexes user traffic onto off-the-shelf sockets to implement multipath data transfer. POLYCORN uses TCP sockets as its subflows. Although QUIC is better than TCP in terms of Head-of-Line blocking mitigation, especially in multiuser settings, we choose the “fallback” TCP sockets primarily because we encountered extensive rate limitation cases when launching QUIC flows in our measurements. This observation agrees with the findings in [41] to reveal that UDP traffic will most likely be treated as malicious flow by cellular carriers when sending in large volume, which situation might not disappear soon in most developing and under-developed countries. Therefore, we believe our choice is better for long-term real-world deployment. As for multiuser traffic scheduling, POLYCORN maintains a separated send/reinject buffer and a metadata set including user source

IP, amount of sent traffic, etc, for each flow. With those metadata, in operation POLYCORN first determines which user/flow to serve, then checks the flow’s send buffer to choose a packet to send. Finally, POLYCORN runs HSRSCH to choose interfaces to send the packet, as described in §4.2.

6 Evaluation

6.1 Experimental Setup

We carried out the experiments on Beijing-Shanghai HSR route, the one carrying most HSR passengers in the country.

Deployment on Operational System. We deployed POLYCORN mobile relay and server proxy on the high-speed train LTE gateways and public cloud servers respectively, with the same hardware configuration described in §2.1. More specifically, the mobile relay runs CentOS 7.3 with MPTCP kernel 0.94 (Linux 4.14) – we adhere to CentOS for POLYCORN deployment on the LTE gateway because it runs other mission-critical train-ground communication services developed by the operators and third-party IT service providers.

Fairness in Comparative Study. We made the following efforts to improve fairness in evaluating POLYCORN:

- *MPTCP Baseline* is configured in decoupled rather than default coupled congestion control mode (used in [15]) because the relay-proxy suite acting as an end-user traffic aggregation and delegation point should harness more wireless bandwidth from multiple cellular carriers instead of treating itself as a single user or session – it makes the baseline stronger and comparative evaluation fairer.
- *Pairwise study.* We carried all the experiments in the side-by-side concurrent test setting for 50 times with different software configuration tailored for fairness in different scenario, including comparing POLYCORN with MPTCP variants (Fig. 9a) and its own variants for microbenchmark (Fig. 9b) in single session bulk data download (§6.2), and comparing POLYCORN with SPTCP (Fig. 9c) and MPTCP (Fig. 9a) in multi-user instance messaging settings (§6.3). Specifically, we managed to obtain exclusive access to four SIM cards with two for each carrier respectively from the HSR WiFi service division, pair each transport software solution (*e.g.*, SPTCP, MPTCP and POLYCORN) with two cards from different carriers, and perform all the experiments on the operational HSR with a speed of 300+ km/h. Note that the scheduler and system design of POLYCORN can easily scale to more than two

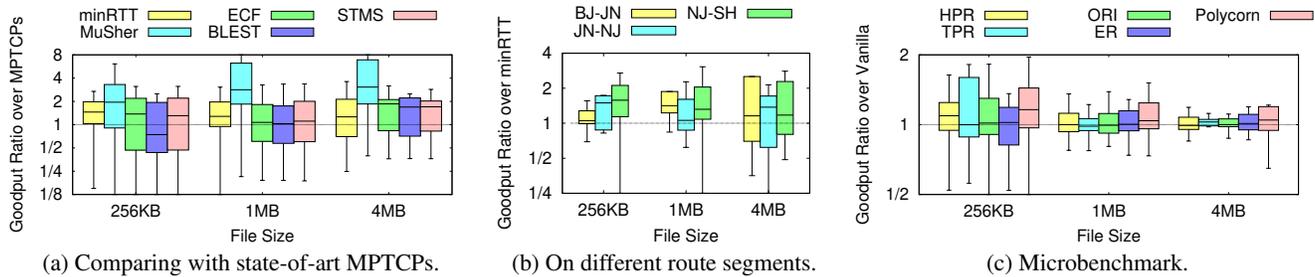

Figure 10: Bulk data downloading time comparative evaluation.

interfaces in LTE, 5G, *etc.* We choose to perform evaluations with two cards primarily because that is the maximum number we can obtain permission to access presently.

6.2 Bulk Data Download Performance

We first evaluate the performance of POLYCORN in comparison to the state-of-the-art MPTCP solutions and its own variants for microbenchmark from a single session perspective. We use fixed-size flows of 256 KB, 1 MB, 4 MB to examine POLYCORN’s performance in a pairwise manner. Specifically, we choose to use average goodput ratio of test object to its opponent as the primary metric instead of showing their absolute value. This is because the cellular link quality and the associated mobile networking performance differs significantly from one trackside location to another – the large variance for a single performance profile prevents comparative quantitative illustration and analysis between the two solution in the same testing environment.

Comparison with MPTCP Schedulers. We examine the efficacy of POLYCORN by showing its goodput ratio relative to the state-of-the-art MPTCP schedulers in Fig. 10a. We make three key observations: First, POLYCORN wins in almost all the cases, demonstrating that the four data-driven scheduler designs collectively and successfully improve the networking performance under different corner cases unique to HSR that are not well handled by all the state-of-the-art MPTCP scheduling strategies. Second, minRTT (as the default MPTCP scheduler) performs similarly compared with BLEST [28] (1 MB and 4 MB), ECF [27], and STMS [18], and outperforms MuSher [17]. This indicates that the strategies assuming predictable path heterogeneity are not advantageous over the simplest (and generic) one when encountering the highly dynamic networking environment. Specifically, POLYCORN outperforms minRTT by 1.45x, 1.28x, and 1.26x for 256 KB, 1 MB, and 4 MB respectively with overall 1.31x. In general, all the state-of-the-art schedulers trust and exclusively rely on their estimations of network condition to make interface scheduling decisions accordingly, while the fluctuating network nature on HSR makes the estimations error-prone and degrade the accuracy of the scheduling decisions. This is also why MuSher performs worse than others in our case: it assigns traffic to interfaces according to the quickly varying ratio of throughput on each interface and failed to catch up with the changes; others who rely more on RTT performed

better simply because RTT is relatively less variable. POLYCORN chooses to employ coarse-grained but more reliable event information and achieves better performance. Third, POLYCORN performs worse than BLEST in the shortest flow. Unlike POLYCORN that tries to improve bandwidth utilization (*i.e.*, Tail-aware Path Rejection), BLEST does not schedule packets on the path that would potentially cause head-of-line blocking, and hence achieves zero tail delay. This benefit comes at the cost of reduced bandwidth utilization, and will not continue to stay in a long flow.

Different HSR Route. We also examine the robustness of POLYCORN in different segments on the Beijing-Shanghai HSR route with different cellular coverage and terrain patterns of different channel characteristics [42]. As shown in Fig. 10b, POLYCORN consistently outperforms minRTT – the performance gain of POLYCORN on Beijing-Jinan (plain/rural), Jinan-Nanjing (hills/rural), Nanjing-Shanghai routes (urban/plain) are 19.4%, 25.2%, 44.9%, respectively.

Microbenchmark. We further study the performance gain of HRSCH and our four individual scheduler designs over POLYCORN Vanilla (*i.e.*, POLYCORN with minRTT scheduler). We plot the goodput ratio of the aforementioned five multipath transmission schemes and POLYCORN Vanilla in Fig. 10c. The four proposals all positively improve POLYCORN’s performance by 7.0%, 18.8%, 4.2%, and 2.9% on average for the three different file sizes, and they cumulatively contribute to 16% goodput gain.

- *Handover-failure-aware Path Rejection* is designed to mask the impact of packet loss during the disconnected period and the consequent RTO to the TCP (*e.g.*, slow start) by receiving or predicting handover from explicit signals from LTE real-time analytic and/or our LinkDB information and take action accordingly. Specifically, by sending redundant cross-flow copies during the period any interface encountering disconnection, as shown in Fig. 11a, POLYCORN can recover from the disconnection much faster, *i.e.*, achieve 1.2x and 1.5x as mean and median values within 2 seconds after handover failure, which typically lasts a few seconds or longer.
- *Tail-aware Path Rejection* is used to avoid the out-of-order delay caused by the slow paths by refusing to inject data on the interface that may increase the flow completion time. As shown in Fig. 11b, the tail delay was reduced by 5.6% on average and 15.6% in 95 percentile compared to POLYCORN

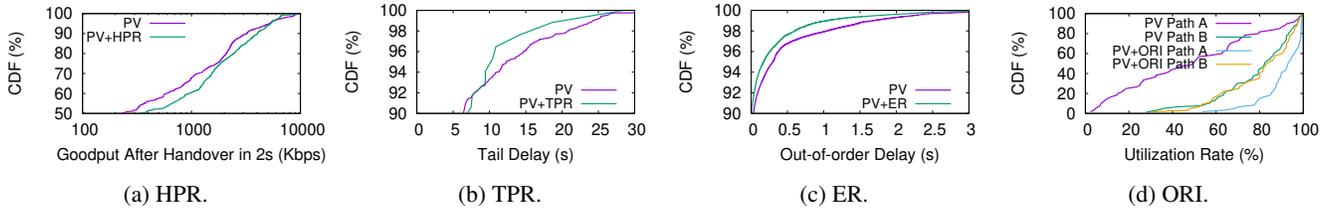

Figure 11: POLYCORN microbenchmark comparative evaluation.

(PV: Polycorn Vanilla; HPR: Handover-failure-aware Path Rejection; TPR: Tail-aware Path Rejection; ER: Extended Reinjection; ORI: Opportunistic Redundant Traffic Injection.)

Vanilla. This mechanism is useful especially for those tail delay greater than 10 seconds, which is due to the high packet loss rate and prolonged retransmission time of the interfaces with abnormal high RTT.

- *Extended Reinjection* mainly focuses on reducing extremely high retransmission time and leads to a significant reduction of out-of-order delay, which is shown in Fig. 11c. It reduces out-of-order delay by 23% among all the out-of-order packets, and 4% out-of-order delay among all the packets.

- *Opportunistic Redundant Traffic Injection* aims to proactively update the performance metrics of interfaces that have been idle for a while due to higher measured RTT. This helps HRSCH more quickly discover recovered paths and improve path utilization. As shown in Fig. 11d, POLYCORN Vanilla simply ignores the path with much higher RTT. By employing opportunistic probing mechanism, the utilization rate of the path appears to be worse is increased by more than 60%, which allows better bandwidth utilization from all the paths.

Remarks. We note that POLYCORN exhibits non-trivial variation in its performance, and sometimes it falls behind the counterpart solutions. There are two major reasons: 1) It is difficult to exactly *repeat* tests on HSR: minor difference in test location results large difference in network condition – given the fluctuating network delay, the remote proxy (*i.e.*, sender) cannot accurately learn about the location of the train; 2) POLYCORN works with inaccurate handover failure predictions and TCP performance metrics. Our schedulerlets could tolerant minor errors in the context data, *e.g.*, comparative operators tolerates minor error in RTT. However, there exist cases where other solution has the proper information to make right scheduling decisions while POLYCORN does not.

6.3 Multi-user Instant Messaging Performance

We next evaluate POLYCORN in a multi-user setting, and choose instant messaging, the most popular application of HSR passengers as a representative use case for a case study. To best emulate the application behavior, we establish a long-lived TCP connection (adopted by many instant messaging application including WeChat, the most popular one in China) between POLYCORN mobile relay and server proxy for each user. We let each user sends 100 messages concurrently with pre-generated intervals following the exponential distribution. Each messaging event includes a 100-byte uplink message

and an immediate 4-byte downlink one. Note that POLYCORN adopts a symmetric scheduler design for both downlink and uplink, which makes our data-driven interface scheduling work with uplink without extra effort. We perform concurrent pairwise experiments for POLYCORN vs. SPTCP and POLYCORN vs. MPTCP-minRTT respectively – SPTCP with round-robin scheduling cross different SIM card is the current operational solution used by the HSR WiFi systems due to its simplicity and interface-level fairness.

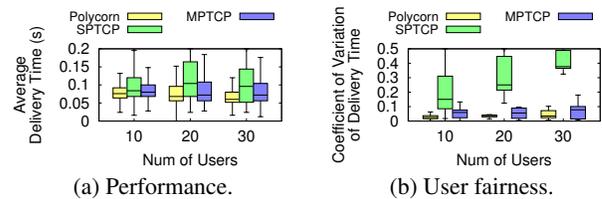

Figure 12: Multi-user instant messaging evaluation.

Experimental Results. Benefiting from the multi-stage data-driven scheduler design, POLYCORN outperforms SPTCP and MPTCP in both performance and user fairness. As shown in Fig. 12a, POLYCORN consistently improves aggregated instant messaging performance when the number of users ranges from 10 to 30. On average, POLYCORN reduces delivery time by 45% and 16% in comparison to SPTCP and MPTCP respectively, and tail delay, *e.g.*, 90 percentile, by 34% and 14%. In terms of user fairness, we use the coefficient of variation to quantify the variance of message delivery time regardless of the mean value across tests on different route segments with diverse networking conditions. As we can see in Fig. 12b, POLYCORN reduces the coefficient of variation by 86% and 49% on average when compared with SPTCP and MPTCP respectively, which significantly improves fairness across different on-board users.

7 Discussion

POLYCORN for 5G. Our evaluation does not cover 5G because the 5G CPE (Customer Premise Equipment) is not available on our HSR WiFi system yet. However, we believe POLYCORN’s techniques remain applicable to 5G. For example, a recent measurement reveals that on 5G HSR, the handover failure rate is comparable to LTE [20], and multiple studies suggest that 5G suffers from higher bandwidth fluctuation and packet losses compared to 4G [20, 26].

Fairness. We discuss two fairness issues here. First, the fairness among POLYCORN users is ensured by POLYCORN’s multi-user scheduling algorithm (we use proportional fair scheduling, see §4.7). Second, the fairness between POLYCORN users and non-POLYCORN users (who use their own cellular data plan) is typically guaranteed by the LTE base station. Also, POLYCORN uses unmodified TCP congestion control for each multiplexed long-lived TCP connection established for each sim card. This further minimizes the risk of POLYCORN being overly aggressive.

Other Mobile Applications. We have evaluated POLYCORN on bulk download (with different sizes) and instant messaging (with different number of users). Other applications popular on HSR include web browsing and short videos. Short video traffic may resemble bulk download that POLYCORN can effectively handle, whereas web browsing further involves client-side processing overhead, which may reduce the effectiveness of POLYCORN that only optimizes content delivery.

Scalability. The POLYCORN architecture natively supports adding more wireless interfaces (*e.g.*, SIM cards) and pairs of onboard mobile relay & in-network server proxy to meet the scalability requirement. We leave larger-scale evaluations of POLYCORN as our future work.

Head-of-Line (HoL) Blocking Issue in TCP Reuse. POLYCORN uses one multipath connection formed with TCP subflows to transmit all user traffic. The use of TCP will inevitably introduces the HoL blocking at both intra-connection and inter-user level due to its byte-level ordering guarantee, which is an overkill in POLYCORN’s multi-user multiplexing context. We envision that this problem will be solved by (MP)QUIC with its support of out-of-order delivery and cross-path acknowledgment [43, 44].

8 Related Work

Mobile Networking Performance Improvement. A plethora of research efforts have been devoted to improve network performance (under high mobility) through developing robust handover schemes [26], simplifying cellular control plane [45, 46], and fixing base station-side policy configuration bugs [47, 48]. Unlike POLYCORN, all the above approaches require modifications to the cellular infrastructure. There are also studies at upper layers, *e.g.*, designing customized single-path transport protocol [49] and optimizing congestion control algorithms [50–54]. POLYCORN instead proposes a holistic multipath solution with new optimization dimensions.

Performance-enhancement Proxy (PEP). In vehicular systems, PEPs are often deployed on mobile relays, to leverage carrier diversity and UDP encapsulation for bandwidth aggregation and mitigating link failure, *e.g.*, through stripping [11, 55], opportunistic erasure coding [12], and flow splicing [13]. Specifically, the work [35, 55] present the idea of location-aware link characteristics (*e.g.*, throughput and avail-

ability) prediction and packet scheduling. PEPs can also be deployed in fixed locations in the Internet [56–58]. POLYCORN synthesizes all the ideas above and presents four multipath scheduling strategies dedicated to addressing the unique networking challenges in extreme mobility.

Multipath Transport Architecture. Transmitting data over multiple paths can be realized at different layers, *e.g.*, WNIC driver [59, 60], in-kernel transport layer [36, 61], light kernel modification [21, 22], and UDP encapsulation [62–64]. Differing from the above, POLYCORN is an entire userspace solution reusing Linux TCP for the benefits of OS/middleware compatibility, application transparency, and good runtime performance, with multipath, multi-user multiplexing support.

Scheduling over Heterogeneous Paths. Several generic multipath transport schedulers have been proposed to mitigate the head-of-line blocking and out-of-order delay incurred by imbalanced subflows, such as opportunistic declining [28] and migrating [27], intra-chunk opposite scheduling [65], out-of-order transmission [18], and reactive bandwidth probing [17]. None of them considers HSR-specific aspects, and many of them [27, 28, 65] only work for two paths. Horde [66] and miDRR [67] allows user/app to specify their QoS requirement and perform packet scheduling accordingly. RAVEN [14] achieves low latency by extensively leveraging redundant transmission over multiple paths. HRSCH brings new optimization dimensions integrated through a composable schedulerlet pipeline, and strikes a balance where overall throughput is not harmed by large amount of redundant traffic and latency of short flows are preserved.

9 Conclusion

The popularity of HSR systems brings the requirement of high-performance data networking under extreme mobility more tangible than ever. In this work, we have addressed the challenge of bringing seamless Internet service to passengers on HSR by synthesizing multipath transmission and data-driven scheduling techniques into a practical and readily deployable system design. Extensive experimental results have demonstrated the effectiveness of our system design dedicated to extreme-mobility. We believe that our upper layer optimization solution can seamlessly cooperate with the ongoing 5G/NextG(-Unlicensed) evolution.

A Example for Tail-aware Path Rejection

Fig. 13 exemplifies how tail-aware path rejection works on HSR. In this example, the traffic consists of a flow whose FIN packet was received by POLYCORN (so all the subsequent packets are tail packets). There are two paths A and B, whose estimated RTT and send buffer occupancy levels are plotted in the top and bottom subfigure, respectively. Path A has a low RTT and its send buffer is almost full, whereas Path B has a high RTT and its buffer occupancy level is low. MPTCP's default minRTT scheduler frequently schedules tail packets to Path B because Path A is busy (congestion window being full). However, our algorithm usually rejects Path B because the flow completion time will reduce if we wait for Path A to become available and send tail packets over A. This results in a large number of path rejection instances.

Abstract – We present the design, implementation, and evaluation of X-AR, an augmented reality (AR) system with non-line-of-sight perception. X-AR augments AR headsets with RF sensing to enable users to see things that are otherwise invisible to the human eye or to state-of-the-art AR systems. Our design introduces three main innovations: the first is an AR-conformal antenna that tightly matches the shape of the AR headset visor while providing excellent radiation and bandwidth capabilities for RF sensing. The second is an RF-visual synthetic aperture localization algorithm that leverages natural human mobility to localize RF-tagged objects in line-of-sight and non-line-of-sight settings. Finally, the third is an RF-visual verification primitive that fuses RF and vision to deliver actionable tasks to end users such as picking verification. We built an end-to-end prototype of our design by integrating it into a Microsoft HoloLens 2 AR headset and evaluated it in line-of-sight and non-line-of-sight environments. Our results demonstrate that X-AR achieves decimeter-level RF localization (median of 9.8 cm) of fully-occluded items and can perform RF-visual picking verification with over 95% accuracy (F-Score) when extracting RFID-tagged items. These results show that X-AR is successful in extending AR systems to non-line-of-sight perception, with important implications to manufacturing, warehousing, and smart home applications. Demo video: youtu.be/bdUN21ft7G0

1 Introduction

The past few years have witnessed an increasing interest in augmented reality (AR) systems. Major tech companies - including Microsoft, Meta, Apple, and Google - have invested billions of dollars in developing AR technologies [7, 25, 52, 51]. A significant driver for these investments is the role that AR systems are expected to play in boosting efficiency across Industry 4.0 sectors including manufacturing, warehousing, logistics, and retail. For example, in e-commerce warehouses, AR headsets can boost labor efficiency by guiding workers in picking, sorting, and packing orders and returns [26]. Similarly, in manufacturing settings, AR headsets can guide employees by visualizing assembly tasks, automatically labeling tools in the environment, and helping users find parts they need [28]. More generally, AR headsets are expected to make workers more efficient by annotating their environments, visualizing their next tasks, and guiding them in executing these tasks [27, 30].

To realize their full potential, AR headsets need to deliver the above capabilities in real-world industrial en-

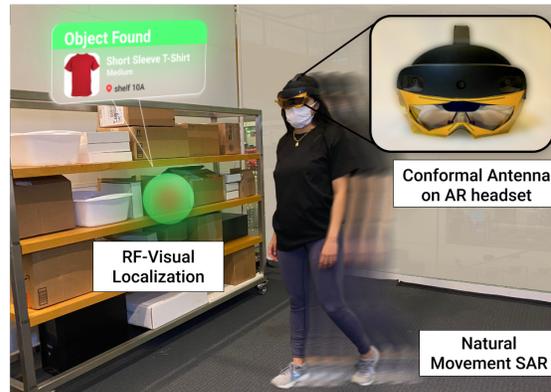

Figure 1: **X-AR**. X-AR fuses RF measurements with visual information and leverages natural human motion to localize RFID tagged items in the environment. The system uses a custom-designed, conformal, light-weight antenna mounted on an augmented reality headset and displays information to the user.

vironments, which are typically dense and highly cluttered. For example, a typical warehouse or dark store is dense with packages, and a standard manufacturing plant is dense with materials and compartments. In these environments, the majority of items are occluded due to being inside a box, under a pile, or behind other packages. Such occlusions make it difficult for existing headsets to perceive these items, which in turn prevents them from identifying and locating the items or guiding workers towards them. This limitation stems from the fact that today's AR headsets perceive their environment through cameras or other vision-based sensing systems which are inherently limited to line-of-sight (LOS) [6, 38]. Such line-of-sight restriction hinders AR systems from boosting worker efficiency where it is most needed, namely in cluttered and dense industrial environments.

In this paper, we ask the following question: *Can we design and build an augmented reality system that can sense fully-occluded objects and expand the perception of humans beyond the line of sight?* With this capability, augmented reality would go beyond any natural human ability and truly augment the way we interact with the world, enabling significant advances in warehouse logistics, manufacturing, retail, and more. For example, AR headsets with non-line-of-sight (NLOS) perception could identify and localize specific items (e.g., customer orders, tools, materials) even when they are fully occluded, helping workers avoid a lengthy search process. Additionally, such AR headsets could be used to automate inventory control of items in warehouses or retail stores without needing to see all objects, and can alert

workers to misplaced items hidden behind occlusions.

To realize this vision, our approach is to leverage Radio Frequency (RF) signals, which, unlike visible light, can traverse everyday occlusions such as cardboard boxes, plastic containers, wooden dividers, and clothing fabric. Indeed, recent advances in RF sensing have demonstrated the potential to use RF signals to sense and accurately localize items in non-line-of-sight and highly cluttered environments [17, 40, 39]. Among existing RF sensing technologies, we are particularly interested in leveraging UHF RFID (Radio Frequency IDentification) tags due to their widespread adoption in supply chain industries (for example, over 93% of US retailers have adopted UHF RFIDs [5]). Our vision is to bring RFID sensing and localization to AR headsets to provide them with non-line-of-sight perception and augment human visual abilities for applications in warehouse automation, e-commerce fulfillment, and manufacturing.

We would like to build a system that realizes the above vision while satisfying the following requirements:

1. *AR-compatibility*: The system must seamlessly integrate with an AR headset without impacting the performance of its existing sensors and displays (i.e., without obstructing the headset cameras or the user field of view).
2. *Seamless Mobility*: The system must operate correctly with natural human mobility. Specifically, it must be able to accurately localize RFIDs (in LOS and NLOS settings) without requiring the user to perform unnatural movement patterns, which may hinder their productivity.
3. *Actionability*: The system should provide users with actionable tasks (e.g., guide the user where to search) and inform users of task success (e.g., verify to a warehouse picker whether or not they picked the right order).
4. *User-friendliness*: The system needs to be compact and lightweight, so that the user can easily wear the AR headset and move around to complete their tasks.

Satisfying the above requirements is challenging and cannot be realized by simply integrating a state-of-the-art RFID localization system with an AR headset. In particular, the majority of accurate RFID localization solutions require multiple antennas that are separated by meter-scale distances [39, 40], making them too bulky to mount onto an AR headset. Solutions that don't require such antenna arrays typically rely on robot-mounted antennas that need to be moved on predefined trajectories [58, 17, 15], making them incompatible with natural human mobility. In addition to these challenges, delivering AR-actionable tasks goes beyond simple RF localization and requires new mechanisms to fuse RF and vision perception under natural mobility and display the output on the headset.

In this paper, we present X-AR, an augmented reality headset with a built-in RF sensing system. A user wearing X-AR can freely walk in their environment (e.g., a

warehouse or manufacturing plant), and the headset automatically identifies and localizes items in the environment, even when they are not in line-of-sight. Using this information, X-AR guides the worker towards items of interest (tools, packages, etc.) and verifies whether or not they have picked up the correct item. Our system introduces multiple innovations that together allow it to satisfy the above requirements:

1. AR-Conformal Wideband Antenna: X-AR introduces the design of an ultra-lightweight and wideband antenna that is conformal to the headset (described in §3). Our unique antenna design matches the shape of the AR glasses visor, as depicted in Fig. 1, and does not block the user's view or any sensors. The antenna also achieves the radiation, bandwidth (BW), and gain properties required to perform accurate RFID localization.

2. RF-Visual Synthetic Aperture Radar: X-AR does not make restrictive assumptions about the user's motion pattern when localizing the RFID tags in the environment, and opportunistically leverages natural human mobility. To do this, X-AR first uses the visual information from the AR headset camera to self-localize in the environment. It then uses the RFID measurements collected during the user's motion to create a synthetic aperture radar (SAR) and localize RFID tagged items with high accuracy. In addition, X-AR introduces a number of techniques to handle localization artifacts and constraints that arise from natural human motions such as natural head tilts and RFID backscatter radiation properties. We describe this localization method in detail in §4 and show how the system guides the user to the item's location and displays it on the AR headset.

3. RF-Visual Verification: The final component of X-AR's design is a mechanism that verifies when the user has picked up their desired RFID-tagged item. Such verification is important to avoid costly errors such as picking and shipping the wrong order to a customer in e-commerce warehouses. One might assume that such a capability can be simply realized by localizing the RFID-tagged target item to within a user's hand once they've picked it up (i.e., using the same localization mechanism described up). In practice, doing so is challenging because, unlike the above scenario where the user's walking emulates a synthetic aperture, a user picking an item stays in a relatively fixed location. To address this challenge, X-AR leverages the RFID tag's mobility instead. Specifically, it performs a *reverse* SAR to localize the headset with respect to the picked item's trajectory. In §5, we describe this technique in detail and show how X-AR fuses the AR-headset's hand-tracking capability with reverse SAR to perform the verification with high accuracy.

We implemented an end-to-end prototype of X-AR. We mounted a custom-designed conformal antenna on

Microsoft HoloLens 2 headset [9]. The antenna is connected to bladeRF software defined radios [47] that communicate with the AR headset through an edge server. Our algorithms are written in the C driver and operate in real-time, and we program the HoloLens through Unity to display item locations and labels, guide the user to the target items, and show the verification results.

We evaluated X-AR's performance over 230 experimental trials. Our evaluation demonstrated that:

1. X-AR's conformal antenna achieves all desired specifications in terms of weight (<1g), size (conformal), BW (200 MHz), and gain (around 0 dB).
2. X-AR accurately localizes RFID tagged objects in line of sight and non line of sight scenarios with a median accuracy of 9.8 cm. Even the 90th percentile accuracy remains within a foot and a half (45 cm). In contrast, a standard SAR-based baseline has more than double the error, achieving a median accuracy of 24.8 cm and a 90th percentile accuracy of 99.1 cm.
3. X-AR tracks the movement of the RFID tag and the user's hand to automatically verify what object has been picked up with over 95% accuracy (F-Score). Even if the user picks up a box with the RFID-tagged item inside it (rather than picking up the item itself), the F-Score remains over 91%.

Contributions: X-AR is the first augmented reality headset that can sense through occlusions and perceive fully occluded objects. This system introduces three key innovations: 1) A custom-designed, conformal, wideband, and light-weight antenna that can be integrated with a commercial AR headset, enabling RFID localization without obstructing the user's or cameras' view, 2) An RFID localization system that opportunistically leverages natural user motion to create a non uniform RF-Visual synthetic aperture radar and to localize and visualize the RFID tagged objects in 3D, 3) A verification mechanism that performs reverse RF-Visual localization to verify whether the user has picked the target item, in line-of-sight, non-line-of-sight, or occluded settings.

Although X-AR enables non-line-of-sight perception for augmented reality headsets, our current implementation still has a few limitations. First, X-AR is currently designed to operate on a single headset, and still has no mechanisms to extend to multiple coordinated headsets. Second, the range of the RF measurements are limited to 3m; however, future antenna design iterations can achieve an even longer range. Finally, X-AR only demonstrates two actionable tasks: guiding the user toward a target item, and verifying the target item is in the user's hand. As research evolves, it would be interesting to extend this system to other tasks. Despite these limitations, X-AR marks an important step in bringing RF sensing to AR and opens the door to future works bridging these fields.

2 System Overview

X-AR is a next-generation augmented reality system capable of perceiving objects in both LOS and NLOS conditions. The system can identify, locate, and label RFID-tagged items in the environment. It leverages an RF sensing module to read passive, off-the-shelf UHF RFID tags attached to items of interest. By combining this information with visual data from the AR headset's camera sensors, it locates RFID-tagged items with high accuracy.

X-AR is designed to be used in practical environments, such as warehouses, manufacturing plants, and retail stores. It opportunistically leverages human motion (i.e., as the user walks around and picks up items) in order to localize tagged items in the environment, guide the user towards them, and verify when the user has picked them up. For simplicity, the remainder of this paper discusses the system in a single tag scenario. However, X-AR can easily extend to multiple RFID tags in the environment. Using the EPC Gen 2 protocol, X-AR can read each RFID tag separately, and perform the same localization and verification algorithms for each tag.

3 AR-Conformal Antenna

X-AR introduces a conformal antenna that can be mounted on the headset to identify, locate, and verify UHF RFID tags, without interfering with the headset's operation or constraining the user. Here, we describe our AR-conformal antenna design, its requirements, challenges, and the path describing its evolution from a conventional antenna structure to one satisfying all the desired needs. To perform RFID localization from the headset in the field of view of the user, the antenna needs to satisfy the following requirements:

- **Wideband operation around 900 MHz:** The antenna needs to maintain a matched operation and a good gain over a BW of at least 200 MHz to match the bandwidth requirements of state-of-the-art RFID localization systems [39, 40].
- **Conformal and unobstructive:** The antenna must be designed on a flexible substrate to easily conform to the HoloLens' visor without obstructing a user's field of view or the cameras mounted on the front of the headset.
- **Lightweight and small form-factor:** The antenna must maintain an ultra-light weight (< 1g) and be simple and easy to mount on the AR's visor.

Existing solutions in state-of-the-art wideband RFID localization systems do not satisfy these properties [16, 17, 40, 39, 14]. In particular, they rely on rigid, relatively-large, and often bulky antennas. For example, the majority of these systems leverage large patch antennas that are 26 cm × 26 cm × 3.3 cm and weigh approximately 1.04 kg, while others rely on log-periodic antennas that measure 15 cm × 13 cm × 0.01 cm. These solutions are too bulky and would obstruct the field of

Figure 2: **Conformal Antenna Design.** (a) Fabricated single-loop antenna mounted on the headset (dimensions 122×51 mm). (b) Fabricated conformal antenna (dimensions 165×64 mm). (c) These plots show the measured gains of the single loop (blue) and AR conformal (red) antennas vs frequency while mounted on the headset and worn by the user. The horizontal green line is used to highlight the 3-dB bandwidth.

view of the AR headset, thus are ill-suited for our use case. While some RFID localization systems utilize compact and lightweight antennas [58, 57, 59], these antennas have a narrow band of operation, which makes them unsuitable for our use case.¹

Below, we describe our investigation in designing the AR-conformal antenna to satisfy the above requirements.

3.1 Investigating a Single Loop Design

We first investigated whether we could achieve the above properties using a single loop antenna design. Our choice of a single loop was motivated by the fact that a loop can wrap around the outline of the visor, delivering a small form factor not obstructing the field of view. Also, the loop is a simple antenna that does not require a ground plane, making it easy to mount on an AR headset.

Fig. 2a shows the picture of our initial design of a loop antenna, fabricated on a $100 \mu\text{m}$ thin polyimide substrate, and mounted on the HoloLens. Notice how our antenna (almost) follows the perimeter of the visor, thus not obstructing its view. In order to identify the appropriate dimensions corresponding to an operation around 900 MHz, we performed our antenna simulations in Ansys High Frequency Simulation Software (HFSS). In designing these antennas, we leveraged polyimide films because of their good electromagnetic properties, their common use for applications requiring flexible electronics, and their wide availability at low-cost. This antenna also weighs less than 1g, thus it satisfies our requirements of a small form factor while maintaining a light weight.

To investigate the bandwidth requirement, we mounted the antenna on the headset, worn by the user, and measured its gain over the frequency of interest. This was done by illuminating it with a transmitter antenna of a known gain and using a vector network analyzer (VNA) to extract the S parameters of the loop antenna (specifically the S21 parameter).

Fig. 2c plots the gain of the loop with respect to frequency, showing 3 dB BW of approximately 100 MHz around 780 MHz. This shows the loop antenna design

¹As mentioned in §1, past systems that leverage these antennas require either bulky arrays or a robot to move the antenna on a pre-defined trajectory, neither of which are suitable for an AR localization system.

would not allow us to achieve the desired 200 MHz of BW. It should be noted the loop antenna delivers a resonant frequency of 900 MHz and a gain of 3.8 dB when tested in air. However, its gain degraded by 3 dB and frequency detuned by 120 MHz when placed on the headset visor and worn by the user. This behavior is often observed with wearable antennas [32, 41], where the frequency of operation and antenna radiation properties degrade when mounted on a new material. Thus, while the loop antenna is conformal, unobstructive, lightweight, and small, it did not satisfy the BW requirements.

3.2 Wideband AR-Conformal Antenna

Motivated by a desire to increase the bandwidth of the single-loop conformal antenna, we investigated how strategies such as tapering (i.e., gradually changing the width of the loop) and slotting (i.e., adding slotted gaps in the loop) can help us achieve the desired bandwidth. Through an iterative design and simulation processing (whereby the simulation was performed using Ansys HFSS), we reached the design shown in Fig. 2b. Notice how we carefully chose the dimensions of the antenna to perfectly match the shape of the visor, without blocking any of the cameras. We also added tapers to the outline of the antenna and integrated slots on the top and bottom lines around the nose to achieve a wideband operation.

Similar to the loop antenna, we conducted gain measurements to assess the 3-dB bandwidth of our conformal antenna while mounted on the headset and worn by the user. The red plot in Fig. 2c shows the gain of our new antenna as a function of frequency. Notice how the 3 dB bandwidth of the gain is now 200 MHz - from 775 MHz to 975 MHz. This shows that the antenna achieves the desired gain pattern in the frequency range of interest. Note that the negative gain realized by these wearable antennas is normal with ultra-thin substrates due to close proximity with lossy material such as the headset and human tissues [48, 19]. In principle, it is possible to further optimize the gain of the antenna, however, the negative gain could be easily overcome by transmitting at a higher power, thus maintaining a constant effective radiation pattern (typically referred to as EIRP). It should be also noted that the detuned frequency observed with

the measured loop due to placement on headset was accounted for in the HFSS simulations for the new antenna, by simulating the structure on plexiglass that mimics the headset’s visor, and thus resulted in the proper resonant frequency during measurements. Finally, we also simulated the radiation pattern of the conformal AR antenna on the headset as well as measured its gains across frequencies and elevation angles (see appendix).

It should be noted that while this antenna was designed to match this headset, the design could be adapted for different visor shapes, depending on the location of the cameras and other components that cannot be blocked.

4 RF-Visual Synthetic Aperture Radar

In the previous section, we described the custom, conformal, and lightweight antenna that X-AR uses to sense RFID tags in the environment. In this section, we describe how X-AR uses these RFID measurements, along with visual information from the AR headset’s camera to locate RFID tags with high accuracy through RF-Visual Synthetic Aperture Radar (SAR). For ease of exposition, we discuss localizing a single tag, but the same approach generalizes to any number of tags in the environment.

4.1 Background on SAR

X-AR’s localization builds on a technique called Synthetic Aperture Radar (SAR). At a high level, SAR leverages the same localization principle as antenna arrays, where measurements from multiple antenna locations are combined to localize a wireless device in 2D or 3D space. SAR differs from standard antenna arrays in that it moves a single antenna, collecting measurements from different physical locations to emulate an antenna array. Formally, we can estimate the power P received from every point in space using the following equation:

$$P(x,y,z) = \left\| \frac{1}{M} \frac{1}{N} \sum_{j=1}^M \sum_{i=1}^N h_{i,j} e^{\frac{4\pi d_i(x,y,z)}{\lambda_j}} \right\|^2 \quad (1)$$

where M is the number of frequencies used, $h_{i,j}$ is the channel measurement of the i^{th} location with the j^{th} frequency, d_i is the distance from (x,y,z) to the i^{th} location, and λ_j is the wavelength of j^{th} frequency.

To localize the tag, we find the (x,y,z) location with the highest power. Formally, the location of the tag, p_{tag} :

$$p_{tag} = \operatorname{argmax}_{(x,y,z)} (P(x,y,z)) \quad (2)$$

For more details on SAR please refer to the Appendix.

4.2 AR-Based SAR

Since it is infeasible to mount an antenna array on an AR headset, X-AR builds on SAR-based RFID localization. Specifically, X-AR opportunistically leverages natural human motion to collect wideband measurements from different locations and uses them to construct a synthetic aperture radar to localize RFID tagged items.

However, bringing SAR to an AR headset faces a number of challenges. Unlike prior systems that leverage SAR (e.g., robots or airplanes), X-AR cannot rely on a constant velocity or predictable trajectory. For example, humans naturally accelerate and decelerate and move slightly side-to-side as they walk, making it difficult to predict the exact antenna location. Moreover, recall that X-AR aims to opportunistically leverage human motion as opposed to controlling the user’s trajectory, making it even more challenging to control the antenna’s location.

Self-Tracking. To address these challenges and localize the antenna over time, X-AR leverages the AR headset’s built-in self-tracking capability. Existing AR headsets can self localize by extracting feature points from their cameras’ visual data and performing visual-inertial odometry (VIO). They then track these points over time to build a map of the environment and derive their 6D pose (i.e., location and rotation) within this map [38, 42].

To leverage this built-in localization, X-AR requires an additional transformation. Specifically, the headset tracks its location as the center of the user’s head, but the antenna is mounted on the front of the visor. This transform is essential since SAR relies on small changes in the RFID channel and therefore requires precise locations. This transform can be formulated as [55]:

$$\begin{aligned} W_{P^A} &= W_{R^H} \times H_{P^A} + W_{P^H} \\ W_{R^A} &= W_{R^H} \end{aligned} \quad (3)$$

where W_{P^A} and W_{R^A} are the position (x,y,z) and quaternion rotation of the antenna in the world frame W ; W_{P^H} , W_{R^H} are the position and quaternion rotation of the Hololens in the world frame. The x,y,z translation from the Hololens H to the antenna A is defined as H_{P^A} . The position and rotation of the Hololens are obtained from the vision-based AR self-tracking. We empirically measure the translation from the Hololens’s center to antenna (H_{P^A}) since this translation is fixed and results from mounting the antenna on the headset.

After applying the transformation, X-AR uses them as the antenna array locations. This allows it to then exploit wideband measurements as per Eq. 1 to opportunistically apply SAR along the user’s trajectory.

RFID Localization. Fig. 3 shows an example of X-AR’s RFID localization (shown in 2D for simplicity). Fig. 3a shows an overhead view of a user walking through the environment. RFID measurements are taken during the user’s trajectory, resulting in the measurement locations shown by the red stars. These measurements are then used to compute the power at each point in the workspace using Eq. 1 to estimate the tag’s location. Fig. 3b shows this power as a heatmap with yellow indicating areas of higher power and blue indicating areas of lower power. The tag’s location (red dot) overlaps with the area of highest power, showing that the localization was successful. While the above description focused on 2D localiza-

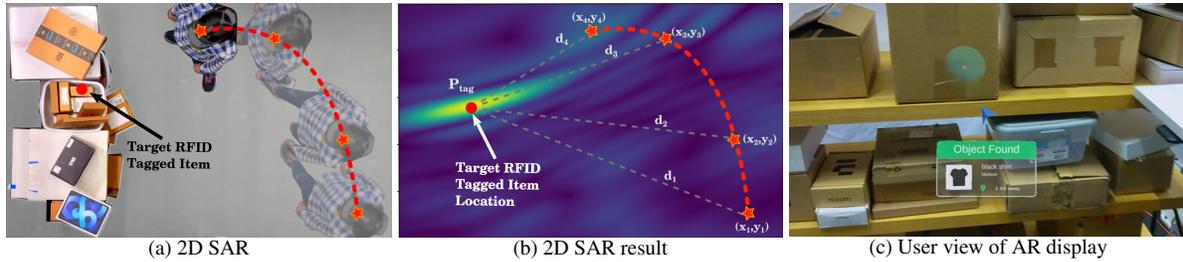

Figure 3: **AR-Based SAR.** (a) As the user moves naturally, X-AR collects RF measurements. (b) Using RF-Visual SAR, X-AR creates a heatmap of the RFID tag’s possible location. The target RFID location overlaps with the area of highest power (yellow), indicating a successful localization. (c) The user’s view from the Hololens application. The sphere shows the estimated tag location and the arrow points to it.

tion, the same method extends to 3D as per Eq. 2, enabling X-AR to localize items in 3D space.

Holographic Visualization. Once the item has been localized, X-AR leverages holographic visualization to display its location to the user and guide them towards it. To do this, X-AR leverages the transforms described in Eq.3 to compute the tag’s location in the world frame. Fig. 3c shows an example from the user’s perspective as displayed on the AR headset. In this example, X-AR places a spherical hologram around the estimated location, and a floating arrow appears in order to guide the user towards the localized tag for object retrieval. The arrow is programmed to float slightly above the user’s eye level at a fixed distance in front of them. For every frame update, the application queries the location and rotation of the user in the world space. It then computes their directionality to update the pointing vector of the arrow to properly guide the user towards the target object.

4.3 Practical Considerations

Standard wideband SAR systems typically design their antennas to have uniform gain across the entire frequency band. However, off-the-shelf UHF RFID tags are not designed to be wideband and therefore have significant variability in their antenna gain across frequency. In general, measurements with frequencies further from the tag’s resonant frequency (typically 900MHz) will be weaker and therefore more susceptible to noise. These weak measurements can introduce significant error in the location estimate. To overcome this, we introduce a weighted SAR formulation that biases the estimation towards confident measurements to improve the accuracy.

To do this, X-AR starts by quantifying its confidence in each of its measurements using the signal-to-noise ratio (SNR). For any wideband measurement with an average SNR below a certain threshold, X-AR is unlikely to be able to accurately estimate the RFID channel and it therefore removes the measurement from the SAR formulation entirely. The remaining measurements all contain useful information, however, as described above, certain frequencies in each wideband measurement may have weaker responses due to the tag’s frequency dependent response. To prioritize frequencies with stronger responses, X-AR applies an SNR-based weighting func-

tion to each frequency in a measurement.

This is formalized in the following equation:

$$P(x, y, z) = \left\| \sum_{j=1}^M \sum_{i=1}^N \begin{cases} w_{i,j} h_{i,j} e^{\frac{4\pi d_i}{\lambda_j}} & \overline{SNR}_i > \tau \\ 0 & \overline{SNR}_i < \tau \end{cases} \right\| \quad (4)$$

$$w_{i,j} = \frac{SNR_{i,j}}{\max_{k \in [1, M]} (SNR_{i,k})} \quad (5)$$

where $w_{i,j}$ is the weight for the i^{th} location and j^{th} frequency, and τ is the SNR threshold for removing poor measurements. $SNR_{i,j}$ is the SNR of the i^{th} location with the j^{th} frequency, and \overline{SNR}_i is the average SNR across all frequencies for the i^{th} location.²

A few additional points are worth noting:

- In practice, the self-localization frame rate is different from that of the RFID channel measurements. To overcome this, X-AR linearly interpolates between Hololens self-tracked locations to find the corresponding location of the mounted antenna for any given measurement.
- X-AR continues to collect measurements until it has become confident in the tag’s location. To determine its confidence, it finds all (x,y,z) locations whose power is within 0.75dB of the peak power.³ It then computes a bounding box around these locations. When this bounding box’s size falls below a threshold, X-AR declares the localization complete and visualizes the location.

5 RF-Visual Verification

So far, we explained how X-AR opportunistically leverages human motion to localize RFID-tagged target items and visualize them on the AR headset for retrieval. In principle, this visualization should be sufficient to indicate to the user to pick up the item within the holographic sphere shown in Fig. 3c. In practice, however, the user may still pick up an incorrect item. For example, multiple items may lie within the glowing sphere.⁴ Even if the user knows what they’re looking for (e.g., red shirt), there might be several items that are visually similar to each other or in similar packaging in the region. More generally, the picked item may be incorrect because the

²When computing $w_{i,j}$ in our implementation, we offset all of the SNR values and clip them at 0 to avoid negative weights.

³In practice, other thresholds are possible, but a looser threshold would reduce the confidence and hence the localization accuracy.

⁴The size of the sphere is determined by the confidence interval from RFID localization accuracy which is around 10-20 cm.

picker is prone to human error.

To ensure that the user has picked up the correct item, X-AR incorporates a mechanism for picking verification. We describe *RF-Visual Verification*, which enables an accurate and seamless verification of grasped items.

5.1 RF-Visual R-SAR

At the most basic level, the goal of X-AR’s RF-Visual verification primitive is to verify whether the correct item is *in* the user’s hand after they have picked up an object. Said differently, it aims to localize the RFID-tagged target item to within the user’s palm. At first blush, one might assume that such a capability is trivial given that X-AR already has a mechanism to localize RFIDs, as described in the previous section on RF-Visual SAR. However, the two localization problems are fundamentally different. Unlike the earlier scenario where the user’s walking emulates synthetic aperture, a user picking an item is in a relatively fixed location. Hence, one cannot leverage the user’s movements to localize the item.

To localize the item despite the user’s stationary position, X-AR leverages the RFID tag’s mobility instead. Fig. 4a shows a sample scenario, demonstrating how the tag itself traces an antenna array. X-AR leverages this emulated array in order to localize the AR-headset (more specifically, the antenna on the headset) with respect to the array. This formulation is the reverse of the SAR described in §4, where the RFID tag was stationary, and the AR conformal antenna on the headset was moving with the user. Notably, in §4, we could leverage the AR headset’s self-tracking capability to track the antenna locations. Here, we still need a mechanism to track the RFID locations in order to properly apply the antenna array equations.⁵ To track the RFID’s location as it moves, our idea is to leverage the *hand-tracking capability* of the AR headset. Specifically, AR headsets like the Microsoft HoloLens 2 can detect and track multiple feature points on a user’s hand, including their palm [8]. Thus, if the user picks up the correct RFID-tagged item, then the RFID traces a similar trajectory to the user’s palm as shown in Fig. 4a.

X-AR leverages the above observation and applies the antenna array equations on the hand’s trajectory in order to localize the headset. If the headset’s estimated location using this method coincides with the headset’s visual-inertial odometry-based location, that indicates that the target RFID tagged item was accurately retrieved and is indeed in the user’s hand. On the other hand, if the headset localization fails, the failure indicates that the target RFID tag is not in the user’s hand. Below, we formalize the above intuition by describing scenarios where the user picks the correct item and compare it to a scenario where the user picks an incorrect item.

⁵In principle, one could use ISAR [11]. It is less desirable than SAR because the former suffers from a larger direction location ambiguity.

(a) Scenario where the User Picks the Correct Item.

Fig. 4a shows an example where the target item is in the user’s hand. Here, the palm location (P_{palm}) and the tag location (P_{tag}) are similar. As the user’s hand moves, P_{palm} and P_{tag} change similarly together. As a result, the target tag’s location can be accurately approximated with the palm location over time for applying SAR and estimating the AR conformal antenna’s location according to the following equation:

$$P(x, y, z) = \left\| \sum_{j=1}^M \sum_{i=1}^{N_v} h_{ij} e^{\frac{4\pi d(t_i)}{\lambda_j}} \right\| \quad (6)$$

$$d(t_i) = |(x, y, z) - P_{\text{palm}}(t_i)| \quad (7)$$

$$(x_h, y_h, z_h) = \max_{x, y, z} P(x, y, z) \quad (8)$$

where N_v is the number of measurements, t_i is the time of i^{th} measurement, $d(t_i)$ represents the distance at time t_i from the (x, y, z) position to the user’s palm location, $P_{\text{palm}}(t_i)$. X-AR obtains $P_{\text{palm}}(t_i)$ through vision based hand tracking. The SAR estimated headset location, (x_h, y_h, z_h) , is the position that emanated the maximum power. Remember that when the user has the target item in their hand, $P_{\text{palm}}(t_i)$ is similar to the target RFID location at time t_i .

Fig. 4c shows the result of applying SAR to localize the headset in the form of a 2D heatmap from a side view. For simplicity, the result of antenna array projections is sliced in the plane that coincides with the real-world plane containing the user’s body and the RFID-tagged item. In this heatmap, yellow indicates higher probability of the headset location, while navy blue indicates low probability. As the figure shows, the location of highest power (the pink dot) is very close to the actual location of the headset antenna (the white star), indicating that the headset has been accurately localized.

(b) Scenario where the User Picks an Incorrect Item.

Next, consider a scenario where the user picks up an incorrect item, as shown in Fig. 4b. Here, the user’s palm location (P_{palm}) changes as the user’s hand moves, but the target RFID tag location (P_{tag}) does not change. In this case, when X-AR uses the user’s palm location to estimate the tag location for the SAR, it will fail to accurately locate the AR conformal antenna location.

Figure 4d shows the result of applying SAR in this scenario. Notice how the heatmap displays multiple high probability regions that are far from the actual headset location. In this case, the highest probability location (depicted by the pink dot) which corresponds to the SAR-based estimate of AR conformal antenna’s location is far from the actual location of the headset antenna (depicted by the white star). Thus, the SAR based headset localization fails because of large error. Since the headset knows its actual location (using the self-tracking via visual-inertial odometry as described in §4), it can determine that the reverse localization has failed, and use this information to determine that the target RFID tag is not

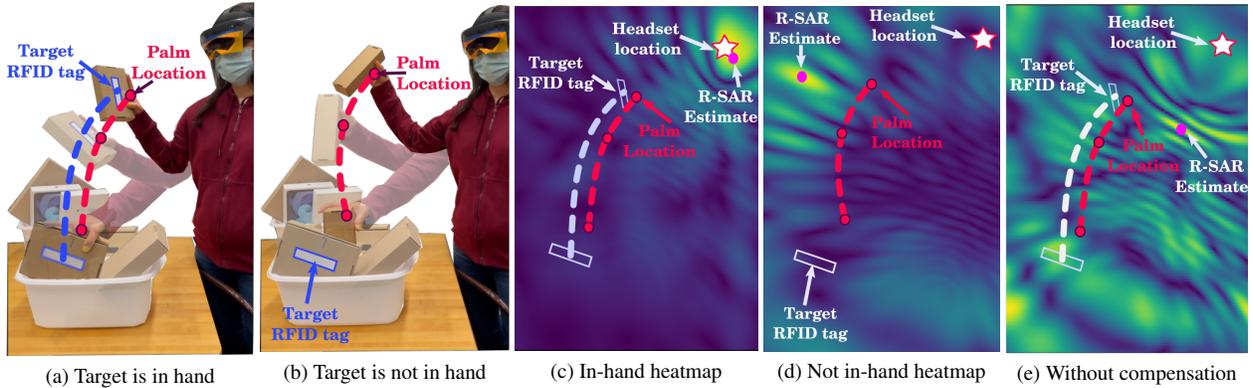

Figure 4: **RF-Visual In-Hand Verification.**(a) The RFID trajectory (blue dashed line) is similar to the palm trajectory (red dashed line) when it is in-hand. (b) The RFID’s location (blue rectangle) differs significantly from palms trajectory (red line) when not in-hand. (c) When the tag is in hand, RF-Visual R-SAR accurately estimates the headset location (pink dot) relative to the actual headset location (white star). (d) The R-SAR estimation of the headset location (pink dot) is not accurate when the tag is not in hand. (e) Without compensating for natural head movement, RF-Visual R-SAR cannot locate the headset accurately even when the target RFID is in the user’s hand.

in the user’s hand.

The criteria for declaring that the target tag is in the user’s hand is that the headset localization error should be within an acceptable range and can be formulated as follows:

$$\|(x_h, y_h, z_h) - (x_G, y_G, z_G)\| < \tau \quad (9)$$

where (x_G, y_G, z_G) is the headset’s location based on built-in odometry, and τ is threshold for localization error.⁶

5.2 Compensating for Natural Tilts

Our above description assumes that the user’s head is perfectly still as they are picking an item. In practice, a user’s head naturally tilts during picking, and its important to compensate for these tilts in the reverse SAR localization.⁷As a result of head movement throughout the retrieval process, the distance of user’s palm to headset’s initial location can be different from the actual distance from the user’s palm to the headset’s antenna location.

In Fig. 4a, we had shown the result of SAR after compensation. For comparison, Fig. 4e shows the result of applying SAR without compensating for the user’s natural head movements. Multiple high probability regions are visible in the heatmap showing that if the natural head movements are not accounted for, the SAR estimated head location may have a large error and the item in the user’s hand may be incorrectly classified.

To address this issue, X-AR tracks these natural head movements through the visual-inertial odometry and compensates for them in the RF-Visual SAR formulation. Specifically, X-AR translates the palm position from current headset coordinate to the initial headset coordinate. This can be formulated by replacing $d(t_i)$ in Eq. 6 with $\hat{d}(t_i)$ as follows:

$$\hat{d}(t_i) = \|(x, y, z) - (P_{palm}(t_i) - [P_{head}(0) - P_{head}(t_i)])\|$$

⁶In our implementation, τ is 0.3m. Note that the length of the AR-conformal antenna is 0.165m. We experimented with different τ ’s and found this achieves a good balance between precision and recall.

⁷Note that these tilts remain too subtle to perform SAR on the head movement itself, but are sufficiently large to make reverse SAR inaccurate if they are not accounted for.

where $P_{head}(t_i)$ is the visual-inertial odometry-based head location at time t_i . In this new formulation, $\hat{d}(t_i)$ represents the compensated distance from head’s initial position to the palm location at time t_i . The headset’s estimated initial location, $P_{head}(0)$, is the same as (x_G, y_G, z_G) in Eq. 9. X-AR uses the same criteria as Eq.9 for the headset’s initial location to determine if the target item is accurately retrieved by the user. In the system evaluation, we demonstrate how much this compensation is critical for RF-Visual Verification. We also note:

- X-AR can also use the camera visual data to determine if and when the user grasps an item by tracking her hands and fingers. It can use this information to trigger the RF-Visual verification module.
- The retrieval process often includes grasping and removing items to declutter the surroundings of the target item before the user actually grasp the target item. As a result, X-AR uses the latest received N_v RFID measurements⁸ at each point of time for the RF-Visual verification. When the latest N_v satisfy the Eq.9’s criteria, X-AR notifies the user that the target item is in her hand by showing text stating that target item is retrieved.

6 Implementation & Evaluation

Physical Setup: We implemented X-AR on a Microsoft HoloLens 2. We mounted our custom conformal antenna on the front visor of the AR headset and connected it to two Nuand BladeRF 2.0 Microsoft software radios [47]. Our device was tested using standard off-the-shelf UHF RFID tags [4](3-5 cent each). We tagged common items such as office supplies or clothes and placed them in boxes of different arrangements.

RFID Reader: To obtain wideband RFID channel measurements for localization, we implemented the EPC Gen 2 protocol [31] on a wideband RFID reader design similar to [17]. In order to transmit and receive signals from a single antenna, we introduced a CS-0.900 circulator to the reader. To cancel self-interference and extend

⁸In our implementation, N_v is 35.

the range, we implemented over-the-wire nulling through the BladeRF’s MIMO capability[47] and a ZAPD-2-21-3W-S+ 2-Way Pass DC Splitter. We connected the reader to a Raspberry Pi to collect and process RFID measurements from the software defined radios.

Software: We implemented the processing described in §4 and §5 on an edge server running Ubuntu 20.04 on an Intel(R) Core(TM) i9-10900X CPU @ 3.70GHz. The code is developed in Python and C++ and uses ROS [50] to enable multicore processing. We developed our own application for the HoloLens to stream device transforms and tracked hand locations to the edge server via TCP protocol and present the designed UI to the user. The application was developed in C# in Unity3D [56] and Visual Studio IDE [43]. On the Raspberry Pi, we implemented code in Python to stream the processed RFID channel estimates to the edge server.

Evaluation Environment: We evaluated X-AR in multipath-rich indoor settings that mimic warehouses, retail stockrooms, and dark stores, which are cluttered with boxes. Fig. 3c shows a sample evaluation environment. Across experimental trials, we changed the arrangement of stacked boxes, moving them near metal shelving and/or wooden bench tops. Since our evaluation setups were created in a lab, they were also surrounded by furniture including chairs, desks, and computers. These environments also had typical wireless interference from various technologies, as well as multipath interference from building occupants who walked around the environment while going about their daily activities. Across our experimental trials, a user wears the X-AR headset and walks around to find and pick up an RFID-tagged target item. To evaluate localization with various human trajectories, we asked users to walk in several different patterns. These patterns included walking towards the target object, in a diagonal path approaching the target, and in 2D “L” or “V” shaped trajectories with respect to the target. We tested objects of different sizes/shapes across both LOS and NLOS settings. In LOS, the tagged object was not occluded from the AR headset’s field of view. For NLOS settings, the RFID-tagged target was hidden inside a box or behind clutter. Across trials, we varied the target RFID-tagged object’s location to cover various potential scenarios.

Baselines. We implemented 2 state-of-the-art baselines: *SAR baseline:* Our first baseline is SAR-based localization algorithm (similar to [58, 65]). In this baseline, we used the AR-based VIO similar to X-AR to obtain antenna locations. However, we limited the localization to only frequencies within the UHF ISM band (around 22 MHz), and did not implement X-AR’s weighting optimizations as described in §4.3.

Time-of-Flight baseline: Our second baseline implements state-of-the-art time-of-flight(ToF) estimation us-

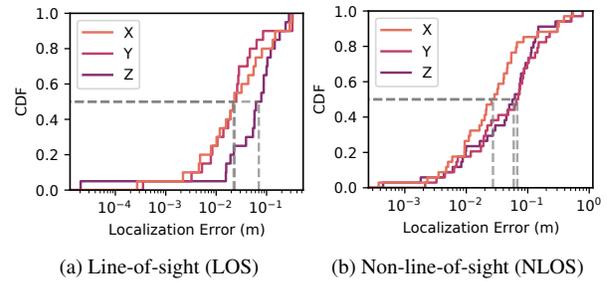

Figure 5: **3D Localization Accuracy.** CDF plots of X-AR’s RF-visual SAR localization accuracy in the x/y/z dimensions for LOS and NLOS.

ing wideband RFID measurements (similar to [40, 17]). For this baseline, we selected 6 measurements from the user’s trajectory (similar to [17], spaced evenly in time), computed the ToF-based distance estimates (using the algorithm from [40]), then performed robust trilateration to compute the final 3D location (as in [17]).

For fairness of comparison, in both baselines, we applied the same initial SNR filter as X-AR to remove low-confidence measurements.

Ground Truth: To measure the localization accuracy of our system, we used the AR headset’s built-in spatial awareness to determine the origin of the coordinate system in each trial. In each experimental trial, we aligned the tag’s location with the HoloLens’s origin. This was done by manually moving the RFID tag to the origin (displayed as a hologram by the AR advice) so that it aligns with the HoloLens origin at the beginning of each trial. Subsequently, the localization accuracy was computed as the difference between X-AR’s RFID tag estimated location and the HoloLens’ origin. This was repeated for each experimental trial.

7 Results

We ran 234 trials to evaluate the performance of X-AR.

7.1 3D Localization Accuracy

We first evaluated the accuracy of our system in localizing target RFID-tagged items in the environment. We define the localization error to be the euclidean distance between the system’s estimated location and the ground-truth location. We ran 54 experimental trials to measure the performance of RFID localization. In each trial, the user walked in a different motion pattern and X-AR automatically localized the target item via RF-visual SAR as described in §4.

Fig. 5 plots the CDF of the localization error across the experimental trials in both line-of-sight and non-line-of-sight scenarios. We plot the localization error along the x(orange), y(pink), and z(purple) dimensions. We note:

- In LOS settings, the median errors are 2.1 cm, 2.1 cm, and 8.4 cm along the x, y, and z dimensions, respectively. In NLOS settings, the median errors are 1.9 cm, 6 cm, and 7.7 cm along the x, y, and z dimensions, respectively. These results demonstrate that X-AR can achieve

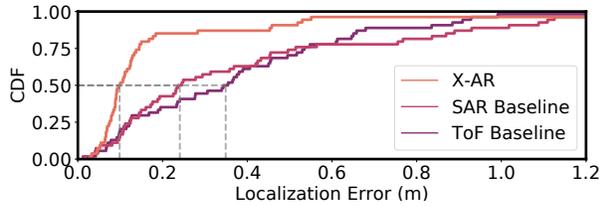

Figure 6: **Comparison to Baseline Localization Accuracy.** CDF plots of L2-norm error for X-AR (orange), SAR (pink), and ToF (purple).

centimeter-level localization accuracy in each dimension while opportunistically leveraging human motion that is not known a priori or directed in a particular way.

- The median L2 norm of localization error for the LOS and NLOS scenario are 9.6 cm and 10.6 cm. Therefore, there is no significant difference between localization error for NLOS and LOS, showing that X-AR’s is able to augment the AR device with perception capabilities for both LOS and NLOS conditions.

- The localization accuracy along the x-axis is generally better than along y and z (especially in the NLOS scenario). This is because in our experimental setup, the object is located on a shelf against a wall. The user walks toward the shelf but not past it, meaning the RFID measurements are only on one side of the RFID in the y direction. On the other hand, the user walks parallel to the shelf and measurements are taken on both sides of the RFID along the x-axis leading to a better accuracy in the x direction than in the y direction. Note that the aperture in z direction (vertical direction) is very small since the user’s head does not move vertically.

Baseline Comparison: We compare the performance of our system to the two baselines described in §6. We used the same experimental trials for X-AR and the baselines.

Fig. 6 plots the CDF of the total localization error for X-AR (orange), SAR Baseline (pink), and Time-of-Flight Baseline (purple). For simplicity, we show the L2-norm distance error (rather than the error along each of the x/y/z dimensions). We make the following remarks:

- For X-AR, the median and 90th percentile localization errors are 9.8 cm and 45 cm, respectively. These results are in-line with those reported above (as L2-norm in 3D).
- For SAR Baseline, the median and 90th percentile localization errors are 24.8 cm and 99.1 cm, respectively. This shows that by leveraging our system’s custom wideband antenna and wideband RF-visual SAR techniques, X-AR can achieve over 2× performance improvement in both the median, and 90th percentile over a system that is limited to the UHF ISM band, thus demonstrating the value of our customized wideband conformal antenna design and RF-visual SAR localization scheme.
- The Time-of-Flight baseline has a median and 90th percentile localization errors of 34.9 cm and 78.8 cm. This shows that X-AR has an improvement of over 3× in the median and almost 2× in the 90th percentile. We note

that the baseline’s performance is worse than that reported in prior work [40, 17]. This is because that prior work had control over the aperture of measurements (i.e., through physical antenna placement or controlling robotic motion). In contrast, when applying these techniques to an AR system with natural human motion, the aperture cannot be optimized and the resulting accuracy is poor. This demonstrates the benefit of our AR-based SAR techniques when utilizing natural human motion.

Impact of Walking Pattern: Next, we investigated the impact of different walking patterns on X-AR’s localization accuracy. Recall that we asked users to walk in different patterns: vertically toward the tag’s plane, diagonally toward the tag, as well as L-shaped and V-shaped trajectories. To understand the impact of different motion patterns on localization accuracy, we measured the 10th, median and 90th percentile for each of these patterns and reported them in Table 1. We note:

	Vertical	Diagonal	L-shape	V-shape
10 th percentile	5.7 cm	3.8 cm	7.9 cm	6.3 cm
50 th percentile	10.8 cm	12.5 cm	9.8 cm	8.4 cm
90 th percentile	47.7 cm	51.0 cm	14.9 cm	13.3 cm

Table 1: **Trajectory Impact.** Location error for different trajectories.

- All walking patterns have a similar median localization error, between 8.4 to 12.5 cm. This shows that X-AR works well in different motion patterns and is generally robust to different trajectories. It also suggests that X-AR does not need to constrain the user to a pre-defined 2D trajectory to achieve good localization performance.
- Interestingly, we noticed that 90th percentile accuracy is markedly different across these motion patterns. In particular, while the L-shaped and V-shaped patterns have a 90th percentile around 15 cm, this error increases to around 50 cm for linear motion patterns (diagonal & vertical). This is likely due to the differences in spatial diversity and aperture variability across these motion patterns. In particular, L-shaped and V-shaped trajectories involve independent mobility in two dimensions, while the diagonal and vertical trajectories involve mostly linear motion patterns, giving less overall aperture.

Impact of Aperture. We investigated the impact of the trajectory’s aperture size on localization accuracy through a micro-benchmark evaluation. To do this, rather than providing the RF-visual SAR algorithm with the entire trajectory for localization, we trimmed the trajectory of each trial to a certain maximum aperture. For example, to evaluate an aperture of 0.6 m, we only provided the first 0.6 m of the user’s trajectory to the localization algorithm.⁹ We repeated the same process for apertures of different lengths, and computed the localization accuracy for each of them across all the experimental trials.

⁹The aperture of a trajectory is defined by the diagonal of the bounding box encompassing the measurements in that trajectory.

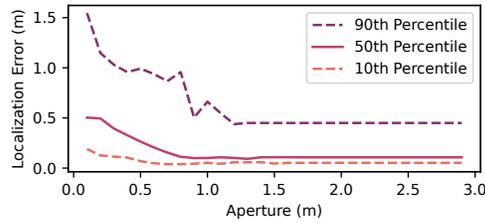

Figure 7: Impact of Aperture. Localization error vs the aperture of the user’s trajectory. The plots show the 10th, 50th, and 90th percentiles.

Fig. 7 plots the L2-norm localization error as a function of the aperture. The plot shows the 10th (orange), 50th (pink), and 90th (purple) percentile errors across all experimental trials. We make the following remarks:

- When limiting the aperture to 0.1 m, the 50th and 90th percentile errors are 0.5 m and 1.5 m respectively. As the aperture increases to 0.8 m, these errors drop to 0.11 m and 0.96 m. This shows that for small apertures, X-AR’s performance greatly improves as the user walks further.
- After the aperture reaches 0.8 m, the median errors become relatively constant. For example, expanding the aperture to 1.2 m only decreases the median error by 2 cm. This shows that increasing aperture after 0.8 m does not improve the median localization accuracy.
- The 90th percentile continues to improve as the aperture is increased from 0.8 m to 1.2 m, dropping by 0.43 m. This shows that larger apertures improve reliability.
- X-AR visualizes the RFID tag on the AR device once the user’s walking trajectory allows for adequate RF measurement aperture, such that X-AR is confident about the RFID tag’s location, as described in §4.3. As a result, the time it takes X-AR to find the requested item is dependent on the user’s walking speed and trajectory.

Impact of SNR-based Weighting Function. We investigated how weighting measurements based on the received SNR impacts the localization accuracy of X-AR. We processed the experiments with SNR-based weighting (Eq.4) and with uniform weighting (Eq.1) and calculated the L2 norm of RFID localization error. Our results showed that the SNR-based weighting improves the robustness of the system, specifically in the 90th percentile localization accuracy. While the uniform weighting and SNR-based weighting have a similar median errors (around 10 cm), the 90th percentile in our SNR-based weighting approach is 45 cm, while the uniform weighting approach has 71 cm error.

7.2 In-Hand Verification

Next, we evaluated X-AR’s ability to successfully determine if the correct RFID tagged object was retrieved by the user. We conducted 180 trials in total. In each trial, the user grasped a tagged or non-tagged item and moved their hand in a pick and place motion. In each trial, X-AR predicted whether the RFID tag was in the user’s hand or not, (i.e., the correct item being picked or not). We define a successful trial as one in which X-AR correctly

	Precision	Recall	F-score
Extracting RFID-tagged item (LOS)	98%	100%	98.9%
(without compensation)	98%	98%	98%
Picking boxed RFID-tagged item (NLOS)	100%	85.1%	91.9%
(without compensation)	100%	74.3%	85%
Large Object (LOS+NLOS)	100%	87.5%	93%
Small Object (LOS+NLOS)	98%	93%	95.4%

Table 2: **In-hand Verification Accuracy.** The table reports the results for in-hand verification across different evaluation scenarios. The results are reported as percentages for precision, recall, and F-measure.

determines whether or not the tag was in the user’s hand.

Table 2 reports the results for X-AR’s in-hand verification algorithm. Here, *Precision* indicates the number of trials where the target item was correctly classified in-hand divided by the overall number of trials that systems classified the target item as in-hand. *Recall* indicates the number of trials where target item was correctly classified in-hand divided by the overall number of trials where the target RFID tagged item was actually in the user’s hand. We make the following remarks:

- X-AR achieves a 98% precision rate, and 100% recall rate. These values demonstrate that when the user retrieves an item, X-AR can reliably and correctly predict whether the target item has been picked up.
- The system has 98% precision rate, which indicates 2% of the trials when the system registered it as a potential retrieval, the user has picked up an incorrect item (e.g., non-tagged item, or potentially an item that is tagged with a different RFID). We suspect the reason for some trials being mistakenly registered as positive arises from multipath. Specifically, even though the user did not pick up the target RFID-tagged item in these trials, the wireless signal reflecting off the user’s hand during motion creates an array of the multipath reflections. Such multipath arrays may have inadvertently allowed localizing the headset, resulting in false positives.

Picking Boxed RFID-tagged items (NLOS): We also evaluated whether X-AR can accurately verify when a user picks up an RFID-tagged item that remains *inside* a box during the picking process. While such scenarios are less likely in practice (e.g., in warehousing or retail), they may arise and serve to test the limit of our system in performing RF-visual verification of RFIDs in NLOS.

The results for this experiment are shown in the third row in Table 2. The results show that even though the recall rate drops, X-AR remains largely successful in performing the verification, achieving a precision and recall rate of 100% and 85.1%. This change in performance can be attributed to the fact that when target tags are not in line-of-sight (and are inside a box) their distance to the user’s palm is markedly higher. This offset between the tag location and visually extracted palm location impacts the reverse SAR calculation. In the future, this may

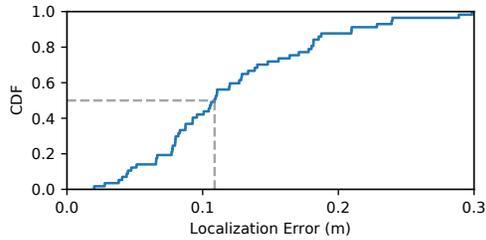

Figure 8: **CDF of Reverse SAR.** CDF plots of the headset’s localization accuracy by applying R-SAR on the trajectory of the target item.

be compensated for by estimating the potential location of the RFID inside the box and/or investigating different features from the AR headset’s built-in hand-tracking.

Impact of Motion Compensation: Recall from §5 that X-AR’s RF-visual verification primitive compensates for head tilts in the reverse SAR localization process. To investigate the impact of such compensation, we processed the same experimental trials as above (for both LOS and NLOS scenarios) without performing motion compensation and reported the results in Table 2. The table shows that the recall rate drops for both LOS (from 100% to 98%) and NLOS scenarios (from 85.1% to 74.3%). This demonstrates that by accounting for head tilts, X-AR’s accuracy in prediction markedly improves.

Impact of Target Object Size: Next, we investigated the impact of target object size on the verification accuracy. Specifically, we divided our experimental trials between objects of smaller and larger sizes. The object size was determined by their longest dimension, using 10 cm as a divider between objects that we referred to as small and large - i.e, objects with largest dimension < 10 cm classified as small, and those with a dimension >10 cm classified as large. In practice, choosing a different threshold does not make a significant difference, as the primary goal of this experiment was to micro-benchmark the impact of object size on verification accuracy.

The last two rows of Table 2 show the results comparing the accuracy for different object sizes, covering both LOS and NLOS scenarios. The table shows that smaller items have higher recall rate (93%) than larger items (87.5%). This can be attributed to the fact that for larger items, there is a larger offset between the tag location and palm location. Specifically, recall from §5 that X-AR approximates an RFID’s location as the user’s palm location (extracted from the AR-headset’s hand-tracking module). As a result, the smaller the object is, the more accurate this approximation is, leading to higher accuracy for smaller objects. In the future, it would be interesting to explore mechanisms that adapt the threshold to the object size, or alternatively leverage the RFID location inside the box and apply a transformation to the user’s palm to compensate for these differences and achieve higher accuracy for larger objects.

Reverse SAR Localization Accuracy. Our final result looks into the reverse SAR localization accuracy. Re-

call from §5 that X-AR’s verification component relies on the ability to correctly localize the headset (specifically the AR-conformal antenna) by applying SAR on the mobile tag. To investigate this primitive, we evaluated the method’s ability to correctly locate the position of the user’s head. Here, we defined the ground truth of the location of the user’s head to be the visual-inertial odometry-based location and estimated the error by calculating the euclidean distance between the ground truth and X-AR’s predicted location. We computed the localization error for all scenarios where the user picks up an RFID tagged item.¹⁰ Here, we included experimental trials from LOS scenarios described above.

The CDF of the localization error is plotted in Fig. 8. The figure shows that the method allows localizing the headset using SAR with a median accuracy of 11 cm and a 90th percentile accuracy of 19.6 cm. These results show that even with simple pick and place movements, X-AR can accurately locate a user’s head using reverse SAR techniques, while compensating for head movements. This high localization accuracy is why the system can accurately verify picking RFID-tagged items.

8 Related Work

RFID Localization. RFID localization is a well-studied problem in the networking community with researchers exploring various techniques including received signal strength (RSS) [20, 46], angle of arrival (AOA) [13, 36, 71], and wide-band sensing [40, 16, 39]. The closest to X-AR is past work that leverages motion for RFID localization, which falls in two main categories. The first places an antenna on robots that move along *predefined* trajectories and leverage these trajectories to localize the tags [57, 29, 45, 53, 17, 16, 44, 70, 14]. Our system does not require users to move along specific (unnatural/robotic) trajectories, yet can still localize accurately by leveraging natural movement. The second category tracks RFIDs that are already in motion, e.g., for gesture recognition [59, 65, 21, 66]. Our work differs from these in that it can also localize stationary tags by using an AR mounted antenna. Thus, our work is the first to bring fine-grained RFID localization to AR headsets, addressing challenges that span antenna design, natural human mobility, and various localization artifacts.

Augmented Reality. Augmented Reality (AR) refers to systems that overlay a virtual world on top of the physical world to enable new experiences and interactions [12, 35]. Most prior work that leverages RF in AR systems does not involve headsets altogether and simply visualizes tagged items on a screen or a smartphone [49, 37, 62, 63]. This includes past work that

¹⁰Note that the error for non-tagged items is much higher since the formulation does not hold. Empirically, the median localization error for those scenarios is over a meter.

deploys an RFID localization infrastructure in the environment and uses it to localize tags and visualize their locations on a screen [49, 37]. It also includes robotic systems mounted with RFID readers and cameras to scan the environment and send the result for visualization on a screen [62, 63]. X-AR builds on this area and brings RFID localization to AR headsets, addressing the associated challenges in antenna design, human mobility, and headset-based localization. X-AR is also related to past work that involves users wearing RFID readers on their hands or in their backpacks to detect objects in the environment [69, 54] or self-localize [64, 37]. X-AR differs from these systems in directly integrating the localization and sensor fusion into the headset itself, resulting in a more natural and seamless AR experience.

Conformal Antennas. Antenna design is a mature field that targets satisfying multiple requirements such as compactness, robustness to flexing, radiation pattern, and weight. The closest to our work are Bluetooth headset antennas designed to radiate outwards while close to a human head, and designed to be mounted around the ear or on glasses handles [23, 22, 34, 33]. These past designs differ from our work in their bandwidth requirements, desired radiation pattern, and form factor. Other wearable antennas were designed for safety helmets [24] or smart glasses [60], but were either too bulky and obstructive or lacking the wideband operation desired for wideband RFID localization. Loop antennas are simple, and do not require a ground plane, but are inherently narrowband. Past techniques such as tapering and slots help improve their bandwidth, but none of the existing wideband loop antenna designs can simultaneously operate at the desired frequency range while matching the dimensions of the visor [68, 61, 67]. Our proposed design takes advantage of wideband antenna techniques to deliver a broadband, compact, and conformal loop antenna that perfectly fits on the headset's visor without covering the cameras or blocking the user's view.

9 Discussion and Limitations

Antenna Placement: In principle, one could design alternate versions of our X-AR system by placing the antenna on top of the headset, on the user's shoulder, or even in the user's hand. However, these alternative approaches are suboptimal in most scenarios compared to X-AR's design. For example, in warehouses, pickers are more efficient when they can use both hands (rather than carrying an antenna with one hand all the time). Similarly, mounting large and heavy antennas on their shoulders or heads would create undesirable additional weight which may impact their balance. That said, it is possible that such alternate implementations may be useful in certain use-cases and can be explored as the research evolves.

Transmission Power: X-AR's transmit power is lower

than that of existing wrist-worn RFID readers [10] since bladeRF software-defined radios transmit less than 8dBm. This is also lower than the power transmitted by Apple AirMax headphones, which use Bluetooth 5.0 technology and have a maximum transmission power of 20 dBm [1, 2]. In production systems, X-AR could leverage a deployed RFID reader infrastructure to power RFID tags in the environment, and an X-AR headset for wideband measurements for localization, UI, etc.

RFID reliability: Our implementation of X-AR inherits the typical limitations of RF/RFID signals. For example, it cannot detect or localize items inside closed metallic boxes. However, it can still read RFIDs on metal or liquid bottles if proper tags are used. Moreover, due to its wideband sensing capabilities, it can work in multipath-rich environments, including those with metal shelving, as demonstrated in our evaluation.

Form factor: As X-AR moves closer to commercial deployments, we envision that the entire RF sensing hardware can be integrated into the headset. In particular, while our proof-of-concept prototype was implemented using software radios and a Raspberry Pi, future versions may be designed in form factors similar to existing RFID reader chips (e.g., Lepton3 [18] that are around 1"x1"x0.1"), thus small enough to fit into AR headsets.

Range: The operation range of X-AR is approximately 3-4 meters which is similar to mobile (portable) handheld RFID readers on the market [3]. While this range is lower than stationary readers (which can reach around 10 m), that is primarily because stationary ones typically transmit much higher power. In contrast, handheld readers usually transmit lower power to conserve their battery life, and we envision the same would be desired for future readers integrated in headsets like X-AR.

10 Conclusion

The past few years have witnessed remarkable advances in augmented reality and its metaverse applications. Motivated by these advances, this paper brings a new sensing modality to AR systems through networked RF sensing, giving them the ability to perceive what used to be invisible to the human eye and to existing AR headsets. In doing so, the paper opens the door to more exciting capabilities and applications at the intersection of RF sensing and AR systems. As the research evolves it would be interesting to explore how various networked wireless sensing modalities and sensor fusion techniques - spanning RFID, WiFi, mmWave, and THz - can further augment augmented reality and open new possibilities in visualization and interaction.

Appendix

Simulated and Measured Antenna Performance

Fig. 9 shows the simulated radiation pattern of the antenna mounted in this figure on the Hololens for visualization, demonstrating that the pattern is almost omnidirectional (with a directivity of 4 dB), allowing the RF sensing module to localize items in the surrounding 3D environment. The fabricated conformal antenna was then placed on the headset and worn by the user to measure the gain across frequencies and elevation angles. The user was tilting their head up and down to mimic a scenario where they are looking for an item in the environment. The measured gains demonstrate the ability of the antenna to operate efficiently across a wide range of frequencies and elevation angles.

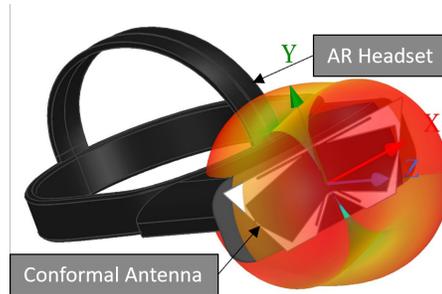

Figure 9: **Conformal antenna 3D radiation pattern.** Simulated radiation pattern of AR-conformal antenna visualized on the AR headset.

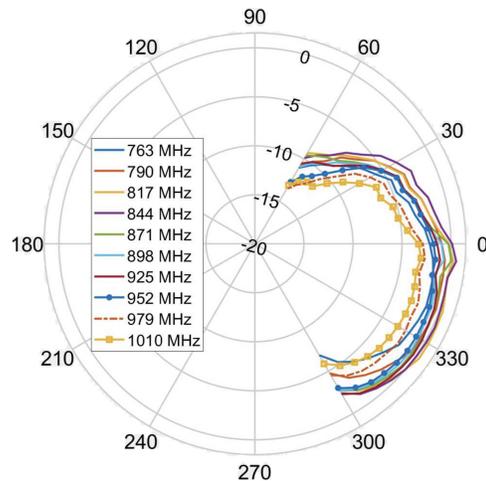

Figure 10: **Conformal antenna measured gains.** Measured gains across different elevations of AR-conformal antenna when mounted on the headset and worn by the user. The user was tilting their head up and down to cover the elevation plane.

Background on SAR

Performing RFID localization using SAR involves 3 steps:

1. The first step is to compute the RFID’s channel at each measurement location. As an RFID reader queries different tags in the environment, it can compute the wireless channel h for each of these tags by leveraging the received signal $s(t)$ and the tag’s known packet preamble $p(t)$ using the following equation [40]:

$$h = \sum_t s(t)p^*(t) \quad (10)$$

where $p^*(t)$ is the conjugate of $p(t)$.

2. Given the wireless channel from different antenna locations, the second step is to estimate the power arriving from each (x,y,z) location within the workspace. This can be done with the following equations:

$$P(x, y, z) = \left\| \frac{1}{N} \sum_{i=1}^N h_i e^{\frac{4\pi d_i(x,y,z)}{\lambda}} \right\|^2 \quad (11)$$

$$d_i(x, y, z) = \sqrt{(x - x_i)^2 + (y - y_i)^2 + (z - z_i)^2} \quad (12)$$

where $P(x, y, z)$ is the estimated received power, N is the number of measurements taken, h_i is the i^{th} channel estimate, and λ is the wavelength of the used signal.¹¹ (x_i, y_i, z_i) is the location of the i^{th} measurement, and d_i is the distance from (x_i, y_i, z_i) to (x, y, z) .

3. The third step is to localize the tag by assigning its location to the (x, y, z) location with the highest power. Formally, the location of the tag, p_{tag} , is:

$$p_{tag} = \operatorname{argmax}_{(x,y,z)}(P(x, y, z)) \quad (13)$$

Finally, past work has shown that including frequency diversity (i.e., wideband measurements) in addition to SAR's spatial diversity can improve the localization accuracy. To do this, wideband SAR takes measurement across a wide range of distinct frequencies and coherently combines the measurements for each frequency and each location. Formally:

$$P(x, y, z) = \left\| \frac{1}{M} \frac{1}{N} \sum_{j=1}^M \sum_{i=1}^N h_{i,j} e^{\frac{4\pi d_i(x,y,z)}{\lambda_j}} \right\| \quad (14)$$

where M is the number of frequencies used, $h_{i,j}$ is the channel measurement of the i^{th} location with the j^{th} frequency, and λ_j is the wavelength of j^{th} frequency.

Impact of Headset Self-Tracking Error

As mentioned before, X-AR uses the headset's built-in self-tracking to enable AR-based SAR and localize RFID tags in the environment. One important question is whether the accuracy of the Microsoft Hololens' self-tracking is sufficient to support SAR and accurate RFID localization, especially over a random human walking trajectory. Prior reports have evaluated the accuracy of Hololens self-tracking [38] showing an average error of 0.56 cm.

To investigate the impact of self-tracking error, we simulated X-AR's SAR-based RFID localization and added an average of 0.56cm self-tracking error into our simulation. We compared this to a simulation of SAR with an ideal self-tracking system (i.e., 0 cm self tracking error). Fig. 11 plots a CDF of the L2 norm of the simulated localization error for a headset with ideal tracking (orange) and for a headset with simulated self-tracking error (purple). We make the following remarks:

- When simulating the Hololens with self-tracking error, X-AR is able to achieve a median of 8.1 cm. This high accuracy demonstrates that the self-tracking accuracy of the Hololens is sufficient for SAR-based localization.
- The simulated localization accuracy is close to the empirical evaluation (9.8 cm in §7.1).

¹¹Note that the exponent contains an extra multiple of 2, since the signal travels $2d_i$ from the antenna to the tag and back to the antenna.

- When simulating an ideal headset (with no tracking error), the median localization error is 2.7 cm. This implies that as the AR headset self-tracking technology evolves, the performance of X-AR in localizing RFID tagged target items will further improve (albeit, it's not clear whether 2.7cm would yield meaningful UI/UX improvements for our use-cases on top of the 8.1cm accuracy).

Abstract

Acoustic sensing is increasingly popular owing to widely available devices that support them. Yet the sensing resolution and range are still limited due to limited bandwidth and sharp decay in the signal at inaudible frequencies. Inspired by recent development in acoustic metasurfaces, in this paper, we first perform an in-depth study of acoustic metasurface (AMS) and compare it with the phased array speaker. Our results show that AMS is attractive as it achieves a significant SNR increase while maintaining a compact size. A major limitation of existing AMS is its static configuration. Since our target may be at any possible location, it is important to support scanning in different directions. We develop a novel acoustic system that leverages a metasurface and a small number of speakers. We jointly optimize the configuration of metasurface and transmission signals from the speakers to achieve low-cost dynamic steering. Using a prototype implementation and extensive evaluation, we demonstrate its effectiveness in improving SNR, acoustic sensing accuracy, and acoustic communication reliability over a wide range of scenarios.

1 Introduction

Motivation: Acoustic sensing and communication are becoming increasingly popular due to widely available devices that support it, including smartphones, smart speakers, and many IoT devices. Many interesting sensing systems have been proposed using acoustic signals (e.g., [15, 25, 35–39, 42, 51, 57, 65]). For example, [35, 36, 42, 51, 57, 65] develop smartphone based approaches that transmit inaudible acoustic signals to track a target’s distance, position, and movement. [38, 52] enables more accurate sensing by exploiting a microphone array on a smart speaker. [11] develops acoustic communication systems as an NFC alternative, [9] designs an underwater messaging system using acoustic signals

since acoustic signals attenuate slower than RF signals. Refer to [5, 12] for more comprehensive surveys on the underwater acoustic communication systems. Despite significant advances in acoustic sensing, there is a fundamental limit on its sensing range and resolution as shown in the Cramer-Rao bound, which indicates the sensing resolution is limited by SNR and the number of transmitters and receivers. Similarly, acoustic communication also faces similar challenges according to the Shannon capacity.

In order to further improve the performance, one could increase the number of transceivers. However, increasing the number of transceivers increases the cost, size, and energy consumption. In addition, existing sound cards cannot support more than 8 channels. All of these factors significantly limit their applicability in a real-world deployment.

Another option is to adopt an acoustic lens (or acoustic metasurface, AMS). Like optical lenses, acoustic lenses can steer the direction of acoustic wave propagation and focus in a certain region. However, an acoustic metasurface is usually bulky due to the large wavelength of acoustic waves. Recently there emerged some metasurface quantization designs (e.g., [40, 41]). They comprise many sub-wavelength cells, where each cell can act like a mini-antenna and modify the phase and/or intensity of the incident wave so that collectively the AMS can manipulate the wave in an interesting way (e.g., steer the outgoing wave towards a certain direction).

Our approach: Inspired by the potential benefit of AMS, we first compare a passive AMS with beamforming using multiple speakers. We find beamforming using 3 and 6 speakers increases SNR by 4.7dB and 7.9dB, respectively. In comparison, an acoustic metasurface of size 16×16 cells under 1 speaker increases SNR by 15.5dB. The results suggest AMS is attractive since it can significantly increase the SNR using a compact design without consuming power. To achieve a similar SNR increase, we need 36 speakers spanning 30cm, which is bulky and challenging to deploy.

While passive AMS is attractive, the existing AMS can support only static configuration (e.g., always beamform towards

Yongzhao Zhang, Yezhou Wang, Lanqing Yang, Yihong Liu did this work as interns at Microsoft Research Asia and Yi-Chao Chen did this work as a visiting researcher at Microsoft Research Asia.

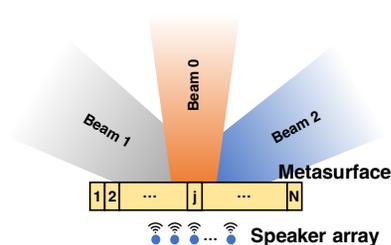

Figure 1: Dynamic beam steering with speaker array and acoustic metasurface (AMS).

a fixed angle). Since the target can be at any location, dynamic beam steering is necessary. One option is through the mechanical movement of the AMS, which not only increases the cost but also limits the speed of adaptation. In this paper, we propose combining beamforming using a small number of speakers with AMS, as shown in Figure 1, to achieve the best of both worlds: the use of AMS allows us to keep the number of speakers low while still achieving sharp beam, large SNR gain, and high resolution; the use of beamforming even using very few speakers can enable dynamic steering without movement. A small number of speakers with a passive AMS can achieve similar beamforming resolution as a large number of speakers. For example, our evaluation shows using an AMS with 16×16 cells and a 6-speaker phased array is comparable to a $9 \times 16 = 144$ phased array in terms of beam width.

To this end, we develop a novel algorithm to jointly optimize the AMS configuration and beamforming weights for the phase array. Specifically, the joint AMS and beamforming design can be formulated as an optimization problem whose objective is to maximize the signal strength along each of the desired angles (e.g., sampled from a range of angles) and minimize the performance variance across these angles and energy in the side lobes. We use the gradient projection method to solve the optimization problem. In addition, we augment our optimization framework to further optimize the speakers' placement and improve the performance.

Based on our designed algorithm, we implement an acoustic system that comprises a 3D-printed AMS, 6 speakers, and a microphone. We apply our algorithm to steer the outgoing beam in real time. We evaluate our design using (i) SNR of the received signal, (ii) sensing performance (i.e., distance estimation using Frequency Modulated continuous Waves (FMCW) and angle estimation using the MULTiple SIGNAL Classification (MUSIC) algorithm), and (iii) the communication error.

Our contributions can be summarized as follow:

- Using extensive evaluation and analysis, we shed light on the benefits of phased array versus AMS.
- We jointly optimize AMS and phased array configurations to enable dynamic beam steering and high SNR.
- We further improve the performance by optimizing the speaker placement.

- We develop an acoustic system based on our joint design of AMS and beamforming and apply it to acoustic sensing and communication. Our evaluation shows our system yields a significant improvement in SNR, distance estimation, angle estimation, and communication reliability. In particular, leveraging AMS and phased array allows us to dynamically steer the beam to the desired direction and boost SNR by 18.4dB over a single speaker without AMS. The improved SNR in turn increases the acoustic sensing and communication ranges. Our approach increases the sensing range from 1.5m in a single speaker without AMS to 4m using 6-speaker with AMS; similarly, it increases the communication range from 0.8m to 3.9m.

Paper outline: We review existing work in Section 2, and introduce acoustic metasurface in Section 3. We describe our algorithm to jointly optimize AMS and speaker array system in Section 4. We present our simulation and testbed experiment results in Section 5. We discuss the limitation and future work in Section 6. We conclude in Section 7.

2 Related Work

Our work is closely related to wireless sensing, acoustic communication, acoustic metasurface, and phased array.

Wireless sensing: Wireless sensing has become increasingly popular due to many important applications. Many algorithms and systems have been developed recently using acoustic [15, 25, 30, 35, 42, 45, 51, 57, 64, 65, 67], WiFi (e.g., [21, 47, 50]), mmWave (e.g., [20, 58, 61]), and RFID signals (e.g., [17, 34, 53–55]).

Among them, acoustic sensing is appealing due to its high accuracy and widely available commodity devices that support it. They use time of flight (e.g., BeepBeep [45]), Doppler shift (e.g., AAMouse [64]), FMCW (e.g., [35, 42]), phase (e.g., [57]), correlation (e.g., [43]), channel impulse response (e.g., Strata [65]), and Angle of Arrival (AoA) (e.g., [38, 49, 56]) for sensing. Some works also leverage machine learning for acoustic sensing (e.g., by applying neural networks to either post-processed signals or raw signals) and show ML based sensing is promising.

There are also significant works on sensing using RF signals. Some leverage similar algorithms as in acoustic sensing, while others explore new features and algorithms. For example, [33] use Channel State Information (CSI). Tagyro [59] tracks rotation using an array of passive RFID tags and two orthogonal RFID reader antennas. [46] further exploits polarization to track rotation and translation movement. [22] pushes the tracking accuracy to sub-centimeter level using a large phased array and large bandwidth.

Acoustic Communication: Sound has been a popular way of communicating information. Interestingly, we can also encode and transmit digital data over the acoustic channel. At a high level, it is essentially the same as RF communication but uses a different frequency. A number of interesting systems have been developed for acoustic digital communication (e.g., [11, 23, 66]) as an alternative to Near Field Communication (NFC) owing to the wide availability of speakers and microphones that support acoustic communication. Many of them leverage OFDM due to its robustness to multipath fading. Therefore, we also adopt the OFDM based acoustic communication in our work.

Acoustic metasurface: Ultimately, the accuracy of acoustic sensing depends on the SNR and numbers of speakers and microphones. Acoustic metasurface can boost SNR using a passive 2D structure, which can help improve sensing performance. A metasurface has many unit cells, and each cell can be potentially treated as a mini sound source. In this way, AMS effectively increases the number of speakers, thereby improving sensing resolution. By controlling the phase and/or amplitude of acoustic wave propagation through each unit cell, AMS can manipulate the wave fields. Many designs of acoustic metasurface have been proposed in the literature [6, 32]. Coiling-up space structure [27–29, 40, 41, 60] achieves phase manipulation by forcing acoustic waves to propagate along a coiled path. Helmholtz-resonator-like structure [13, 26] produces a tunable phase velocity and a high transmission efficiency with multiple Helmholtz resonators. Membrane-type structure [14, 19, 44, 62, 63] eliminates reflection with carefully designed membrane resonators. The above designs are not reconfigurable. There are active acoustic metasurfaces [10, 18, 24], as well. They use mechanical structure or emerging materials that can be deformed under the control of a magnetic field or electric current. However, these designs are expensive and bulky to implement.

Our work is inspired by [40, 41]. [40] develops a powerful methodology that assembles many sub-wavelength pre-manufactured 3D units into an acoustic metasurface. Each unit encodes a specific phase offset. By re-arranging these units, one can produce many different metasurfaces. Since acoustic sensing/communication usually use inaudible sounds with much smaller wavelength to avoid disturbance, the coiling-up metasurface is more compact than Helmholtz-resonator and membrane-type structure. [41] discusses several applications of these metasurfaces, including generating acoustic collimator, acoustic magnifying glasses, and acoustic telescopes. Our work goes beyond [40, 41] by enabling dynamic steering through combining multiple speakers with AMS and applying it to acoustic sensing and digital communication.

[16] proposes using 3D-printed metamaterial to cover the microphone and embed the direction-based signature. During the calibration stage, recordings from all possible angles are

collected. During the online usage, the current recording is compared with all recordings collected in the calibration to find the best match, which is used for AoA estimation. [7] develops an acoustic sensing system that uses 3D printed smart surface to embed direction information into the signals for generating a depth map. Our work is related to the above work but goes beyond them by (i) eliminating labor-intensive calibration and (ii) directly increasing SNR and sensing resolution, which can benefit any sensing or communication approaches instead of tailing to one specific sensing scheme. Therefore our design is more general and support more applications. Moreover, our optimization framework for configuring AMS and a speaker array is flexible and can support a range of important what-if analyses. Our adoption of a regular shaped AMS also makes it easier to analyze and optimize its impact on the overall system performance.

Phased array: Multiple transmitters and/or multiple receivers can be used to strengthen the received signals. At the transmitter end, beamforming can be used to generate transmissions that arrive in phase at the receiver so that the multipath signals are added up constructively. At the receiver end, the receiver can compensate for the phase difference of the received signals across different antennas to ensure constructive combining. As mentioned earlier, in order to achieve a comparable gain of AMS, a large phased array is necessary, which increases the size, cost, computation, and power. This motivates our design of AMS based sensing and communication system.

3 Acoustic Metasurface

In this section, We provide background on acoustic metasurface and its properties.

3.1 Background of Acoustic Metasurface

The ability to shape acoustic fields has diverse applications, such as high-quality sound production, particle manipulation, non-invasive therapies, and increasing sensing and communication range and resolution. One way to shape the acoustic fields is to use phased arrays by controlling the phase and amplitude of the transmission signals emitted from each of the speakers. The cost, power consumption, and size of a phased array rapidly increase with the number of speakers.

A few recent research papers show that acoustic metasurfaces could be a promising solution. An acoustic metasurface is a 2D structure that consists of many sub-wavelength cells [40, 41]. By carefully designing each of its cells, we can manipulate acoustic waves in an interesting way. Each unit cell can be viewed as a mini sound source. To perform beamforming in a certain direction, we can ensure the paths going through different cells in the metasurface add up constructively in the desired direction. This can be achieved by

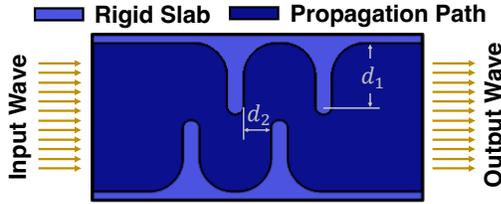

Figure 2: The structure of a unit cell is mainly determined by the parameters d_1 and d_2 . Different lengths of the propagation paths induce different phase delay at the output.

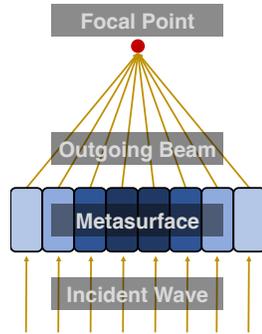

Figure 3: A metasurface consists of multiple unit cells and beamforms towards a focal point by properly configuring the unit cells.

letting each unit cell compensate for the phase difference. For example, without special design, in the desired direction, the path going through cell 1 differs from cell 2 by $\phi_{1,2}$. To ensure the signals from these two paths add up constructively, we can design the unit cell 1 and cell 2 to compensate phase difference $\phi_{1,2}$. One way to achieve this is to impose different geometric structure so that the path going through cell 2 is $\frac{\phi_{1,2}}{2\pi} \lambda$ longer than cell 1.

Figure 2 shows an example structure of unit cells used in [40]. Assume the sound waves pass through the unit cell from the left. The curved propagation path will increase the time it takes to penetrate the unit cell, which essentially introduces a phase shift to the outgoing wave. The structures of different unit cells are determined by two dominant parameters: d_1 and d_2 [40], which result in different propagation path lengths and hence different phase delay. One way to determine d_1 and d_2 is through enumeration in a simulator (e.g., COMSOL [2], which is a widely used finite-element-based multiphysics simulator).

We arrange the unit cells in a straight line to form a 1D metasurface, or in a rectangle to form a 2D metasurface. By introducing an appropriate phase shift at each cell, we can achieve beamforming. Figure 3 shows an example. To make it easy to assemble/re-assemble a metasurface, [40] quantizes the types of unit cells into 16 choices, which covers the phase shift from 0 to 2π . So for each unit cell, we can choose one

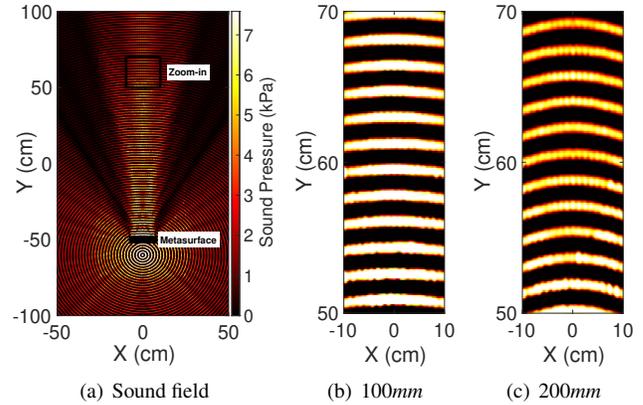

Figure 4: (a) Sound field simulated in COMSOL with a 16×1 metasurface when we transmit $20kHz$ sound at the focal point (100mm). Part of the energy is concentrated in a specific direction. (b) and (c) show the sound field in the zoom-in area when the speaker is placed at 100mm and 200mm, respectively. When the speaker is at the focal point, the signal coming out of the metasurface is a parallel wave.

whose phase shift is the closest to our desired shift.

3.2 Properties of Acoustic Metasurface

High transmission efficiency: As shown in Figure 2, the unit cells have intricate maze-like internal structures, with four parallel bars positioned orthogonal to the direction of incoming sound waves. Interestingly, the transmission efficiency is high and reaches 98% on average across all unit cells [40]. This is due to the following two major reasons: i) The sub-wavelength cells produce diffraction and cause the energy of sound to bypass the parallel bars instead of being reflected back; and ii) The bars inside each unit cell are curved instead of sharp angles to reduce acoustic impedance and maintain high transmission efficiency. Overall, the acoustic metasurface has negligible power loss, so we do not consider the power loss when developing AMS.

Focusing behavior: Figure 3 shows that an incident plane wave is focused at a focal point after passing through the metasurface. Due to the reciprocity principle [8], when a point source is placed at the focal point, the signal coming out of the AMS should be a plane wave towards the direction orthogonal to the metasurface. Figure 4(a) and 4(b) show an example scenario, where the source is placed at 100mm, which is the focal point. We observe the outgoing wave is nearly parallel in one direction. Second, when the source is not at a focal point, the wave is no longer parallel, as shown in Figure 4(c), and the energy of the signal will be dispersed to nearby directions, making signal strength attenuates faster. Since we want to concentrate the energy in one direction and make the sound wave propagate in a longer range, plane waves are preferred.

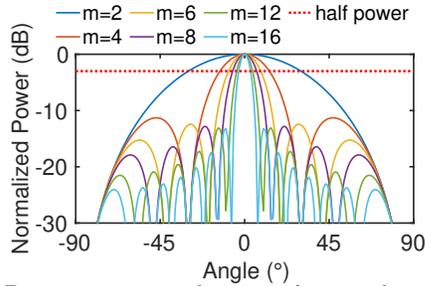

Figure 5: Beam patterns under a varying number of speakers m . The received sound is normalized by dividing it by the maximum power and then converted to decibels.

Adaptation: Once a metasurface is printed, the mapping from the incoming wave to the outgoing wave is fixed. Since the target can be in any direction, it is important to change the direction of the outgoing wave. Given the fixed metasurface, one way to change the direction of the outgoing wave is to move the AMS either through translation movement or through rotation. While movement is feasible, mechanical movement is slow, consumes significant power, causes wear and tear, and may even require operator intervention. Therefore, in this paper we seek a software-based approach to realize fast dynamic adaptation.

4 Phased Array with Metasurface

The passive acoustic metasurface is a fixed 2D structure. Once designed, it converts from the incident wave to the outgoing wave in a fixed manner. For practical use, it is desirable to dynamically adjust the direction of the wave coming out of the metasurface. We can achieve this using either mechanical movement or beamforming using a phased array. We take the latter approach due to its software control and eliminating the need of movement. An important question is how to configure the metasurface and phased array to realize our desired beamforming. Below we first introduce phased array and then describe how to use phased array with metasurface to achieve dynamic control at a low cost.

4.1 Phased Array

Phased arrays use beamforming to combine signals from multiple speakers constructively. Beamforming can be applied to either senders or receivers or both. There are a number of beamforming algorithms. They vary in the optimization objectives: some maximize the signal, while others minimize interference.

In analog beamforming, beamforming is performed on analog signals at the transmitter before sending to the air or at the receiver before the analog to digital conversion. In digital beamforming, beamforming is performed on digital signals at the transmitter before digital to analog conversion or at the receiver after analog to digital conversion.

The beamforming capability depends significantly on the number of speakers and their separation. As Figure 5 shows, the beam width in the desired direction is relatively large and the sidelobes are significant when the number of speakers is within 8. The half power beam width (HPBW) at 0° (i.e., perpendicular to the speaker array) can be approximated as follows [48]: $\theta_{0.5} \approx \frac{0.886\lambda}{md}$ where λ is the wave length, m is the number of speakers, and d represents the speaker separation, which is usually recommended to be $\frac{\lambda}{2}$. For example, the HPBW will be 59.6° , 25.5° , 16.9° , and 6.3° when the number of speakers is 2, 4, 6, and 16, respectively. The beam width for a general angle can be derived as follows: $\theta_{0.5s} = \frac{\theta_{0.5}}{\cos\theta_s}$, where θ_s is the steering angle and $\theta_{0.5s}$ is the HPBW of the steered beam. This indicates that the scanning range should not be too large and usually we let $\theta_s \leq 60^\circ$. These results show that the acoustic beamforming resolution using a small phased array is limited.

4.2 Phased Array Coupled with Metasurface

Passive AMS is not reconfigurable on-the-fly once it is assembled. To provide dynamic adaptation while achieving high resolution and long range, we propose using a small number of speakers along with an acoustic metasurface. We optimize the speakers' beamforming so that the outgoing wave from the AMS is towards our desired angle.

More specifically, phased array can control the direction of the output signal, which serves as the incoming signal towards the AMS. By optimizing the transmission signals, we can potentially generate any shaped waves coming out of the AMS. The use of multiple speakers allows us to achieve fast dynamic control without movement. In order to fully realize this capability, we should carefully design the AMS to cover a wide range of angles and control the transmission signals from multiple speakers in order to dynamically generate the desired signal coming out of the AMS. Below we first formulate the problem and then present our solution.

4.2.1 Problem Formulation

As shown in Figure 1, there are M speakers. Let w_i denote the codeword for the i -th speaker, where w_i is a complex number whose magnitude and phase are the scaling factor and phase shift for the i -th transmission signal, respectively. There are N unit cells in AMS. The acoustic signal received by the j -th AMS cell from the i -th speaker $S_{i,j}$ can be computed as follow, where t_i is the i -th speaker's transmission signal and H_{ij} denotes the channel between the i -th speaker and j -th cell.

$$S_{i,j} = H_{ij}w_it_i \quad (1)$$

Since the relative position between the AMS cell j and transmitter i is pre-determined, we can derive $H_{i,j} = F(d_{i,j}) = a(d_{i,j})e^{-j2\pi f \frac{d_{i,j}}{c}}$, where c is speed of acoustic signal, $d_{i,j}$ is

the distance from the i -th transmitter to j -th cell, $a(d_{i,j})$ is the amount of signal attenuation at the distance $d_{i,j}$, and $F(\cdot)$ is a function that models how the channel attenuates with the distance $d_{i,j}$.

We can take the placement of the phased array into account, denoted as x , and re-write the above relationship in a matrix form as follows:

$$S_{in} = H(x)w \quad (2)$$

We omit the transmission signal t_i before beamforming hereafter because it is the same at each speaker.

Each cell in AMS modifies the incident signal (e.g., by adding a path delay and/or changing the amplitude). Such a modification can be captured using a matrix, denoted as G , and the design of G will be covered in Sec 4.2.3. Then the signal coming out of the AMS becomes

$$S_{out} = GH(x)w \quad (3)$$

Finally, let R_d denote the signal in a given steering direction d from the AMS. R_d can be derived as follow, where K_d denotes the steering vector corresponding to the direction d between the AMS and target.

$$R_d = K_dGH(x)w \quad (4)$$

Our goal is to design the AMS and codeword of the speaker array to maximize the signal strength along each angle of interest. For example, if we want to support a scanning angle from -60° to 60° , for each angle within the range, we want to maximize the signal strength. Note that the AMS has a fixed configuration across all angles, while the codeword can change for each beamforming angle as in typical beamforming scenarios. Therefore, the signal of interest R can be derived as follow:

$$R = KGH(x)W \quad (5)$$

where R is a matrix of size $d \times d$ (each row represents the received signal from a given direction d and each column represents the steering direction), K is a $d \times N$ matrix specifying the steering vector from the N unit-cell AMS, G is an $N \times N$ matrix and its diagonal elements specify how the N -cell AMS translates the incident signal into outgoing signal, $H(x)$ is an $N \times M$ matrix specifying the channel from M transmitters to N -cell AMS, and W is $M \times d$ codebook for M speakers corresponding to d directions.

The channel H and steering vector K are fixed and can be derived analytically. Given H and K , we want to find the optimal static AMS configuration G and codebook W to perform beamforming across a wide range of angles. Since we optimize the power of the beams in each direction, we use the power P of the received signal R hereafter, which is denoted by $P = |R|^2$.

The structure of our received signals P can be visualized in Figure 6, where we aim to have high signal strength along the

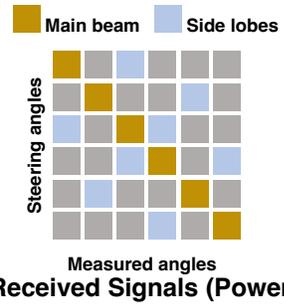

Figure 6: The structure of the received signal at various angles.

diagonal elements, which indicates our signal is beamformed towards the desired steering angle.

Our objective function comprises the following 3 terms:

Sum Power: Due to the use of a static metasurface design and the need to accommodate a wide range of angles, our goal is to maximize the sum of power across all d directions. This can be derived as follow:

$$L_{power} = \text{tr}(P) \quad (6)$$

where $\text{tr}(\cdot)$ is the trace of a matrix (i.e., the sum of the diagonal elements in the trace). This is shown in Figure 6.

Minimum Variance Criterion: Solely maximizing the total power may introduce some dead zones for certain directions. To avoid that problem, we add the variance of P 's diagonal as the penalty term L_{var} to ensure all directions are covered:

$$L_{var} = \text{var}(\text{diag}(P)). \quad (7)$$

For generality, we introduce a weight matrix Q , which can put different weights on different angles. As a result, we have:

$$L_{var} = \text{var}(\text{diag}(PQ)) \quad (8)$$

where $Q = \text{diag}(q_1, q_2, \dots, q_l)$ is a set of weights to control. If we have prior knowledge about the target's (approximate) location, we can increase the entries in Q that correspond to the locations close to the target.

Minimum Sidelobe: Suppressing the side lobes is critical for sensing and communication. In the signal processing literature, extensive works have been done to control sidelobe level (SLL). Sidelobe nullification and minimization are two common methods. Some methods require prior knowledge about the sidelobe's direction, while other methods minimize the maximum sidelobe. We experiment different ways of suppressing sidelobes and find minimizing the average SLL (i.e., minimize the sum of absolute values of all non-diagonal peaks in P) is most effective in our context.

We observe that the non-diagonal peaks shown in Figure 6 are considered as sidelobes and can degrade the overall performance. Therefore, we propose to minimize the sum of non-diagonal peaks as follows:

$$L_{sidelobe} = \sum \text{non-diagonal peaks} \quad (9)$$

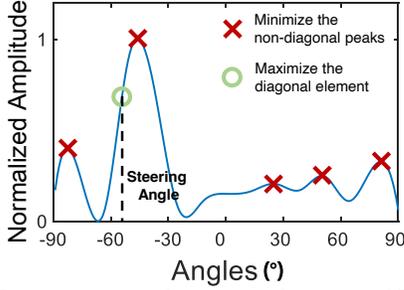

Figure 7: Beam pattern when steered to a specific angle during optimization. Minimizing the non-diagonal peaks helps reduce the side lobes and increase the directivity.

To derive $L_{sidelobe}$, we identify peaks in the P matrix (e.g., using `findpeaks()` function) and then sum up the peaks that are in non-diagonal entries of the matrix. It not only reduces the sidelobes, but also improves the quality of the main lobe. As shown in Figure 7, if the highest peak is a non-diagonal element, we also minimize it to revise the direction.

Putting together, we have the following optimization model:

$$\begin{aligned} \min_{W, \Theta, x} \quad & -L_{power} + \mu L_{var} + \gamma L_{sidelobe} \\ \text{s.t.} \quad & \begin{cases} |G_{ii}| = 1, (i = 1, 2, \dots, N) \\ |W_{ij}| \leq 1 (i = 1, 2, \dots, M, j = 1, 2, \dots, d). \end{cases} \end{aligned}$$

where μ and γ are parameters controlling the importance of the variance and sidelobe terms, respectively. We have two constraints on the magnitude of the metasurface parameters G and codebook W . Both G and W should be no more than 1.

The constraints on the magnitude of metasurface G are called constant modulus constraints (CMC). It is well-known that problems involving CMC are nonconvex and NP-hard [31]. $|G_{ii}| = 1$ refers to the points on the surface of an N dimensional hypercube, which indicates each metasurface cell does not change the magnitude of the incoming signal. These are non-convex constraints. $|W_{ij}| \leq 1$ are constraints on the magnitude of the phased array. The set contains the entire hypercube and includes the interior. Thus, it is a convex set. Therefore, for the phased array codebook, we restrict the amplitude to be within 1 instead of exactly equal to 1 to make the problem easier to solve.

4.2.2 Optimization

Our problem is a non-linear constrained optimization problem. Due to the presence of the constraints, we cannot directly apply the gradient descent scheme. Therefore, we use the gradient projection method, which ensures the solution after each gradient descent update still falls within the feasible set Ω . Specifically, if the $k+1$ -th update (i.e., $x^{(k+1)} = x^{(k)} + \alpha_k d^{(k)}$) makes the solution fall outside the feasible region, where α_k is the learning rate and $d^{(k)}$ is the gradient, we project it to a point inside the feasible set Ω as follows:

$$x^{(k+1)} = \Pi[x^{(k)} + \alpha_k d^{(k)}] \quad (10)$$

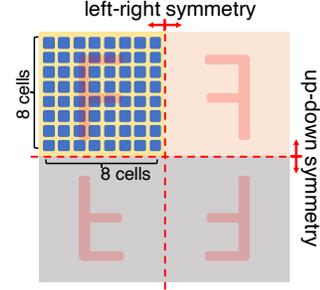

Figure 8: The symmetry property of a 16×16 metasurface.

where Π is projection operator, and $\Pi[x]$ is called the projection of x in Ω . To do that, we normalize the amplitude of G_{ii} after each update and normalize W_{ij} if it is larger than 1. As a result, we use Adam optimizer in Pytorch for optimization. Adam is an extended version of stochastic gradient descent that adapts the learning rate for each parameter. We modify the output from the Adam during each iteration using Equation 10 to ensure constraints are satisfied.

4.2.3 Additional Design Details

In this section, we describe how to get the input required for optimization.

Symmetry Property of AMS As mentioned earlier, the diagonal of variable G should represent the phase delay for metasurface cells. Our metasurface is a 2D structure. We observe that the configuration of the AMS should be left-right symmetric and up-down symmetric, as shown in Figure 8, since the scanning performance should be the same in left and right in the azimuth direction and the beam pattern should also be the same in top and bottom in the elevation direction. By utilizing the left-right and up-down symmetry property, we can reduce the search dimension for G by 75%.

Codebook Since the range of the steering angle is from -60° to 60° , the codebook is also symmetric between the positive angles and negative angles. Therefore, we can optimize half of the codebook (i.e., corresponding to the steering angle in $(-60^\circ, 0)$) and copy them to generate the codebook for $(0, 60^\circ)$.

Channel From Phased Array to Metasurface The channel $H(x)$ can be determined based on the speakers and metasurface cells' positions. Let $x = \{x_1, x_2, \dots, x_M\}$ denote the speakers' locations, and $g = \{g_1, g_2, \dots, g_N\}$ denote the metasurface cells' locations. We can derive the channel as follows:

$$H(x) = \begin{bmatrix} F(\|x_1 - g_1\|) & \dots & F(\|x_M - g_1\|) \\ F(\|x_1 - g_2\|) & \dots & F(\|x_M - g_2\|) \\ \vdots & \ddots & \vdots \\ F(\|x_1 - g_N\|) & \dots & F(\|x_M - g_N\|) \end{bmatrix} \quad (11)$$

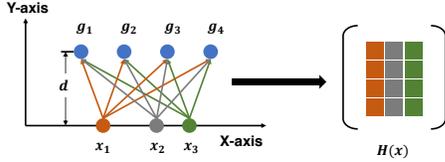

Figure 9: Derive channel matrix H with varying speaker distributions x . Consider 3 speakers and 4 metasurface cells as an example. We can derive the distance between each speaker and metasurface cell to get the channel H between the phased array and metasurface.

where $\|\cdot\|$ denotes the distance between two points (i.e., a speaker and a metasurface cell) and $F(\cdot)$ denotes the function that maps the distance to the wireless channel, including the amplitude and phase. Figure 9 shows an example.

We can either (i) take a given phased array setup (e.g., uniformly distributed linear array) as the input or (ii) optimize the phased array setup. In the latter case, we treat x_i as the optimization variables along with the other variables. Note that we do not impose any constraints on x because we already consider the symmetry property of metasurface G and codebook W . Equation 11 assumes a single line-of-sight path between the phased array and metasurface, which is realistic since the metasurface is close to the phased array and there is no blockage.

4.2.4 System Design

In this section, we provide further details of our system design, including the AMS design, codebook design, and array placement.

We sample angles from -60° to 60° with 1° apart. Therefore, for a 6-speaker system, the codebook W is a 121×6 matrix, which contains 121 independent codewords for 121 directions and 6 speakers. Figure 10 shows the amplitude and phase of the optimized codebook, where the first speaker is set as the reference and is aligned to be zero phase. Since our goal is to maximize the sum power of diagonal elements, the amplitude of each element in the codebook is 1 to achieve the maximum transmission power, while the phase is manipulated to generate our desired sound field at the metasurface.

Next, we reconstruct the phase distribution of the metasurface by utilizing the diagonal elements of G and the symmetry property. The results are given in Figure 11(a). This is different from that of [40] due to the presence of a phased array. As mentioned in Sec. 3, the phase shift of each AMS cell is quantized to 16 levels for flexible design and assembly/disassembly. Then the final AMS can be assembled by choosing the unit cells with the closest phase shift, as shown in Figure 11(b), where the color reflects the unit cell index and a higher index indicates a larger phase shift.

We can either (i) place speakers in the phased array uniformly or arbitrarily and feed the placement to our optimization algorithm or (ii) let our algorithm optimize the placement

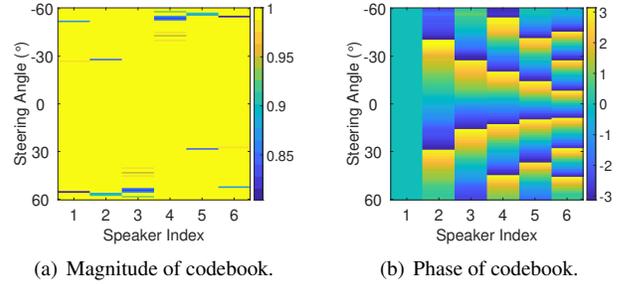

Figure 10: The optimized codebook design, where the first speaker is set as the reference. The magnitudes of the codebook are all close to 1, but some are slightly less than 1 since their constraints are ≤ 1 .

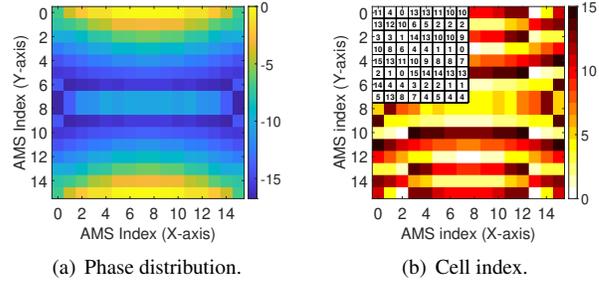

Figure 11: Phase distribution and cell indices of the optimized 16×16 metasurface design, where the cell index is the index to one of the 16 quantized phase shifts. The numbers in the upper left corner denote the cell indices for the top left metasurface and we omit the other parts for brevity due to the left-right symmetry and top-bottom symmetry.

along with other configuration parameters. In evaluation, we compare uniform placement and optimized placement.

5 Performance Evaluation

In this section, we first present our evaluation methodology and then describe performance results.

5.1 Evaluation Methodology

We use the experiment setup shown in Figure 12 for our evaluation. The system can be divided into three parts: speakers, microphones, and an acoustic metasurface (also referred to as an acoustic lens or AMS). We use uniform placement as the default configuration. In this case, we have 6 identical miniature speakers (16Ω , $0.25W$) as the transmitter. Each speaker is connected with an operational amplifier THS4001 [4] to amplify the voltage and a power amplifier LM386 [3] to amplify the current. The distance between the centers of adjacent speakers is $8.6mm$, which is a half wavelength of $20kHz$ sound. We used 4 microphones to form a microphone array as a receiver. The distances between the 4 microphones were $3.06cm$, $2.04cm$, and $3.06cm$ to reduce ambiguity and obtain better performance [38]. All speakers and microphones are

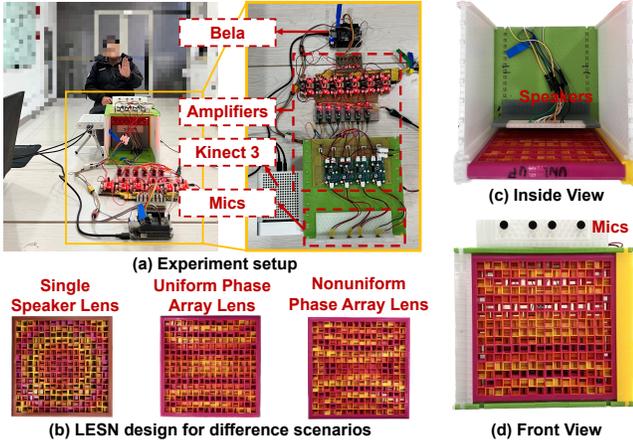

Figure 12: System setup.

connected to the same Bela board [1] for signal synchronization. We also optimize speaker placement using the approach described in Section 4.2.

We construct an acoustic lens according to our optimization in Section 4.2.2. Our lens consists of 256 (16×16) unit cells, spanning over $15\text{cm} \times 15\text{cm}$. Since the unit cells are quantized into 16 choices, we 3D print 16 different types of unit cells and assemble them to an acoustic lens according to the evaluation scenario. For example, we assemble an acoustic lens for a 1-speaker setup, a different acoustic lens for 6 speakers with uniform separation, and another one for 6 speakers with non-uniform separation, as we jointly design the metasurface with the speaker array. To ensure most signals coming out of the speakers go through the acoustic lens, we place our lens 2cm away from the speaker array. For a single speaker, we follow the setup in [41] where the lens is placed 10cm away from the speaker array.

We evaluate our approach in terms of (i) SNR, (ii) sensing accuracy, and (iii) communication performance. For acoustic sensing, we use Kinect V3 to get the ground truth distance and angle of arrival (AoA). We let the speakers transmit the following FMCW signal: $tx(t) = \cos(2\pi f_{min}t + \frac{\pi Bt^2}{T})$, where $f_{min} = 16\text{kHz}$, $B = 4\text{kHz}$, and $T = 0.1\text{s}$. We quantify the sensing accuracy using distance error and angle of arrival error.

1D MUSIC is a widely used AoA estimation algorithm. It computes the auto-correlation matrix R of the received signals x as $R = x^H x$, where x is a $1 \times N$ vector and x^H is the conjugate transpose of x , and then performs eigenvalue decomposition on R . Let R_N represent the noise space matrix, which is the space spanned by the $N - M$ smallest eigenvectors, where M is the number of signals. The peak in the pseudo spectrum $p(\theta) = \frac{1}{a(\theta)^H R_N R_N^H a(\theta)}$ corresponds to the AoA.

For acoustic communication, we encode the data using OFDM. Each OFDM frame contains 180 BPSK symbols, which are striped onto 12 subcarriers spanning over $18\text{kHz} - 20\text{kHz}$. We use CDMA as FEC code to improve resilience

and the code rate is 50%. We quantify the communication performance using bit error rate (BER) and frame error rate (FER). While there are other coding schemes for acoustic communication, the benefit of our approach (i.e., acoustic lens with a speaker array) is likely similar across different acoustic coding schemes.

Unless otherwise specified, all results are from **testbed experiments**: we use a 6-speaker array with an equal separation of 9.4mm between the two adjacent speakers and 16×16 acoustic lens; in device-free acoustic sensing experiments, the microphone array is 3cm above the acoustic lens to track the distance and AoA of a person's hand so that the signal from the speaker to the target goes through the metasurface and the signal reflected from the target and received by the microphone array does not go through the metasurface; in acoustic communication experiments, the receiver is at 1.5m away from the speaker array. We also evaluate the impact of various parameters by varying their values.

5.2 SNR Comparison

We first compare various schemes in terms of SNR.

5.2.1 Beam Pattern

We place a receiver at 1.5m away, 0° from the speaker(s) and measure the sound field intensity. Figure 13(a)(c)(e) compare the beam patterns of six schemes in COMSOL simulation [2], and Figure 13(b)(d)(f) compare them in testbed. The six schemes include: (i) a single speaker without lens (**w/o PA + w/o lens**), (ii) a single speaker with a lens (**w/o PA + w/ lens**), (iii) a phased array without lens (**w/ PA + w/o lens**), (iv) a phased array with a lens (**w/ PA + w/ lens**), (v) an optimized phased array without lens (**w/ opt-PA + w/o lens**), and (vi) an optimized phased array with a lens (**w/ opt-PA + w/ lens**). Our goal is to focus the transmission signal in any desired direction. As we can see, (vi) yields the highest peak in the desired angle, which is 1.2, 2.9, 10.5, 10.5, and 18.4dB higher than (iv), (ii), (v), (iii), and (i), respectively. Optimized array placement yields 1.2dB gain over uniform placement. Leveraging acoustic lens yields 15.5dB gain when applied to a single lens, but its angle cannot be adapted and is always fixed at 0° . Combining a phased array having a uniform separation with an acoustic lens allows us to focus the beam in the desired direction while achieving 17.2dB gain over a single speaker without lens and 9.3dB gain over a phased array without lens.

We further evaluate the signal strength and vary the steering angle, as shown in Figure 14. The improvement of (vi) over (iv) shows the benefit of the optimized array placement, and the improvement of (vi) over the other schemes shows the benefit of combining lens and phased array in the optimized placement. These results show that (vi) yields a high SNR gain across a wide angle from -60° to 60° .

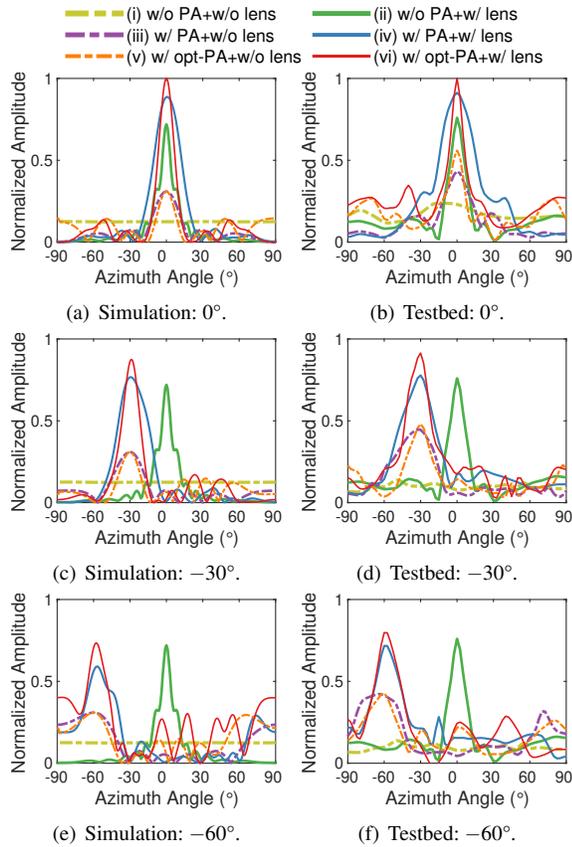

Figure 13: The amplitude of the acoustic signal at various angles of steering. The amplitude is normalized by dividing it by the maximum amplitude of the signal received at 0° . (a)(c)(e) show the results from the simulation using COMSOL and (b)(d)(f) show the results from the testbed.

5.2.2 Beam Width

The 2D structure of our lens design allows us to focus beams in both the azimuth and elevation directions. To show the impact of the beam width in both directions, we measure the sound field in a far field plane, which is parallel to the surface of the lens. Figure 15 plots the sound field of three different beams steered to 30° , 60° , and 90° , respectively. As we can see, the linear phased array can only focus beams in the azimuth direction. In comparison, the acoustic lens can focus beams in both the azimuth and elevation directions. According to COMSOL simulation shown in Figure 16, the acoustic lens with a 6-speaker phased array generates a comparable beam pattern to a 16×1 array in the elevation direction and a comparable beam pattern to a 9×1 array in the azimuth direction. Therefore, the acoustic lens with a 6-speaker phased array is comparable to a $9 \times 16 = 144$ phased array in terms of beam width. This is a significant reduction in cost, size, energy, and computation. Moreover, we also find that equipping a 6-speaker phased array with acoustic lenses of sizes

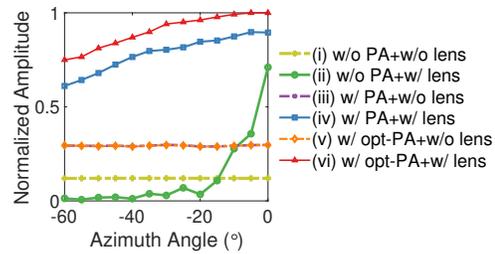

Figure 14: Power gain while steering at various angles. The amplitude is normalized by dividing it by the maximum amplitude of scheme (vi). The testbed uses a 16×16 acoustic lens and 6 speakers to form a phased array.

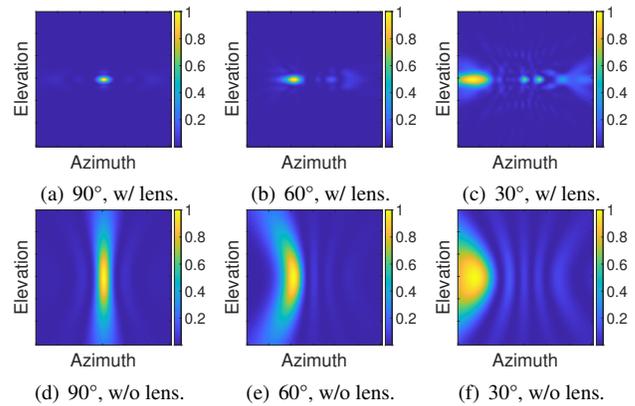

Figure 15: In the COMSOL simulation, comparing the sound signal strength using a phased array (6 speakers) with and without the acoustic lens in the azimuth direction.

32×32 , 48×48 , and 64×64 yield similar beam patterns to 16×28 , 20×40 , and 30×48 phased arrays, respectively.

5.2.3 Frequency Response

Our acoustic metasurfaces are designed for 20kHz sound, but we use $16\text{-}20\text{kHz}$ and $18\text{-}20\text{kHz}$ for acoustic sensing and communication, respectively. To understand how the lens works at a different frequency, we test the frequency response of the lens. We first calibrate the speaker(s) and microphone(s) and use compensation to generate close to a flat frequency response in the received signal. We then transmit a sine wave with a frequency varying from 10kHz to 22kHz and record the received sound at 1m and 0° from the speaker. We test all lens configurations, including a single-speaker lens, uniform phased-array lens, and non-uniform phased-array lens. Fig. 17 shows the frequency response. As expected, the peak of the lens frequency response is 20kHz . It drops rapidly after 20kHz . Fortunately, the frequency response remains stable in $14\text{kHz}\text{-}20\text{kHz}$, which means that we can use this band for sensing and communication.

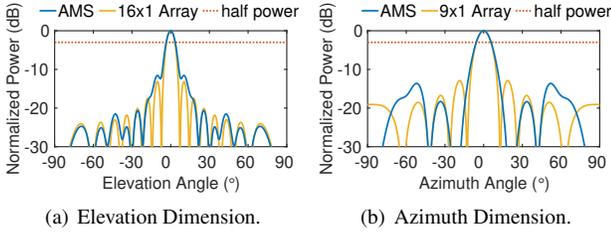

Figure 16: Using a 16×16 acoustic lens with a 6-speaker phased array is comparable to a 9×16 phased array in terms of beam width in the elevation and azimuth direction according to COMSOL simulation.

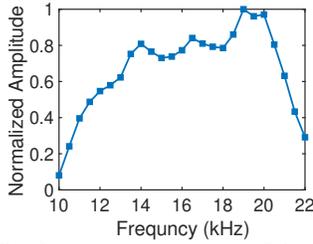

Figure 17: The frequency response of the acoustic lens.

5.2.4 Impact of Lens Size and Phased Array Size

Figure 18(a) plots the received power of (vi) in the desired direction using different lens sizes. We only plot -60° to 0° as the result from 0° to 60° is symmetric. We make several observations. First, as we would expect, increasing the lens sizes improves the normalized power (i.e., the received power is normalized by dividing by the power of 32×32 lens at 0° and $1.5m$ away). In particular, the normalized power increases from 0.29 using 8×8 lens to 0.42 using 12×12 lens, to 0.62 using 16×16 lens, to 0.76 using 24×24 lens, and to 0.83 using 32×32 lens at -60° . Second, comparing the simulation (solid curves) with the testbed results (dotted curves), we observe high consistency, which validates the fidelity of our simulation.

Figure 18(b) further plots the normalized power (i.e., the received power is normalized by dividing by the power of $m = 16$ phased array at 0° and $1.5m$ away) of (iv) as we vary the number of speakers. As expected, increasing the number of speakers from 2 to 4, 6, 8, and 16 increases the normalized power to 1.3x, 1.6x, 1.8x and 2.1x, respectively.

5.3 Distance Estimation Performance

Next we evaluate the impact of our approach on distance estimation accuracy. As described in Section 5.1, we evaluate the benefit of acoustic lens and phased array on the well-known distance estimation techniques: FMCW.

Figure 19(a) plots the errorbar of the distance estimation error, where the center, lower bound, and upper bound of the errorbar correspond to median, 25%, 75% of the distance error, respectively. (vi) performs the best and out-performs

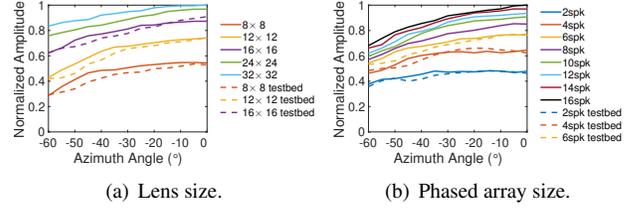

Figure 18: The impact of lens size and phased array size on the received power of (iv). Dotted curves represent results from the testbed experiments while solid curves represent results from COMSOL simulation.

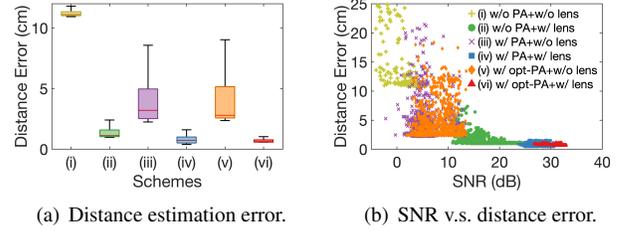

Figure 19: The distance estimation performance using acoustic lens.

(i), (ii), (iii), (iv), and (v) by 93%, 25%, 76%, 12%, and 72%, respectively. To better understand where the improvement comes from, we plot the distance estimation error of each FMCW chirp and its corresponding SNR in Figure 19(b). We can see that, as expected, the FMCW chirp with a higher SNR leads to a lower error. The optimized phased array with acoustic lens has the highest SNR, so it yields the lowest distance estimation error.

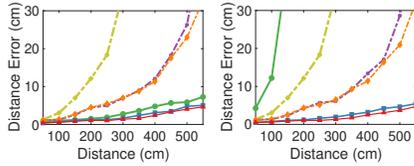

5.3.1 Impact of Measurement Distance

We evaluate the impact of distance on the distance estimation error as shown in Figure 20. As we can see in Figure 20(a), (vi) performs the best and out-performs (i), (ii), (iii), (iv), and (v) by 94%, 45%, 79%, 18%, and 81%, respectively. (vi) increases the operation distance from $0.5m$ in (i) to $3.5m$. Note that $3.5m$ operation distance is very good considering the total power of our 6 speakers is only $0.1W$. In comparison, [38] achieves $4.5m$ operation distance using a $2.5W$ speaker.

5.3.2 Impact of Measurement Angle

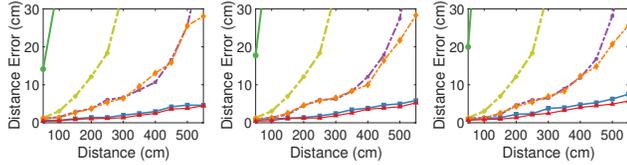

Next we further show the impact of measurement angle on the distance estimation performance. From Figure 20(b)-(e), we can see that (vi) still performs the best in all directions and out-performs (i), (ii), (iii), (iv), and (v) by 93%, 99%, 77%, 21%, and 76%, respectively. However, when we increase the measurement angle from 0° to 15° , 30° , 45° , and 60° , the distance error of (vi) also increases from $1.28cm$ to $1.30cm$, $1.32cm$, $1.86cm$, and $2.47cm$, respectively.

(a) Lens size.

(b) Phased array size.

Figure 21: The impact of lens size and phased array size on the distance estimation error of (iv).

5.3.3 Impact of Lens Size and Phased Array Size

We evaluate the impact of lens size on distance estimation performance. We experiment with 4×4 , 8×8 , 12×12 and 16×16 lenses in our testbed. As shown in Figure 21(a), increasing the lens size improves the distance estimation errors. A 16×16 lens reduces the error over a 4×4 , 8×8 , and 12×12 lens by 73%, 62%, and 36%, respectively.

We also evaluate the impact of phased array size. As shown in Figure 21(b), increasing the array size improves the distance estimation due to the enhanced SNR. For example, a 6-speaker phased array with AMS reduces the distance estimation error over 1-, 2-, and 4-speaker phased array by 95%, 91%, and 80%, respectively.

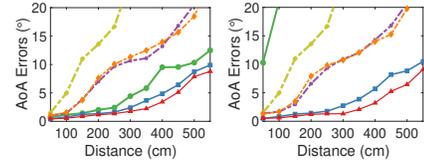

5.4 AoA Estimation Performance

In this section, we compare the AoA estimation using 1D MUSIC as introduced in Section 5.1.

5.4.1 Impact of Measurement Distance

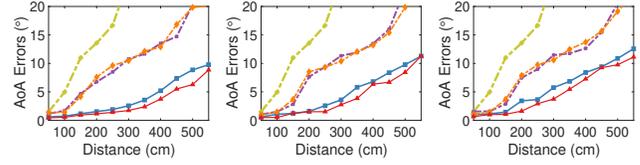

Figure 22(a) plots the AoA error versus the measurement distance. In all schemes, the distance estimation errors increase with an increasing distance. (vi) performs the best and reduces the AoA error of (i), (ii), (iii), (iv), and (v) by 92%, 44%, 76%, 16%, and 77%, respectively. The result shows that

(i) w/o PA+w/o lens (ii) w/o PA+w/ lens (iii) w/ PA+w/o lens
 (iv) w/ PA+w/ lens (v) w/ opt-PA+w/o lens (vi) w/ opt-PA+w/ lens

(a) Lens size.

(b) Phased array size.

Figure 23: The impact of lens size and phased array size on the AoA estimation error of (iv).

our approach effectively improves AoA sensing accuracy by increasing the SNR.

5.4.2 Impact of Measurement Angle

We further show the impact of measurement angle on AoA estimation. Figure 22(b)-(e) plots AoA estimation error for other directions. When the distance is small, the AoA estimation error remains low across all measurement angles of interest; when the distance is large, the AoA error increases more rapidly with the increasing angle. This is expected because when SNR is sufficiently high, the measurement angle has less impact; but when SNR is low, the measurement angle matters. (vi) out-performs (i), (ii), (iii), (iv), and (v) by 90%, 96%, 81%, 26%, and 82%, respectively.

5.4.3 Impact of Lens Size and Phased Array Size

As shown in Figure 23(a), increasing the lens size effectively reduces the AoA estimation error. For example, increasing the lens size from 4×4 to 8×8 improves AoA estimation by 32%, increasing from 8×8 to 12×12 improves by 53%, and increasing from 12×12 to 16×16 further improves by 46%.

Figure 23(b) further plots the AoA estimation as we vary the array size. Increasing the array size improves SNR and reduces the AoA estimation error. Using a 6-speaker phased array reduces the AoA error by 96%, 74%, and 52% over

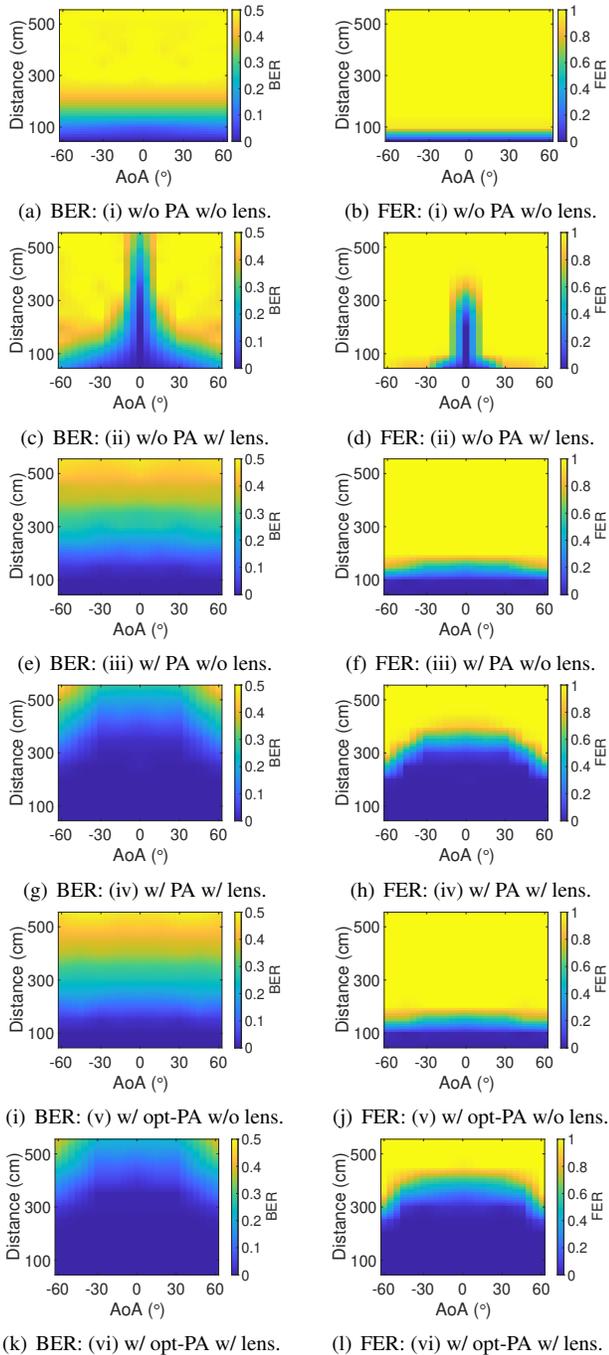

Figure 24: The impact of distance and AoA on the communication performance.

using 1-, 2-, and 4-speaker phased array, respectively.

5.5 Acoustic Communication Performance

Finally, we evaluate the impact of our approach on acoustic communication performance.

5.5.1 Impact of Distance

We put the speakers at a fixed location and gradually increase the distance between the microphone and the speakers. We tested the above six scenarios for communication. Figure 24 shows the bit error rate (BER) and frame error rate (FER) across different AoAs at different distances. We can see that both BER and FER increase with the distance. Due to the use of fixed modulation and FEC, the FER rapidly increases after the distance goes beyond a certain point. If we define the communication range as the range corresponding to 50% FER, we observe that (vi) has 3.9m communication range as shown in Figure 24(l). In comparison, (i), (ii), (iii), (iv), and (v) have communication ranges of 0.8m, 3.0m, 1.5m, 3.5m, and 1.5m, respectively.

5.5.2 Impact of AoA

Figure 24 also shows the impact of AoA on BER and FER in our testbed. (vi) achieves low error rates within 60° and 2.8m. This is good coverage considering the total power of our 6 speakers is only 20mW. In comparison, for the same 60° coverage, the other schemes' range is much smaller.

6 Discussion

Acoustic metasurfaces can effectively boost the signal quality, and improve sensing and communication performance. Compared with a large phased array, our approach of using a small phased array and metasurface is more compact, cost effective, and energy efficient. To fully realize the potential of AMS, several challenges remain to be addressed in the future: (i) further reducing the AMS size so that it can be applied to more applications (e.g., mobile devices), (ii) supporting a wider band, and (iii) further simplifying fabrication process. Figure 17 shows that our AMS can support 16-20KHz within 20% amplitude loss. This is sufficient for our purpose but may need further improvement if a wider band is required.

7 Conclusion

In this paper, we develop a novel acoustic system that uses AMS and multiple speakers together to achieve dynamic steering and high SNR. The increase in SNR can be translated into higher accuracy in distance and AoA estimation and larger communication range in acoustic communication. Encouraged by the promising results, we plan to explore more applications that can benefit from our design.

Skyplane: Optimizing Transfer Cost and Throughput Using Cloud-Aware Overlays

Paras Jain, Sam Kumar, Sarah Wooders, Shishir G. Patil, Joseph E. Gonzalez, and Ion Stoica
University of California, Berkeley

Abstract

Cloud applications are increasingly distributing data across multiple regions and cloud providers. Unfortunately, wide-area bulk data transfers are often slow, bottlenecking applications. We demonstrate that it is possible to significantly improve inter-region cloud bulk transfer throughput by adapting network overlays to the cloud setting—that is, by routing data through indirect paths at the application layer. However, directly applying network overlays in this setting can result in unacceptable increases in cloud egress prices. We present Skyplane, a system for bulk data transfer between cloud object stores that uses cloud-aware network overlays to optimally navigate the trade-off between price and performance. Skyplane’s planner uses mixed-integer linear programming to determine the optimal overlay path and resource allocation for data transfer, subject to user-provided constraints on price or performance. Skyplane outperforms public cloud transfer services by up to $4.6\times$ for transfers within one cloud and by up to $5.0\times$ across clouds.

1 Introduction

Increasingly, cloud applications transfer data across datacenter boundaries, both across multiple regions within a cloud provider (multi-region) and across multiple cloud providers (multi-cloud). This is in part due to privacy regulations, the availability of specialized hardware, and the desire to prevent vendor lock-in. In a recent survey [26], more than 86% of 727 respondents had adopted a multi-cloud strategy across diverse workloads. Thus, support for fast, cross-cloud bulk transfers is increasingly important.

Applications transfer data between datacenters for batch processing (e.g. ETL [9], Geo-Distributed Analytics [54]), and production serving (e.g. search indices [34]). Extensive prior work optimizes the throughput of bulk data transfers between datacenters within application-defined minimum performance constraints [34, 36, 38, 64]. All major clouds offer services for bulk transfers such as AWS DataSync [5], Azure AzCopy [22], and GCP Storage Transfer Service [31].

From the perspective of a cloud customer, transfer throughput and cost (price) are the two important metrics of transfers in the cloud. Thus we ask *how can we optimize network cost and throughput for cloud bulk transfers?* We study this question in the context of designing and implementing Skyplane, an open-source cloud object transfer system.

A seemingly natural approach is to optimize the routing protocols in cloud providers internal networks to support higher-throughput data transfers. Unfortunately, this is not feasible for two reasons. First, rearchitecting the IP layer routing protocol to optimize for high-throughput bulk transfer could negatively impact other applications that are sensitive to network latency. Second, cloud providers lack a strong incentive to optimize data transfer to other clouds. Indeed, AWS DataSync [5], AzCopy [22], GCP Storage Transfer [31], AWS Snowball [62], and Azure Data Box Disk [12], all support data transfer *into*, but not *out of*, their respective clouds. Improvements to cross-cloud peering must be achieved with the cooperation of both the source and destination providers.

Skyplane’s key observation is that we can instead identify *overlay paths*—paths that send data via intermediate regions—that are faster than the direct path. The throughput of the direct path from Azure’s Central Canada region to GCP’s `asia-northeast1` region is 6.2 Gbps. Instead, Skyplane can route the transfer via an intermediate stop at Azure’s US West 2 with a throughput of 12.4 Gbps for a $2.0\times$ speedup (Fig. 1). Crucially, this can be implemented on top of the cloud providers’ services without their explicit buy-in.

We are not the first to propose the use of overlay networks on the public Internet [8]. However, these techniques ignore two key considerations of public clouds: **price** and **elasticity**.

First, the highest-bandwidth overlay path may have an unacceptably high **price**. Cloud providers charge for data egress separately for each hop along the overlay path. To reduce the cost of the overlay, it is essential to transfer data along cheap paths to trade off price and performance. For example, in Fig. 1, one can achieve 13.9 Gbps by instead using Azure’s East Japan region as the relay, but the cost would be $1.9\times$ that of transferring data directly. In contrast, using Azure’s

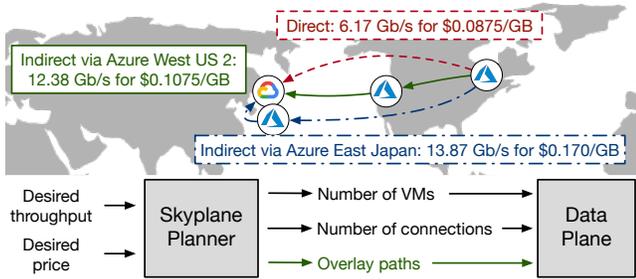

Figure 1: **Cloud-aware overlays:** Skyplane optimally transfers across cloud regions and providers subject to the user’s cost and throughput requirements. Skyplane finds the visualized overlay path from Azure’s Central Canada region to GCP’s asia-northeast1, which is 2.0× faster but just 1.2× higher in price than the direct path.

West US 2 region has only a 1.2× cost overhead with similar performance. Thus, Skyplane operates in a richer *problem space* than traditional application-level routing—one where cloud instance and cloud egress fees are significant.

Second, whereas the bandwidth between two nodes in a traditional network overlay [8] is considered “fixed,” in Skyplane’s setting it depends on **elasticity**—the ability to allocate more resources at each cloud region. For example, one can increase the capacity of any overlay path by simply allocating more VM instances in each cloud region. There are a limited number of physical machines at each cloud region, which cloud providers pass on to users in the form of instance limits. An overlay enables improved throughput beyond this limit. Thus, Skyplane operates in a richer *solution space* than traditional application-level routing—one where we must choose the number of VMs to use as relays due to cloud elasticity.

Skyplane addresses both **price** and **elasticity**, empowering users to navigate the trade-off between price and performance while leveraging the elasticity of cloud resources. Users can ask Skyplane to maximize bandwidth subject to a cost ceiling, or minimize cost subject to a bandwidth floor.

At the heart of Skyplane is a planner that computes a data transfer plan, subject to the user’s constraints, that specifies the overlay path to use and amount of cloud resources to allocate along that path. Price and elasticity make it challenging to compute the plan. Our insight is that, with some care, planning can be formulated as *linear* constraints. Thus, Skyplane’s planner can discover the optimal plan by solving a mixed-integer linear program (MILP), or closely approximate the optimal plan by solving a relaxed linear program (LP). Both can be accomplished using a fast, off-the-shelf solver.

Our Skyplane prototype¹ outperforms AWS DataSync by up to 4.6× and GCP Storage Transfer by up to 5.0×. Skyplane also outperforms academic baselines such as RON by 34% while reducing cost by 62%.

2 Background

Network overlays In the early 2000s, network overlays emerged as a technique for *application-level routing* without the *participation of underlying network providers*. These network overlays can be designed to improve performance or reliability. Notable network overlays include Chord [60], Resilient Overlay Networks (RON) [8], Bullet [41], Baidu BDS [65] and Akamai’s backbone [52, 58].

Although ISPs may have broad visibility into their networks, the metrics that ISPs use to select routes may not align with user preferences. Wide-area networks today do not allow specification of alternative routing preferences while network overlays provide applications a mechanism to control routing decisions. For example, Akamai uses a network overlay to reduce the latency of CDN misses while RON routes around network outages via an unaffected intermediate host.

RON is implemented by periodically measuring network performance via probes embedded in a fixed set of routers. When path outages occur, RON selects an intermediate relay router to circumvent the outage. This intermediate router is selected to have low packet loss or latency to/from the client and server. Optionally, RON can use a model of TCP Reno’s throughput [53] to select intermediate routers. RON will generally select only a single intermediate node.

Wide-area networking in the cloud From the perspective of cloud customers, the cloud is *elastic*—additional resources can be allocated on demand. For example, an overloaded cloud application can leverage the cloud’s elasticity by allocating additional VM instances. However, the physical reality of the cloud is that there are only finite resources at each region. Therefore, cloud providers impose *service limits* on their customers for resources such as VMs.

Each VM’s network bandwidth is throttled according to its instance type. For example, an AWS m5.8xlarge instance can use at most 10 Gbps of network bandwidth, and an Azure Standard_D32_v5 instance can use at most 16 Gbps of network bandwidth. Furthermore, only some of the available bandwidth can be used for egress traffic to another cloud provider. The policies differ by cloud provider. AWS limits VM egress bandwidth to the larger of 5 Gbps or 50% of total bandwidth [4], GCP limits VM egress bandwidth to any public IP address to 7 Gbps [30], and Microsoft Azure has no egress limit beyond the total bandwidth limit for a VM. Of course, the actual achievable TCP network bandwidth is subject to congestion control which may be less than the limit.

Cloud egress pricing Cloud providers charge egress prices for network traffic leaving a cloud region. Importantly, egress prices are assessed based on the *volume* of data transferred, not the rate at which it is transferred. Transferring a file at 10 Mbps or at 10 Gbps will result in the same egress charge. Egress charges introduce asymmetry in billing—there is no corresponding ingress charge for transfers into a cloud.

For intra-cloud transfers (i.e., transfers between two regions or zones in the same cloud), transfers between geographically distant endpoints are priced more than transfers between nearby endpoints. In contrast, inter-cloud transfers (i.e., transfers between two cloud providers) are billed at the same rate regardless of the transfer’s geographic distance. For example, the egress price from a single Azure region is billed at the same rate for *any* destination outside of Azure, including any region in AWS or GCP [6, 29, 51].

Egress prices typically dominate the cost of a bulk transfers. For example, if a VM sends data at a rate of 1 Gbps for an hour on AWS with an Internet egress price of \$0.09/GB, the total egress charge will total \$40.50, which far exceeds the VM price of \$1.50 (for m5.8xlarge) [6].

Cloud object storage AWS, Azure, and GCP provide object storage APIs that allow customers to save data attached to a string key. Data is stored immutably and therefore any updates require writing a new version. Unlike POSIX file systems, object stores do not provide atomic metadata operations (e.g., rename). Consistency models vary across providers. Cloud object stores store copies of a blob on multiple machines to improve availability and durability. Large objects support concurrent writes via sharding. Read throughput of a single shard may be limited by the provider (e.g. 60 MB/s for Azure [13]).

3 Overview of Skyplane

Skyplane allows applications to efficiently transfer large objects from an object store in one region to an object store in another cloud region or provider. To use Skyplane, the user installs the Skyplane client locally and configures it with access to cloud provider-supplied credentials. Then, the user submits a job, together with a constraint on price or bandwidth. The job specifies which objects to transfer, the source cloud provider and region, and the destination cloud provider and region. The constraint can have one of two forms: it can ask Skyplane to optimize either *bandwidth subject to a price ceiling*, or *price subject to a bandwidth floor*.

Skyplane itself comprises a *planner* (Fig. 1, bottom) and a *data plane* (Fig. 2). Given the user’s job and constraint, the planner produces an optimal data transfer plan to complete the job subject to the constraint. The planner relies on a profile of the network throughput between different cloud regions. The data plane is responsible for executing the data transfer plan: allocating cloud resources (e.g., VMs), transferring data between them, and interacting with object stores.

3.1 Overlay formulation in Skyplane’s planner

Suppose the user needs to transfer an object from a source cloud region, *A*, to a destination cloud region, *B*. A naïve object transfer system might spawn VMs in regions *A* and *B*, and transfer data via a TCP connection between the two VMs.

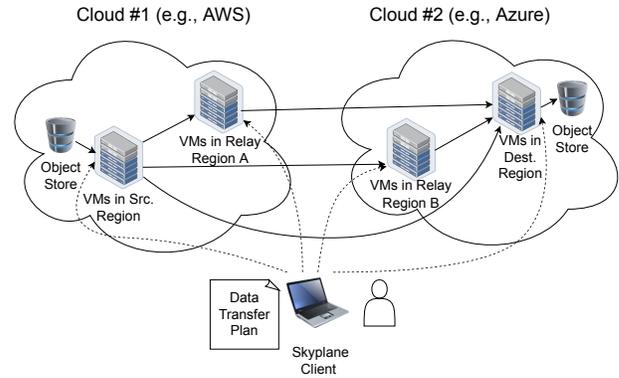

Figure 2: Skyplane splits an example data transfer over three paths: the direct path, and two indirect paths. Dashed lines indicate control orchestration (e.g., for spawning VMs) and solid lines depict the flow of object data.

Skyplane improves performance compared to this baseline by applying principles from overlay networks [8]. For example, Skyplane may identify a third cloud region, *C*, and transfer data from *A* to *B* via *C*. This is accomplished at the application layer; Skyplane will spawn a VM in region *C*, set up TCP connections from *A* to *C* and from *C* to *B*. We refer to intermediate regions like *C* as *relay regions*.

The baseline approach ($A \rightarrow B$) routes data along the “direct path,” since it uses the default path provided by the Internet. However, Skyplane ($A \rightarrow C \rightarrow B$) routes data along the an “indirect path,” that may not be on the Internet-provided default path. An indirect path may use multiple relays although a single relay is usually sufficient.

A key difference between Skyplane and classical overlay networks is that Skyplane takes price into account when choosing the overlay path to use for a job. Concretely, Skyplane’s planner uses a *price grid* and a *throughput grid* to determine which indirect path to use. The price grid specifies the price of transferring data between each pair of cloud regions, in each direction. We computed the price grid based on information on the cloud providers’ websites and from querying the cloud APIs. The throughput grid is collected by measuring the network, as we explain in the next subsection.

Note that throughput grid measurements are made using TCP connections, subject to TCP congestion control. Thus, the throughput grid measures the bandwidth available to a *single user* for transferring data, accounting for cross-traffic from other users’ flows. We assume a high degree of statistical multiplexing in wide-area network traffic—in other words, that the bandwidth consumed by a single user’s bulk transfer is negligible compared to the total available inter-region bandwidth. This allows a Skyplane user to compute a data transfer plan without regard to other users’ bulk transfers using Skyplane or other bulk transfer tools—all cross traffic from other users is assumed to be accounted for in the throughput grid.

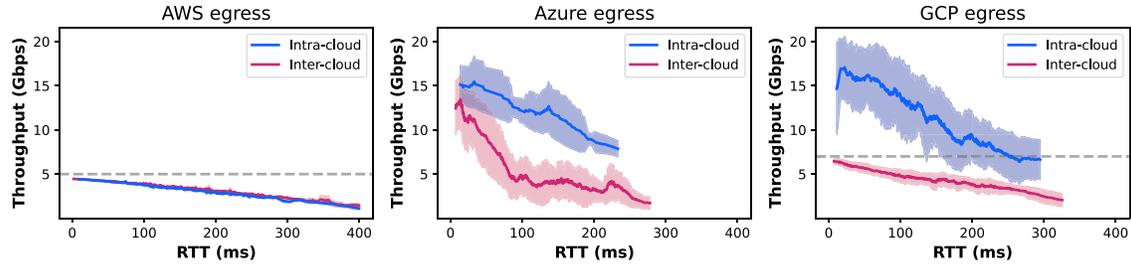

Figure 3: **Intra-cloud vs. inter-cloud links:** Inter-cloud links are consistently slower than intra-cloud links for network routes from Azure and GCP. Service limits are shown with a dashed line; GCP throttles inter-cloud egress to 7 Gbps while AWS throttles *all egress traffic* to 5 Gbps.

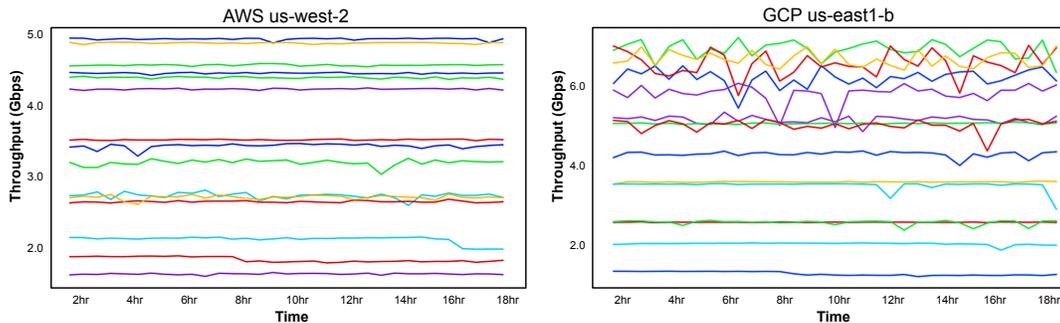

Figure 4: **Stability of egress flows over 18 hour period:** Continuous probes of cloud networks over one day reveal that routes from AWS have stable throughput over time. Paths between GCP regions are noisy but have a consistent mean.

As we show in the next subsection, the bandwidth of inter-region TCP connections is relatively stable in the short term, validating our assumption of high statistical multiplexing.

3.2 Profiling cloud networks

The planner relies on a profile of the network throughput between pairs of cloud regions. We collected a throughput grid by measuring the TCP goodput between each region pair using `iperf3`. In total, computing this profile cost approximately \$4000 in egress charges.

Fig. 3 displays the relationship between network latency and throughput for profiling routes originating from GCP and Azure for our measured throughput grid. For GCP, we leverage internal IPs which improve intra-cloud bandwidth. For both GCP and Azure, intra-cloud routes had lower tail RTTs than inter-cloud routes. We observe that in both GCP and Azure, inter-cloud links are slower than intra-cloud links. As Azure has no service limit for egress bandwidth, we see the fastest intra-cloud links achieve up to the NIC capacity of 16 Gbps. However, both GCP and AWS encounter egress throttling at 7 Gbps and 5 Gbps respectively.

A natural question is how frequently the throughput grid must be re-measured. Fig. 4 visualizes achieved throughput from AWS `us-west-2` and GCP `us-east1-b` taken every 30 minutes over an 18 hour timespan. Throughput is very stable

over time for both inter-cloud and intra-cloud routes from AWS `us-west-2`. Routes from GCP `us-east1-b` to AWS destinations is similarly very stable but intra-cloud routes to GCP destinations are less stable. Regardless, the overall rank order of regions by throughput remains mostly consistent over medium-term timescales. Thus, it should be sufficient to profile networks relatively infrequently (i.e. every few days). In practice, this information could be collected by third-party service, or measured via active probing along live transfers.

3.3 Skyplane’s data plane

Skyplane’s data plane executes data transfers using the plan computed by Skyplane’s planner. Ephemeral VMs for a single transfer, called “gateways,” are provisioned in the source region, destination region, and overlay regions for a transfer plan. Each source gateway reads a small shard of data from the object store and transfers data via intermediate gateways to the destination where the shard is written.

Skyplane reads data from an object store in the source cloud region and writes data to an object store in the destination cloud region. We focus on the object stores provided as a service by AWS S3, Azure Blob Storage, and Google Storage. Unlike a traditional overlay network, there is no central Skyplane service that allocates resources to each user from a pool of “Skyplane resources.” Instead, Skyplane can be understood

as a local service run by each user that is invoked when an application needs to transfer data. Skyplane directly allocates cloud resources on the user’s behalf when processing a job, and manages those resources to transfer the user’s data across cloud regions. This allows Skyplane to allocate and manage each user’s resources according to their cost and performance objectives, independently from the cloud providers’ existing data transfer services, while relying on clouds to offer a large pool of resources and manage isolation between users.

4 Principles of Skyplane’s planner

Skyplane’s planner² is responsible for developing a plan for transferring data across the wide area to complete an object transfer job submitted by a user or their application (Fig. 5). This plan describes the overlay path and the amount of cloud resources to allocate along that path to facilitate the transfer.

Skyplane’s planner supports two modes:

Cost minimizing: The planner will minimize cost subject to an application-specified throughput constraint.

Throughput maximizing: The planner will maximize throughput subject to an application-specified cost constraint.

As we will describe in §5, Skyplane finds the optimal plan by formulating it as an Mixed-Integer Linear Program (MILP) and using a fast but exponential-time solver. This section describes the degrees of freedom available to the optimizer to navigate the price-performance trade-off for the user’s specified constraint. Our goal is to describe what aspects of the plan are at the planner’s disposal, justify why it is reasonable to vary those aspects of the plan, and describe certain techniques available to the planner to manage the price-performance trade-off. Note that the planner is not directly programmed to use these techniques; they are merely patterns that it discovers in the course of finding the optimal MILP solution.

4.1 Achieving low instance and egress costs

That bandwidth costs dominate the cost of data transfer (§2) is both a challenge and an opportunity for Skyplane. It is an opportunity because it allows Skyplane to be competitive with the price of using data transfer tools provided directly by the cloud providers (e.g. AWS DataSync, AzCopy, GCP Cloud Transfer Service), as those tools incur bandwidth costs but not instance costs. It is a challenge for Skyplane because it implies that, used naively, indirect paths are much more expensive than direct paths. This is because egress bandwidth is charged for each hop along the path. For example, for a path $A \rightarrow C \rightarrow B$, the bandwidth cost must be paid for both $A \rightarrow C$ and $C \rightarrow B$, which could be *double* the cost of transferring over the direct path. As a result, it is crucial for Skyplane’s optimizer carefully manage egress transfer costs.

²Explore Skyplane’s planner at <https://optimizer.skyplane.org>

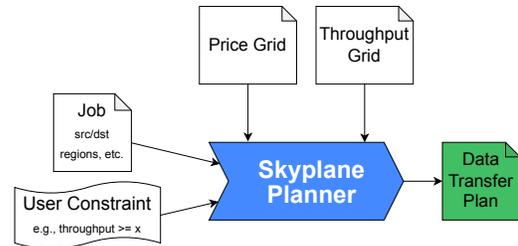

Figure 5: Skyplane’s planner considers throughput and cost constraints from the user along with per-cloud price information and an inter-region throughput profile grid to determine the optimal data transfer plan.

4.1.1 Choosing the relay region

One way for Skyplane to manage the additional cost associated with indirect paths is to carefully choose the relay region C to minimize this cost. For example, suppose that a user needs to transfer an object from AWS *us-west-2* (region A) to Azure UK South (region B). The direct path $A \rightarrow B$ would require the user to pay \$0.09 per GB, the cost of bandwidth leaving AWS’ network. If the relay region C is chosen in *us-central-1* or *us-east-1*, then the overall bandwidth price will only increase slightly; while the $C \rightarrow B$ transfer still incurs \$0.09 per GB, as data is leaving AWS’ network, the $A \rightarrow C$ bandwidth only costs \$0.02 per GB, as it is an intra-continental transfer within the cloud provider’s network. Skyplane’s planner can use the throughput and price grids to identify relay regions that improve the performance of the transfer while minimizing additional bandwidth costs.

4.1.2 Combining multiple paths

Another way to manage the cost of indirect paths is to split the data transfer over multiple paths, in order to make fine-grained trade-offs between price and performance. For example, suppose that Skyplane identifies a high-bandwidth indirect path, but that the path is more expensive than the user’s price ceiling. Skyplane can still benefit partially from that indirect path by sending part of the data over that path, at higher cost, and the remaining data over the direct path $A \rightarrow B$, at lower cost. Thus, Skyplane may average the price and performance of multiple paths, when doing so allows Skyplane to more optimally satisfy the user’s constraints.

4.2 Parallel TCP for high bandwidth

Skyplane uses parallel TCP connections—that is, bundles of TCP connections—to achieve high goodput over a chosen path. This is a well-known technique for achieving good performance, particularly for wide-area transfers [1, 59]. Our Skyplane implementation uses up to 64 outgoing connections for each VM instance, as we empirically measured that using

additional connections typically resulted in diminishing benefits in aggregate goodput. When collecting measurements for the throughput grid, we make sure to use 64 parallel connections to measure the achievable TCP goodput for each ordered pair of regions.

It is known that using multiple TCP streams in parallel may cause an application to obtain more than its “fair share” of bandwidth [25, §A.1], particularly in contexts where networks are running at nearly 100% utilization [36]. Our view is that, despite this, it is acceptable to use multiple TCP connections in parallel in the context of Skyplane. There are three reasons for this. First, it is common for applications to use parallel TCP, including for workloads like bulk data transfer [1, 44]. It is important for Skyplane to appropriately compete with such applications for limited bandwidth. Second, the user pays the cloud provider for bandwidth, both in the form of the bandwidth price (total amount transferred) and the instance price (rate at which data can be transferred), and it is natural for users to be able to make use of the bandwidth that they pay for. Third, cloud providers control the datacenter network, and can shape traffic in the presence of congestion to ensure that each customer gets a fair share of bandwidth.

4.3 Multiple VMs for high bandwidth

For a given overlay path, Skyplane must allocate sufficient resources along the path to achieve high bandwidth. However, the achievable outgoing bandwidth from a VM instance is limited, as described in §2.

Therefore, Skyplane may allocate multiple VM instances at certain regions along the path, to increase *aggregate* data transfer rate of the VMs at each region. Although simply using larger VMs may seem like a viable alternative, it is less effective than using multiple instances due to per-instance bandwidth limits. Skyplane uses a fixed VM size, and its planner chooses how many instances to allocate in each region, under the assumption that TCP goodput scales linearly with the number of allocated VM sizes.

It may seem that Skyplane can achieve an arbitrarily high bandwidth by spawning many instances in each region. Unfortunately, this simple strategy does not work because cloud resources are not perfectly elastic. The finite capacity for VMs in a datacenter is passed down to cloud customers in the form of service limits, which limit the number of VM instances, and therefore the amount of network bandwidth, that users can allocate in each region. While users can request limit increases, these are ultimately subject to resource availability. To model this, Skyplane’s planner takes into account a limit on the number of instances that a user can allocate per region.

5 Finding optimal transfer plans

Skyplane’s planner searches for cost-efficient high-throughput transfer plans that jointly specify the overlay path, TCP con-

Variables	
$F \in \mathbb{R}_+^{ V \times V }$	Throughput grid
$N \in \mathbb{Z}_+^{ V }$	VMs per region
$M \in \mathbb{Z}_+^{ V \times V }$	TCP conn. per region
Constraint: goal throughput	
$\text{TPUT GOAL} \in \mathbb{R}_+^{ V \times V }$	User’s desired throughput
Constants: provider limit	
$\text{LIMIT}^{\text{link}} \in \mathbb{R}_+^{ V \times V }$	Throughput grid limit
$\text{LIMIT}^{\text{conn}} \in \mathbb{Z}_+^{ V \times V }$	TCP connection limit
$\text{LIMIT}^{\text{ingress}} \in \mathbb{Z}_+^{ V }$	VM limit
$\text{LIMIT}^{\text{egress}} \in \mathbb{Z}_+^{ V }$	Egress bandwidth limit
Constants: provider cost	
$\text{COST}^{\text{egress}} \in \mathbb{R}_+^{ V }$	Egress cost (\$/Gbit)
$\text{COST}^{\text{VM}} \in \mathbb{R}_+^{ V }$	VM cost (\$/s)

Table 1: Symbol table for Skyplane’s ILP formulation.

nections between regions and VMs to provision per region.

At the core of Skyplane’s planner is an optimizer that finds the optimal plan using off-the-shelf Linear Programming (LP) solvers. We formalize the constraints of our problem as Mixed Integer LP (MILP) which can quickly be solved in under 5 seconds with an open-source solver. The problem can be further relaxed into a continuous LP which is solvable in worst-case polynomial time via interior point methods [39].

Independently optimizing for each variable then combining partial solutions would not guarantee a globally optimal solution. It is therefore important that Skyplane’s planner models all variables in an integrated search space to obtain provably optimal data transfer plans.

5.1 Cost minimizing overlay paths

Flow networks can naturally represent overlay networking topologies like those used by Akamai [58]. We start with a min-cost flow problem. The following primal LP finds the optimal flow matrix $F \in \mathbb{R}_+^{|V| \times |V|}$ for a network topology graph $G = (V, E)$ where nodes represent regions and edges are links:

$$\begin{aligned}
 & \arg \min_{F} \quad \langle C, F \rangle \\
 & \text{subject to} \quad \sum_{(c,v) \in E} F_{c,v} \geq \text{TPUT GOAL} \\
 & \quad \quad \quad \sum_{(u,v) \in E} F_{u,v} = \sum_{v,w} F_{v,w} \quad \forall v \in V - \{s, t\} \\
 & \quad \quad \quad 0 \leq F \leq \text{LIMIT}^{\text{link}}
 \end{aligned} \tag{1}$$

where s and t are the source and destination regions, $\text{LIMIT}^{\text{link}} \in \mathbb{R}_+^{|V| \times |V|}$ is the maximum capacity for each link and $C \in \mathbb{R}_+^{|V| \times |V|}$ is the cost per unit of bandwidth between regions. We use the same notation for matrix and vector inner products: $\langle C, F \rangle = \sum_{u,v} C_{u,v} F_{u,v}$.

5.1.1 Objective: Minimize cost from egress and VMs

Min-cost flows do not accurately reflect the cost of transfers in the cloud. The total cost of a transfer in Skyplane includes *egress cost* and *VM cost*. Note that this objective is not linear; we present a linear reformulation in Sec. 5.1.1. We present the full objective is in the in Equation 4a.

Modeling egress cost Unlike physical networks, virtual networks in the cloud will charge the same amount if 1GB of data is sent at 1 Mbps or 10 Gbps. Transfers are priced according to *egress volume* (\$ per GB, $\text{COST}^{\text{egress}}$) rather than *bandwidth* (\$ per Gbps). We can update the cost function to instead model the transfer cost by first computing how much the overlay path costs to run per unit time and then scale that by the runtime for a transfer. We denote the total volume of the transfer as VOLUME. Total egress cost is then:

$$\underbrace{\langle F, \text{COST}^{\text{egress}} \rangle}_{\text{Egress cost per s}} * \underbrace{\text{VOLUME} \div \sum_{v \in V} F_{s,v}}_{\text{Transfer time}} \quad (2)$$

Modeling VM cost Multiple VMs can increase aggregate bandwidth as discussed in Sec. 4.3. To optimally trade-off parallel VMs with the overlay, we introduce a new decision variable $N \in \mathbb{Z}_+^{|V|}$ that models the number of instances use to transfer data per region. VM count per region may vary due to asymmetric egress and ingress limits. To accurately consider transfer costs from VMs, we add the the following instance cost expression to Equation 2 where COST^{VM} is a vector containing the cost per second per VM in each region:

$$\underbrace{\langle N, \text{COST}^{\text{VM}} \rangle}_{\text{VM cost per s}} * \underbrace{\text{VOLUME} \div \sum_{v \in V} F_{s,v}}_{\text{Transfer time}} \quad (3)$$

Linear reformulation of the objective As written, the objective in Equation 4a is not linear due to a product of variables between F and N . By reformulating the problem to instead consider finding a plan that provides *exactly* TPUT GOAL (instead at least), the runtime for the transfer can be reduced to a constant $\text{VOLUME} \div \text{TPUT GOAL}$.

5.1.2 Constraints: Cloud provider service limits

Resources are not infinite at cloud regions; providers limit the number of VMs that a user may provision and in some cases, providers may throttle the performance of ingress and egress.

Per VM ingress and egress limits AWS and GCP each throttle egress from their clouds via SDN policies. For AWS, instances with 32 cores or less are limited to 5 Gbps. For GCP, individual flows are limited to 3 Gbps and total egress is service limited to 7 Gbps. Ingress is bottlenecked by VM NIC bandwidth. We constrain the maximum ingress bandwidth per VM to $\text{LIMIT}^{\text{ingress}}$ via Constraint 4f and the maximum egress bandwidth per VM to $\text{LIMIT}^{\text{egress}}$ via Constraint 4g.

Constraining TCP connections Using parallel TCP connections is a well known approach to improve WAN performance as discussed in Section 4.2. Yet, bandwidth does not scale linearly with connections (Figure 9a). We introduce a decision variable $M \in \mathbb{Z}_+^{|V| \times |V|}$ representing the number of connections between a *pair of regions* (not per VM pair). Constraint 4b ensures M is constrained by N and $\text{LIMIT}^{\text{conn}}$ (typically 64 per VM). We then limit the total incoming and outgoing connections with Constraints 4i and 4h.

Per-region VM limits We introduce the variable $N \in \mathbb{Z}_+^{|V|}$ to denote the number of VMs per region. N must be under the global instance cap in Constraint 4j. The optimizer linearly scales the maximum number of egress TCP connections per region by the number of VMs provisioned in each region.

5.1.3 Continuous relaxation of MILP

To improve solve times, N and M are relaxed into real valued variables $N \in \mathbb{R}_+^{|V|}$ and $M \in \mathbb{R}_+^{|V| \times |V|}$. Rounding variables down performs comparably to randomized rounding with solutions $\leq 1\%$ from optimal. The relaxed problem has worst case polynomial time complexity [39].

5.1.4 Full formulation of the cost optimal solver

All variables and constants are listed in Table 1. The full formulation of Skyplane’s optimizer is:

$$\arg \min_{F, N, M} \frac{\text{VOLUME}}{\text{TPUT GOAL}} (\langle F, \text{COST}^{\text{egress}} \rangle + \langle N, \text{COST}^{\text{VM}} \rangle) \quad (4a)$$

subject to

$$F \leq (\text{LIMIT}^{\text{link}} \odot M) \div \text{LIMIT}^{\text{conn}} \quad (4b)$$

$$\sum_{v \in V} F_{s,v} \geq \text{TPUT GOAL} \quad (4c)$$

$$\sum_{u \in V} F_{u,t} \geq \text{TPUT GOAL} \quad (4d)$$

$$\sum_{u \in V} F_{u,v} = \sum_{u \in V} F_{v,u} \quad \forall v \in V - \{s, t\} \quad (4e)$$

$$\sum_{u \in V} F_{u,v} \leq \text{LIMIT}_v^{\text{ingress}} * N_v \quad \forall v \in V \quad (4f)$$

$$\sum_{v \in V} F_{u,v} \leq \text{LIMIT}_u^{\text{egress}} * N_u \quad \forall u \in V \quad (4g)$$

$$\sum_{v \in V} M_{u,v} \leq \text{LIMIT}^{\text{conn}} * N_v \quad \forall u \in V \quad (4h)$$

$$\sum_{u \in V} M_{u,v} \leq \text{LIMIT}^{\text{conn}} * N_u \quad \forall v \in V \quad (4i)$$

$$N_v \leq \text{LIMIT}^{\text{VM}} \quad \forall v \in V \quad (4j)$$

5.2 Throughput maximizing overlay paths

Directly solving for a throughput maximizing path under a cost ceiling is non-trivial as we cannot use the linear reformulation of the cost objective. We can approximate a solution by solving for the minimum cost transfer plan at a range of many throughput goals. The result of this procedure is a Pareto

frontier curve (as shown in Fig. 9c). A throughput maximizing solution can be extracted from this curve. The quality of approximate solution will depend on how many samples are used. A single AWS `c5.9xlarge` instance can evaluate 100 samples in under 20 seconds.

6 Implementation of Skyplane

We implemented Skyplane in Python 3. Skyplane’s planner uses the proprietary Gurobi library to solve MILP instances (used in our evaluation), but the Coin-OR library can be used instead to avoid this dependency. Our implementation currently supports the three major cloud providers: Amazon Web Services, Microsoft Azure, and Google Cloud Platform.

We use `m5.8xlarge` instances on AWS, as smaller VM sizes were subject to burstable networking performance, which we wished to avoid [4, 7]. For consistency, we used `Standard_D32_v5` instances on Microsoft Azure and `n2-standard-32` instances on Google Cloud.

A user initiates a transfer from their application with the *Skyplane client*. The client provisions VMs in each region according to the transfer plan and runs the *Skyplane gateway* program on each VM. The gateway is responsible for actually reading from source object stores, relaying data through overlay regions and writing to destination object stores.

While transfer time is dominated by network throughput, the time to spawn gateway VMs contributes to the transfer latency. To minimize unnecessary bloat in VM images, we use compact OSes such as Bottlerocket [3] and package dependencies via Docker.

Skyplane assumes that objects are broken up into small *chunks* of approximately equal size. Applications can often do this without significant burden; for example, machine learning applications store data as `TFRecords`, which are easy to split into small chunks. This allows Skyplane to read and write data quickly from and to cloud object stores, by issuing many read/write operations in parallel to different chunks.

To mitigate the impact of straggler connections, Skyplane dynamically partitions data across TCP connections as they become ready to accept more data. This is in contrast to tools like GridFTP [1], which assign data blocks to connections in a round-robin fashion. The downside is that, for plans that use multiple overlay paths, the amount of data sent on each path may deviate from the targets computed at planning time, which could cause the actual cost of transferring data to deviate from the cost predicted by Skyplane’s planner.

To avoid overflowing buffers at relay regions, Skyplane uses hop-by-hop flow control to stop reading data from incoming TCP connections when a VM’s queue of chunks reaches capacity. Bufferbloat-type problems [28] are not a concern for Skyplane, with regard to queued chunks, as we pipeline transfers to optimize for throughput instead of latency.

7 Evaluation

To evaluate Skyplane, we investigate transfer time and price. We will sometimes use transfer throughput as a proxy for transfer time. In our price calculations, we include both instance cost and egress cost.

7.1 Experimental setup

We evaluate Skyplane with 20 AWS regions, 24 Azure regions and 27 GCP regions. For all experiments, we use public IP addresses attached to the VMs for transferring data. In some cases, one can achieve better performance for intra-cloud overlay hops by using private IP addresses assigned to each VM. For GCP this yields higher performance; for AWS and Azure it may yield higher performance, but requires peering virtual networks which incurs additional fees.

Furthermore, Azure and GCP allow one to select *network tiers* to control whether data is transferred via the cloud provider’s network or via the public Internet. The Skyplane prototype utilizes external IPs over standard network tiers. That said, Skyplane is not incompatible with optimizations like VPC peering or hot-potato routing tiers to reduce cost and improve performance which we leave to future work. We use the CUBIC congestion control protocol in experiments.

7.2 How much faster is Skyplane than existing data transfer solutions?

Existing cloud providers offer data transfer tools such as AWS DataSync, GCP Storage Transfer, and Azure AzCopy for low-cost transfers of bulk data into their respective clouds. These tools do not disclose what mechanisms they use to transfer data—for example, the number of VMs and TCP connections (if any) used for a transfer, or the QoS (if any) associated with the network traffic. When evaluating Skyplane, we restrict Skyplane to use at most 8 VMs in each region. This is conservative; for example, on equalizing \$/GB for some routes, Skyplane could provision *up to 262 VMs* per region within DataSync’s service fee. Moreover, while these services only support data transfer *into* their respective clouds, Skyplane supports data transfer between every region pair.

We consider transferring the training and validation set for ImageNet [23]. We specifically use the `TFRecords` as generated by Google as part of the Cloud TPU benchmark example [23]. We evaluate flows between regions within a single cloud (intra-provider) and between clouds (inter-provider). We expected that data transfer within each cloud provider (e.g., between AWS’s `us-east-1` and AWS’s `us-west-1`) to perform well as they have full visibility into their networks and can utilize private interfaces with higher performance than over public API. For example, Azure Blob Storage throttles per-object reads for third-party VMs [50]. Our experiments

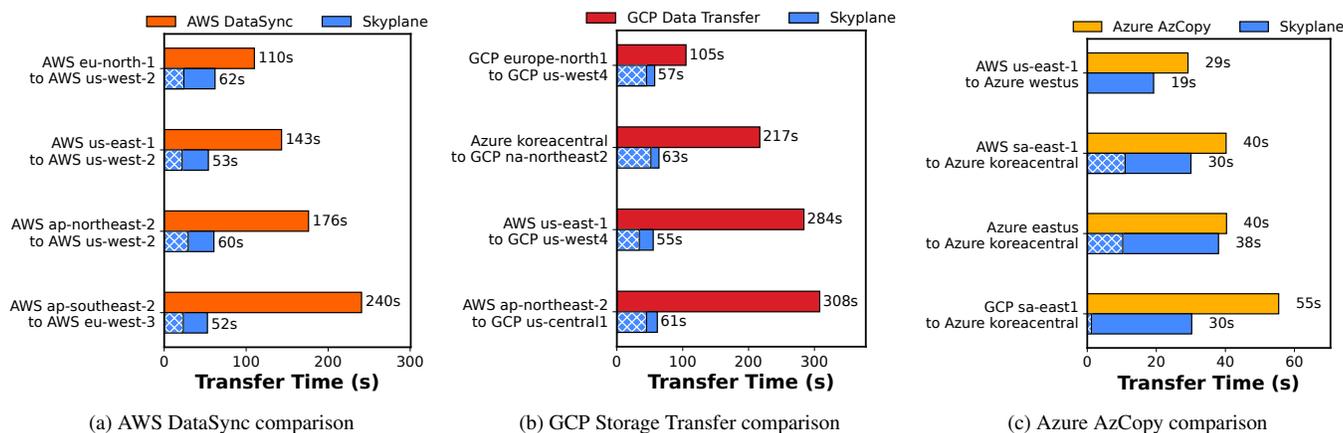

Figure 6: **Comparison to cloud transfer systems:** The thatch pattern in each bar represents the storage I/O overhead.

did observe this behavior. However, Skyplane benefits from parallelizing the transfers.

We compare against AWS DataSync, GCP Storage Transfer and Azure AzCopy in Fig. 6. We evaluated Skyplane with a cost budget cap that is lower than the service fee for cloud transfer services in all our experiments. For each source-destination pair, we additionally measured the time to transfer procedurally-generated data using Skyplane; this allows us to break out the overhead of reading and writing to cloud storage as a “thatched” region in each bar. Skyplane significantly outperforms AWS DataSync and GCP Cloud Transfer in all configurations. In certain cases, Azure AzCopy performs about as well as Skyplane. We chose the `koreacentral` region because we expected the greatest improvements from the overlay in that region; however, storage overheads (the “thatched” regions of the bars), not networking overheads, dominated the runtime. It is possible that AzCopy avoids the Azure Blob Storage I/O overhead that dominates Skyplane’s transfer time by leveraging Azure’s Copy Blob From URL API call to download data directly into the servers running Azure Blob Storage [11].

7.3 How much faster are the overlay paths?

The planner optimally explores the trade-off between improved throughput and cost for cloud data transfers. We explore solving for the optimal transfer path between all pairs of clouds regions between all cloud providers. We evaluated 22 AWS regions, 23 unrestricted Azure regions and 27 GCP regions which leads to 5,184 possible replication routes. It would be too expensive to transfer a large amount of data along each path in order to measure the empirical achieved throughput; therefore we use the planner to generate a plan and compare the resulting plan with the direct path, both in terms of expected throughput and cost. We compute predicted costs for transferring a 50 GB dataset between each possible

source and destination. We report the speedup relative to Skyplane with a direct connection between each set of instances. Notice that the baseline is itself an ablation of Skyplane and it generally outperforms existing cloud transfer services to begin with (see §7.2).

The results are shown in Fig. 7. For each pair of source and destination clouds, we show distribution of predicted throughputs across region pairs, both with Skyplane’s planner restricted to the direct path and allowing Skyplane’s planner to use overlay paths. The results show that Skyplane’s overlay routing meaningfully improves achievable throughput between cloud regions. Note that transfers out of AWS cannot exceed 5 Gbps and transfers leaving GCP cannot exceed 7 Gbps due to these cloud providers’ caps on egress bandwidth.

7.4 Where are transfer bottlenecks?

To understand how the overlay improves throughput, we characterize the fraction of transfers that are bottlenecked at each location. In Fig. 8, we visualize the percentage of transfers from §7.3 that were bottlenecked at a VM in the source region, the network link leaving the source region, a VMs in optional overlay regions, a network links leaving an overlay region, and a VM in the destination region. We consider a particular location to be a bottleneck if utilization is over 99%. Multiple locations may simultaneously be a bottleneck for one transfer.

For Skyplane with overlay routing disabled, the network link from the source to the destination region is the most common bottleneck for transfers. In a small set of cases, the source VM is a bottleneck for the transfer. Generally, the direct path is not fast enough to saturate the maximum egress bandwidth limit for a VM. The overlay shifts source link bottlenecks by reducing the number of transfers bottlenecked by the source link by 32%. The bottleneck shifts to the source VM or in some cases a network link leaving an overlay region.

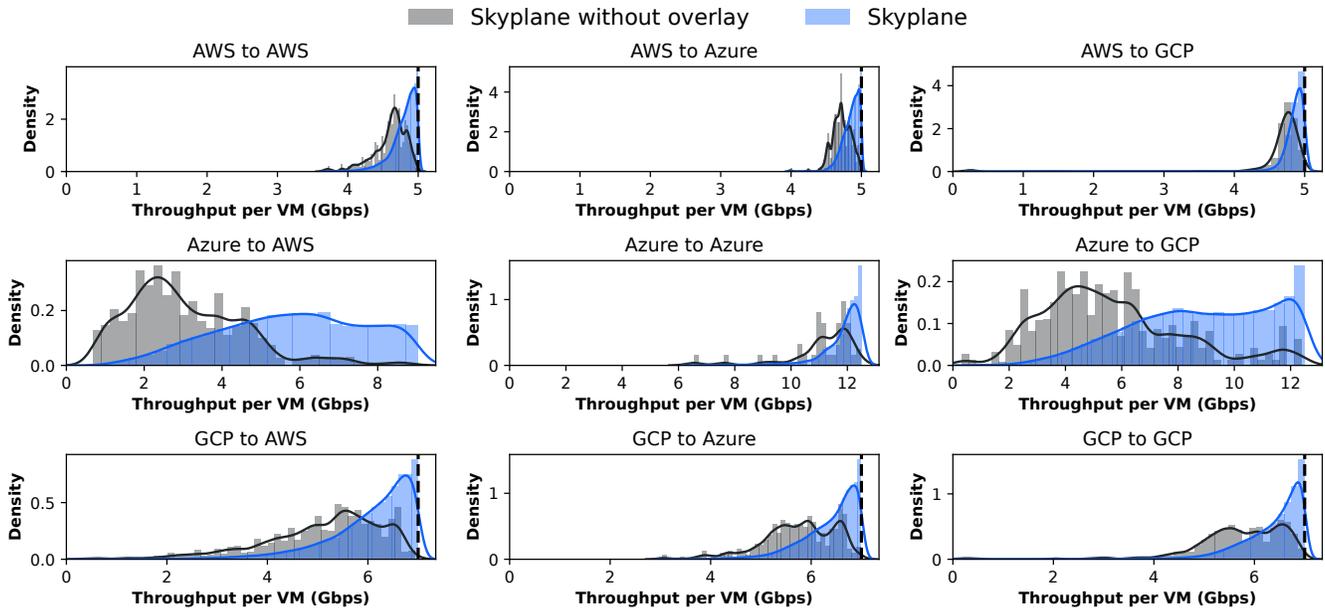

Figure 7: **Ablation of predicted overlays:** Overlay routes improve throughput per VM instance. We visualize the distribution of predicted throughput by the planner with all optimizations enabled (Skyplane) and with all optimizations except for overlay routing (Skyplane without overlay). The AWS and GCP egress limits are displayed with a dashed line.

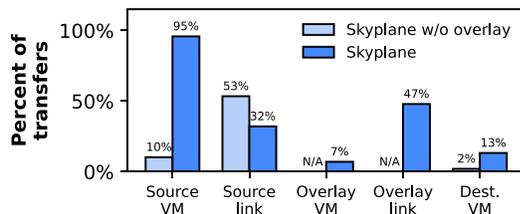

Figure 8: **Transfers bottlenecked at each location:** For transfers in Fig. 7, we visualize what percentage of transfers were bottlenecked at various locations. Enabling the overlay shifts bottlenecks from the network to the VM.

7.5 Skyplane microbenchmarks

Impact of parallel TCP connections Fig. 9a shows the impact of varying the number of parallel TCP connections used to transfer data between VMs. For this experiment, the source VM was located in AWS `ap-northeast-1` and the destination VM was located in AWS `eu-central-1`. Skyplane transfers 32 GB of synthetic, procedurally-generated data in these experiments to avoid incurring object store I/O overheads and thereby isolate network performance. The black dashed line shows the expected throughput, assuming that bandwidth scales linearly with the number of parallel TCP connections up to AWS' 5 Gbps egress cap. The blue line shows Skyplane's achieved throughput, and the green line uses Skyplane's achieved throughput using the BBR congestion con-

trol algorithm (used only this experiment). For this experiment, the source VM was located in AWS `ap-northeast-1` and the destination VM was located in AWS `eu-central-1`. Skyplane's achieved throughput plateaus below the 5 Gbps egress cap, and 64 connections is enough to come close.

Impact of parallel VMs Fig. 9b shows the impact of using multiple VMs in each region to achieve higher aggregate throughput. The black dashed line shows the expected throughput, assuming that bandwidth scales linearly with the number of VMs. Although Skyplane's performance is significantly less than the expected throughput for a large number of gateways, the graph shows that using parallel VMs is an effective way for Skyplane to scale its aggregate bandwidth. Additionally, using parallel VMs is a particularly valuable tool in the context of inter-cloud transfers, as Skyplane can use multiple VMs in one cloud provider to circumvent the egress limit. For example, for an overlay hop from an AWS region to an Azure region, one may allocate many instances in AWS but few in Azure, to account for AWS' egress cap.

Trade-off between cost and throughput Fig. 9c shows the impact on overlay path throughput as the price budget is varied. We adjusted the cost budget afforded to the planner (x-axis), and plot the throughput predicted by the planner for the output plan (y-axis). We show three routes where the overlay benefits are considerable (Azure `westus` to AWS `eu-west-1`), good (GCP `asia-east1-a` to AWS `sa-east-1`) and minimal (AWS `af-south-1` to AWS

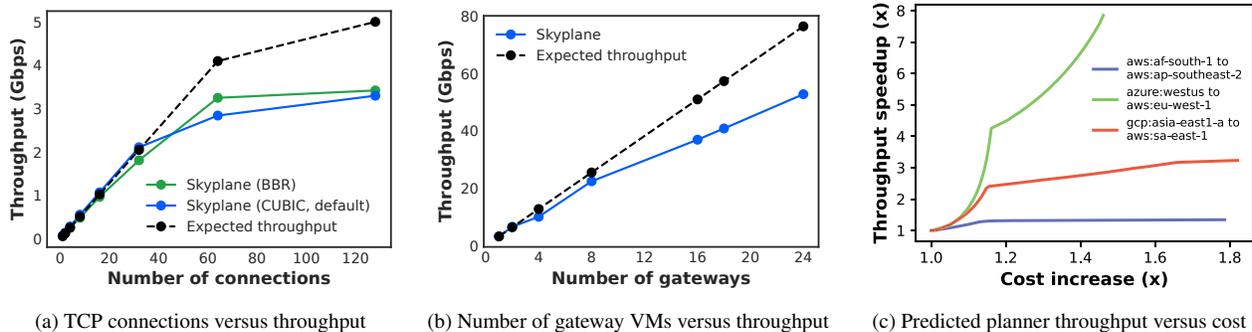

Figure 9: **Skyplane ablations:** We evaluate the impact of parallel TCP connections, parallel gateway VMs and overlay cost.

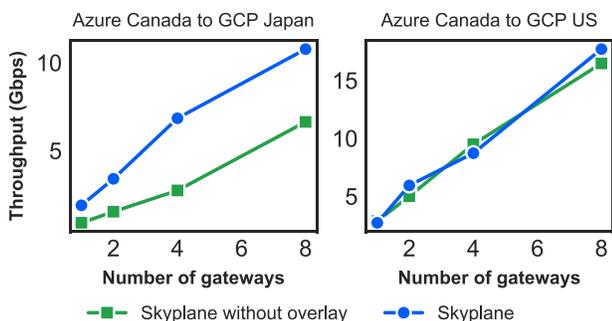

Figure 10: **Scaling VMs versus overlay:** In situations where the direct path is slow, the overlay is faster than simply scaling the number of VMs used alone.

ap-southeast-2). As the cost budget increases, Skyplane uses increasingly complex overlay topologies, adding new overlay paths as the instance limit (1 VM, in this case) is saturated in each region. Each elbow in the plot (e.g. $1.2\times$ for the Azure to AWS route) represents a point where Skyplane adds a new overlay route via a faster but more costly region. At some point, the planner cannot increase throughput further as the overlay network is saturated.

Is it better to use VMs to form overlay paths or parallelize the direct path? Given a limited number of VMs (§4.3), a natural question is whether it is better to use those VMs to form overlay paths or to parallelize the direct path. In Fig. 10, we evaluate Skyplane with and without the overlay enabled for various numbers of VMs in the context of an inter-continental transfer and an intra-continental transfer. For the inter-continental transfer, using the VMs with overlays enabled provides a $2.08\times$ geomean speedup compared to using those VMs to parallelize the direct path. However, for the intra-continental transfer, there is little benefit to using VMs in overlay paths ($1.03\times$ geomean speedup).

Table 2: **Comparison with academic baselines:** Skyplane outperforms RON’s path selection heuristic implemented in Skyplane [8].

Method	Time	Throughput	Cost
GCT GridFTP [1, 10] (1 VM)	133s	1.03 Gbps	\$1.40
Skyplane (1 VM, direct)	73s	1.71 Gbps	\$1.40
Skyplane w/ RON routes (4 VMs) [8]	21s	6.02 Gbps	\$2.27
Skyplane (cost optimized, 4 VMs)	32s	3.88 Gbps	\$1.56
Skyplane (throughput optimized, 4 VMs)	16s	8.07 Gbps	\$1.59

7.6 Comparison against academic baselines

In Table 2, we compare Skyplane with RON [8] and the community-maintained fork [10] of GridFTP [1] for a 16 GB data transfer from Azure East US to AWS ap-northeast-1. To isolate network throughput from I/O overheads, we benchmark the transfers without object stores (VM to VM only).

We use the open-source GCT fork of GridFTP [10]. Although GCT GridFTP theoretically supports striped transfers across multiple machines, we were unable to find a supported non-commercial implementation. To make a fair comparison, we run both GCT GridFTP and Skyplane with a single VM per region. Skyplane is $1.6\times$ faster than GCT GridFTP.

We implement RON’s path selection heuristic in Skyplane to compare overlays between RON and Skyplane. Our results show that Skyplane has better cost and throughput than RON. Skyplane with routes from RON’s path selection heuristic achieves $3.5\times$ higher throughput than Skyplane with a single VM but at 62% cost overhead. Skyplane’s planner instead finds overlay paths with up to $4.7\times$ higher throughput than the direct path within a 14% cost overhead.

8 Related Work

Skyplane builds on the overlay network literature [8, 16, 58]. As discussed in §1, Skyplane adapts classical overlays to the cloud setting, accounting for the price of network bandwidth

and leveraging the elasticity of cloud resources. CRONets [16] briefly discusses cost, but focuses on comparing cloud-based options to private leased lines. Unlike Skyplane, it does not discuss how to manage the cost of cloud resources. Lai et al. [46] find relay regions improve throughput in AWS when utilizing a single TCP connection but find the 2 Gbps instance NIC limit from their chosen instance class limits the benefit of overlay paths. CloudCast [56] examines the use of triangle overlays in the cloud to reduce network latency while Skyplane examines throughput.

Several existing efforts [27, 49, 55] aim to optimize bulk data transfers by reducing the amount of data transferred. Such techniques are complementary to Skyplane; one can first apply these techniques to reduce the amount of data to transfer, and then apply Skyplane's techniques to transfer that reduced data efficiently. Unlike Skyplane, these works do not use cost when selecting the network path to use for a transfer.

Another line of research aims to improve bulk data transfers by improving resource management. GridFTP [1] is a tool for wide-area transfers that techniques such as using multiple machines and TCP connections. GridFTP sends all data over the direct path and does not utilize overlays. Khanna et al. [40] explore application of network overlays to GridFTP but do not consider elasticity and egress price in the cloud. Other solutions, like Pockets [59], also use parallel TCP connections for high bandwidth. Pied Piper [14] also explored how cloud resource elasticity could be used to improve cloud data transfers, but utilize a different mechanism than Skyplane.

There have been decades of improvements and optimizations at the transport layer to make TCP perform better in large-BDP settings within TCP itself [2, 15, 17, 33], while others concern operating system support for TCP [20, 24, 48]. Improvements to TCP are complementary to Skyplane. CodedBulk [61] uses network coding to complete bulk-transfer multicast jobs quickly [61]. Another set of research [18, 63, 64] investigates how to schedule urgent and non-urgent bulk transfers to meet a transfer's deadline. None of these techniques consider the cost of transferring data in the cloud.

Traffic engineering (TE) systems, like Google's B4 [35, 36] and BwE [43] and Microsoft's SWAN [34], Cascara [57], and BlastShield [42], are used internally by cloud providers to navigate the cost-performance trade-off in their wide-area networks. The precise nature of the trade-off differs from Skyplane in two ways. First, TE systems consider costs in terms of the *bandwidth* provisioned (e.g., the cost of installing long-distance cables [36], or the 95th percentile bandwidth for peering links [57]). In contrast, Skyplane considers cost from the perspective of a cloud customer, where the cost depends on the volume and not bandwidth of data transferred. Second, TE systems like Cascara [57] assume a static topology and aim to reallocate bandwidth to save cost, with a global view of a single provider's network. Skyplane optimizes a single user's transfer, with the ability to use overlay regions in multiple cloud providers' networks.

Skyplane has similarities to Content Delivery Networks (CDNs) [58], most notably in that both make use of overlay networks. However, Skyplane's focus is different from CDNs. CDNs focus on caching objects near users, in order to provide low network latency. In contrast, Skyplane focuses on transferring large amounts of data quickly, with a focus on achieving high bandwidth rather than low network latency such as in workloads like ML training and database replication. CDNs are more suitable for workloads where popular objects need to be replicated to many regions so that geo-distributed users can access them with low network latency.

One application of bulk transfers is VM migration [19, 32, 37, 45] that balance VM downtime and bandwidth consumed when transferring VMs. Supercloud [37] uses a network of vSwitches in an overlay that maintains TCP connections upon migration, not to provide high bandwidth at low cost.

Some existing research efforts and commercial products focus on bulk transfer jobs that are not time-critical. For example, Laoutaris et al. [47] propose techniques to reduce the cost of transferring data for delay tolerant applications.

Cloud providers provide services for bulk transfer, such as AWS Snowball [62], Azure Data Box [12], and GCP Transfer Appliance [21], that have users ship their data via physical drives via the postal service. For sufficiently large transfers, these services may allow data to be transferred into the cloud datacenter more quickly than using the Internet.

9 Conclusion

This paper explores how to efficiently transfer data between cloud regions using cloud-aware overlay networks. Our key observation is that principles from overlay networks can be applied to the cloud setting to identify high-quality network paths that lead to fast transfer times. However, adapting principles from overlay networks to the cloud setting requires consideration of cloud resource pricing, most notably the egress fees associated with network bandwidth. Skyplane manages the trade-off between performance and cost when performing bulk data transfer. It works by accepting a user- or application-provided constraint on performance and solving a mixed integer linear program (MILP) to obtain the optimal data transfer plan. Skyplane can reduce the time to transfer data by up to $5.0\times$ at minimal additional cost.

Abstract

Implementing distributed protocols under a standard Linux kernel networking stack enjoys the benefits of load-aware CPU scaling, high compatibility, and robust security and isolation. However, it suffers from low performance because of excessive user-kernel crossings and kernel networking stack traversing. We present Electrode with a set of eBPF-based performance optimizations designed for distributed protocols. These optimizations get executed in the kernel before the networking stack but achieve similar functionalities as were implemented in user space (e.g., message broadcasting, collecting quorum of acknowledgments), thus avoiding the overheads incurred by user-kernel crossings and kernel networking stack traversing. We show that when applied to a classic Multi-Paxos state machine replication protocol, Electrode improves its throughput by up to 128.4% and latency by up to 41.7%.

1 Introduction

Distributed protocols such as Paxos [37] for state machine replication are important building blocks for highly-available distributed applications. For example, Google’s Chubby [6] uses a variant of classic Paxos [37] and Multi-Paxos [36] to implement a highly-available lock service, powering their business-critical GFS [16] and Bigdata [7] applications. Google’s globally-distributed database Spanner [8] and Microsoft’s data center management tool Autopilot [22] also run Paxos protocols to maintain their high availability.

Existing high-performance implementation of distributed protocols tends to be radical and not readily-deployable. DPDK-based kernel-bypass approaches [27, 79] allow direct access to the underlying NIC hardware, but require application developers to build their own networking stack and maintain compatibility with the evolving kernel networking stack [75]. DPDK also dedicates CPU cores to busily poll the network interface for I/O competition, sacrificing CPU resources and wasting energy during low I/O loads. This is especially a problem for embedded devices [51, 60, 70] where CPU resources are rare. Other approaches co-design specialized distributed systems with niche network hardware including RDMA [11, 28, 76], FPGA [23], SmartNICs [66], and programmable switches [25]. These advanced hardware devices are not widely available in today’s cloud environments, and systems built on top of them tend to be difficult to design, implement, and deploy [27].

Instead, we would prefer the widely-deployed and well-maintained standard kernel networking stack that also provides load-aware CPU scaling and strong security and isolation among different applications [5, 59]. However, implementing distributed protocols under the standard kernel networking stack often gives poor performance. The root causes are the high packet processing overhead in the kernel networking stack and heavy communications in distributed protocols. Our measurement shows that over half of CPU time is spent on the kernel networking stack in a typical Paxos deployment (§2); such overhead is mainly caused by user-kernel crossings (and associated context switches) and traversing the kernel networking stack. Moreover, when using a classic leader-based Multi-Paxos protocol [43, 54] to implement state machine replication, e.g., with five replicas, processing a single request would require the leader node to send/receive *fourteen* messages in total (see Figure 1a), suffering from the kernel stack overhead fourteen times¹.

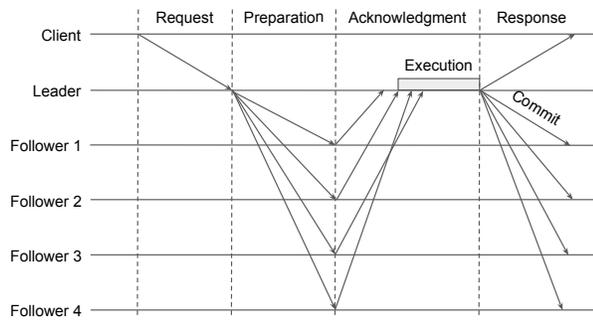

In this paper, we focus on accelerating Paxos protocols inside data centers by offloading protocol operations to the kernel via eBPF (i.e., extended Berkeley Packet Filter) [46, 49]. eBPF allows safely executing customized yet constrained functions inside the kernel at various locations. Similar to kernel bypass, the offloaded operations get executed immediately after the NIC driver receives the packet, without user-kernel crossing and kernel networking stack traversing. Unlike kernel bypass, eBPF is an OS-native mechanism such that eBPF-offloaded operations do not sacrifice security and isolation properties while amenable to load-aware CPU scaling without busy-polling.

The key challenge is, given the constrained programming model of eBPF, *which parts of Paxos protocols to offload that can greatly reduce kernel stack overhead while being implementable and efficient in eBPF*. Note that the eBPF subsystem requires every offloaded function to be statically verified to guarantee kernel security, which only allows limited instructions, bounded loops, static memory allocation, etc.

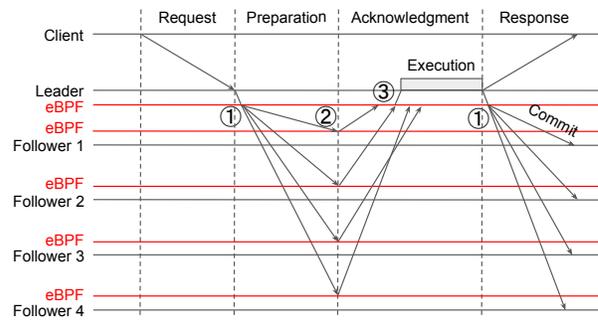

Our insight is that common operations of Paxos protocols, e.g., message broadcasting and waiting on quorums, incur large kernel stack overhead, but are naturally offloadable by existing eBPF programming capacity. For example, Paxos protocols require a leader node to broadcast preparation messages to follower nodes; if implemented using multiple `sendto()` syscalls conventionally, it would incur multiple user-kernel

*Equal contribution

¹Linux `io_uring` [1] can reduce user-kernel crossings, but cannot reduce kernel stack traversing (see §8 for details).

(a) The Multi-Paxos/Viewstamped Replication protocol.

(b) Electrode-accelerated Multi-Paxos/Viewstamped Replication.

Figure 1: Normal case execution of the leader-based Multi-Paxos/Viewstamped Replication protocol vs. Electrode-accelerated one with 5 replicas. Electrode offloads ①: message broadcasting (§4.1), ②: fast acknowledging (§4.2), and ③: wait-on-quorums (§4.3) to eBPF to reduce the kernel networking stack overhead.

crossings and kernel networking stack traversing. Instead, eBPF has a `bpf_clone_redirect()` [45] function that enables us to clone an in-kernel packet buffer multiple times and send them to different destinations; this eBPF-based message broadcasting only needs one user-kernel crossing and one kernel networking stack traversing. Besides broadcasting, we also utilize eBPF to reduce unnecessary wake-ups of user-space applications when waiting on quorums, and optimize how follower nodes handle preparation messages by early acknowledging before entering the kernel networking stack. The final result of these three eBPF-based optimizations is Electrode² (Figure 1b). When applying Electrode to a classic leader-based Multi-Paxos protocol, it achieves up to 128.4% higher throughput and 41.7% lower latency. This translates into up to 112.9% higher throughput and 19.3% lower latency for a Paxos-based transactional replicated key-value store.

Electrode has some limitations: it currently targets protocols implemented in UDP and relies on application-level retransmission to handle packet loss. This works well for Paxos protocols whose requests are usually small enough to fit into a single packet, and data center environments where packet loss is rare [28, 61].

2 Background

2.1 Consensus Protocols

Distributed protocols that coordinate and synchronize among a collection of nodes have become an indispensable part of the modern data center application stack. Storage systems in data centers replicate data for fault tolerance and availability. For instance, Berkeley-DB [55] uses a consensus protocol to replicate its logs over a set of distributed replicas. Transactional storage systems like H-Store [71] and Spanner commit their updates to multiple replicas in order to be more failure resilient. At the heart of most replication-based systems is a consensus protocol [36, 37, 43, 54] that ensures that operations execute in a consistent manner across all replicas.

²Electrode is a Pokémon that has a high speed score.

Here, we consider a set of nodes either functioning as clients or replicas. Clients are the users of a particular application-level service hosted by a collection of replicas. It should also be noted here that clients could often just be other servers within the same data center. Clients submit requests to one or more replicas, which triggers a round of agreement to occur. Paxos is a common protocol that is used to obtain an agreement in the presence of node and network failures.

Since applications often need to reach agreements on many client requests, servers use agreement protocols like Paxos to implement a state machine-based abstraction that requires all the replicas to process the exact same set of client requests in the same order. This log-based state machine abstraction is often optimized by the use of a leader. In a leader-based protocol, all the instances of agreement on client requests are mediated through the leader and the leader also dictates the order of the log.

In Figure 1a, we have an example of VR (Viewstamped Replication), a leader-based Multi-Paxos protocol that uses Paxos for running agreements on individual requests. The leader here is responsible for ordering all client requests by assigning sequence numbers to them, and the followers (non-leader nodes) are responsible for responding to the leader and applying all the updates in the order in which they’re sequenced by the leader.

The leader is also responsible for initiating agreement by sending out a preparation message to all the other replicas. The leader then waits for a quorum of acknowledgments from all the other replicas before broadcasting a commit message to all the replicas. A successful iteration of this two-round protocol ensures that all non-failed replicas have the client’s request. And the sequence number assigned by the leader determines the order in which all the replicas process this client’s request. This pattern of broadcasting and waiting on quorums is common in many distributed protocols [38, 39, 80].

To gain more insights into the performance of the Multi-Paxos/VR protocol under the standard Linux kernel networking stack, we measure the CPU time breakdown of the leader node, shown in Table 1. There is 44.7% +

Function Name	Description	% CPU
<code>__libc_sendto()</code>	User function to send packets.	44.7
<code>sock_sendmsg()</code>	Kernel function to send packets.	32.2
<code>__alloc_skb()</code>	Allocate <code>sk_buff</code> for packets.	4.5
<code>dev_queue_xmit()</code>	Transmit <code>sk_buff</code> .	6.8
bookkeeping	For sock, IP, and UDP layers.	20.9
user-kernel crossing	Interrupt, mode switching, etc.	12.5
<code>__libc_recvfrom()</code>	User function to recv packets.	11.8
<code>sock_recvmsg()</code>	Kernel function to recv packets.	5.7
user-kernel crossing	Interrupt, mode switching, etc.	6.1

Table 1: CPU time breakdown for the leader node when running the Multi-Paxos/Viewstamped Replication protocol with 5 replicas. See §7 for measurement setup.

11.8% = 56.5% of time spent on the `__libc_sendto()` and `__libc_recvfrom()` functions, while 20.9% + 12.5% + 6.1% = 39.5% of time spent on user-kernel crossing and kernel networking stack bookkeeping. These numbers concrete our previous motivations that implementing distributed protocols under kernel networking stack incurs significant overhead on user-kernel crossings and kernel stack traversing (while eBPF can potentially save them).

2.2 eBPF and Hooks

BPF (i.e., Berkeley Packet Filter) [49] enables user-space applications to customize packet filtering in the kernel. A BPF program, written in some predicates on packet fields, is triggered by the kernel event that a packet arrives at a NIC driver. Once triggered, the BPF program will run inside a kernel virtual machine with limited registers and scratch memory, and a reduced instruction set [49]. For example, the well-known `tcpdump` [20] command-line packet analyzer is based on BPF.

eBPF extends the BPF by increasing the number of registers and adding stack memory. The increased number of registers and stack memory enable the eBPF program to execute more complex operations—the developers can use a C-like language to express customized operations. This C-like code is compiled into an eBPF bytecode by the Clang/LLVM toolchain and runs inside the kernel virtual machine via just-in-time compilation.

eBPF also introduces various powerful in-kernel data structures called *eBPF maps*, which, paired with various helper functions, are used to store and maintain states across multiple triggering of eBPF programs. Example eBPF maps include array, per-CPU arrays, queues, stacks, and hashMaps [46]. These maps are also used to communicate among different eBPF programs and between eBPF programs and user-space processes. Each eBPF map can be identified by a `map_path` through the file system, e.g., `/sys/fs/bpf/<map_name>`, and user-space processes can access a map based on its path.

The kernel events that can trigger eBPF programs are called *eBPF hooks*. There are many hooks existing in Linux kernels

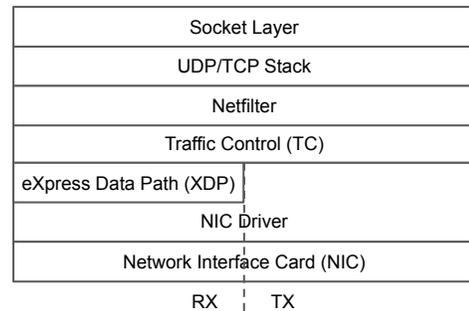

Figure 2: Linux kernel networking stacks and eBPF XDP/TC hooks.

and various device drivers, such as hooks in NIC drivers right after it receives a packet. User-space applications can attach eBPF programs to these eBPF hooks to customize the handling of corresponding kernel events.

Constrained programming model: An eBPF program needs to go through strict verification by an in-kernel eBPF verifier before attaching to an eBPF hook and running inside the kernel. The verification process does a static sanity check to make sure the eBPF program does not have out-of-bounds memory access (i.e., safety) and will always terminate (i.e., liveness). The verifier basically enumerates all possible cases of every conditional branch and loop to make sure every execution path meets the safety and liveness requirements. Because the verification tends to be time-consuming, each eBPF program can only contain up to 1 million instructions. For a larger eBPF program, the developer needs to split it into multiple smaller eBPF programs and uses *tail calls* to let one eBPF program call another one in a continuation manner.

Because of the strict verification process, dynamical memory allocation is not supported in eBPF programs; instead, eBPF programs can only rely on eBPF maps with capacity *specified statically* to maintain in-kernel states.

Due to these limitations, eBPF is commonly used in kernel tracing, profiling, and monitoring [3, 63] and L2-L4 low-level packet processing such as load balancing [14].

XDP (eXpress Data Path) [21, 64] technique implements an in-kernel eBPF hook that enables attached eBPF programs to process RX packets directly out of the NIC driver (Figure 2). Such processing gets triggered before any `sk_buff` [31] allocation or entering software socket queues, thus bypassing any higher-level networking stacks (e.g., UDP, TCP, Socket). XDP-based packet processing normally achieves comparable throughput and latency as DPDK-based kernel-bypass packet processing [21].

TC (Traffic Control) [47] is another important layer/hook which locates right after the XDP (Figure 2). In the TC layer, the `sk_buff` data structure has already been allocated by the kernel networking stack, thus the performance of TC-based packet processing will be slightly worse than XDP. However, the TC hook allows attached eBPF programs to process both RX and TX packets and manipulate the packet `sk_buff`. For

example, one can clone the `sk_buff` for a TX packet and thus implements packet broadcasting in the TC layer.

3 Electrode Overview

Electrode is a framework for offloading Paxos protocols under kernel networking stack to in-kernel eBPF programs to reduce user-kernel crossings and kernel networking stack traversing. Electrode has two goals in designing its eBPF offloads: 1) largely reducing kernel stack overhead to improve performance, and 2) carefully partitioning user- and kernel-space functionalities to keep offloads implementable and efficient inside the eBPF subsystem.

To achieve the first goal, Electrode carefully extracts generic and performance-critical fast-path operations from Paxos protocols to offload to the eBPF. As shown in Figure 1b, Electrode offloads message broadcasting (§4.1), fast acknowledging (§4.2), and wait-on-quorums (§4.3). These operations, if purely implemented in the user space, would involve many user-kernel crossings and kernel stack traversing, causing significant kernel stack overhead as shown in §2. Once implemented in the eBPF, message broadcasting allows the leader node to efficiently send preparation and commit messages to multiple follower nodes, by cloning and sending packets in the kernel; fast acknowledging enables follower nodes to buffer preparation messages in the kernel, and quickly respond to the leader node without involving user-space processes; wait-on-quorums lets the leader node eBPF program wait for a quorum number of acknowledgments from follower nodes, and only notify user-space processes once. Moreover, to simplify how user-space applications use these eBPF-based accelerations, Electrode further designs a set of user-space APIs (Table 2). Each API corresponds to one operation that Electrode offloads to the eBPF, and is used to invoke the offloaded function or retrieve eBPF processing results.

To achieve the second goal, Electrode keeps complicated slow-path operations of Paxos protocols in the user space. Specifically, Electrode leaves the procedures of failure recovery and handling message loss/reordering (i.e., gap agreement) to user-space applications, using similar mechanisms as VR [43] and NOPaxos [40]. These procedures involve accessing dynamic ranges of memory, which is hard to implement in eBPF under the static verification (see §8 for details).

Overall, Electrode has the following workflow: first, user-space applications attach eBPF programs to various hook locations corresponding to a network interface; then, user-space applications use Electrode APIs to invoke eBPF-offloaded functions or retrieve eBPF processing results; finally, the eBPF programs intercept and process target packets in the kernel without going through the networking stack or user-space applications (i.e., Paxos protocols in our case). Electrode targets accelerating the handling of messages that can fit into one ethernet packet (i.e., up to 9KB for jumbo frames). This is well-suited for locks, barriers, and configuration parameters [25, 78] that Paxos protocols commonly maintain. Non-

target packets still go through the stack and reach user-space applications, without impacting applications' other operations or protocol semantics.

Finally, we note that Electrode does not aim to offload every operation of Paxos protocols to the eBPF, because of eBPF's constrained programming model vs. the diverse set of operations that Paxos protocols and related services could have. For example, currently, Electrode does not offload client-facing request/response handling. There are two reasons: 1) Paxos clients normally serialize/deserialize their requests using widely-used libraries such as protocol buffers [19]; however, parsing or constructing protocol buffers is difficult in eBPF, because it involves complex pointer arithmetics and conditional branches which cannot easily pass the eBPF verifier. 2) client-facing requests/responses are normally embedded into application-level services like the Chubby lock service [6], but it is hard and inefficient to implement them in eBPF because of the strict eBPF verifier and the lack of dynamic memory allocation. We discuss more on Electrode's offloading decisions in §8.

4 Electrode Designs

4.1 Message Broadcasting in TC

In Paxos protocols, one-to-all message broadcasting is widely used. For example, 1) the leader node sends preparation messages to all follower nodes, and 2) (after receiving enough acknowledgments from followers) the leader node sends commit messages to all follower nodes.

To implement the above message broadcasting, the most common way is sending the same message multiple times in the user space to different destinations. However, the overhead (i.e., user-kernel crossing and kernel networking stack traversing) of this implementation on the leader node increases linearly as the number of followers increases, while the overhead on each follower node remains constant. Thus, the leader node essentially becomes the system bottleneck, e.g., Table 1 has shown that 44.7% of CPU time is spent on sending messages on the leader node.

An alternative implementation is to use IP multicast [42, 68, 77]. However, IP multicast normally requires support from the underlying network switches (e.g., storing a large number of multicast group-table entries for the whole network topology) [68, 77] or considerable modifications of the Linux networking stack [42].

Electrode approach: Electrode provides a flexible host-based broadcasting solution by utilizing eBPF on the TC hook. Here, we require the eBPF program that implements broadcasting operations to attach to the TC hook, because only the TC hook can intercept and process outgoing packets (§2.2). After attaching the eBPF program, user-space applications can call the `elec_broadcast()` function shown in Table 2 with specified `sock_fd`, message, and a list of destination IPs to broadcast the message to these destinations through the socket.

Function Name	Arguments	Output	Description
elec_broadcast	sock_fd, message, {dst_ips}	status	Broadcasts <message> to all destinations through <sock_fd>
elec_poll_message	map_path	messages	Polls buffered messages from an eBPF-maintained in-kernel ring buffer identified by <map_path>
elec_check_quorum	received_message	bool	Checks if <received_message> (acknowledgment) indicates quorum reaching

Table 2: Electrode user-space APIs.

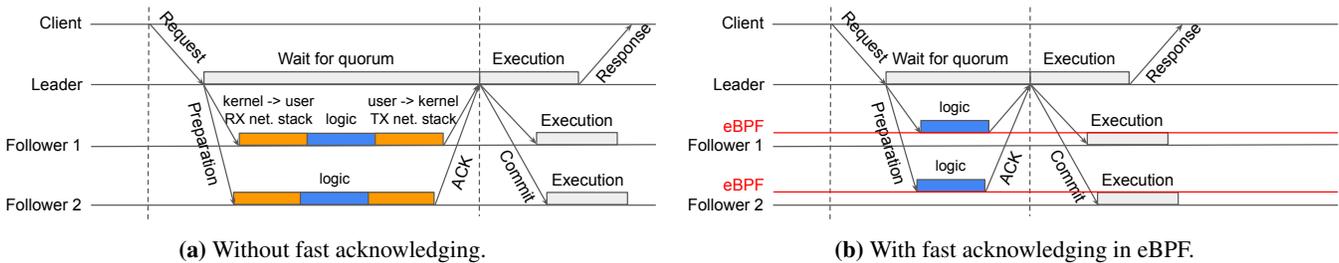

Figure 3: Fast acknowledging in eBPF reduces Paxos request latency. This example follows Figure 1, but omits followers 3 and 4 for brevity.

Under the hood, the eBPF program makes clones of the message packet using the `bpf_clone_redirect()` [45] helper function, modifies the destination addresses of cloned packets accordingly, and sends these packets out. The benefit of cloning packets and broadcasting in the kernel compared with sending the same message multiple times in the user space is that we only need to cross the user-kernel boundary and traverse the UDP and socket layer once.

Handling message loss: Electrode relies on application-level timeout and retransmission to handle message loss, similar to modern RPC-based applications [13, 69]. Specifically, if the leader node does not receive a response after a certain time of sending a request, it will resend the request; once a request experiences several timeouts, the leader node will mark the destination node as dead and start Paxos failure recovery. An alternative approach to handling message loss is doing retransmission in the kernel, which could save user-kernel context switching overheads, but such savings become marginal as packet loss happens rarely in data centers [28, 61]; it would also involve complex message buffer management in kernel/eBPF, hurting performance.

4.2 Fast Acknowledging in XDP

As shown in Figure 3a, a significant portion of Paxos request latency comes from the round-trip delay between the leader node and follower nodes. Note that the ACK messages in this figure mean Paxos protocol acknowledgments, not TCP acknowledgments. For Paxos protocols under the kernel networking stack, this round-trip delay includes not only physical propagation and transmission delay, but also the delay caused by the kernel networking stack (i.e., user-kernel crossing and networking stack traversing). As the fabric latency of nowadays data center network reaches a few tens of microseconds [48] or sub-ten microseconds [18, 27], the latency of the kernel networking stack, which is also around sub-ten microseconds [59], becomes non-negligible.

Electrode approach to reducing the Paxos request latency is to optimize the preparation handling in follower nodes by directly buffering the preparation messages into an in-kernel log and early acknowledging to the leader node. At the same time, user-space applications asynchronously poll and consume the buffered messages from the log, using the `elec_poll_message()` function shown in Table 2. Under the hood, the function calls a corresponding eBPF syscall to poll messages in batches, amortizing kernel crossing overhead. This asynchrony does not break the correctness of Paxos protocols because as long as a preparation message gets buffered into the log, it will be eventually processed by the user-space Paxos protocols, and the message processing order has been specified by the sequence number assigned by the leader node. Figure 3b shows that this approach removes *two* user-kernel crossings and networking stack traversing from the critical path of the Paxos request.

Note that not every preparation message can be handled using fast acknowledging; in some non-critical path cases (e.g., message loss/reordering, and node failure) where the eBPF program cannot handle because of its constrained programming model, our eBPF program can detect them and directly forward preparation messages to user-space Paxos protocols (detailed in §6).

In-kernel log implementation: The in-kernel log temporarily stores incoming early-acknowledged preparation messages, which are polled and consumed by user-space applications concurrently. To implement this in-kernel log, we use a special eBPF map named `BPF_MAP_TYPE_RINGBUF` [30] (introduced from Linux kernel 5.8). This map implements an efficient multi-producer single-consumer (MPSC) ring buffer using shared memory and a lightweight spinlock, where we can have multiple writers in eBPF and one reader in user space. Based on our measurement, the time of pushing a preparation message into the ring buffer is roughly equal to memcpying this message, in cases without any lock contention. Note

that the in-kernel ring buffer also has a fixed size, because eBPF does not support dynamic memory allocation; in case it becomes full, the eBPF program can detect them and directly forward preparation messages to user-space applications.

4.3 Wait-on-Quorums in TC + XDP

Another common operation in Paxos protocols is the leader node waiting for a quorum number of acknowledgments (ACKs) from follower nodes (i.e., wait-on-quorums). Assume there are $2f + 1$ replicas including one leader node and $2f$ follower nodes. In most Paxos protocols, once the leader collects f ACKs from different follower nodes, the Paxos request is considered *committed*.

Conventionally, wait-on-quorums is implemented by the user-space applications that receive all ACKs and count towards the quorum number. However, each acknowledgment handling incurs the overhead of the user-kernel crossing and traversing the kernel networking layer. The total overhead of handling all ACKs is linear to the number of follower replicas (i.e., $2f$). Moreover, among these $2f$ ACKs, only the first f ones are required to commit a Paxos request.

Electrode approach: Electrode moves the leader-side wait-on-quorums operations to the eBPF, requiring only one user-kernel crossing and one networking stack traversing. Electrode maintains an array of bitsets (and other metadata) in eBPF, each of which indicates whether a Paxos request has reached the quorum. Electrode only forwards ACK messages that indicate reaching the quorum to the user-space applications, while dropping others. Electrode maps each Paxos request to a specific bitset by using the unique increasing sequence number assigned by the leader node (§2). Note that we use the bitset instead of a counter to check if the quorum gets reached; this is because a timed-out preparation request could cause duplicate ACK messages from follower nodes, and we want to avoid double counting.

Electrode maintains the bitset setting and clearing (i.e., zeroing out) operations through two eBPF programs hooked at TC and XDP layers, respectively. The TC-hooked eBPF program intercepts each outgoing preparation message and clears the indexed bitset, while the XDP-hooked eBPF program intercepts each incoming ACK message from follower nodes and sets the bit corresponding to the follower node's index in replicas.

As shown in Listing 1, the `tc_ebpf` function/program intercepts each outgoing preparation message and clears a specific bitset indexed by the sequence number in each message. Line 6 checks if it is the first time to intercept a preparation message corresponding to this Paxos request, by comparing the `seq` stored along this bitset and the `seq` extracted from the message; if so, it updates the stored `seq` in the array and clears the bitset that may have been used by previous Paxos requests (line 17-18).

The `xdp_ebpf` program intercepts each incoming ACK message, updates the indexed bitset, drops most of the ACK

```

1 # Processing outgoing preparation message
2 # pkt: the packet of the message
3 # seq: unique increasing sequence number (from pkt)
4 def tc_ebpf(pkt, seq):
5     idx = seq % array_length
6     if array[idx].seq != seq
7         array[idx].seq = seq
8         array[idx].bitset.clear()
9     forward(pkt) # to follower node
10
11 # Processing incoming ACK message
12 # pkt : the packet of the message
13 # seq : unique increasing sequence number (from pkt)
14 # node_i: follower node index (from pkt)
15 def xdp_ebpf(pkt, seq, node_i):
16     idx = seq % array_length
17     if array[idx].seq == seq
18         array[idx].bitset.set(node_i)
19         if array[idx].bitset.count() == f
20             pkt.mark_quorum_reach(true)
21             forward(pkt) # to user-space application
22         else: drop(pkt)
23     else: # bitset overwritten by tc_ebpf
24         pkt.mark_quorum_reach(false)
25         forward(pkt)

```

Listing 1: Maintaining the fixed-length bitset array to achieve wait-on-quorums in eBPF. Each bitset operation is also protected by a spinlock; we omit it here for simplicity.

packets, and only forwards packets to user-space applications that indicate reaching quorum or array overflow (explained in the next paragraph). Lines 17-18 check if this bitset corresponds to the `seq` in the ACK message, and set the proper bitset bit if so. Line 19 further checks if this ACK message reaches the quorum: if so, lines 20-21 will mark the packet as quorum-reaching and forward it to user-space applications; otherwise, line 22 just drops the packet. Once the user-space applications receive a quorum-reaching packet—checked by calling the `elec_check_quorum()` function shown in Table 2, it can directly consider this Paxos request as committed.

Handling array overflow: In some cases, a bitset might be overwritten by the `tc_ebpf` because of the fixed size of the bitset array. `xdp_ebpf` detects such array overflow in lines 17&23; once detected, lines 24-25 will mark the packet as *not-quorum-reaching* and forward it to user-space applications. Once the user-space applications receive a not-quorum-reaching packet, it resends the preparation messages to all follower nodes and waits for ACKs again. In practice, the leader node could limit the number of in-flight preparations while provisioning a large bitset array, such that the array overflow does not normally happen.

RSS: Electrode supports RSS (Receive-Side Scaling) which distributes incoming packets to different NIC queues and CPU cores. Specifically, Electrode has two receive-side optimizations: fast acknowledging and wait-on-quorums. For fast acknowledging, the eBPF programs in the follower node could maintain separate in-kernel ring buffers on different cores to avoid synchronization overhead during log append-

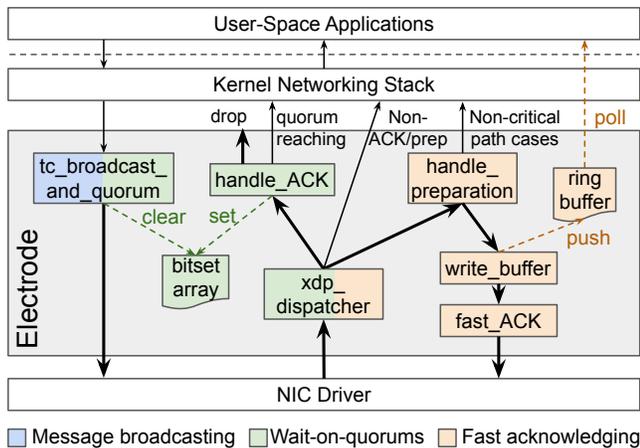

Figure 4: eBPF program structure of Electrode. The thickness of solid lines indicates traffic volume (the thicker, the higher).

ing, and use spinlocks to synchronize accesses to small shared in-kernel states (e.g., `ebpf_seq` in §6); the user-space applications asynchronously pull messages from all ring buffers, and process messages following the order specified by their embedded sequence numbers. For wait-on-quorums, the eBPF programs in the leader node could use atomic instructions to count how many ACKs it has received and check if the quorum is reached.

5 Electrode Implementation

Electrode is prototyped with six eBPF programs written in a restricted C language, and we utilize the Clang/LLVM toolchain for compiling source code to eBPF bytecode. These eBPF programs consist of 500 lines of C code in total. Application developers can also customize their own eBPF programs based on needs, e.g., only processing packets with a specific source port like [25]. Our prototype does not implement the RSS handling yet.

Figure 4 shows the structure of the six eBPF programs. One program can transfer its control flow to the next program via the eBPF tail call. We break the implementation into these six programs because of 1) avoiding breaking the instruction limits in the eBPF verifier (§2.2), and 2) modularity. In the following, we describe each program in detail.

- `tc_broadcast_and_quorum`: This program intercepts outgoing preparation messages. It implements the message broadcasting mechanism (§4.1) and the `tc_ebpf` function in Listing 1 for wait-on-quorums (§4.3). For broadcasting, we generate multiple clones of the preparation packets using the `bpf_clone_redirect()` [45] helper function.
- `xdp_dispatcher`: This program checks the types of incoming messages and calls corresponding message handlers. It only intercepts the ACK (only received on the leader node) and preparation (only received on follower nodes) messages, and calls the corresponding `handle_ACK` and `handle_preparation` programs. It directly forwards

other types of messages to user-space applications.

- `handle_ACK`: This program implements the `xdp_ebpf` function in Listing 1 for wait-on-quorums (§4.3). In common cases, it drops most ACK messages, and only forwards the quorum-reaching ACK messages to user-space applications.
- `handle_preparation`: This program implements various checks to detect non-critical path cases where it should forward messages to user-space applications (§4.2). In normal cases (mostly), it will call `write_buffer` to begin `fast_ACK`.
- `write_buffer`: This program stores message/packet data into an in-kernel log for user-space applications to poll and consume. As mentioned earlier, We use the eBPF ring buffer [30] to implement the log data structure. This program then calls the `fast_ACK` program.
- `fast_ACK`: This program reuses and modifies the received packet buffer to create an ACK packet and sent it out. This requires swapping the src-dst IP addresses and filling the corresponding fields of the ACK message.

6 Apply Electrode to Multi-Paxos

Optimizing throughput: We apply the eBPF-based message broadcasting (§4.1) and wait-on-quorums (§4.3) mechanisms to the leader node in the Multi-Paxos protocol. This implies two throughput optimizations: 1) when the leader node sends out preparation messages to follower nodes, it relies on eBPF to broadcast these messages instead of sending them one by one; and 2) when the leader node is waiting for a quorum number of ACK messages from follower nodes, it only needs to process the quorum-reaching ACK message while the other ACK messages are pruned/dropped by the eBPF program. These two optimizations largely reduce the number of user-kernel crossings and kernel networking stack traversing, thus alleviating the CPU bottleneck on the leader node and improving system throughput.

Optimizing latency: We apply the eBPF-based fast acknowledging mechanism (§4.2) to each follower node in the Multi-Paxos protocol. In normal cases (e.g., without packet loss/re-ordering, and all nodes are alive), the preparation messages from the leader node are quickly buffered and acknowledged by the eBPF program in the follower nodes, bypassing both the kernel networking stack and the user-space Multi-Paxos protocol. This reduces the commit latency of each Multi-Paxos request by twice the time of user-kernel crossing and kernel networking stack traversing.

Detecting non-critical path cases in fast acknowledging: As mentioned in §4.2, there are some non-critical path cases in fast acknowledging where the eBPF program must detect them and forward the incoming packets to the user-space Paxos protocols. To understand why non-critical path cases happen and how to detect them, we first elaborate on the Multi-Paxos/VR protocol shown in §2, following the literature [43]. In the Multi-Paxos protocol, the leader node assigns

each Multi-Paxos request a unique and strictly increasing sequence number, `seq`. Each replica including both the leader node and follower nodes maintains locally a view number, a status, and its last observed `seq`; each message sent by a replica will piggyback these three variables. The view number indicates which (leader) election epoch this replica is in; the status indicates if this replica is during a leader election (`status_viewchange`), recovering (`status_recovering`), or normal state (`status_normal`). This protocol requires a follower node to only process a preparation message if the node is in the normal state, and the message has a matched view and strictly increasing `seq`; otherwise, the follower node needs to drop the message, or execute a complex view-change or state-transfer procedure [43,54]. Therefore, the non-critical path cases for Multi-Paxos are:

1. the follower is during a leader election or recovering,
2. the follower receives a message with an unmatched view that is either (a) stale or (b) newer,
3. the follower receives a message with a non-strictly-increasing `seq` caused by message (a) loss/reordering or (b) duplication.

These cases only happen when replicas fail or join, or messages get lost/reordered, which is less common in data centers [27,61].

To detect these non-critical path cases in eBPF, we maintain an `ebpf_status`, an `ebpf_view`, and an `ebpf_seq` variable in the eBPF program using the eBPF map. In particular, these three variables can be updated by the user-space Multi-Paxos protocols to reflect the current protocol state. Listing 2 shows the detection pseudocode. Line 5 detects case 1, and line 6 detects case 2(a); for these two cases, the eBPF program needs to drop the packet. Line 7 detects cases 2(b) and 3(a), and forwards the packet to the user space to execute the view-change or state-transfer procedure. For case 3(b), i.e., `msg_seq < ebpf_seq + 1`, the eBPF program function replies an ACK (line 11), because it could be a re-transmitted preparation message due to timeout.

Handling the cases 2(a)&3(a) in fast acknowledging is tricky, because it (i.e., forwarding packets to the user space for processing) involves the concurrency between the user-space protocols and the kernel-space eBPF program, while eBPF only supports map-based communication *but not synchronization* between the user and kernel. Our approach is to let the user-space protocols *detach* the eBPF program from the hook while executing the view-change or state-transfer procedure. Specifically, once a user-space protocol receives a preparation message corresponding to the case 2(a) or 3(a), it detaches the eBPF program, then it finishes the view-change or state-transfer procedure, next it updates the `ebpf_status`, `ebpf_view`, and `ebpf_seq` properly, and finally it reattaches the eBPF program. This guarantees the cases 2(a)&3(a) are exclusively handled by the user-space protocol, avoiding the synchronization between the user and kernel. An alternative approach to achieving the same effect as eBPF detach-reattach

```

1 # pkt      : the packet of the preparation message
2 # msg_view: view piggybacked by the pkt
3 # msg_seq : unique increasing sequence number (from pkt)
4 def detect_non_crit_path_cases(pkt, msg_view, msg_seq):
5     if (ebpf_status != status_normal): drop(pkt)
6     if (msg_view < ebpf_view): drop(pkt)
7     if (msg_view > ebpf_view or msg_seq > ebpf_seq + 1):
8         forward(pkt)
9     if (msg_seq == ebpf_seq + 1):
10        append_log(++ebpf_seq, pkt)
11    reply_ack(pkt)

```

Listing 2: Detecting non-critical path cases during fast acknowledging for Multi-Paxos. Assume the protocol works in a single core, in line with prior Paxos work [40,44,61].

is to use an eBPF map with a branch testing before any Electrode logic. The first packet in the non-critical path can update this map atomically and let all following packets directly go to the user-space application (i.e., closing Electrode optimizations); later, the user-space application can update this map to reopen Electrode optimizations.

There are a few caveats: 1) After the user-space protocol detaches the eBPF program, it needs to poll the in-kernel ring buffer again, in case the eBPF program still appends a few messages to the ring buffer before detaching. Note that the eBPF map can outlive the eBPF program, as long as the user-space process holds a reference to it, because its lifetime is managed through reference counting [50]. 2) While the user-space protocol is setting the `ebpf_seq` value and is about to reattach the eBPF program, some preparation packets might just pass the eBPF hook location but have not been processed by the user-space protocol, e.g., queued in the socket layer. In this case, the user-space protocol actually has set a smaller `ebpf_seq` value in the map; once the eBPF program gets reattached, it will trigger more case 3(a) (lines 7&8). Our solution to this problem is: after the user-space protocol finishes the view-change or state-transfer procedure, it first sends a `stop_sending_preparation` message to the leader node to stop it from sending preparation messages, then it polls the socket to drain and process any queued packet, next it sets the proper `ebpf_seq` value, finally it sends a `resume_sending_preparation` message to the leader node to resume sending preparation messages, and reattaches the eBPF program. These two messages should be sent using reliable transport like TCP to handle packet loss.

Generalizability: Electrode’s eBPF-based optimizations are generic to many more distributed protocols, which normally consist of broadcasting and wait-on-quorums operations. More discussions can be found in Appendix A.

7 Evaluation

This section answers the following questions:

1. How do Electrode and each optimization improve the performance of the Multi-Paxos protocol (§7.1 and §7.2)?

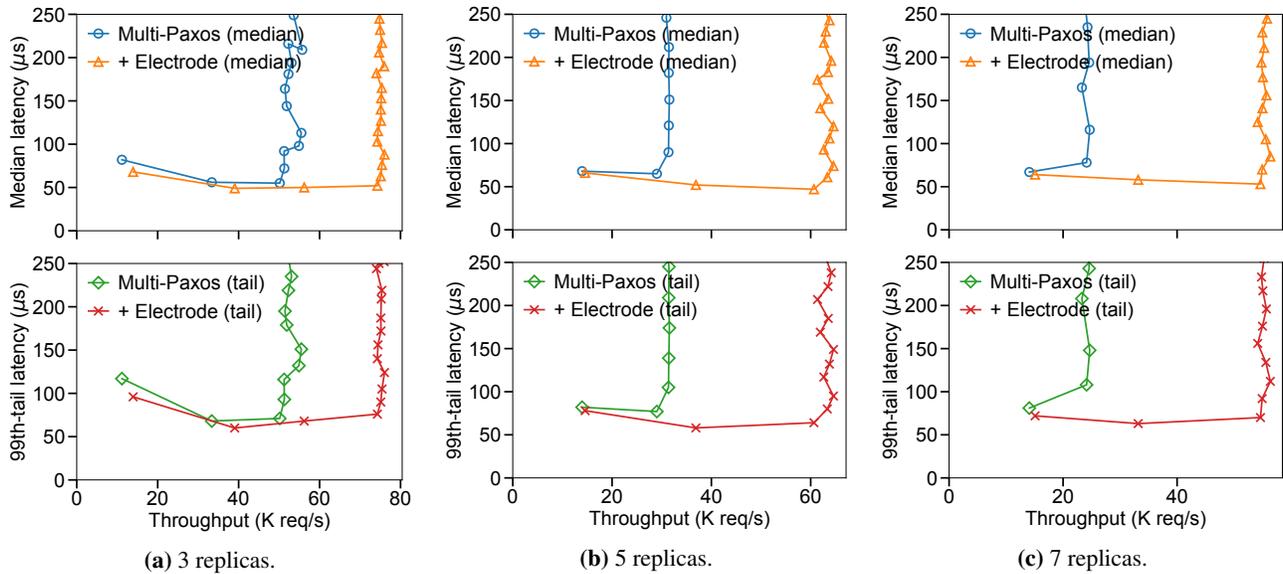

Figure 5: Performance comparison of the Multi-Paxos protocol vs. Electrode-accelerated one with different numbers of replicas.

2. How does Electrode improve the performance of real-world Paxos-based applications (§7.3)?
3. How does Electrode save kernel stack overhead (§7.4)?
4. How does Electrode compare to kernel-bypassing (§7.5)?

Testbed setup: We use eight x1170 servers from Cloud-Lab [12], each of which has a ten-core Intel E5-2640v4 CPU at 2.4 Ghz, 64GB memory, and a Mellanox ConnectX-4 25 Gbps NIC. Each server runs an unmodified Ubuntu 20.04 OS with kernel v5.8.0. All servers are connected using a two-level topology: five Mellanox 2410 as rack switches (each connecting to forty x1170 servers) and one Mellanox 2700 as the spine switch. One server is dedicated as the client server that generates Paxos requests, and other servers run the Paxos protocol with 3/5/7-replica configurations. By default, we configure each server to use one core for interrupt processing and another core for Paxos processing, following the performance optimizations in [41]. We disable irqbalance to avoid out-of-order packet deliveries as much as possible (which would hurt Paxos performance), in line with prior Paxos work [40,44,61]. Unlike prior Paxos work [32,40,61], we *do not* use IP multicast which requires specialized support from the network (§4.1).

Measurement methodology: The client server runs multiple Paxos/application clients, and each client sends Paxos/application requests in either a closed-loop or open-loop manner. In closed-loop experiments, each client sends the next request once it receives the response of the last request; we vary the number of clients and measure the corresponding throughput, and median and 99th-percentile tail latency, in line with prior Paxos work [40,44,61]. In open-loop experiments, each client sends requests one by one at a specific time interval, such that the overall request rate reaches a specified value; we use enough clients (i.e., they could saturate the Paxos servers), specify different request rates, and measure the corresponding

CPU utilization of each replica node.

Comparisons: We use the Multi-Paxos/VR protocol implementation in the SpecPaxos [61] open-sourced code [35] as the baseline, and optimize it using Electrode. We also run a transactional replicated key-value store similar to the one in SpecPaxos [61] atop the baseline Multi-Paxos protocol and Electrode-accelerated Multi-Paxos protocol. All implementation uses the standard UDP stack and socket layer from the Linux kernel.

7.1 Overall Results

Figure 5a, 5b, and 5c show the performance comparison of the Multi-Paxos protocol and the Electrode-accelerated one when using 3, 5, and 7 replicas, respectively. In each figure, we vary the number of clients sending Multi-Paxos requests in a closed-loop manner, and report throughput and median and 99th-percentile tail latency. All curves eventually hit a “hockey stick” in their median or tail latency growth when the system reaches its maximum throughput.

Throughput: the Electrode-accelerated Multi-Paxos protocol achieves 34.9%, 104.8%, and 128.4% higher maximum throughput than the original Multi-Paxos protocol under 3, 5, and 7 replicas, respectively. The large throughput improvements benefit from the eBPF-based broadcasting and wait-on-quorums which reduce the kernel stack overhead significantly on the leader node. With more replicas, the improvement becomes more significant. This is because, for each Multi-Paxos request, the leader node will send more preparation and commit messages, and handle more ACK messages; thus the eBPF-based broadcasting and wait-on-quorums can save more user-kernel crossings and kernel networking stack traversing.

Latency: the Electrode-accelerated Multi-Paxos protocol achieves 12.5%, 20.0%, and 25.6% lower median latency than the original Multi-Paxos protocol with 2 clients (before

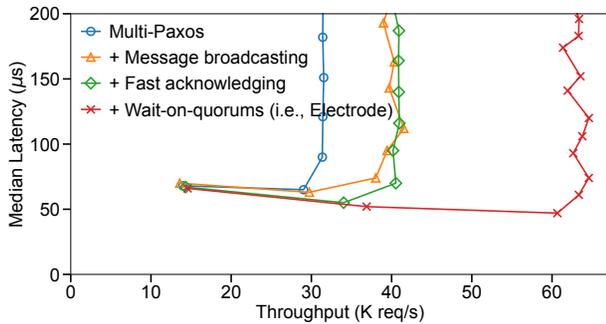

Figure 6: Performance impact of different optimizations for Electrode-accelerated Multi-Paxos protocol (with 5 replicas).

the “hockey stick”) under 3, 5, and 7 replicas, respectively; the corresponding tail latency is 11.8%, 24.7%, and 41.7% lower. The latency reduction mostly comes from the fast acknowledging in the follower nodes, which, for each Multi-Paxos request, saves the time of two user-kernel crossings, two kernel networking stack traversing, and one wake-up of the user-space process. With more replicas, the latency reduction becomes larger. This is because the fast acknowledging bypasses user-space process scheduling and avoids unpredictable scheduling delays [48] by the OS; for the original Multi-Paxos, with more follower nodes, such unpredictable scheduling delays would raise the chance of follower nodes straggling, thus increasing commit latency. Besides, for Multi-Paxos under 3/5 replicas and Electrode under 7 replicas, their latency curves first decline a bit and arrive at the lowest point, then rise and reach the “hockey stick”. This is because, under lower throughput, the Linux scheduler would schedule the Paxos process off the CPU more frequently, while under higher throughput, the Paxos process is mostly scheduled on the CPU.

7.2 Performance Gain Breakdown

Figure 6 shows the performance impact of different optimizations for the Electrode-accelerated Multi-Paxos protocol with 5 replicas. Similar to §7.1, we vary the number of clients sending Multi-Paxos requests in a closed-loop manner, and report the throughput and latency. eBPF-based message broadcasting improves the maximum throughput of the Multi-Paxos protocol by 31.7%; fast acknowledging further reduces the median latency by 4.3%-12.7% (before the “hockey stick”); finally, wait-on-quorums improves the maximum throughput by 57.7%. Overall, we find that the two throughput optimizations (i.e., eBPF-based message broadcasting and wait-on-quorums) have almost no impact on the median latency, while the latency optimization (i.e., fast acknowledging) does not nearly impact maximum throughput. This division of labor demonstrates good modularity of each optimization design in Electrode, and each design can be independently used to accelerate more distributed protocols as shown in Table 4.

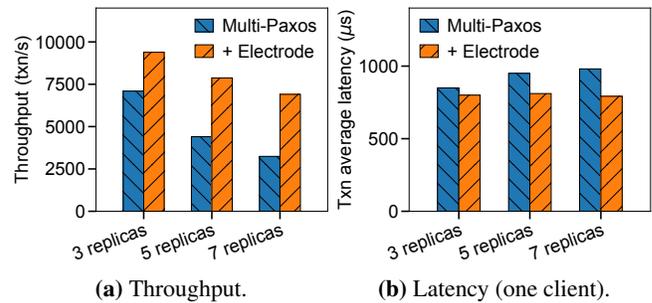

Figure 7: Performance comparison of a transactional key-value store atop the Multi-Paxos protocol vs. Electrode-accelerated one.

7.3 Application Performance

To demonstrate how Electrode can bring benefits to real-world Paxos-based applications, we run a transactional replicated key-value store (similar to the one in SpecPaxos [61]) atop the Multi-Paxos protocol and Electrode-accelerated one. This key-value store supports serializable transactions using two-phase commit and optimistic concurrency control (OCC). Clients use `BEGIN_TXN`, `COMMIT_TXN`, `ABORT_TXN`, `SET`, and `GET` operations to express transactions. We use a synthetic workload derived from the Retwis application [56]—an open-source Twitter clone. This workload consists of four types of transactions with different ratios, and each one issues different numbers of `GET` and `PUT` operations. The workload details can be found in Table 2 of [80]. We vary the number of clients that execute transactions in a closed-loop manner, and measure the maximum throughput these clients can achieve and the average latency under one client.

Figure 7a and 7b shows the maximum throughput and average latency of the key-value store atop the Multi-Paxos protocol vs. Electrode-accelerated one under different numbers of replicas, respectively. Overall, Electrode improves the key-value store throughput by 32.3%-112.9% and latency by 5.9%-19.3%. The improvement becomes larger with more replicas, due to the similar reasons described in §7.1. The latency of the key-value store atop the original Multi-Paxos gradually increases with more replicas, while Electrode-accelerated one’s remains relatively stable, because the former is more vulnerable to follower nodes straggling (§7.1).

7.4 CPU Utilization

One design goal of Electrode is to reduce the kernel networking stack overhead (§3) when implementing Paxos protocols. Thus, in this subsection, we study the impact of Electrode on CPU utilizations, which indicates how much kernel stack overhead gets reduced.

Figure 8a and 8b show the CPU utilization of the leader node and follower nodes, respectively, for the Multi-Paxos protocol and Electrode-accelerated one with different offered throughput. The experiments are done in an open-loop manner to control the offered throughput when measuring CPU utilization. The CPU utilization covers both the core handling

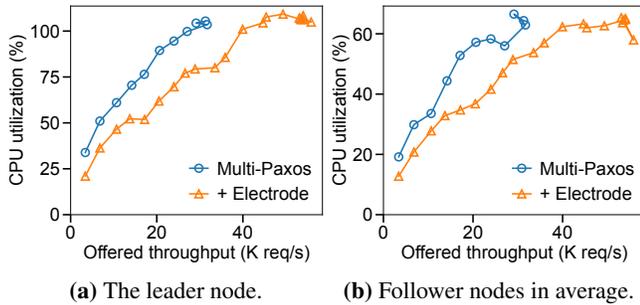

Figure 8: CPU utilization comparison of the Multi-Paxos protocol vs. Electrode-accelerated one (with 5 replicas).

interrupts and the core running Paxos. With higher offered throughput, the CPU utilization gradually increases, demonstrating the load-aware CPU scaling provided by the kernel networking stack (§1). We note that for DPDK-based Multi-Paxos protocol implementation, the CPU utilization would be always 100% because DPDK busily polls the network interface. Overall, Electrode reduces the CPU utilization by 22.7%-38.0% on the leader node and 16.0%-35.7% on the follower nodes, benefiting from the reduced user-kernel crossings and kernel stack traversing.

7.5 Comparison with Kernel-Bypassing

Electrode still handles client-facing requests/responses and initiates message broadcasting using the Linux kernel networking stack (§3); thus, it will achieve lower performance than pure kernel-bypassing approaches. This subsection compares the performance of Electrode with a kernel-bypassing baseline, aiming to reveal the performance upper bound of kernel-based approaches and identify the possible improvements for future work.

We choose Caladan [15] and use its high-performance DPDK-based UDP stack to implement our kernel-bypassing baseline. Similar to Caladan, our baseline dedicates one CPU core for packet polling and another core for running the Paxos protocol. We also configure the Caladan runtime to never idle the Paxos core even under low request load.

Table 3 compares the latency and throughput of kernel-based Multi-Paxos and the kernel-bypassing one. To exclude the latency incurred by the client-side kernel stack, we tested all three Paxos implementations with a request generator implemented using Caladan. Electrode achieves 1.4-1.6x lower latency and 2.0x higher throughput than vanilla Linux, but it still has 2.2x higher latency and 2.4x lower throughput compared to pure kernel-bypassing. The performance gap between Electrode and kernel-bypassing exists, because there are still substantial Paxos messages going through the kernel networking stack in Electrode. In particular, our profiling shows that, on the leader node, around 59.5% CPU time is spent on `__libc_sendto()` caused by frequent `dev_queue_xmit()` and `sk_buff` clones. Although eBPF-based broadcasting reduces a significant number of user-kernel crossings and sock-

	Lowest median/99p latency	Maximum throughput
Vanilla Linux	59/69 μ s	32 K req/s
Electrode	38/49 μ s	65 K req/s
Kernel-bypassing	17/22 μ s	154 K req/s

Table 3: Performance comparison of kernel-based Multi-Paxos vs. kernel-bypassing one (with 5 replicas).

/UDP/IP layer traversing, it cannot fundamentally optimize how the Linux kernel manages NICs and packet buffers. Finally, we note that Electrode’s goal is to provide generic eBPF-based accelerations for distributed protocol implementations that stick to kernel networking stacks because of compatibility, security, isolation, and elastic CPU scaling.

An additional evaluation regarding how the interrupt coalescing feature of modern NICs impacts Electrode is in Appendix B.

8 Discussion and Future Work

Electrode’s offloading decisions: Electrode decides to leave four components of the Multi-Paxos protocol to the user space: 1) failure recovery, 2) handling packet loss and reordering, 3) handling client-facing requests/responses, and 4) executing application-specific operations after reaching the consensus. The first two components involve complex operations on the log, e.g., scanning the log and sending inconsistent entries to other replicas, and inserting missing log entries received from others. These operations require accessing dynamic ranges of log entries, which would fail the eBPF static verification. The last two involve complex serialization/deserialization and application-level operations (see §3). We note that it is possible to offload these four components into eBPF by modifying the kernel eBPF subsystem or verifier—we leave this as future work.

How to improve the eBPF subsystem for offloading? Verifying memory accesses more smartly could make more application operations offloadable. The current eBPF verifier only allows accessing static ranges of memory, which hinders many applications with complex memory accessing behaviors. Another useful construct in eBPF would be dynamic memory allocation, which could ease the maintenance of more advanced data structures in eBPF. To avoid memory leaks, a possible solution could be enforcing Rust-style single-owner memory semantics.

io_uring [1] was recently introduced into the Linux kernel to support efficient batching of asynchronous I/Os via shared memory between the user and kernel space, thus reducing the overhead of frequent user-kernel crossings. Therefore, when implementing Paxos protocols using `io_uring`, it can help reduce the overhead of message broadcasting, which accounts for 12.5% of CPU time based on Table 1. However, each preparation and ACK message still goes through the

full Linux networking stack and wakes up user-space applications, incurring significant overhead; Electrode can be used together with `io_uring` to reduce such overhead. A recent work XRP [82] shares a similar view regarding `io_uring`.

Electrode on shared environments: Electrode requires attaching eBPF programs to the network interface, which then processes every packet accordingly. However, multiple Electrode applications might share the same NIC and attach different eBPF programs that might interfere with each other. We can use the SR-IOV (Single Root IO Virtualization) feature that is widely available in modern NICs [2, 9] to avoid such interference. SR-IOV virtualizes a physical network interface into multiple virtualized ones; the Electrode eBPF program can be attached to only one virtualized interface, without impacting others (e.g., used by non-Paxos applications). Besides SR-IOV, Electrode can also check the port numbers of incoming packets in eBPF, and only execute optimizations if the port numbers belong to target Paxos applications.

Accelerating leader-less consensus protocols using eBPF: Electrode targets at leader-based consensus protocols such as Paxos [37] and its variants [36, 43, 54], because they are the most-used ones by modern distributed applications [6, 8, 22]. Electrode's eBPF-based optimizations could also be applied to leader-less consensus protocols, e.g., EPaxos [52], Mencius [4], SD-Paxos [81], etc. For example, replicas in EPaxos could acknowledge preparation messages earlier in an eBPF program before entering the kernel networking stack, thus reducing latency. We leave the exploration of applying Electrode to leader-less consensus protocols as future work.

9 Related Work

Kernel-bypass and hardware offloading: Overheads of the monolithic kernel networking stack have spurred various attempts to design new kernel-bypassed networking stacks like mTCP [24], eRPC [27], Demikernel [79] and more [15, 29, 33, 48, 57, 67], which attempt to eliminate the kernel from the I/O datapath. But all of these solutions are not backward compatible with solutions that already use the standard kernel networking stack, and they incur more costs in terms of CPU cycles and energy during low I/O loads due to busy-polling. Electrode attempts to leverage eBPF to unclog some of the bottlenecks in the kernel networking stack for distributed protocols without completely having to shift to kernel-bypassed stacks.

Similarly, network offload solutions attempt to offload I/O-intensive operations to specialized hardware, e.g., RDMA [11, 28, 76], FPGA [23], SmartNICs [66], and programmable switches [10, 25]. But they come with limited interfaces for programmability and need custom hardware to be installed.

Co-designing distributed systems with networks: There have been attempts to optimize distributed systems by co-designing them with data center networks for improved performance. SpecPaxos [61] attempts to leverage the natural order of packet delivery in data centers to optimize the ordering of

messages needed for state machine replication. NoPaxos [40] uses in-network switches to sequence packets for a similar purpose. Eris [39] further applies in-network sequencing to distributed transactions to avoid coordination overhead. These are orthogonal ways to optimize distributed systems and can be used in conjunction with Electrode.

Distributed protocols in data centers: Data centers have a variety of distributed protocols that are deployed for fault tolerance and data consistency. These include replication protocols like Mencius [4], EPaxos [52], chain replication [74], SDPaxos [81], and transaction protocols like TAPIR [80] and Meerkat [72]. Since many distributed protocols share similar patterns of communication like broadcasting and quorum responses, Electrode can be applied to speed up these distributed protocols as well.

eBPF applications: For a long time, eBPF was only used for packet filtering [49], monitoring [3, 63], and load balancing [14] because of its restricted programming model. Now, it is shown to be able to offload small yet critical operations to improve application performance. CCP [53] mentions that it may be possible to leverage the JIT feature of eBPF to gather datapath's congestion measurements for congestion control. BMC [17] uses eBPF to implement an in-kernel cache to accelerate UDP-based Memcached GET requests and achieves significant throughput improvement. Syrup [26] uses eBPF maps to share incoming request information across OS, networking stacks, and application runtimes to enable user-defined scheduling. SPRIGHT [65] employs fast eBPF-based packet forwarding to accelerate sidecar proxies in serverless computing. XRP [82] offloads storage functions (e.g., B-tree lookups) into the kernel using eBPF to reduce kernel storage stack overhead. SynCord [58] leverages eBPF to inject workload-specific and hardware-aware kernel lock policies specified by application developers. Electrode further demonstrates that eBPF can be used to accelerate distributed protocols under the kernel networking stack.

10 Conclusion

Electrode is a system that accelerates distributed protocols using safe in-kernel eBPF-based packet processing before the networking stack. Electrode retains the benefits of using the standard Linux networking stack (e.g., good maintenance, elastic CPU scaling, security, and isolation), while optimizing the performance-critical operations of distributed protocols (e.g., broadcasting, and wait-on-quorums) in a non-intrusive manner. When applying Electrode to a classic Multi-Paxos protocol, we achieve up to 128.4% higher throughput and 41.7% lower latency. We believe that the designs of eBPF-based optimizations in Electrode can motivate more research on improving networked application performance while maintaining the standard Linux networking stack.

Electrode code is available at <https://github.com/Electrode-NSDI23/Electrode>.

Types	Protocols	Applying message broadcasting	Applying fast acknowledging	Applying wait-on-quorums
Replication	Primary-backup	The primary broadcasts requests to backups.	Each backup buffers messages in the kernel and quickly responds to the primary.	The primary waits for responses from all backups.
	Chain	None	Each replica (except for the last one) buffers write requests in the kernel and forwards them to the next replica.	None
Concurrency control	Two-phase locking	A transaction coordinator broadcasts LOCK and UNLOCK requests to all shards.	Each shard maintains a lock table in the kernel and directly handles lock acquiring and releasing.	A transaction coordinator waits for responses from all shards.
	OCC	None	Each shard checks in the kernel if the committing transaction's timestamp conflicts with all other running ones.	None
Atomic commitment	Two-phase commit	A transaction coordinator broadcasts PREPARE and COMMIT requests to all shards.	Each shard buffers PREPARE messages in the kernel and responds to the coordinator, and handles COMMIT requests by polling the buffered messages.	A transaction coordinator waits for responses from all shards

Table 4: Applying Electrode to more distributed protocols.

APPENDIX

A Electrode Generalizability

Table 4 summarizes how the classic replication, concurrency control, and atomic commitment protocols can leverage Electrode optimizations. For example, the primary-back replication, two-phase locking, and two-phase commit protocols follow the pattern of sending requests to multiple nodes and waiting for a quorum number of responses; thus they naturally fit well with the eBPF-based message broadcasting and wait-on-quorums. Together with the above protocols, the chain replication [74] and opportunistic concurrency control (OCC) [34] protocols include some critical-yet-simple operations like storing messages in memory, maintaining a lock table, and checking timestamp conflicts; these operations are also suitable for offloading to the eBPF following the fast acknowledging mechanism.

B Impact of Interrupt Coalescing

During benchmarking, we noticed that the interrupt coalescing [62] (IC) feature of modern NICs has a big impact on the measured performance. In IC, after an incoming packet triggers an interrupt, the kernel networking stack waits until a threshold of packets arrives or a timeout gets triggered, aiming to amortize the interrupt cost. In our scenarios, we find it significantly hurts latency and performance predictability in our settings; similar results are also reported in [73]. Thus, in all our experiments, we disable IC by default.

Figure 9 shows the performance impact of IC on the Multi-Paxos protocol and Electrode-accelerated one, by varying the number of open-loop clients. With IC, load-latency curves become unpredictable with two “hockey stick”s. The second “hockey stick” is because the extremely high load triggers coalescing/batching much more packets in one interrupt. Overall, IC does not nearly impact the maximum throughput for the Multi-Paxos protocol and Electrode-accelerated one, but it increases the latency by 57.4%-129.2% and 9.1%-246.8% with 1-3 clients (before the first “hockey stick”). Moreover,

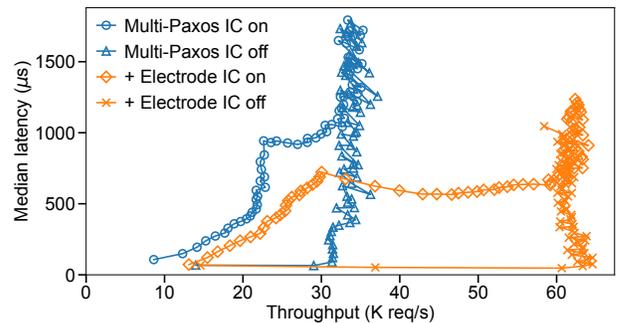

Figure 9: Performance impact of interrupt coalescing (IC) on the Multi-Paxos protocol vs. Electrode-accelerated one (with 5 replicas).

enabling IC decreases the one-client throughput by 38.3% and 10.1% for the original Multi-Paxos and Electrode-accelerated one, respectively.

Electrode performance with IC: Electrode accelerates the maximum throughput of the Multi-Paxos protocol by 81.4% and latency by 32.7% with 1 client (before the first “hockey stick”) when IC is on.

Nu: Achieving Microsecond-Scale Resource Fungibility with Logical Processes

Abstract. Datacenters waste significant compute and memory resources today because they lack resource *fungibility*: the ability to reassign resources quickly and without disruption. We propose *logical processes*, a new abstraction that splits the classic UNIX process into units of state called *proclefs*. Proclefs can be migrated quickly within datacenter racks, to provide fungibility and adapt to the memory and compute resource needs of the moment. We prototype logical processes in Nu, and use it to build three different applications: a social network application, a MapReduce system, and a scalable key-value store. We evaluate Nu with 32 servers. Our evaluation shows that Nu achieves high efficiency and fungibility: it migrates proclefs in $\approx 100\mu\text{s}$; under intense resource pressure, migration causes small disruptions to tail latency—the 99.9th percentile remains below or around 1ms—for a duration of 0.54–2.1s, or a modest disruption to throughput (<6%) for a duration of 24–37ms, depending on the application.

1 Introduction

Compute and memory are valuable and expensive resources in datacenters today, but they are inefficiently utilized [46, 76]. A key reason for this inefficiency is a lack of *fungibility*—the ability to reassign resources quickly and without disruption between different users and across different machines. Without fungibility, resources are stranded and over-provisioned for fear of running short, even as resource consumption naturally fluctuates in datacenter applications [2, 7, 18, 34, 39].

Existing systems fail to provide fungibility because current abstractions for compute work and memory state (VMs, containers, processes) are too coarse-grained (§2). To address this problem, we introduce the abstraction of a *logical process*. Logical processes provide fungibility, while retaining a familiar programming model similar to traditional processes. A logical process consists of many smaller *proclefs*, atomic units of state and compute that can be independently migrated under resource pressure to achieve fungibility. Like a traditional process, a logical process has its own address space, isolated from other processes. But unlike a traditional process, a logical process can spread across many machines in datacenter racks as a result of the migration of its proclefs. Intuitively, logical processes break down the monolithic nature of traditional processes into many proclefs. A proclef consists of a heap (state) and a set of user-level threads and their execution contexts (stacks and register values). A runtime system that manages the logical process responds to spikes in load by migrating proclefs quickly to a machine with spare resources.

To realize logical processes and proclefs, we had to address three challenges. First, proclef migration must be fast and react to resource pressure before resources are exhausted. Second, communication between proclefs and migration of proclefs must impose little overhead or disruption on the application, especially if migration itself consumes resources when they are short. Third, the programming model of logical processes and proclefs must support practical datacenter applications.

We respond to these challenges as follows. First, we divide process state into proclefs, which are small relative to an entire process, so they can be migrated orders of magnitude faster than VMs or processes. Second, we optimize our software stack to take full advantage of modern datacenter networks (at 100–400 Gbit/s). This pushes performance far enough for proclefs to migrate in $\approx 100\mu\text{s}$. We also scale proclefs across machines with minimal communication overheads by using a single program image across machines and an optimized RPC stack. Third, we use a global address space to provide a programming model that is process-like and intuitive. This makes it possible to statically check types, and enables computation shipping by passing function pointers between proclefs.

We prototyped logical processes and proclefs in Nu, a system that provides a C++ class API and a Caladan-based user-level threading and kernel-bypass networking runtime [28]. Nu targets environments with tens of racks: hundreds of machines connected with an overprovisioned network that provides high full-bisection bandwidth (100–400 Gbit/s) and low latency (10–20 μs). We implemented three applications using Nu. The first is a version of the DeathStarBench social network application [29], originally implemented using microservices. The Nu version of this application is simpler, shorter, and has an order of magnitude better performance than the microservice version, while preserving scalability. The second application is k-means clustering on Phoenix MapReduce [63], which represents a compute-intensive workload with high parallelism. Phoenix MR originally supported thread parallelism in a single NUMA machine, but the Nu version scales across multiple machines while also delivering comparable single-machine performance. The third application is a scalable key-value store implemented in Nu as a hash table whose buckets are distributed across multiple proclefs.

We evaluate Nu in a setup of 32 servers with 100 GbE NICs that are connected through a top-of-rack switch. Our evaluation shows that Nu achieves high efficiency and fungibility: it reacts quickly to resource pressure and migrates

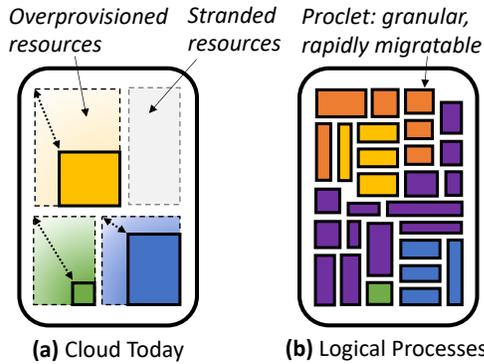

Figure 1: (a) Resources are wasted as they are overcommitted for peak use (gradient) or stranded as additional tasks do not fit (gray). (b) Proclets permit tighter packing, which fits more tasks (orange, purple) that can be migrated away quickly under resource pressure.

proclets without disruption to the application workload. Nu migrates proclets in $\approx 100\mu\text{s}$ and its migration exceeds the rate at which the Linux kernel can allocate memory ($\approx 7\text{GB/s}$), so Nu handles even intense resource pressure. Under this memory pressure, the social network app adds $122\mu\text{s}$ to the 99.9th-percentile client latency for a period of 0.86s; the key-value store app adds $52\mu\text{s}$ for 2.1s; and k-means loses 2.9% throughput for 37ms. Under intense compute pressure, disruption is higher, but still short-lived: the key-value store adds $1,053\mu\text{s}$ for 0.54s; and k-means loses 5.8% throughput for 24ms. Finally, Nu’s logical processes are efficient in the absence of resource pressure, and match or exceed the performance of strong baselines on one or more servers.

Nu has some limitations. First, logical processes require developers to structure applications as proclets. This may not be feasible for every application (§3.3), but we have shown that it is feasible for three very different applications. Second, Nu currently considers only two resources, memory capacity and compute load. We expect other resources can be added (network, caches, memory bandwidth, etc.), but that remains future work. Third, Nu targets deployments where network bandwidth is plentiful and latencies low.

Nu is available as open-source software [66].

2 Motivation: Resource Fungibility

Cloud computing originally promised to deliver utility computing, with fine-grained, pay-per-use sharing of compute resources, rather than fixed-size machines that customers must purchase and own [4, 31]. But, almost two decades later, the operational reality is different: although end-users can readily rent resources, cloud providers still provision and offer these resources in fixed-size units and over long time horizons.

We argue that a key problem in this setting is the lack of fungibility—the ability to reassign resources quickly and without disruption between different users and across different machines. Users today submit requests for fixed allocations (number of cores, memory, etc.) as determined by so-called “instances” (or “slots”, “tasks”). These allocations tend to over-

estimate actual resource use, which fluctuates at sub-second time scales. Providers bin-pack instances onto the available servers [33, 35, 71, 76, 77]. This is inefficient because users must size instances for peak rather than typical usage, leaving substantial resources idle most of the time. Providers can reclaim some of these wasted resources by overbooking and scheduling best-effort instances in them [2, 44, 76, 84]. But this practice is disruptive, as machines can get intermittently overloaded, leading to performance degradation (e.g., high tail latencies), which is particularly problematic for latency-sensitive workloads [28, 44]. In response, the cluster manager must kill some best-effort instances to free up resources. But doing so is also disruptive because the work done by a killed instance can be wasted and may need to be redone. Moving the instance usually is not an option as it requires an expensive VM or process migration that can take seconds or minutes because the state to be moved is large, and it requires the cluster manager to find a destination machine that has sufficient resources to take over the entire (indivisible) instance.

In other words, today’s cloud is not fungible (Figure 1(a)). Resources can only be reassigned on fairly long timescales, larger than the timescales over which resource consumption fluctuates. The underlying reason for this problem is that current abstractions for compute work and memory state—VMs, containers, and processes—are too coarse-grained.

A more efficient design would avoid disruption and reassign resources quickly and at fine granularity. This would make it easy for providers to increase utilization by densely packing instances across machines while rebalancing and migrating work as necessary, instead of killing instances under resource pressure. In addition, this would eliminate the burden on users to predict and specify peak per-machine resource usage for each instance, allowing them to instead pay for resources as they are used.

Our approach to fungibility. To provide fungibility, we revisit the *process*, a core OS abstraction that dates back to the 1960s. Traditionally, a process is an instance of a computer program that runs on one machine, consisting of memory and a set of threads. Our work extends this idea across machines to provide a similar abstraction called a *logical process*.

Logical processes are inspired by logical disks [59, 74]. Much like a logical disk, a logical process combines together disparate physical resources—in this case, machines rather than disks. A logical process automatically scales to use additional machines when more capacity is needed, and can recover from machine failures.

A logical process achieves fungibility through two key ideas (Figure 1(b)). First, a logical process divides program state into fine-grained partitions called *proclets*. Second, proclets are migrated quickly between machines in response to memory or compute resource pressure. Each proclet runs on one machine at a time, and proclets communicate with each other through efficient message passing.

Because proclets are fine-grained, migrations complete

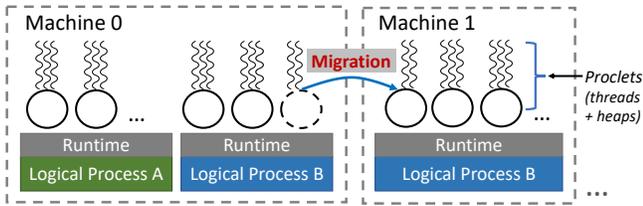

Figure 2: Logical processes spread across machines. Each logical process is comprised of proplets that include a heap (shown as a circle) and threads (shown as squiggles). Proplets rapidly migrate to other machines in response to resource pressure.

quickly, causing minimal performance disruption. Inspired by prior work that shows that decomposition into small units simplifies placement [51, 57], proplets’ fine granularity makes packing them onto machines simple and avoids complex and time-consuming bin-packing on allocation or migration.

Alternative approaches. There are a few other approaches to improving fungibility, but they have drawbacks. One can migrate VMs [20, 78], containers [22], or processes [49], but migration is slow due to their state size. An alternative that maintains the process abstraction is to use distributed shared memory (DSM) to spread a normal process across machines [83]. But DSM systems experience high coherence overheads with shared memory, leading to poor performance. PGAS [5, 17, 54] is a type of DSM that can avoid such overheads, but its applicability is limited to parallel applications.

Another approach to fungibility is to adopt new programming models to distribute the application into smaller units, as with distributed objects [6, 13, 21, 30, 70, 82], microservices, and serverless functions. These models depart significantly from the familiar process abstraction, and they are built on top of traditional, coarse-grained instances that limit their fungibility. They also have high RPC messaging overheads (and cold start delays for serverless functions [72]) that grow in cost as their units become smaller. Alternatively, parallel programming frameworks [8, 15, 23, 26, 50, 81] partition work via rigid compute patterns (e.g., partition-aggregate, actors). This constrains the programming model and requires data to be statically placed on machines.

Finally, some techniques provide fungibility, but in limited form. Far memory systems [32, 67, 79] can incrementally extend the memory of a process, but they perform well only when the remote memory is cold. Request load balancing can make compute fungible, but it is mostly suited for stateless or read-only services. These two techniques are complementary to logical processes and can be combined with them.

3 The Logical Process Abstraction

A *logical process* exists across one or several machines and contains a collection of proplets. Proplets are fine-grained partitions of program state that form units of migration. Proplets can be individually migrated between machines to relieve resource pressure (Figure 2).

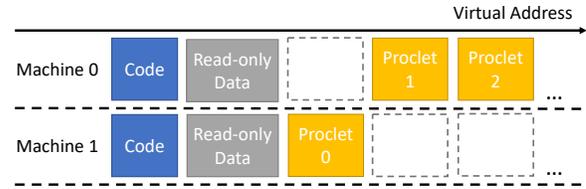

Figure 3: The address space layout of a logical process running on two machines. Read-only code and data is mapped everywhere, while proplets are mapped in exactly one machine at a time.

A proplet consists of a heap and a set of threads that can access the heap concurrently via shared memory. A proplet never shares its heap memory directly with other proplets. Instead, each proplet has an associated *root object*, which defines a remote method interface that other proplets use to access its state. This approach allows developers to build full programs from proplets in a natural, object-oriented way. The root object may store references (pointers) to ordinary local objects stored on the proplet’s heap.

The number of machines allocated to a logical process can change over time in response to shifts in the resources available on each machine. Each machine handling logical processes runs a separate runtime instance. The runtime provides location-transparent communication between proplets, detects resource pressure, migrates proplets between machines, and cleanly handles failures.

Developing software for logical processes is similar to normal UNIX processes. Code can spawn threads, use synchronization primitives to coordinate access to shared memory, and allocate memory using standard APIs like `malloc` or `new`. But there are two major differences. First, developers must partition their program state into proplets. Second, in most cases, developers must use runtime APIs instead of making system calls or performing I/O directly. We describe the logical process abstraction in more detail in the following.

3.1 Address Spaces and Cache Coherence

A logical process uses an identical address space layout on each machine. This simplifies migration, as pointers remain valid across machines without swizzling. Runtime instances coordinate to keep their layout synchronized during initialization and whenever new proplets are created.

Figure 3 shows an example address space layout for a logical process running on two machines. Code and shared data segments are mapped read-only on all machines. Consequently, the machines must be binary-compatible, but not necessarily identical architectures (e.g., AMD and Intel x86 CPUs). Read-only data can store large static arrays, tables, and other inputs that all proplets might need. Proplets’ heaps, on the other hand, are readable and writable, only mapped on one machine at a time, and only ever accessible by the owning proplet. (This contrasts with distributed shared memory [3, 10, 25, 40, 52, 68, 69], which typically provides cache coherence across machines.) In other words, *no proplet can share*

```

1 struct Accumulator {
2     Accumulator(int val) : val_(val) {}
3     void Add(int n) { std::scoped_lock l(mu_); val_ += n; }
4     int Get() { std::scoped_lock l(mu_); return val_; }
5     std::mutex mu_; int val_;
6 };
7
8 void mainfunc() {
9     // Creates two proclefs with root class Accumulator.
10    auto p1 = make_proklet<Accumulator>(10);
11    auto p2 = make_proklet<Accumulator>(10);
12    // Invokes Get() on p1; prints 10.
13    std::cout << p1.Run(&Accumulator::Get);
14    // Invokes a closure on p1; prints 15.
15    std::cout << p1.Run(+[&Accumulator &a] { a.Add(5);
16        return a.Get(); });
17    // Invokes Get() asynchronously; prints 25.
18    auto f1 = p1.RunAsync(&Accumulator::Get);
19    auto f2 = p2.RunAsync(&Accumulator::Get);
20    std::cout << f1.get() + f2.get();
21    // Adds p2's value to p1 by invoking a closure on p1.
22    p1.Run(+[&Accumulator &a, proklet<Accumulator> p] {
23        auto v = p.Run(&Accumulator::Get); a.Add(v); }, p2);
24    // Arguments statically type checked; DOESN'T COMPILE!
25    // p1.Run(&Accumulator::Add, 10, 20);
26    // Proclefs are freed when mainfunc() gets out of scope
27 }

```

Figure 4: Code sample for logical processes. Proclefs have a root class with methods containing the app logic. Proclefs can create other proclefs, run methods synchronously or asynchronously, and run closures. Closures can take proclefs as arguments to chain execution.

memory with another proklet. Instead, proclefs communicate via remote method invocation, which passes arguments by copying if the proclefs are co-located on a machine or by network transfer if they are on different machines.

This design avoids writable shared memory across machines and aligns well with current datacenter networks, which provide high throughput and low latency, but lack hardware support for cache-coherent memory across machines. Additionally, this design enables fault isolation, as it allows one proklet to fail independently from others on different machines. A failure can cause a proklet's memory to disappear at any time, and these errors can be cleanly reported via return codes of remote methods. This allows us to use standard distributed systems techniques (e.g., replication) to make critical proclefs fault-tolerant.

Proklet migrations occur atomically and each proklet runs on exactly one machine at a time. Consequently, cache coherence is available within proclefs, but not across proclefs. This design allows for a normal programming environment inside proclefs, including synchronization across threads (via spinlocks, mutexes, etc.) when they access shared memory within a single proklet's heap.

3.2 Programming Model

Developers write an application as a set of proklet root classes. As in traditional object-oriented programming, each class defines methods and fields. Methods implement the proklet's application logic and expose the API for the proklet to be invoked by other proclefs. Fields specify state internal to the proklet, although additional state can be allocated dynamically in the heap at runtime. Figure 4 shows a running

example in C++.¹ Lines 1–6 define `Accumulator` as the root class for a simple proklet that keeps a value `val_` and exposes two methods `Add` and `Get` to increment and retrieve the value. Here, the methods are one-liners, but in real applications they constitute most of the code.

When a logical process starts up, the runtime launches a main proklet. This proklet typically creates other proclefs by calling function `make_proklet` with their root classes and constructor parameters. In the example, the main proklet invokes function `mainfunc` (for brevity we do not show the main proklet, only `mainfunc`), which in lines 10–11 creates two proclefs with root class `Accumulator`.

Proclefs communicate only via remote method invocations and closures. With remote method invocations, a proklet calls the methods of the root object of another proklet, either synchronously using function `Run()`, or asynchronously using function `RunAsync()`, which returns a future. Lines 13 and 17–18 show a synchronous and two asynchronous invocations of `Get` on proclefs. The two asynchronous invocations run concurrently to hide latency.

With closures, a proklet can implement function shipping [36, 38, 65, 67, 79, 80], and ship a function that invokes methods—interspersed with its own processing logic—on the root object of another proklet. Line 15 shows a closure that invokes `Add` and `Get` on the same proklet. This execution incurs a single roundtrip to the server hosting the proklet, even though it invokes two methods. Shipping code to data in this manner can greatly improve efficiency.

The remote runtime may execute methods and closures on the same proklet concurrently on different threads. Hence, the example uses a mutex `mu_` to protect `val_` against concurrent execution of `Add` and `Get`.

Naming and reference counting. Proclefs need to know about each other before they can communicate. We adopt a proklet naming scheme based on smart *proklet pointers*. These pointers provide safety, convenience, and reference counting through an interface similar to C++'s `shared_ptr`.

Unlike standard RPC frameworks, remote methods or closures can take proklet pointers as arguments. Thus, code can pass handles to proclefs to other proclefs by passing them as parameters, similar to delegating capabilities. This feature permits a remote method or closure to chain together the execution of multiple proclefs while performing computation in between. For example, line 22 shows a closure on proklet `p1` that takes proklet `p2` as a parameter; the closure first calls `p2's Get` method, followed by `p1's Add` method.

Proklet pointers are valid within the entire logical process, even across machines, and the runtime frees a proklet when it loses its last reference. In the example, proclefs `p1` and `p2` are freed automatically when `mainfunc()` goes out of scope.

We considered using global strings as proklet names, but never needed them in building applications. A logical process

¹A logical process can be implemented in other languages too.

is tightly coupled, and we found that passing smart pointers is more convenient than hard-coding strings. Typically, initialization code creates several procllets, and passes around their smart pointers, so the code hands over access directly.

Type checking. Because a logical process uses an identical program image across machines, static type checking of argument types is sufficient for remote invocations. This contrasts with standard RPC frameworks (e.g., Thrift or gRPC), which additionally have to perform dynamic type checking, incurring runtime overheads and requiring extra error handling. Line 24 thus fails to compile because of too many arguments.

Raw pointers into a procllet’s heap are never allowed as arguments; we made this choice to discourage incorrect code that attempts to share memory between procllets. On the other hand, smart pointers are supported, and passing them as arguments causes the objects they own to be copied.

Unlike standard RPC frameworks, procllet invocations allows remote methods and closures to take function pointers and closures as arguments. This is possible as all machines in the logical process map the code segment at the same address.

Network I/O outside a logical process. Logical processes perform their I/O through abstractions provided by the runtime, rather than POSIX syscalls and I/O abstractions. This allows procllets to be machine-independent and migrate between machines without having to move hard-to-migrate local kernel state (e.g., the TCP state machine). In particular, the runtime maintains TCP network connections to clients, which can be either other logical processes or normal processes. These connections allow clients to communicate with specific procllets inside a logical process—or to spread load across groups of stateless procllets—and will forward client requests if the destination procllet has migrated. Similar to existing libraries for distributed request routing [1, 53], the runtime informs client libraries about the procllet’s new location, so that the client knows to expect the response on another network connection and to send future requests there. In our datacenter setting, client and server code are under the control of the same entity, and custom I/O libraries (e.g., for request routing and load balancing) are commonplace [1, 11, 73].

In rare cases, developers can pin procllets that need to use local resources directly to a machine. Such procllets lose their ability to migrate and reduce resource fungibility, so developers should pin procllets only if absolutely necessary.

3.3 Porting Applications to Logical Processes

In principle, any application that can partition its state into fine-grained units can be ported to a logical process (each unit becomes a procllet). This aligns well with existing cloud applications that already partition their state (e.g., microservices, FaaS, distributed frameworks, etc.), though sometimes at a coarser granularity than procllets. There are two main considerations when dividing a logical process into procllets: the procllet granularity and its scope.

Procllet granularity. Choosing the right size for procllets is important. If procllets are too large, resource fungibility suffers. If they are too small, communication overheads increase as remote invocations become more frequent. Developers must choose a sweet spot that provides sufficient fungibility without significant overheads. §6.4.2 shows empirical measurements of procllet performance at different state sizes and invocation compute intensities; in practice, procllets of a few MiB state size work well.

Procllet scope. The next consideration is how to decide what functionality goes into a procllet. One approach is *functional splitting*, which equates a procllet to a logical functional unit in the application (a module, a microservice, a package, etc). Well-known software engineering practices suggest how to choose appropriate units [47, 56]: the unit should include functionality that is intuitively related, that can be described simply, and that can be encapsulated through a compact and easy-to-understand API. The latter property ensures that the interface between procllets is also compact. Another approach is to use *sharding*. Since a functional unit may be much larger than the ideal procllet size, it may help to shard (partition) the unit. For example, consider a large chaining hash table. Each hash bucket of this data structure becomes a separate procllet and stores the procllet pointer in the hash array. To operate on a key in the hash table, the code makes the appropriate method invocation to the corresponding procllet. This results in a distributed key-value store, as procllets are spread across machines, but maintains the hashtable API.

Limitations. Some applications are hard to decompose into procllets, such as applications that manipulate large amounts of state that is not easily divisible (e.g., video encoders, architecture simulation, sorting, or graph processing). For these examples, decomposition may still be possible, but it requires new algorithmic approaches [27, 41, 45, 48, 64].

Other applications may require functionality that is tied to physical hardware resources, such as a GPU or an FPGA. In these cases, procllets that interact with the hardware may need to be pinned, thus reducing the logical process’s fungibility.

3.4 Security and Threat Model

A logical process has the same isolation properties as a UNIX process—viz., its memory is isolated from other processes, but its threads share an address space—but applies this model across multiple machines. Even though procllets lack shared memory, there is no hardware memory isolation (e.g., via the MMU) between the procllets *within* a logical process to enforce this. We made this choice for performance reasons and because it matches the isolation model of UNIX processes. On the other hand, memory isolation is guaranteed across *different* logical processes: each local logical process instance runs in a different UNIX process and is isolated from other logical process instances on the machine.

Address space layout randomization (ASLR) and stack ca-

naries are important defenses against buffer overflow attacks. Although ASLR might at first glance seem incompatible with logical processes' global address space, it works as long as the loader maintains the same randomized address space layout on each machine. Stack canaries also work, as procllets cannot share stack memory and the implementation can maintain a different secret canary value for each procllet.

Finally, logical processes trust the network to provide confidentiality and integrity. This is necessary to make remote method invocation and migration efficient by sending raw data and pointers. Modern datacenter NICs have hardware encryption engines that ensure these properties.

3.5 Fault Tolerance

A procllet may be replicated to tolerate failures. Replication creates backup copies of the procllet's heap, which the runtime places at the same virtual address in different machines. To keep the backup heaps in sync, the primary replica serializes the invocation requests and forwards them to the backup replicas. (This requires procllet operations to be deterministic.) Operations on a replica are totally ordered without overlap within each procllet—a choice that trades off some performance for strong consistency. To reduce replication latency, the primary overlaps execution with the backups, but the primary only returns from an invocation once the backups finish.

When the system detects the failure of the primary (e.g., due to an RPC time out), it atomically promotes a backup to the primary. To keep the same replication factor, it also adds a new backup by pausing the procllet and copies its heap from the new primary to the new backup replica.

4 The Nu Runtime System

We built Nu, a prototype runtime that provides the logical process abstraction and runs inside a normal Linux environment. Nu shares some architectural and implementation building blocks with Caladan [28]. Caladan was a good fit for Nu because it provides a user-level threading package with overheads low enough to hide microsecond-scale latency. For example, if a thread blocks waiting for a remote procllet invocation to return, the runtime can quickly context switch to another runnable thread with little overhead. Caladan uses work-stealing to balance these threads across cores, which reduces tail latency [62]. Caladan also provides an optimized kernel-bypass, user-level TCP/IP networking stack to further reduce procllet communication and migration costs.

Nu adds $\approx 10,000$ lines of C++ code to Caladan. This includes efficient communication infrastructure, a new memory management layer to handle multiple heaps, a well-optimized procllet migration system, and a controller to track the location of procllets. In the following, we describe these components.

4.1 Serialization and Communication

Nu serializes arguments to remote invocations using `cereal`, an efficient, header-only library for serialization [16]. `Cereal` has a compact binary serialization format that supports

most STL types, but prohibits raw pointers and references (`shared_ptr` and `unique_ptr` are still supported). We modified `cereal` so that it can serialize function and procllet pointers. To optimize use of `cereal`, Nu maintains a buffer pool for serialized outputs and eliminates extra data copies.

Nu uses C++ templates to internally produce code at compile time for serialization and deserialization of remote method arguments. This contrasts with RPC frameworks like Thrift, which require code generation and an interface description language. As a result, developers call remote methods without boilerplate, and they benefit from static type checking.

We took several steps to optimize remote method invocations. First, Nu opens one TCP connection on each core for each outgoing machine. These connections use specific 5-tuples, so they have flow-level affinity matched with the core they are associated with, enabling cache-aware steering [42, 60]. This design increases the number of open connections, but Caladan easily scales to 10,000 connections, much more than needed for our target environment. Second, Nu applies adaptive batching to combine remote method invocation payloads (requests and responses) into larger TCP transfers without impacting latency [9]. We modified Caladan to use jumbo frames to increase the benefit of this batching. Third, each connection operates as a closed queuing system, limiting the maximum number of requests in flight. This provides flow control and prevents unbounded memory consumption under overload. Finally, when the caller and callee procllets are in the same machine, Nu substitutes the RPC with a fastpath: a local call without any RPC overheads.

4.2 Memory Management

Nu uses a custom slab allocator to manage each procllet's heap. It includes a per-core object cache to increase scalability, similar to most modern multicore memory allocators [12, 14]. C++ allows a custom definition of `operator new()` that Nu uses to override memory allocations. Nu keeps track of which procllet each thread is associated with and directs allocations to the correct heap. In the future, we plan to explore specialized procllet allocators too. For example, an arena allocator could benefit short-lived procllets because it need not free objects until the procllet terminates, reducing overheads.

4.3 Migration

Nu migrates procllets across binary-compatible machines under resource pressure. Nu separates migration mechanism from policy.

Mechanism. To migrate a procllet, the runtime first sets a migration flag, causing method invocations to the migrating procllet to be rejected and retried. Next, it preemptively pauses and saves register state for all the procllet's running threads to ensure that the data is not mutated during migration. Then, it moves procllet data, including heap, stack, and register state, to the new destination. Finally, the runtime clears the migration flag and contacts the controller to update the location of the

procket, ensuring pending and future method invocations are routed to the new destination (§4.4). We co-designed Nu’s RPC layer with migration, and it routes the results of method invocations on migrated prockets back to the caller.

We optimized Nu’s migration datapath. To improve TCP throughput, we use parallel connections and jumbo frames. We found that Linux’s `mmap` (used for creating the procket space at the destination machine) was a bottleneck, so we modified the Linux kernel to pre-zero freed pages. After this optimization, Nu can migrate at line rate on 100GbE. When we tried 200GbE, `mmap` again became a bottleneck—in this case due to the Linux kernel’s physical frame allocation speed. As a workaround, Nu instead uses `mmap` to pre-fault a small pool of memory at the destination server. Then, on migration, Nu performs `mremap` on that memory to reuse prior frame allocations. Future Linux kernel optimizations might avoid the need for this remapping.

The CPU overhead of migration is moderate in our current prototype: it takes three hyperthreads to saturate 100GbE and five hyperthreads to saturate 200GbE.

Policy. Nu provides an extensible migration policy interface that dictates which prockets to move and where to move them under resource pressure. Many sophisticated policies are possible, including policies that react to several types of resource pressure (e.g., CPU load, cache pressure, memory capacity, memory bandwidth, network bandwidth, etc.), and policies that co-locate frequently communicating prockets to improve locality. Currently, our prototype ignores locality and focuses only on CPU load and memory capacity, two resources often subject to pressure, but we plan to extend it in the future.

Because Nu’s migration is fast, we found that even the simplest policies work well (§6). In particular, Nu needs no sophisticated algorithms to predict future resource use, but rather simply migrates prockets at the last moment, when resources are nearly exhausted. To determine when migrations are needed, a monitoring thread in the runtime polls resource use. For memory, it monitors the amount of free memory and begins migrating once it falls below a threshold (e.g., 1 GiB). For CPU, it monitors system core utilization and begins migrating when a threshold of cores are busy. A better alternative might track the queueing delay of runnable threads, allowing Nu to distinguish actual overload from cases where all cores are busy but not overloaded [19]. We plan to investigate this in the future.

Nu migrates one procket at a time until resource pressure is eliminated. To determine which procket to migrate, Nu uses this formula (where P is the set of prockets on the machine):

$$\arg \max_{p \in P} \left(\frac{RESOURCE_USE(p)}{MIGRATION_TIME(p)} \right)$$

`RESOURCE_USE()` measures a procket’s use of the resource under pressure, and `MIGRATION_TIME()` models the migration time of a procket by considering the size of its heap, as

well as the number of threads it must pause and transfer, and the size of thread stacks. This maximizes the pressure alleviation rate and helps Nu optimize for response speed. Nu’s runtime collects metrics in real time to estimate this rate.

To determine the migration destination, Nu queries a global cluster controller, which monitors resource use across servers and returns possible destinations (described next).

4.4 Controller

Nu has a controller that makes cluster-wide decisions, such as procket placement and virtual address allocation, and tracks information, such as procket location and resource use. Nu assumes that the controller is highly available. Although our prototype controller is centralized, high availability can be achieved through primary-backup replication or simple recovery: the controller keeps only soft state, so it can always restore its state by querying the servers.

Placing prockets. The controller periodically probes servers’ available resources. It uses this information to decide where to place a procket on creation or migration. Currently, it uses a simple policy that spreads prockets evenly across machines.

Allocating virtual address segments. Prockets must use non-overlapping virtual addresses. Therefore, Nu divides the virtual address space into an array of segments. These segments are large enough (4 GiB by default) to leave room for a procket’s heap to grow. The controller keeps lists of allocated and unallocated segments. On procket allocation, the local runtime contacts the controller to obtain an unallocated segment.

Resolving procket location. The controller keeps a location map from the starting logical address of each procket to the IP of the machine hosting the procket. Each local runtime maintains a cache of the location map that contains the prockets it has recently accessed. This eliminates the need for method invocations to communicate with the controller in the common case, moving the controller off the critical path for the steady-state application traffic. When a procket migrates, the controller updates the map. This causes caches to become stale, so a local runtime may send a method invocation to the wrong machine. When this happens, the remote machine returns an error. The local machine then handles the error by invalidating its cache entry and contacting the controller to find the new machine location.

4.5 Replication

Nu optionally provides traditional primary-backup replication for prockets. This works by forwarding procket operations from a primary to backup replicas, akin to traditional state machine replication (SMR). One challenge specific to Nu is that a procket operation can invoke sub-operations on other prockets. The backup replicas will invoke the same sub-operations as the primary, but side-effect causing invocations must occur only once, and replicas must see the same results as the primary’s operations. Nu supports a variant [58] of RIFL [37]’s duplicate detection. Prockets assign a unique

Workload	# proctets	Memory	Compute Intensity [time/invoc.]	Proctet size
SocialNetwork	12 (microservices) + 65,536 (hashtable)	113 GiB	1–100 μ s (variable)	31 KiB–8 MiB
In-memory KVS	65,536	138 GiB	1 μ s (low)	2 MiB
Phoenix k-means	720 (workers) + 1,024 (hashtable)	8.4 GiB	map: 4.6 ms, reduce: 677 μ s	31 KiB–19 MiB

Figure 5: Characteristics of the three case study applications (KVS is an in-memory key-value store, and Phoenix is a MapReduce framework).

ID of the form \langle proctet id $\rangle + \langle$ epoch $\rangle + \langle$ sequence number \rangle to each proctet-to-proctet invocation. Primaries forward their sub-operation invocation results to the replicas, and replicas reuse the results (identified by the unique ID). Returning the saved results instead of re-executing sub-operations ensures all replicas have the same heap state. As with an unreplicated system, if a primary crashes in the middle of an operation, its sub-operations are re-executed if the unfinished operation is retried.

When Nu’s controller detects a failed primary, it promotes a backup to be the new primary and updates its location map with the new primary. However, runtimes may have the old primary in their caches, which could cause a “split brain” situation if the old primary continues to serve requests. A standard epoch-based approach [43, 55] can help Nu avoid this problem: each reconfiguration increments an epoch counter and backup proctets reject operations with outdated epochs.

4.6 Limitations

Our Nu prototype has some limitations. It requires the use of C++, and though the runtime provides many OS services (timers, external and internal network I/O, synchronization, threads, memory allocation, etc.), it does not yet support all services. Despite these limitations, we ported three very different applications to run on Nu.

5 Application Case Studies

We implemented three applications on Nu, which cover a range of proctet sizes, communication patterns, and compute intensities (Figure 5). All applications use a Nu-enabled hashtable library. The hashtable partitions the key space with a hash function and uses proctets as data shards. A root proctet has a vector of proctet pointers to these shards and shares them with client proctets to allow direct communication.

SocialNetwork (from the DeathStarBench suite [29]) is a multi-tier, interactive web service, originally built as 12 microservices. Its overall complexity is high, with a fan-out communication pattern and many microservices that have low compute intensity, making it sensitive to both tail latency and RPC overheads. We ported SocialNetwork to a logical process, turning each microservice into a proctet. However, we found that its compute intensity was sometimes too low and that it lacked autoscaling support; both limit its overall scalability. Therefore, we also built a version of SocialNetwork that is better structured for a logical process: this version merges SocialNetwork’s small, stateless microservices into a single root class, and scales by spawning it as proctets across machines. Both versions have \approx 1,000 LOC, compared to 6,843

LOC in the original, which highlights the simplifications afforded by logical processes. Our implementation replaces the external stores used by microservices (Memcached and Redis) with a backend based on our hashtable, and leverages proctet closures to support Redis-like local operations. We also modified our external I/O subsystem to interact with unmodified Thrift-based clients. This is possible because any root proctet can handle any request, as root proctets are stateless.

KV Store is a key-value store composed of the Nu-enabled hashtable library and an additional 200 LOC. It is a stateful application that is latency-sensitive and uses significant memory, making it hard to migrate. On each machine, the Nu runtime’s external I/O subsystem receives requests from external clients and steers them to the right proctets. The key-value store has low compute intensity (1 μ s/invocation), but large proctet state (2 MiB/proctet).

K-means is a workload from Phoenix MapReduce [63]. Phoenix MR is a NUMA-oriented, shared-memory MapReduce framework designed for single-machine operation. We run k-means—an algorithm that requires multiple iterations—in a Nu-based Phoenix MR port, using proctets to scale across machines. We modified Phoenix’s task scheduler to replace worker threads with worker proctets, ship closures to the workers, and shuffle data between mappers and reducers via our hashtable (changing 548 out of Phoenix’s 3,066 LOC). K-means is compute-intensive (0.7–4.6ms/invoc.), but has smaller proctet state (31 KiB–19 MiB/proctet). Overall, we found it easy to modify Phoenix MR to work in a distributed setting. Our version follows the same partition-aggregate communication pattern that makes distributed MapReduce frameworks sensitive to stragglers in k-means.

6 Evaluation

We evaluate Nu with these three applications, as well as microbenchmarks that measure the impact of specific design decisions. Our evaluation seeks to answer four questions:

1. Can migration in Nu prevent performance disruption during intense resource pressure? (§6.1)
2. How does porting applications to Nu impact their performance? (§6.2)
3. How well does Nu scale with the number of servers? (§6.3)
4. What is the effect of compute intensity, as well as that of our key design decisions, on Nu’s performance? (§6.4)

Setup. Except §6.4.2, all other experiments run on a cluster of 32 physical servers in CloudLab [24]. The servers are c6525-100g instances (24-core AMD 7402P at 2.80GHz,

# of Machines	Controller	Proclet servers	Clients
SocialNetwork	1	26	5
KV Store	1	15	16
K-means	1	30	1

Figure 6: Allocation of machines for each application.

128 GB RAM, Mellanox ConnectX-5 NIC), connected by a 100 GbE network. We run §6.4.2 on c6525-100g servers, c6525-25g servers (i.e., the variant with 25GbE NICs), and our local servers with a 200 GbE network.

Servers run Ubuntu Linux 20.04 with kernel v5.10 patched to pre-zero free pages (§4.3). We disable ASLR, as Nu does not support it yet.

6.1 Application Performance under Resource Pressure

Nu’s proclet-centric design enables fine-grained, rapid migration. The key goal of this design is to achieve high application performance even under resource pressure. To evaluate this, we expose Nu and our applications (§5) to compute and memory resource pressure and measure the application performance as proclets migrate to other machines. We skip SocialNetwork for compute pressure, as this application can handle it with a standard front-end load balancer. We run experiments using 32 machines, one of which serves as the controller (§4.4). The remaining machines are either proclet servers or clients, and we partition them appropriately for the application (Figure 6). To evaluate Nu’s ability to manage disruptions under demanding load conditions, we generate enough client load to use $\approx 70\%$ of CPU capacity across all proclet servers. Then, we induce resource pressure on one proclet server, causing it to migrate its proclets to the other servers.

In these experiments, memory pressure comes from an antagonist process that allocates memory as fast as Linux’s virtual memory subsystem permits (≈ 7 GB/s measured in our machine with 4K pages). Once the memory usage of the machine goes above the threshold, Nu starts to migrate proclets to free memory. A good result would show Nu migrating proclets sufficiently quickly to keep up with the allocation rate of the antagonist, without disrupting application performance. To assess the benefit of rapid migration, we compare Nu against a baseline that emulates MigrOS [61], a recent RDMA-based live migration system. To emulate MigrOS, we throttle Nu’s migration speed to 600 MB/s on average with a 200 ms initial delay. Since migration speed is slower than the antagonist’s memory allocation, the machine starts swapping. We swap to a fast device: Linux `brd`, a block device backed by RAM. (The common alternative—killing processes—is even more disruptive, wastes work, and yields no meaningful baseline.)

Figure 7a shows the 99.9th percentile latency of client requests in the SocialNetwork application. At $t=3.9$ s, the antagonist starts allocating memory, and once Nu’s runtime detects that the free memory size goes below 1 GiB (a con-

figurably threshold) at 4.9s, it starts migrating proclets to another machine. During the migration, client-perceived latency increases by less than 19%. At $t=5.7$ s, all proclets have migrated and latency recovers. Figure 7b shows the same experiment with the baseline (Nu emulating MigrOS’s migration speed). Since it migrates memory slower than the antagonist requests, memory runs out at $t=5$ s and Linux starts swapping. Thus, the 99.9th latency increases from 639 μ s to 206ms. The antagonist finishes at $t=10$ s, and latency eventually recovers as memory use drops. Figure 8 summarizes the results for the same experiment on KVS and k-means, which show a similar trend (graphs in §A.1).

Compute pressure is harder to handle well than memory pressure as the CPU use can spike instantly. Figure 9 shows that Nu experiences a higher performance impact when faced with an antagonist that suddenly uses half the available CPU cores. However, disruption is still short-lived as Nu resolves pressure rapidly through fast migration. By contrast, the performance impact on the baseline lasts $\approx 15\times$ longer.

These results show that Nu frees resources quickly under pressure, migrating proclets faster than Linux can allocate memory. Consequently, the pressuring workload (here, the antagonist) neither runs out of resources nor slows down, and the applications experience only modest tail latency increases. This means that Nu-based applications can use spare resources without risk: Nu can always migrate proclets if other workloads need the resources.

6.2 Comparison with Existing Implementations

Nu seeks to provide logical processes that match or exceed the performance of current architectures even in the absence of resource pressure. Although Nu allows distributed operation, local proclet invocations would ideally match the performance of computing on a single machine. We therefore compare the performance of Nu-based applications to baseline implementations without logical processes on a single machine. We measure tail latency under varying load for long-running services (SocialNetwork and KVS), and throughput for k-means. A good result would show Nu matching the baseline on NUMA-optimized, compute-intensive applications (e.g., Phoenix k-means), and it would outperform the baseline on RPC-based applications because Nu’s fastpath avoids RPC overheads.

Figure 10 shows the results. Nu matches or exceeds the baseline’s performance in all cases. For SocialNetwork (Figure 10a), Nu serves about 850k requests/second with sub-millisecond 99.9th percentile latency. The baseline implementation, which runs microservices in Docker containers and uses Thrift RPCs, scales to only 8,000 operations/second, with a 9–60 ms 99.9th-ile latency (very left of the graph). Nu outperforms the baseline because its fastpath avoids the overheads of loopback RPCs (serialization and network syscalls) with a single machine. For KV Store, Nu outperforms memcached on Linux by 15 \times , serving 12M operations/second to mem-

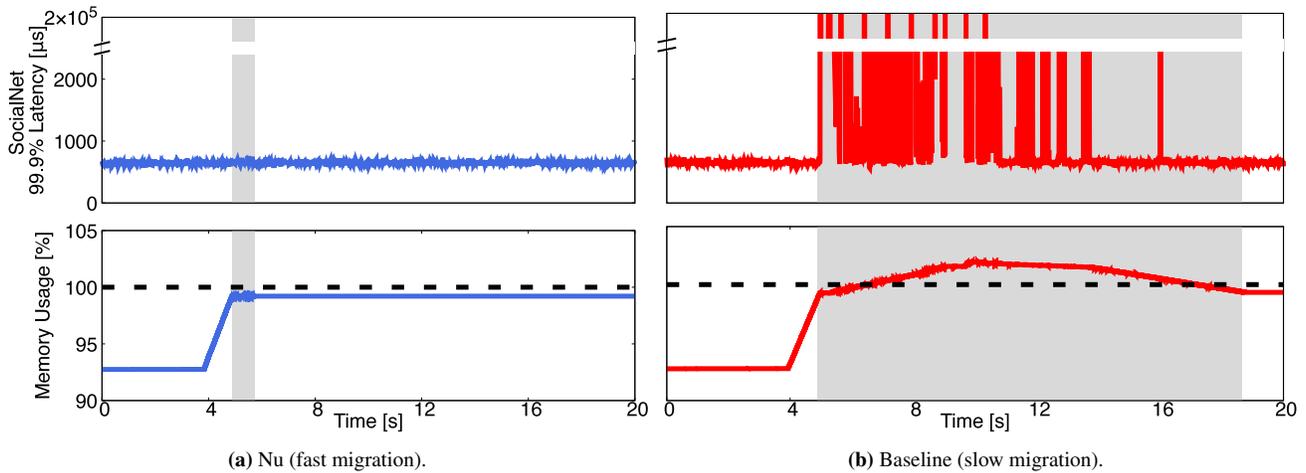

Figure 7: SocialNetwork runs alongside a memory antagonist that starts at 3.9s. When the memory usage reaches the high watermark, Nu starts migrating proclets rapidly (the gray window). By matching the allocation speed of the antagonist, Nu keeps the memory usage flat and resolves the pressure in 0.86s. SocialNetwork’s 99.9th-ile latency is unaffected. By contrast, the baseline fails to migrate fast enough and starts swapping, which leads to 206ms latency (322×). After the antagonist finishes, the memory usage and the latency gradually return to normal.

Workload [Disruption Effect]	Baseline (Slow migration)		Nu (Fast migration)	
	Duration	Effect	Duration	Effect
SocialNetwork 99.9 th Lat. [μ s]	9.14s	206ms (322×)	0.86s	761 μ s (1.2×)
KV Store 99.9 th Lat. [μ s]	60.94s	1.64s (>10,000×)	2.10s	85 μ s (2.6×)
K-Means Tput. [# iters/s]	0.73s	3.25 (-33%)	37ms	4.71 (-2.9%)

Figure 8: Under memory pressure, procllet migration with Nu sees shorter disruption and better performance during disruption than migration at state-of-the-art process live-migration speed (baseline).

Workload [Disruption Effect]	Baseline (Slow migration)		Nu (Fast migration)	
	Duration	Effect	Duration	Effect
KV Store 99.9 th Lat. [μ s]	7.96s	874 μ s (26.5×)	0.54s	1086 μ s (32.9×)
K-Means Tput. [# iters/s]	0.65s	2.41 (-50.3%)	24ms	4.57 (-5.8%)

Figure 9: Under compute pressure, Nu sees short disruption and acceptable performance during procllet migration.

cached’s 800k at sub-millisecond latency (Figure 10b). Crucially, Nu performs as well as the same KV Store running on Caladan [28], which also uses kernel-bypass networking and a user-level threading runtime. Finally, Nu matches Phoenix MR’s performance (Figure 10c). Phoenix MR is designed for scalability on a single NUMA machine, and exploits shared memory for performance, so it is a strong baseline. The k-means workload requires sharing the intermediate clustering result across all workers. In a shared-memory setting, this shared state can be a global variable (as in the baseline), but in a distributed framework would involve per-worker copies. Since Nu supports migration, it must be prepared to oper-

ate distributedly and keep per-worker (per-procllet) copies, which amplifies the application’s cache footprint on a single machine. We therefore compare two Nu setups: per-worker copies (label Nu) and global state (Nu^G), and add a modified baseline with per-worker states (Baseline^P). Nu^G measures the overhead of Nu’s infrastructure with pinned (unmigratable) procllets. The overall results show that Nu’s procllet invocations on a single machine are fast enough to match the performance of single-machine baselines.

6.3 Scalability

Next, we consider how Nu scales as the procllets of a logical process are spread across many machines. For each of our three applications, we run an experiment where the runtime assigns its procllets round-robin across servers. We consider two versions of the SocialNetwork application: the one from §6.2, which we wrote with logical processes and procllet decomposition in mind; and a second version that mirrors the exact microservice decomposition in DeathStarBench. We measure throughput for equal-sized input, i.e., a strong-scaling setup. Because Nu’s local procllet invocation is faster than remote invocation, the single-machine setup has a substantial efficiency advantage, which makes linear scalability difficult to achieve. An ideal result would therefore show scalability close to linear as the number of machines increases.

We show the results in Figure 11. Nu scales well in all three applications, and achieves nearly linear scalability for KV Store and k-means. The SocialNetwork application is the most challenging to scale (Figure 11a). A direct port from the original microservice architecture to Nu (where each microservice becomes one procllet) results in many procllets with methods that have low compute intensity. When invoked remotely, calls to these methods can be costly, while the additional resources of a remote machine speed up the more compute-intensive invocations. On balance, Nu’s throughput

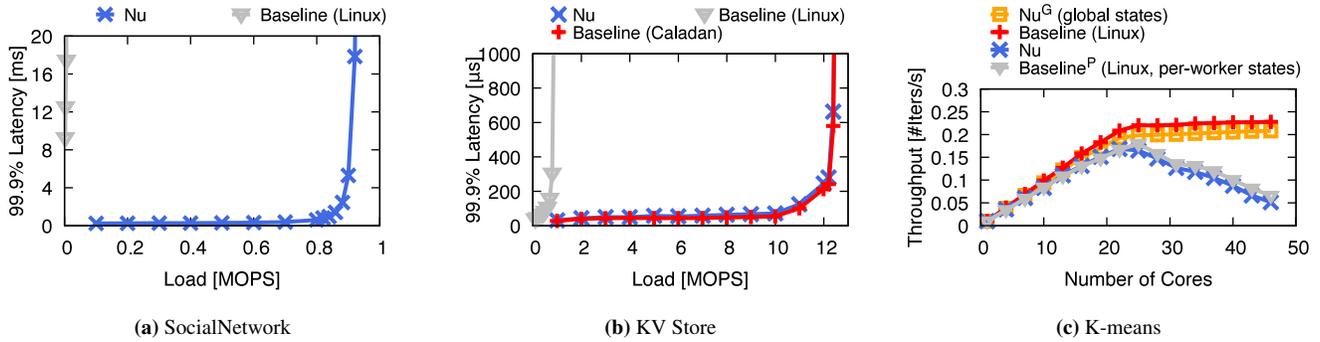

Figure 10: Nu-based applications match or outperform baselines on a single machine. For SocialNetwork, Nu’s fastpath helps it outperform the expensive RPCs in the baseline; in KV Store, Nu matches Caladan’s [28] performance; and for k-means, Nu matches the baseline depending on how state is represented: as a global shared array (typical in a NUMA setting) or as per-worker arrays (as in distributed settings).

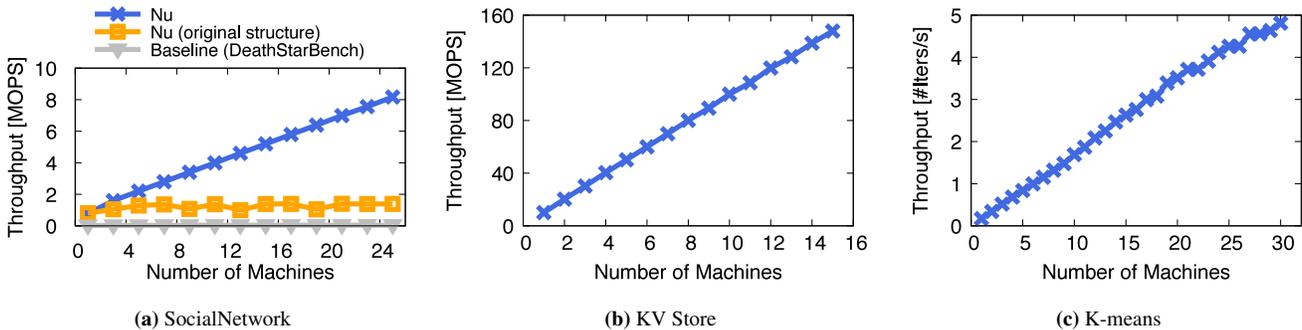

Figure 11: Nu scales well as the number of machines increases. The Nu-native SocialNetwork application, which merges the baseline’s stateless microservices, scales better than the direct port of the baseline because its procllets better amortize the cost of remote invocations. K-means scales sub-linearly as the overhead of broadcasting each iteration’s intermediate results increases with the number of machines.

still increases with the number of machines—from 786k to 1.37M ops/sec—but less so than when the application is decomposed into procllets that have sufficient compute intensity (786k to 8.44M ops/second). However, both Nu-based implementations perform one to two orders of magnitude better than the DeathStarBench baseline (45k ops/sec). The KVS implementation on Nu scales very well (Figure 11b) as it relies on client-side request steering (in response to hints from Nu’s runtime) to direct clients’ requests to the right machine, which then makes a local procllet invocation. K-means (Figure 11c) has high compute intensity, which makes scaling easy.

We conclude from these results that Nu’s logical processes scale well when procllets are distributed across machines if a procllet’s methods have sufficient compute intensity. §6.4.1 evaluates the impact of compute intensity on Nu’s efficiency.

6.4 Design Drill-Down

6.4.1 Impact of Compute Intensity

We now examine the efficiency of Nu’s mechanism for procllet method invocation (§3.2). Intuitively, the more compute an invocation does, the easier it is to amortize the overheads of the invocation (serialization, networking, and threading); yet, the lower these overheads are, the better Nu’s performance becomes. Our experiment is a sensitivity analysis in which we vary the compute duration in a procllet’s method between 0.1

and 50 μ s, and we measure the aggregate invocation throughput. We use sufficient threads to maximize throughput, saturating the machine that runs the procllet. We consider two cases for Nu: two procllets in the same machine (local), and procllets in different machines (remote). We compare the performance of Nu against three common mechanisms to invoke a task: (i) a function call in a Linux process; (ii) an RPC using Thrift, a popular open-source RPC framework [75]; and (iii) an RPC using a modified Thrift that uses Caladan [28] to reduce TCP and threading overheads. We measure throughput in a closed-loop setting. A good result would show performance of Nu close to local function calls for local invocations, and at least as good as Thrift for remote invocations.

The results in Figure 12 show that when the invocation is local, Nu’s performance tracks closely that of Linux function calls. This happens because of Nu’s fastpath for local invocations. When invocation is on a remote procllet, compute intensity (invocation duration) matters. For short invocations (0.1 μ s), Nu is $\approx 13\times$ worse than local function calls, but $2.4\times$ better than Caladan-based Thrift (and $29.4\times$ better than Thrift on Linux). As the invocation becomes more compute-intensive, these gaps close: for a 10 μ s task, Nu’s remote invocation achieves 85% of local function call throughput. We conclude that locality matters for remote procllet invocations with low compute intensity, but that Nu delivers near-single-

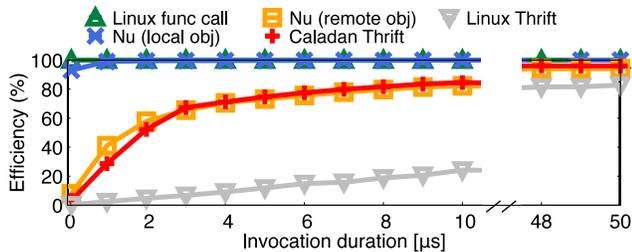

Figure 12: Efficiency (y-axis) of Nu invocations as a function of compute intensity (invocation duration), normalized to Linux function call throughput. Nu’s local procket invocation matches the performance of a function call, and Nu outperforms Linux Thrift by 2.4–29.4× for remote invocations when compute intensity is low.

machine performance for tasks with compute intensity as low as 10μs.

6.4.2 Migration Time and Bandwidth

We now measure the time it takes to migrate a procket in Nu. The experiment migrates prockets of varying sizes to another machine and measures the migration time. We vary the test procket’s memory size by adjusting its heap size, from 64 KiB to 16 MiB. The procket has a single thread with a small stack (64 bytes). A good migration latency would be ≈100μs for modest-sized prockets—orders of magnitude faster than traditional resource balancing mechanisms. For larger prockets, we expect the latency to approach network transfer time.

Heap Size	Migration Time [μs]		
	25 GbE	100 GbE	200 GbE
64 KiB	21	21	9
1 MiB	343	111	61
2 MiB	683	216	108
16 MiB	5,452	1,512	771

Figure 13: Nu migrates prockets with different heap sizes (64 KiB–16 MiB) faster with increasing network speeds (25/100/200GbE).

Figure 13 shows the results. With 100 GbE (i.e., the network setting used for all other experiments), Nu migrates small prockets (up to 1 MiB) in under 125μs. This corresponds to a bandwidth of 3–9 GB/s. For larger prockets (2 MiB–16 MiB), the latency varies from 200μs to 1,500μs, which corresponds to a bandwidth of ≈11 GB/s, close to the 100 GbE line rate. The results of 25 GbE and 200 GbE show similar trends. Procket migration benefits from higher network bandwidth; for example, with 200 GbE, Nu only takes ≈100μs to migrate a 2 MiB procket. We conclude that Nu migrates prockets quickly and that its migration uses the network efficiently.

6.4.3 Controller Performance

To understand whether Nu’s controller can become a performance bottleneck, we benchmark it as a standalone component to measure its capacity. Depending on the type of control message, the controller achieves 0.79–0.96 million msg/s. This is two to three orders of magnitude higher than the real load

demand (542–21,450 msg/s) we measured in the end-to-end experiments (§6.1). This makes sense as Nu’s runtime caches the procket location resolution result, thereby moving the controller off the critical path of steady-state application traffic. The controller is only involved in the control plane of initial procket location resolution and migration.

6.4.4 Procket Replication

Nu allows replicating prockets for fault-tolerant operation. Replication imposes overhead because it forwards all invocations of a procket to a backup in a different machine (§3.5). We measure the invocation throughput of calling 8,192 remote replicated prockets, as we vary the compute intensity as in §6.4.1. These invocations do not have sub-operations. The baseline is the same setup without replication. A good result would show a modest loss of throughput with replication.

Throughput [MOPS]	Compute Intensity [μs]				
	0.1	1	10	20	30
with replication	13.18	10.56	2.52	1.52	1.12
without replication	21.04	14.86	3.56	1.97	1.37

Figure 14: Replicated prockets achieve 63–82% of unreplicated throughput, depending on compute intensity.

Figure 14 shows the results. Throughput drops by 37% with a 0.1μs compute intensity, but this drop gradually shrinks to 18% as compute intensity grows to 30μs. Replication adds ≈1.2μs to each operation to invoke the backup procket, an overhead that gets amortized at larger compute intensities. This result shows that fault-tolerance for critical prockets is feasible and need not come at severe performance cost.

7 Conclusion

We presented logical processes, a new abstraction that decomposes an application into prockets, which are small units of state and compute. Logical processes and prockets solve a key hindrance to increasing datacenter resource utilization: the lack of microsecond-granularity fungibility in resource use.

We found that logical processes and our Nu prototype improve fungibility by making applications granular and migrating prockets quickly under resource pressure. For three applications, Nu matches the performance of strong baselines, scales well, and migrates their prockets within hundreds of microseconds with little disruption to application performance.

Nu is available as open-source software [66].

A Appendix

In this appendix, we include the end-to-end performance results under resource pressure that were not included in §6.1 due to the space constraint.

A.1 Application Performance Under Memory Pressure

Figure 15 presents the 99.9th tail latency of KV store under memory pressure. The results are similar to the SocialNetwork results (Figure 7). Figure 16 shows the K-Means performance under memory pressure using the throughput metrics as it is a batch application. Nu achieves 97% throughput during migration, whereas the baseline only achieves 67% throughput. Here we do not show the memory utilization as K-Means has a tiny per-machine memory footprint. The baseline has lower performance mainly because of the long task pausing time caused by slow migration.

A.2 Application Performance Under Compute Pressure

In the next experiment, we evaluate Nu’s performance under compute pressure. Compute pressure is harder to handle well than memory pressure, since Nu’s solution to resource pressure—procelet migration—itself consumes compute resources. The antagonist process in this experiment is a syn-

thetic CPU-spinning workload that occupies half the CPU cores on the machine, reducing the compute resources available both to the application and to Nu’s procelet migrations. In addition, the CPU load of the antagonist can spike instantly; this is different from the memory load which only increases gradually. Therefore, we would expect a higher impact on application performance than when Nu migrates procleets under memory pressure. A good result for Nu would show that the application still achieves acceptable performance, even if degraded for some (ideally short) time.

Figure 17a shows Nu’s results. At $t=4.9$ s, the compute pressure starts on one machine, taking away half of the application cores, and Nu immediately starts migrating procleets to reduce load on the machine. 99.9th latency increases from $33\ \mu\text{s}$ to $1086\ \mu\text{s}$. This latency spike makes sense as the machine’s compute resources are degraded by 50% and Nu needs additional compute to migrate procleets. The latency gradually decreases as procleets migrate and the other machine starts serving client requests, and soon recovers back to $33\ \mu\text{s}$ as the migration ends at $t=5.44$ s. In contrast, for the baseline, the latency disruption lasts 7.96s, which is 15X of the Nu’s 0.54s duration. Figure 18 shows the result of K-means. Nu takes 24ms to resolve the pressure and achieves 94.2% throughput

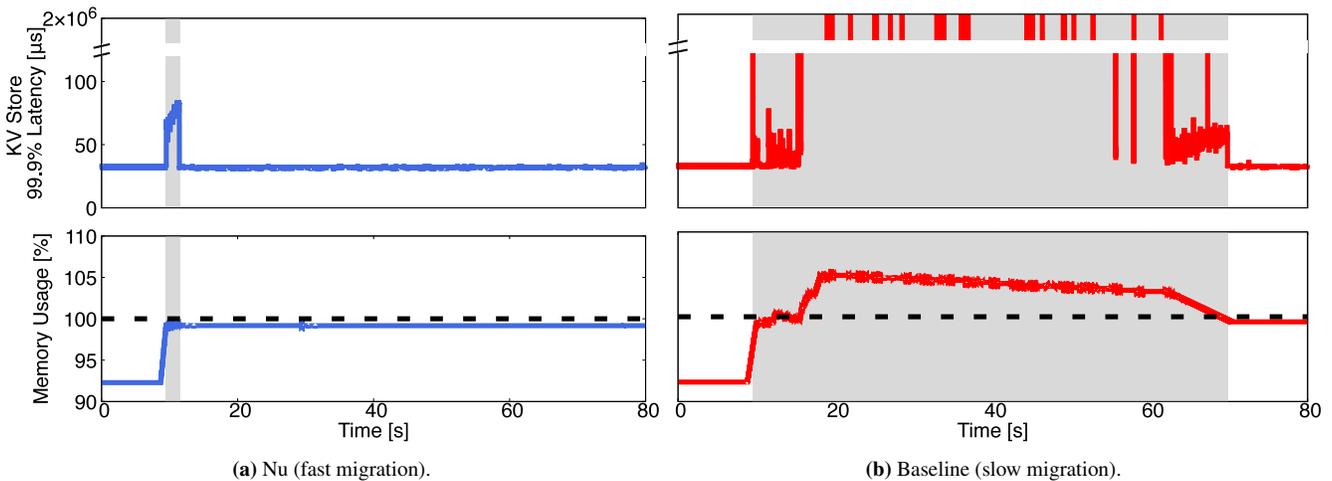

Figure 15: For KV store under memory pressure, Nu is able to maintain 99.9th tail latency under $85\ \mu\text{s}$ as it migrates procleets faster than the memory allocation speed of the antagonist. In contrast, the baseline suffers from poor tail latency ($\approx 2 \times 10^6\ \mu\text{s}$) since it cannot keep up with the allocation speed and has to swap memory.

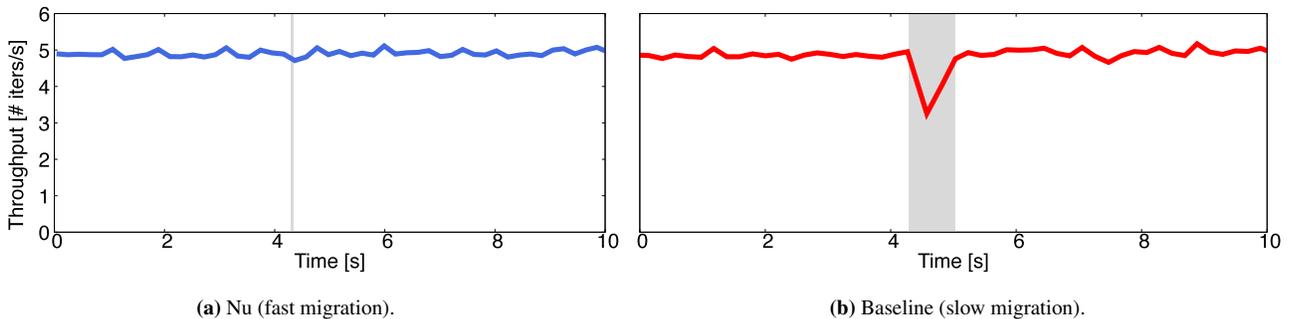

Figure 16: For K-means under memory pressure, Nu maintains stable throughput during migration, whereas the baseline only achieves 67% throughput. We do not show the memory utilization here as K-means has a tiny per-machine memory footprint.

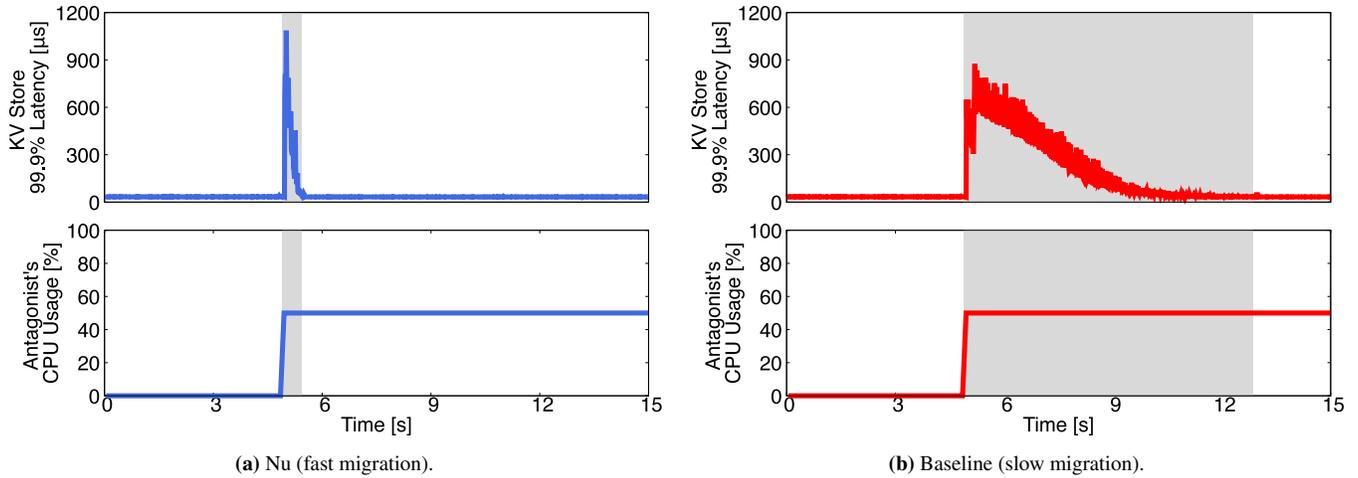

Figure 17: Under compute pressure, the KV store server becomes overloaded and the client-perceived 99.9th tail latency spikes from 33 μ s to \approx 1 ms. Nu only takes 0.54 s to fully recover the performance, while the baseline requires 7.96 s (\approx 15X).

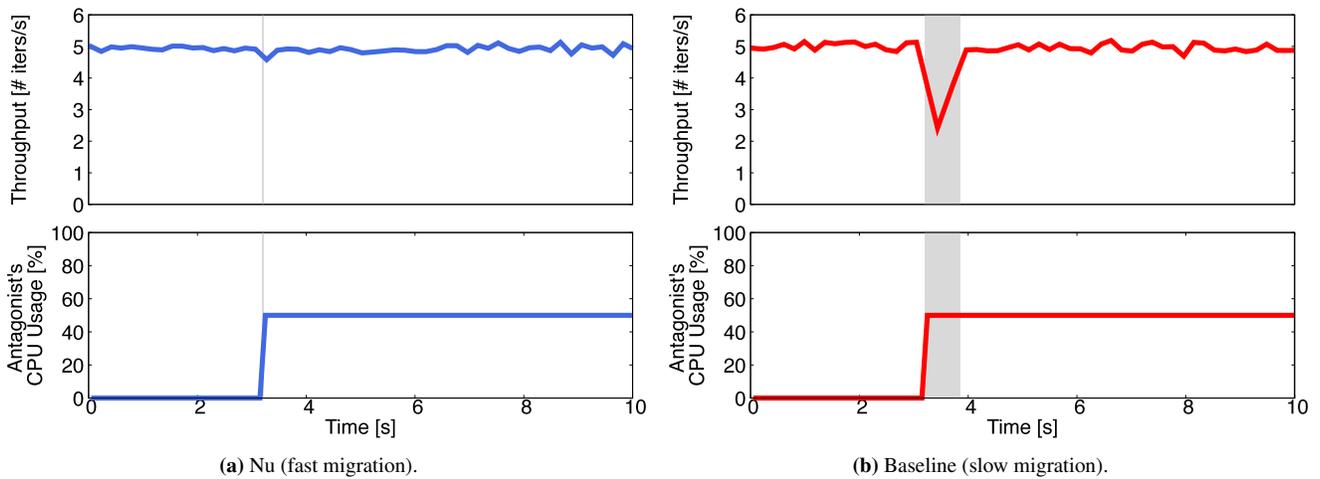

Figure 18: For K-means under compute pressure, Nu takes 24ms to resolve the pressure and achieves 94.4% throughput during migration. In contrast, the baseline takes 0.65s and only achieves 49.7% throughput.

during migration. In contrast, the baseline takes 0.65s and only achieves 49.7% throughput.

These results demonstrate that Nu's logical processes react quickly to CPU pressure. Some performance degradation is unavoidable, but the impact is short-lived: after a sub-second delay, procler migrations relieve the resource pressure.

Enabling High Quality Real-Time Communications with Adaptive Frame-Rate

Abstract

Emerging high-quality real-time communication (RTC) applications stream ultra-high-definition (UHD) videos with a high frame rate (HFR). They use edge computing, which enables high bandwidth and low latency streaming. Our measurements, from the cloud gaming platform of one of the largest gaming companies, show that, in this setting, the queue at the client-side decoder is often the cause of high latency that hurts the user's experience. We, therefore, propose an Adaptive Frame Rate (AFR) controller that helps achieve ultra-low latency by adaptively coordinating the frame rate with fluctuating network conditions and decoder capacity. AFR's design addresses two key challenges: (1) queue measurements do not provide timely feedback for the control loop; and (2) multiple factors control the decoder queue, and different actions must be taken depending on why the queue accumulates. Both trace-driven simulations and large-scale deployments in the wild demonstrate that AFR can reduce the tail queuing delay by up to $7.4\times$ and the stuttering events measured by end-to-end delay by 34% on average. AFR has been deployed in production in our cloud gaming service for over one year.

1 Introduction

Emerging network technologies like 5G have gotten both academia and industry excited about high-quality real-time communication (RTC) applications with ultra-high definition (UHD), high frame rate (HFR), and reduced delays. Examples include cloud gaming [41, 82], virtual reality [37, 88, 63] and 4K video conferencing [40, 49]. Some high-quality RTC services have already been deployed in production (e.g., cloud gaming from Google [3], Microsoft [1], Nvidia [5]). For example, the market share of cloud gaming reached one billion dollars in 2020, with an expected growth rate of 30% [19].

To achieve a satisfactory user experience, those applications need to stream with high resolution, high frame rate, and a low delay (§2). For example, cloud gaming services deliver content with a resolution of $\geq 1080p$ [3] and frame-rate of 60fps [61], while requiring a tail end-to-end delay of less than 100ms [43]. Streaming like this significantly improves users' experience and enables new applications.

This paper argues that, in addition to modulating bitrate to match network capacity, a high-quality RTC system must regulate the queuing at the decoder queue. For traditional standard quality RTC, the time required to decode a frame is much shorter than the interarrival time of frames. Thus, the decoder queue is not a bottleneck and a traditional RTC service only needs to adjust the bitrate to match the network bandwidth. However, in high-quality RTC, the high frame rate reduces the

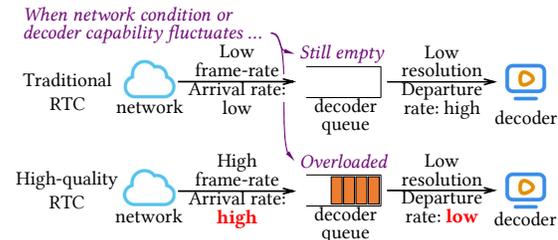

Figure 1: Comparison of the decoder queue between traditional and high-quality RTC applications. Due to the high frame rate and resolution, when network condition or decoder capability fluctuates, high-quality RTC applications may overload decoder queues, leading to high delay at the tail.

time between the arrival of frames at the client, while the high resolution increases the decoding delay for each frame. At the decoder queue, the frame arrival rate frequently exceeds the departure rate, leading to a long queue, as shown in Figure 1. The video delivery is required to not only adapt the bit-rate to the network bandwidth but also coordinate with the decoder queue capacity. From measurements of our production cloud gaming service, Tencent Start [4], we find that video delivery without coordinating the queue capacity could introduce a non-negligible queuing delay at the client-side decoder queue. Moreover, such a queuing delay accounts for a large proportion of delayed frames in satisfying the much tighter delay requirement of high-quality RTC, especially when the network delay has been reduced with recent infrastructure developments (e.g., edge computing [57]). According to our measurements, among all frames with a total round-trip delay of $>100ms$, 57% of them have been delayed at the decoder queue for $>50ms$ (§3.1). Our survey finds that the future demands of UHD and HFR video will further exacerbate the problem, even with the evolution of decoding hardware (§3.1). Therefore, for high-quality RTC, to reduce the end-to-end delay, it is essential to reduce the queuing delay at the decoder.

Not all interventions are effective at regulating the queuing at the decoder queue (§3.2). For instance, decoding delay is not affected much by bitrate. It is affected by resolution, but adjusting the resolution requires the client to request a new key frame. This consumes bandwidth and incurs several extra frame intervals of delay. Discarding a frame at the client also requires a new key frame, which incurs the same cost. Hence, we introduce an *adaptive frame-rate (AFR)* controller, which controls the frame rate at the *encoder*. Reducing frame rate gives the decoder more time to process frames. Hence, it is effective at reducing the queue length. Further, edge streaming services offer short RTTs, which means the control loop to adjust the encoder's frame rate is short.

Note, there have been previous efforts to adapt the frame-rate

(e.g., CU-SeeMe [38] decades ago). However, the development of decoding hardware had made it redundant in the recent decade, and traditional RTC in the recent decade is mostly bottlenecked in the network. In this paper, we show how high-quality RTC, with UHD resolution, HFR, and stringent delay requirements, has changed this. We further improve upon these proposals in two ways. First, existing control mechanisms are based on delay or queue length [60, 34, 77], which are slow to react since they need to wait for the queue to build up. AFR instead relies on the arrival and service processes in addition to the queue length to adjust the frame rate. Second, not all increases in decode queuing delay need to reduce the frame rate. For instance, when queuing delay increases due to a transient burst of arriving packets. Hence, AFR uses two control loops that adjust the frame rate at different time scales.

We implement the AFR controller on both simulators and the production of the cloud gaming service from Tencent Start [4]. Trace-driven simulations and deployments in the wild demonstrate that AFR could effectively reduce the tail queuing delay by up to $7.4\times$, and consequently reduce the ratio of frame stutters measured by total delay by up to $2.2\times$ (§6.1 and §6.5) with negligible overhead. AFR has been deployed on Tencent Start since February 2021, serving millions of sessions. We will release the collected traces and the simulation code.

We make the following contributions:

- We carry out a month-long measurement campaign to motivate the significance of controlling queuing delay at the decoder queue, and identify the unique challenges from high-quality RTC with stringent delay requirements (§3).
- We design a hierarchical frame-rate controller, AFR, to control the decoder queue towards an ultra-short delay under different scenarios for high-quality RTC (§4).
- We evaluate AFR with both trace-driven simulations and large-scale deployments in production in the wild (§5). Our evaluation shows that both queuing delay and total end-to-end delay could be significantly improved (§6). AFR has been used in deployment for over one year.

2 Background: High-Quality RTC

High-quality RTC applications are attracting attention from the industry and academia. A series of high-quality RTC products have been released recently, including cloud gaming [3, 1, 5], virtual reality (VR) [12, 11, 6], and 4K videoconferencing [8]. For example, by generating high-quality content and streaming to the user via Internet, users can enjoy better video quality with low-cost devices. Specifically, the high-quality RTC has the following features standing out from traditional RTC applications:

- *High frame-rate.* Traditional RTC usually delivers content with a low frame rate (LFR) of 24fps [9]. However, high-quality RTC requires a frame rate of up to 60fps, some of which even require a frame-rate of 240fps [73].
- *High resolution.* Most existing RTC applications are delivered at SD resolutions by default (e.g., 360p for Google Meet [7]). In contrast, high-quality RTC applications require a resolution

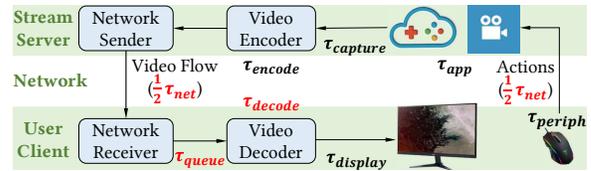

Figure 2: A general delivery pipeline of RTC services. We highlight the major contributing components in the tail end-to-end delay of high-quality RTC according to our measurements in red.

of 1080p to 4K or higher [62].

- *Stringent delay requirement.* Furthermore, high-quality RTC applications also have stringent latency requirements. For example, videoconferencing requires a round-trip interaction delay of 150ms [9] and gaming for 100ms [43].

Existing delivery pipeline. To better understand the bottleneck of high-quality RTC, we present the key components of the existing RTC delivery pipeline in Figure 2. First, the video encoder captures the contents generated from video sources (e.g., gaming applications [23, 57]) and encodes them into video frames. Then, encoded frames are sent over the network from the streaming server to user clients. After that, on the client side, upon receiving new frames from the network, the decoder will decode those frames. Finally, decoded video frames will be displayed on users’ displays.

Optimization goal: low tail delay. With the intelligence from each community, the delay of each component has been intensively optimized in recent research efforts. To reduce the network delay, existing providers either deploy stream servers at the edge [57, 74], introduce low-latency congestion controllers [16, 25], or suggest users use wired connections. For example, recent measurements unveil that cloud gaming services could deliver the RTC streams with an average round-trip network delay of 20ms [57, 26]. Similarly, streaming encoders are optimized for low latency to satisfy the stringent delay requirements in high-quality RTC services [58, 69, 34].

Meanwhile, optimizing the *tail* performance is also critical for user’s experience for high-quality RTC [56]. The increase in tail delay will result in frame stuttering or freezing, degrading the user’s experience. Quality of experience assessment frameworks in video streaming usually individually calculate the stuttering time as a penalty to the user’s experience [33, 80]. Considering the high frame rate of high-quality RTC, further tails of 99th or 99.9th percentiles need to be focused on. For example, at the frame rate of 60fps, even the 99.9th percentile delay could happen every 16 seconds. Especially for applications such as cloud gaming, such a delay might lead to the loss of the game (e.g., stalls when the gamer is discovered by the opponent in a shooting game) [67, 43]. Therefore, it is essential to control the tail delay and reduce frame stutters for high-quality RTC.

3 Motivations and Challenges

In this section, we first explain the formulation of drastic queuing delay in high-quality RTC (§3.1). We then present our thinking over the design choice of adjusting frame rate (§3.2). We

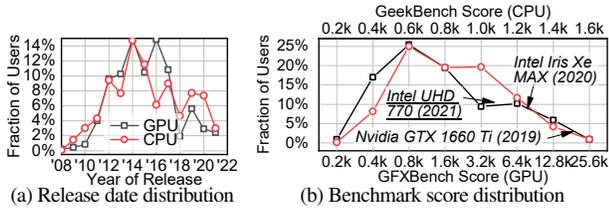

Figure 3: Release year and benchmark score distribution of user devices in production. We use the single-core score in GeekBench [15] for the CPU benchmark and Aztec Ruins Normal Tier score in GFXBench [13] for the GPU benchmark.

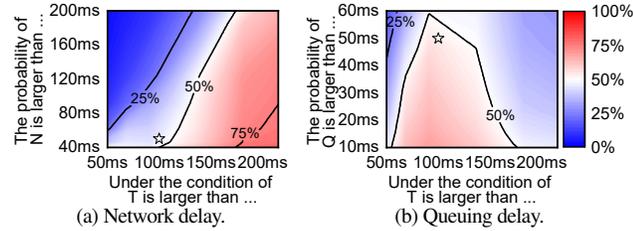

Figure 4: While network delay should usually be blamed when the total delay is above 200ms, queuing delay plays a dominant role among all frames with a total delay of more than 100ms. The color indicates the conditional probability $P(X > X_{th} | T > T_{th})$ for $X \in \{N, Q\}$. Stars denote $X_{th}=50\text{ms}$, $T_{th}=100\text{ms}$.

further analyze the unique challenges of effectively achieving an ultra-short queue (§3.3).

3.1 Motivation: Drastic Queuing Delay

Observation: decoder queuing delay is a critical contributor to the total delay at the tail. We profile the delay of each frame at each stage in the delivery pipeline in Figure 2. We measure the Tencent Start cloud gaming service for a month in 2021, containing tens of thousands of users, with thousands of different CPU and GPU models. We present release dates and benchmark scores of CPU and GPU in Figure 3 and list top models in Appendix B.1. Unless other specified, all measurements in this paper are analyzed from this dataset.

According to our measurements, among all components in the pipeline, the network, queuing (at the decoder queue), and decoding delay are $>10\text{ms}$ at the 99th percentile. We highlight them in red in Figure 2. The tail of the application and encoding delay is light since they are processed on commercial servers, which are stable compared to networks and heterogeneous clients. Therefore, we focus on the network, queuing, and decoding delay in the following discussion. We leave the measurement results to Appendix B.2.

We investigate how these three components contribute to the increase of total delay at the tail. For each frame, we denote N , Q , D , and T as the network, queuing, decoding, and total end-to-end delay. We then calculate the conditional probability of $P(X > X_{th} | T > T_{th})$ for each $X \in \{Q, D, C\}$ from our measurements, where X_{th} and T_{th} are thresholds for statistics. A high conditional probability suggests that the component is more likely the cause of $T > T_{th}$. We calculate the conditional probability with different thresholds, and present the results for

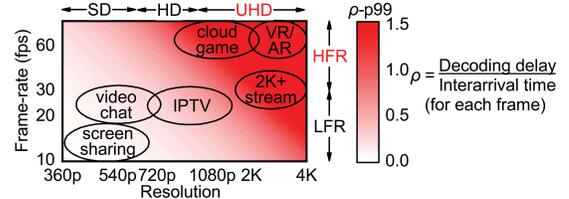

Figure 5: Illustration of the 99th percentile of the utilization ρ of the decoder queue. For high-quality RTC applications (in the top-right corner), the decoder queue is heavily loaded at the tail (shaded red), resulting in an increase of queuing delay at the tail.

network delay and queuing delay in Figure 4.

As we can see, when analyzing the root causes of frames with $T > 200\text{ms}$ for traditional RTC services, network delay has a high probability (shaded red) to be blamed. However, when analyzing the frames with $T > 100\text{ms}$, queuing delay dominates the increase of total delay. Our measurements show that among all frames with an end-to-end total delay of more than 100ms, queuing delay increase happens more frequently than all other component delays: 57% of them have a queuing delay of more than 50ms (stars in Figure 4). Considering the stringent delay requirement of $\sim 100\text{ms}$ for high-quality RTC, the increase in queuing delay plays a dominant role.

Root cause: The UHD resolution and HFR jointly contribute to the increase in queuing delay. Compared to LFR streaming, HFR increases the arrival rate of the decoder queue by reducing the interarrival time between frames. Also, UHD decreases the departure rate compared to SD streaming by increasing the decoding delay of each frame.

Specifically, we illustrate how the frame rate and resolution could affect the load of the decoder queue by presenting the 99th percentile queue utilization in Figure 5. We scale the distribution of interarrival time and decoding delay from our measurements to other frame rates and resolutions. As we can see, for traditional RTC services (the down-left corner), due to their low frame rates and resolutions, the decoder queue still has a utilization of $\rho \ll 1$ at the tail. However, for high-quality RTC applications (the up-right corner), the decoder queue would be heavily loaded, leading to a drastic queuing delay.

The issue is the inconsistency of the decoder’s performance *on average* and *at tail*. In fact, many of the hardware decoders that we measured claim to support UHD and HFR videos (e.g., Nvidia GTX series in Table 4). However, according to our measurement, supporting UHD and HFR does not really mean *consistently* supporting. For example, the decoding delay can fluctuate due to numerous reasons including overheating at the client [64], CPU scheduling (§5.1), and the prediction errors [48], all of which are difficult to control for an application. From our measurement with devices in production, the decoding delay is 18ms at the 99th percentile even with hardware acceleration (Appendix B.2). Note that at the frame rate of 60fps, the interarrival time between frames is 16.7ms, resulting in a heavily loaded decoder queue at the tail.

We further analyze the necessity and sufficiency between the

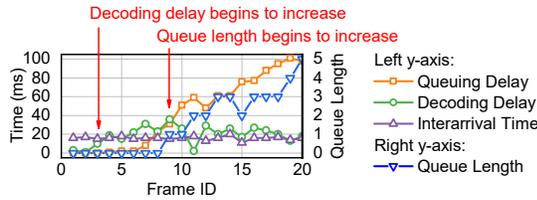

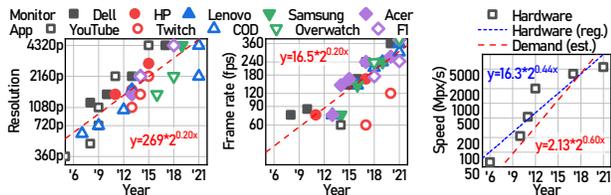

Figure 6: A trace for the accumulation of decoder queue. Note that this is an illustrative example – the distribution of all traces can be found in Appendix B.4.

(a) The maximum supported resolution and frame rate for the top 5 monitor vendors, two streaming existing hardware and platforms (YouTube and Twitch) and three games required decoding speed (Call-of-duty, Overwatch, and F1) [10]. (b) Decoding speed of hardware from demands.

Figure 7: Decoding hardware cannot keep pace with the rapid increase of demands of videos with high resolution and frame rate. Note that the required decoding speed from demands is the frame rate times the *square* of resolution times the aspect ratio.

increase of other components and total delay in Appendix B.3 and figure out that the minor fluctuation of decoding delay leads to the increase of queuing delay. From the queuing theory, when the queue is heavily loaded, the queuing delay will drastically increase [32]. This is because while the decoding delay is continuously fluctuating, the queuing delay is accumulating all the fluctuations of precedent frames. Especially in heavy traffic, a minor fluctuation of the decoding delay could result in a magnitude increase in queuing delay. We refer the readers to [32] for more theoretical analysis. Illustratively, we present a trace from our production service in Figure 6. In the trace, the interarrival time is 16ms, and the decoding delay is 18ms, while the queuing delay is 54ms on average. The continual increase of the decoding delay, although not much by magnitude (18ms) and not long by duration (20 frames, approximately 0.3s), leads to a drastic queuing delay. If such a trace happens with a probability of 1%, we will have a 99th percentile decoding delay of 18ms, and a 99th percentile queuing delay of 55ms. In this case, the tail queuing delay is much higher than the decoding delay, which also contributes to more than half of the end-to-end stutters as analyzed in §3.1.

Trend: hardware decoders cannot keep pace with the increasing demands of UHD and HFR video. User demands for video have increased sharply, as shown in Figure 7(a). For example, the highest supported resolution and frame rate of YouTube have increased from 360p@30fps (7Mpx/s) in 2005 to 8K@60fps in 2015 (2Gpx/s), doubling every 14 months on average. Emerging services at 16K [85, 62] or 240fps [73] further indicate the future demands of UHD and HFR streaming.

However, the decoding speed of the hardware is not increasing as fast. We summarize the decoding speed of state-of-the-art

video decoders from recent academic papers [53, 30, 90, 91, 89, 85]. As shown in Figure 7(b), the decoding speed of the state-of-the-art decoding hardware doubles only approximately every 27 months (blue dotted line). Meanwhile, we also calculate the required decoding speed from the existing demands of videos by multiplying the estimated resolution and frame rate from Figure 7(a) and plot the estimation in red in Figure 7(b). The required decoding speed from demands, doubling every 20 months, (red dashed line) increases much faster than the development of decoding hardware (blue dotted line), indicating the continuous incapability of decoding hardware for UHD and HFR videos.

In addition to the state-of-the-art hardware, there are still a considerable number of low-end and mid-end devices in our users. User devices, even in the same generation, could also be very heterogeneous. For example, in Figure 3, notice that the performance of Intel Iris Xe is 2× better than Intel UHD 770 even though the latter is more recent. Thus, there is heterogeneity in user devices even in the same generation. Moreover, new video codecs (e.g., H.265), although with a higher compression ratio, even slow down the decoding speed by up to 60% [24, 55, 21]. In this case, the mismatch between the decoder and UHD and HFR videos will further exacerbate, making the queuing delay at the tail a lasting issue.

3.2 Choice: Controlling Proper Parameters

We motivate the need to adjust the frame rate. For an encoder, there are three parameters that could be independently set, including the frame rate, bit rate, and resolution. The encoder will automatically optimize other parameters (e.g., quantization parameters) based on current contents to achieve the target frame rate, bit rate, and resolution. We refer readers to [17] for more details on video codec.

We first analyze how these parameters could affect the delay of different components. When the bit-rate increases, the network delay will increase due to the congestion. When the resolution increases, since the decoder needs to decode frames with larger pixels, it needs a longer time to decode. The queuing delay depends on the enqueue rate (i.e., frame-rate) and the dequeue rate (i.e., decoding delay). In contrast, for example, if the bit-rate decreases, yet the resolution is kept the same, the decoding delay for each frame will hardly decrease due to the hardware design of the codec, which we further measure in Appendix B.4. Thus, relying on the total delay (e.g., Salsify [34]) would lead to ambiguity in taking effective actions to reduce the delay.

Therefore, we need to individually control respective parameters to reduce different delays. In response, we adjust the frame rate to control the queuing delay for high-quality RTC. When the fluctuations of the decoder and network result in an increase of queuing delay, it is essential to adjust the encoding parameters to reduce the queuing delay. In this case, after collecting measurements from the client and network, the encoder at the server could accordingly adjust the frame rate for the following frames. We could dynamically specify certain timestamps where new frames are encoded.

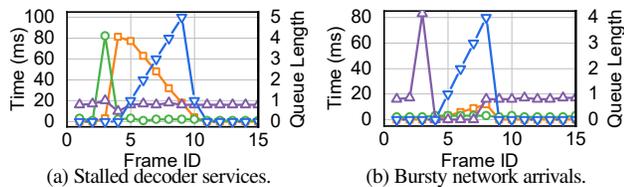

Figure 8: Two traces of transient fluctuations of the decoder queue from online traces. Legends are the same as Figure 6.

We further discuss several potential solutions and concerns of adapting frame rates in Appendix A. In summary, adjusting the resolution or dropping frames is impractical due to the significant overhead of bandwidth. Statically choosing the frame rate based on the client model is also insufficient due to the fluctuation of decoding delay in the runtime. Moreover, since applications have limited control over users’ systems, it is also impractical to control the user’s system (e.g., pinning the application to a CPU core) for a large-scale production-level service [14]. In terms of frame-rate adaption, note that there are previous efforts in the adaption of frame-rate (e.g., CU-SeeMe [38] decades ago). However, as we discussed in §3.1, with the increase in resolution and frame-rate, and the stringent delay requirements, we need to reemphasize the significance of adapting frame rate now. We also show that it is timely enough to control the frame rate over the Internet.

3.3 Challenges

Achieving an ultra-short queue. To achieve an ultra-short queuing delay for the decoder queue, it is challenging to pick the appropriate indicator to inform the controller when it needs to take action. Existing signals (queue length [60] or queuing delay [77, 34]) fail to achieve an ultra-short queuing delay. Since the accumulation of the decoder queue is the consequence of the fluctuation of the arrival or departure process, both the queue length and queuing delay can only be observed when the queue has already been built up. For the example in Figure 6, while the decoding delay starts to increase at the 3rd frame, a non-zero queue length can only be observed by the 9th frame. We also evaluate baselines based on queue length and queuing delay in §5.2.

In response, we want to capture the *earliest signal* to perceive the potential queuing delay. Therefore, instead of measuring the queuing delay, we want to estimate the potential increase of queuing delay predictively. For example, inspired by recent advances in congestion control [36, 50], a straightforward way is to measure the dequeue rate of the decoder queue to estimate the potential increase of the queuing delay.

However, in terms of tails, the arrival process is also fluctuating, which could also lead to an increase in queuing delays. For example, the network delay might increase by ten times at the 99th percentile than the median [25]. In response, to precisely avoid queue accumulation, we extend the designs of [36, 50]: AFR comprehensively measures the arrival and departure process and controls the queuing delay based on queuing theory. We introduce the design in §4.2, and evaluate the necessity of measuring the arrival process in §5.2.

Handling various events. Furthermore, the reason behind

Algorithm 1: Hierarchical AFR control.

Input: Enqueue process $\{A_n\}$, dequeue process $\{S_n\}$, queue states Q . (A_n denotes the interarrival times, and S_n denotes the decoding delays of frames $\{n\}$.)

Output: Target frame rate f .

- 1 $f_0 = \text{StationaryController}(\{A_n\}, \{S_n\})$
 - 2 $\alpha = \text{TransientController}(Q)$
 - 3 $f = \alpha f_0$
-

the formulation of the decoder queue in high-quality RTC is complex. As we introduced in §3.1, the stationary degradation of decoding capacity could lead to the accumulation of the decoder queue, e.g., the traces in Figure 6. Besides, the decoder queue could also be accumulated due to transient contingencies. For example, from our experiences in production, the decoder might contingently experience a sudden decoding lag of ~ 100 milliseconds (e.g., the 3rd frame in Figure 8(a)). The sudden interference in wireless channels might also lead to the bursty arrival of several frames (e.g., the 4th to 8th frames in Figure 8(b)). In both cases, the decoder queue will be accumulated. Since these transient fluctuations happen suddenly, it is challenging for the controller to react by measuring enqueue and dequeue rates.

Thus, AFR differentiates the causes of queue accumulation and reacts respectively to fluctuations at different time scales. We design a stationary controller to avoid queue accumulation in heavy traffic (§4.2), and a transient controller to reduce the queuing delay in contingencies (§4.3).

4 Design – Adaptive Frame-Rate (AFR)

We first analyze the overall workflow of AFR in §4.1, and then present the two controllers of AFR (§4.2, §4.3).

4.1 Workflow Overview

The workflow of AFR is presented in Algorithm 1. Specifically, the stationary controller (§4.2) maintains the queue around an ultra-short target based on dynamics of enqueue and dequeue processes. By measuring the statistics of both processes, AFR calculates the expectation of the queuing delay based on queuing theory. The frame rate can therefore be optimized towards a given queuing delay target (line 1). The transient controller observes the queue states Q (queue length and queuing delay) and calculates the discounting factor $\alpha \leq 1$ (line 2) to further decrease the frame rate when the queue formulates. The final frame-rate is the stationary frame-rate f_0 discounted by α (line 3). In this case, AFR can react to various scenarios of queue accumulation.

4.2 Stationary Controller

As introduced above, we measure the arrival and service processes and control the expected queuing delay of the queue. Specifically, we use the Kingman formula as an approximation of the expectation of queuing delay. Kingman formula is a widely adopted approximation formula of queuing delay [45] for G/G/1 queues. Compared to other approximation methods, in this paper, we adopt the Kingman formula to estimate the queuing delay since its estimation is from *both arrival and departure processes*

without relying on queue states, which could provide the earliest signal for the potential queuing delay. According to the Kingman formula, the expectation of queuing delay τ_{queue} follows:

$$\mathbb{E}\{\tau_{queue}\} \approx \left(\frac{\rho}{1-\rho}\right) \left(\frac{c_a^2 + c_s^2}{2}\right) \mu_s \quad (1)$$

where

$$c_a = \sigma_a / \mu_a, \quad c_s = \sigma_s / \mu_s, \quad \rho = \mu_a / \mu_s \quad (2)$$

(μ_a, σ_a) and (μ_s, σ_s) are the mean and standard deviation of the arrival and service processes:

$$\mu_a = \mathbb{E}\{A_n\}, \sigma_a = \sqrt{\text{var}(A_n)}, \mu_s = \mathbb{E}\{S_n\}, \sigma_s = \sqrt{\text{var}(S_n)} \quad (3)$$

From Eq. 1, the queuing delay is related to the following factors:

- Queue utilization ρ . The queuing delay will increase when the queue is overloaded ($\rho \rightarrow 1$). The current frame rate and decoding delay determine the queue utilization.
- Arrival and service fluctuations c_a and c_s . When the arrival or the service processes fluctuate, the queuing delay will also increase.
- Service time μ_s . Finally, the queuing delay scales with the average decoding delay.

Therefore, we control the expected queuing delay by controlling the right-hand side (RHS) of Eq. 1. We set $\mathbb{E}\{\tau_{queue}\}$ to a pre-defined queuing delay target W_0 . Consequently, the target frame-rate f_0 could be calculated as:

$$f_0 = \rho / \mu_s = 1 / \left(\mu_s \cdot \left(1 + \frac{\mu_s}{W_0} \cdot \frac{c_a^2 + c_s^2}{2} \right) \right) \quad (4)$$

Discussion: Approximation method. The AFR mechanism supports any approximation formula by design. There are other research efforts to control the queue. For example, recent efforts in congestion control [36, 50] directly set the target utilization (e.g., setting $\rho = 0.95$) and calculate the enqueue rate. In this paper, we adopt Kingman formula to capture *both the arrival and departure processes*, as discussed in §3.3. We also evaluate the performance of other baselines in §6.1.

Measurements of queuing dynamics. According to Eq. 4, we need to measure the mean and variance of the arrival and service processes. Similar to the RTT measurements in TCP [44], we adopt the exponentially weighted moving average (EWMA) and exponentially weighted moving variance (EWMV) to estimate the $\mu_s, \sigma_s, \mu_a, \sigma_a$ in Eq. 1 and 2.

$$\begin{aligned} \hat{\mu}_n &= \xi_\mu x_n + (1 - \xi_\mu) \hat{\mu}_{n-1} \\ \hat{\sigma}_n &= \sqrt{\xi_\sigma (x_n - \hat{\mu}_n)^2 + (1 - \xi_\sigma) \hat{\sigma}_{n-1}^2} \end{aligned} \quad (5)$$

where x_n denotes interarrival time A_n or service time S_n . $\hat{\mu}_n$ and $\hat{\sigma}_n$ are the EWMA and EWMV. ξ_μ and ξ_σ are the discounting factors for the measurement of mean and standard deviation, trading off between precision and sensitivity.

However, due to bursty arrival or stalled services (§4.1), both the arrival and service processes could have significantly deviated value. For example, the 3rd frame in Figure 8(a) has a decoding time of 82ms while other frames are below

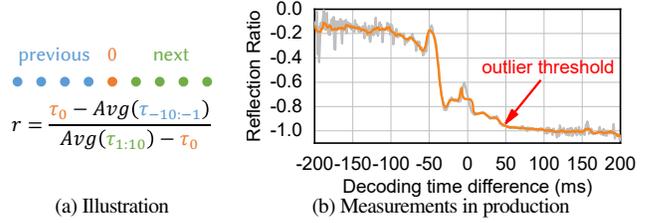

Figure 9: Reflection in outlier removal. Figure 9(b) presents the frequency of frames with $r \in [\frac{1}{C}, C]$. Measurement details in §5.2.

4ms. Such outliers will significantly deviate the estimation of stationary statistics for a long period. In fact, as we discussed in §4.1, these contingent events are designed to be handled by the transient controller. Therefore, we need to filter those outliers out to precisely estimate the stationary status of arrival and service processes. Due to the highly skewed distribution of decoding delay, existing outlier removal mechanisms based on standard deviation (e.g., the three- σ rule [65, 68]) suffer from differentiating stationary state transitions from outliers.

To capture the transitions of the status of decoders while eliminating the influence of the contingent outliers, we introduce an outlier removal mechanism based on priori knowledge from measurements in production. The key intuition is that *decoding delay differences* ($S_n - S_{n-1}$) are related to the probability of being outliers. For example, an increase of 20ms on decoding delay is probably the transition between stationary states (Figure 6). However, a sudden increase of 80ms on decoding delay is likely to indicate that decoding delay is an outlier, which is usually the scenario of contingent stalls in Figure 8(a). This is because commercial decoders are usually able to decode frames at the frame rate of 24fps on average. According to our measurements, when the decoding delay difference is above 50ms, the possibility of being an outlier for that frame is 95%. Thus, we remove frames with a decoding delay difference of >50 ms in the stationary controller, and leave the control of those frames to the transient controller.

We further characterize our observation based on measurements in production. As shown in Figure 9(a), we quantify the outlier with *reflection ratio* r , which illustrates the recovery of decoding delay before and after the potential outlier. The numerator is the difference between the current decoding delay (τ_0) and the average decoding delay of the previous 10 frames ($\tau_{-10:-1}$), and the denominator is the difference between τ_0 and future decoding delay. For outliers of contingent stalled service (e.g., the 3rd frame in Figure 8(a)), their reflection ratios would approach -1. This is because previous frames and subsequent frames have similar decoding delays, while the outlier has a much higher decoding delay ($\tau_0 \gg \tau_{-10:-1} \approx \tau_{1:10}$).

We then plot the relationship between the difference of decoding delay ($\tau_0 - \tau_{-1}$) and the average reflection ratio (r) of all frames with the same difference from our measurements in Figure 9(b). When the decoding time difference is larger than 50ms (marked with a red arrow), the average reflection ratio is less than -0.95, indicating that most frames in this scenario are outliers. Therefore, the stationary controller in AFR does not calculate the

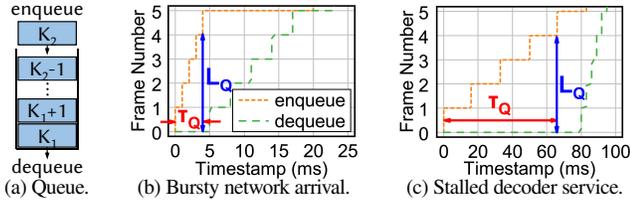

Figure 10: Differences between bursty network arrivals and stalled decoder services. The y-axis is the accumulated enqueue/dequeue frames. For example, the enqueue curve in Figure 10(b) increases from 1 to 2 at 1ms, indicating that frame #2 enqueues at 1ms.

frames with a decoding delay difference larger than 50ms.

Convergence time analysis. To help operators to better understand the behavior of the stationary controller, we investigate the convergence of the stationary controller during state transitions of the service process. We want to answer the following question: During the transition from stationary state (μ_1, σ_1) to (μ_2, σ_2) , how long will the stationary controller take to converge to the new frame-rate and drain the potential accumulation of the queue due to the transition?

We outline the main conclusion here and leave the detailed analysis in Appendix E. When the control loop (round-trip delay) of AFR is τ frames, the convergence time T_0 is bounded w.r.t. τ and W_0 , and is acceptable for most scenarios. For example, when the average control loop of AFR is the interarrival time of one frame ($\tau=1$), and $W_0=2$ ms, the stationary controller could converge to the new stationary state within 2 frames. We illustrate the convergence time of the stationary controllers with more settings in Appendix E.

4.3 Transient Controller

The transient controller is designed to handle the contingent queue accumulations (§4.1). Therefore, we need to first understand how we should react to these queue contingencies.

Understanding queue contingencies. As shown in Figure 8(a) and 8(b), both stalled decoder services and bursty network arrivals will cause a sudden increase in queue length. We illustrate the enqueue and dequeue events of two contingencies in Figure 10. In Figure 10(b), 5 frames arrive at the client together within 4ms, resulting in a queue length of 4 when the 5th frame arrives and observes, as illustrated with the L_Q (blue arrow). In Figure 10(c), the decoder takes 80ms to decode the 0th frame, when queued frames cannot be dequeued to the decoder. Therefore, upon the arrival of the 5th frame, it also observes a queue length of 4.

However, the bursty network arrivals and stalled decoder services should be handled separately. In the scenario of bursty network arrivals, the bottleneck of total delay is still in the network due to its long network delay. As long as the decoder is functional, even if multiple frames arrive at the queue simultaneously, they could be processed efficiently (Figure 8(b)). In this case, the queue will be drained in a short time, and we do not need to reduce the frame rate. In contrast, the stalled decoder service will drastically increase the queuing delay of subsequent frames and needs adaption (Figure 8(a)). Thus, we

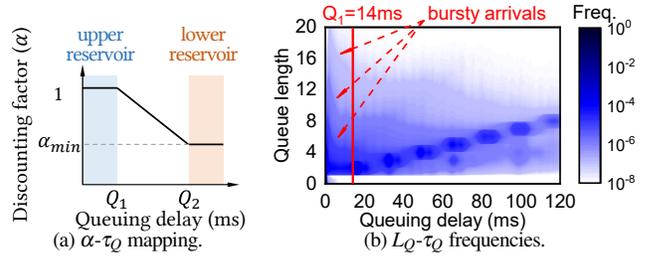

Figure 11: Illustrations and measurements of the transient controller. A series of linearly distributed dark blue clusters in Figure 11(b) indicate that L_Q and τ_Q are linearly correlated.

need to differentiate between the two scenarios.

Since both scenarios result in an increase in queue length, they cannot be effectively differentiated with queue length only. Our insight is that we can differentiate them with the sojourn time of the first frame in the queue. As shown in Figure 10(a), at the arrival of frame K_2 , the sojourn time τ_Q of the first frame K_1 and queue length L_Q observed by K_2 are:

$$\tau_Q = t_{enq}^{(K_2)} - t_{enq}^{(K_1)}, \quad L_Q = K_2 - K_1 \quad (6)$$

where $t_{enq}^{(i)}$ is the enqueue timestamp of frame # i , and frame # K_1 is the frame at the head of the queue. For bursty network arrivals, since frames arrive at the decoder queue simultaneously, when the last frame of the burst arrives, the first frame has only been queued for a short time. For example, τ_Q in Figure 10(b) is 4ms (marked red). In contrast, for stalled decoder service, the head frame has been blocked for a long time, leading to a high τ_Q of 66ms in Figure 10(c). Therefore, we use τ_Q to adjust the frame rate in the transient controller.

Feedback control. For the transient controller, the design space is to find out a mapping between the discounting factor α and the queuing delay τ_Q . Since the transient controller is designed to reduce the frame rate based on the results of the stationary controller, the possible range of α satisfies:

$$f_{min}/f_{max} = \alpha_{min} \leq \alpha \leq 1 \quad (7)$$

where f_{min} and f_{max} are the lower and upper bounds for frame rate required by the application. Since longer τ_Q indicates a more severe load of the queue, the discounting factor should decrease with the increase of τ_Q . Besides, the α - τ_Q mapping should also have the following properties:

First, avoid overreactions. As we discussed above, for bursty network arrivals, τ_Q will also slightly increase due to the volumetric arrived frames. However, since such a transient queue accumulation will be cleared quickly as long as the decoder is functional (Figure 10(b)), we should not decrease the frame rate. Therefore, we need to introduce an upper reservoir (as shown in Figure 11(a)) to avoid overreactions. In the upper reservoir, when a non-zero but small τ_Q is observed ($0 \leq \tau_Q \leq Q_1$), the transient controller will not decrease the frame rate. The reservoir threshold Q_1 should be set based on measurements. We measure the observed L_Q and τ_Q from frames and present the results in Figure 11(b). Peaks near the left axis (marked by red dashed

arrows) represent frames with a long L_Q yet with a short τ_Q , which are due to the bursty network arrivals. Therefore, we set Q_1 to filter out those bursty arrival-related peaks (e.g., $Q_1=14\text{ms}$ in our deployment, the red line in Figure 11(b)).

Second, respond timely. Due to the stringent delay requirements of high-quality RTC applications, a long queuing delay will drastically degrade the users' experiences. Therefore, we need to control the slope of the mapping in Figure 11(a) to effectively reduce the queuing delay. Since α is lower bounded, we could control the slope of the mapping by introducing a *lower reservoir*, as shown in Figure 11(a). We set Q_2 as the maximum tolerable queuing delay:

$$Q_2 = \max(Q_1, \text{Deadline} - \tau_{\text{network}} - \tau_{\text{decode}}) \quad (8)$$

where τ_{network} is the round-trip network delay, and τ_{decode} is the decoding delay μ_s . *Deadline* is the requirement for the total delay of the application. Based on users' experiences in the human-machine interaction and our operational experiences, we set *Deadline* to 100ms in our deployments [43].

5 Implementation

We implement the AFR with a frame-level trace-driven simulator, and deploy the AFR onto a production high-quality RTC service in the wild. In this section, we present the design of our simulator (§5.1), introduce the simulation setup (§5.2) and the deployment setup (§5.3).

5.1 Simulator Design

To faithfully compare and replay the traces for different queue control algorithms, we design a simple simulation environment that models the dynamics of RTC. The simulator maintains the decoder queue and replays the traces collected from online services, where the traces contain the decoding delay, network delay, original queuing delay, and also the arrival timestamp for each frame. Specifically, frames arrive at the decoder queue according to timestamps in traces, wait in the decoder queue for dequeuing, and are decoded according to decoding delays in traces. To avoid frequently sending frame-rate adjustment requests to the servers, frame rates are quantized at the level of 5fps, which is also followed by our online deployment. We implement the potential interference from CPU time-slicing: since the fetching of frames to decoders depends on the CPU, there are possible cases where fetching the frame from the queue to the decoder needs waiting to be scheduled by the CPU by up to several milliseconds [20]. Therefore, we further profile such a delay in the traces and introduce the scheduling waiting time in our simulator. We also implement the response time of the encoder between the new frame-rate actions and new frames generated with the updated frame rate, according to our measurements in §6.4. Please refer to Appendix C for implementation details.

5.2 Simulation Setup

Traces. We measure the frame-level statistics of our cloud gaming service (introduced in §3.1) on two types of clients (Windows and MacOS) and access networks (Ethernet and WiFi). We profile each step of received frames in one of our

	Category	Session	Frame	Playtime
(1)	Windows+Ethernet	29.7k	6.35 B	34.2k hours
(2)	Windows+WiFi	6.4k	1.12 B	6.2k hours
(3)	MacOS+Ethernet	0.4k	40.9 M	0.2k hours
(4)	MacOS+WiFi	2.1k	216 M	1.1k hours
	Total	38.1k	7.73 B	41.7k hours

Table 1: Distribution of our traces on the client type.

production clusters for 24 days in December 2020. This results in a dataset with 7.73 billion frames and 41.7k hours of playtime (Table 1), which is the largest frame-level dataset for interactive streaming to the best of our knowledge.

Parameter settings. There are several parameters in AFR to be determined. Except for the parameters related to the transient controller (§4.3), we set W_0 in the stationary controller to 2ms and the discounting factors in EWMA $\xi_{\text{arrv}}=0.033$ and $\xi_{\text{serv}}=0.25$. We discuss the sensitivity of those settings and their influence on the performance in §6.3.

Metrics. In the evaluation, we mostly measure the delays (including the queuing delay and the end-to-end total delay). As we discussed in §2, the delay in interactive streaming is orthogonal to other video quality metrics (e.g., PSNR [2] or SSIM [76]). The delay, which represents interactivity, is the main optimization goal in this paper. We demonstrate that AFR has negligible degradation on the video quality in §6.4.

Baselines. To evaluate the performance of AFR, we implement existing frame control mechanisms as follows:

- **DropTail** is the frame control mechanism in WebRTC [60]. When frames overflow the queue, the client will first clear the queue, then request a new key frame, and finally drop all frames until the next key frame arrives. We set the queue capacity to 16 frames.
- **QLen-S** observes the current queue length, skips frames from the content generator before the encoder if the queue length is ≥ 1 , and resumes if the queue length is < 1 .
- **QWait-S**. We migrate the frame control mechanisms from existing academic efforts in our simulator [34, 77], and replace the signal from total delay to queuing delay to better reduce the queuing delay. Since these baselines are not designed for stringent delay requirements of 100ms, we also finetune their parameters with our traces. **QWait-S** skips frames before the encoder if the queuing delay is $\geq 32\text{ms}$, and resumes if the queuing delay is $< 4\text{ms}$.

Besides, to evaluate the effectiveness of different components in AFR, we also different variants of AFR:

- **AFR-QLen**. We demonstrate the insufficiency of controlling the frame rate with queue states with a feedback algorithm based on current queue length: it observes the current queue length at the arrival of each frame, and maps the queue length of $\{0, 1+\}$ to frame-rate $\{60, 24\}$ fps.
- **AFR-QWait**. A feedback algorithm maps current queuing delay of $\{(0, 4), (4, 8), (8, 12), (12, \infty)\}$ ms to frame-rate of $\{60, 48, 36, 24\}$ fps. The parameters have also been finetuned with our traces.

- **AFR-TX.** To demonstrate the effectiveness of measuring both the arrival and service process, we further implement a dequeue rate-based algorithm. AFR-TX measures the dequeue rate and sets the target frame-rate with $\rho = 0.8$, where ρ has been tuned with our traces. The dequeue rate is the reciprocal of decoding delay.
- **AFR-Kingman.** Moreover, we individually evaluate the stationary controller of AFR to further illustrate the effectiveness of the transient controller.
- **AFR.** Finally, we put all optimizations in this paper (both the stationary and transient controller) together.

We present how we tune the parameters, and evaluate the trade-offs between frame rate and queuing delay in §6.3.

5.3 Deployment setup

We finally deploy AFR onto our cloud gaming service. The gaming service X employs the H.264 codec to increase the coverage of hardware decoding and adaption towards heterogeneous clients¹, and customizes the codec performance for the optimization of gaming. Tencent Start currently supports 13 production-level games, including action-adventure, first-person shooter, and real-time strategy games. To optimize the network delay, the service is accelerated with multi-access edge computing similar to [74, 57, 86]: Users are split into tens of operation regions with a geographical diameter of hundreds of kilometers. Cloud gaming servers are deployed on clusters in each operation region, resulting in an average round-trip network delay of 15ms (Appendix B.2).

The frame-rate adaption algorithms are implemented on the client side. The AFR controller continuously measures the statistics of the decoder queue, and sends requests to edge servers to adjust the frame rate when necessary. The edge server then forwards the frame-rate adjustment requests to both the video encoder and the gaming application. New frames will be generated following the new inter-frame interval. We evaluate the response timeliness and overhead of video encoder and gaming application in §6.4.

6 Evaluation

We evaluate the AFR controller in the following aspects:

- **Delay improvements.** We present the performance improvements: The ratio of frames with long queuing delay and total delay of AFR has been improved by $2.1\times$ - $26\times$ and 13% - $2.2\times$ against existing baselines (§6.1).
- **Frame-rate maintenance.** We then demonstrate that AFR introduces negligible impacts on the metrics related to frame-rate (§6.2).
- **Parameter sensitivity.** Our evaluation shows that parameters in AFR have a wide range of settings to gain performance improvements against finetuned baselines (§6.3).
- **Microbenchmarking.** We further demonstrate that the timeliness, overhead, and image quality of frame-rate adjustments are satisfactory for online deployment (§6.4).

¹Hardware decoding has a shorter decoding delay than software decoding and supports higher frame rates. H.264 has a higher coverage of hardware decoding support compared to other advanced codecs [54].

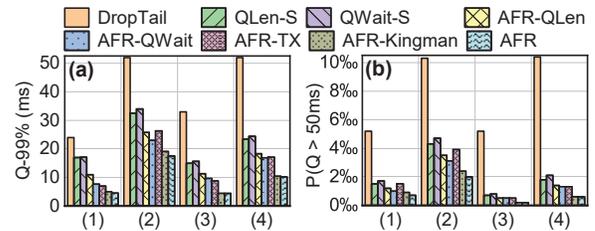

Figure 12: Simulation results of queuing delay (the 99%ile and the ratio of frames with >50 ms queuing delay).

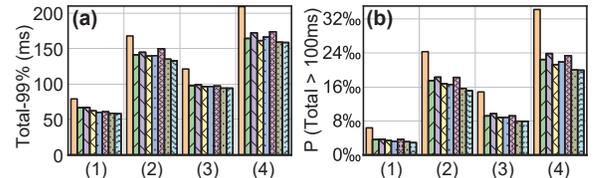

Figure 13: Simulation results of total delay (the 99%ile and the ratio of frames with >100 ms total delay).

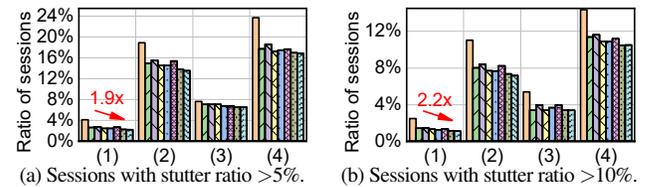

Figure 14: Ratio of sessions with different stuttered frames.

- **Deployment in the wild.** Finally, we report the A/B test results and the deployment progress of AFR on our cloud gaming service online (§6.5).

6.1 Delay Improvements

We compare the queuing delay and the total delay of each frame with AFR and baseline algorithms in four sets of traces (Table 1). We measure the queuing delay in two dimensions: we present the 99th percentile queuing delay and the ratio of frames with a queuing delay >50 ms in Figure 12. We first analyze the results of AFR against three existing mechanisms (DropTail, QLen-S, and QWait-S). AFR could reduce the 99%ile queuing delay by $1.9\times$ to $7.4\times$, and the ratio of severely queued frames by $2.1\times$ to $26\times$ on different sets of traces against three baselines. In this case, the 99%ile queuing delay could be squeezed to 6.9ms. This indicates that AFR could effectively achieve an ultra-short queuing delay. AFR also demonstrates satisfactory performance improvements on the *total end-to-end delay*, which is directly related to users' experiences. AFR improves the 99%ile total delay by 27% to 36%, and the ratio of severely delayed frames (total delay >100 ms) by $1.6\times$ to $2.2\times$ in all traces. We also measure the *session stutter ratio*, i.e. the ratio of frames with a total delay of >100 ms in a session, for each session. We then measure the ratio of sessions with a session stutter ratio of $>5\%$ and $>10\%$, which indicates how many users suffer from unsatisfactory experiences and present the results in Figure 14. For the major population of our service (Cat. (1), Table 1), AFR reduces the stuttered sessions by 17% and 21% compared to the best of the three baselines. For other categories, the ratio of

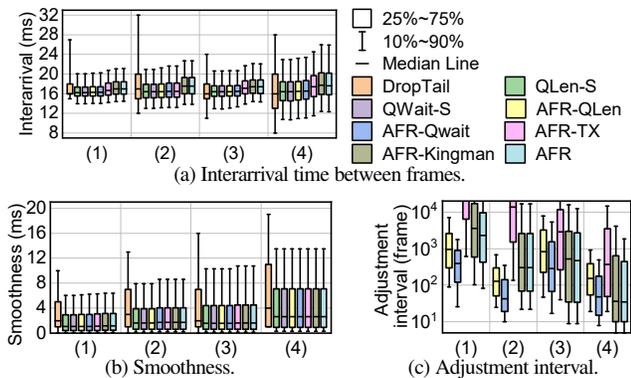

Figure 15: Frame-rate maintenance. Better viewed in color.

stutter sessions has also been reduced by 5% to 37%. AFR could significantly improve experiences for high-quality RTC.

We further understand the performance improvements with the comparisons among different variants of AFR. Compared to DropTail, baselines based on queue states (AFR-QLen, AFR-QWait) could effectively reduce the queuing delay, indicating the necessity of actively controlling the queuing delay (§3.1). Compared to QLen-S and QWait-S, controlling the frame rate achieves better performance than skipping frames from the encoder. This is because skipping frames would drastically degrade the tail frame rate, for which the parameters of baselines are tuned (§6.3). AFR-TX could further reduce the queuing delay than the queue state-based baselines, indicating that observing the service process could know the potential degradation in advance and effectively take actions, validating our analysis in §3.3. AFR-Kingman further improves the performance by 10% against AFR-TX, demonstrating that the fluctuating arrival of the high-quality RTC could also affect the estimation of the decoder queue. AFR finally reduces the tail queuing delay by 2-4% against AFR-Kingman, indicating the necessity of the transient controller to handle contingencies.

Besides, we also find that AFR has larger performance improvements when the network is better. The performance improvements on two sets of Ethernet traces (55% and 37% for Cat. (1) and (3)) are larger than the on WiFi traces (35% and 27% for Cat. (2) and Cat. (4)). Considering the ongoing deployment of next-generation access networks with better network conditions (e.g., 5G and WiFi 6), the necessity of controlling the decoder queue would be more significant.

6.2 Frame-rate Maintenance

Besides, we also measure the effect of AFR on the frame rate. We first measure the interarrival time between frames at the arrival of each frame on the client. For example, a frame rate of 60fps should result in an interarrival time of around 16.7ms. We tune the parameters of each algorithm to keep the 99th percentile of their interarrival time at the same level (details in §6.3). Therefore, for 10-90th percentiles, as shown in Figure 15(a), most algorithms except for DropTail are comparable. Compared to the existing deployed mechanism DropTail, AFR even improves the tail user-perceived frame rate due to its better management of frame

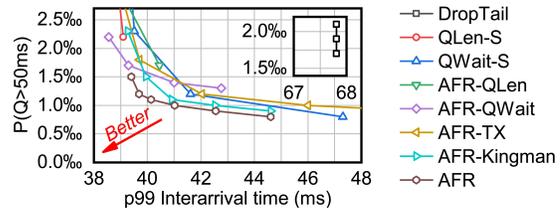

Figure 16: The trade-off between the tail interarrival time and queuing delay. We tune the parameters for baselines and AFR to illustrate the capability of each algorithm in the trade-off.

drops. AFR slightly decreases the median frame rate by 3%-9%, which brings the negligible quality of experience (QoE) degradation to users considering the improvements on delay [71, 81].

We further measure the smoothness of frame-rate, which might also have potential effects on users' experiences [33]. We measure the *differences of interarrival time* as an indicator of the smoothness of frame rate and present the results in Figure 15(b). Except for DropTail, all baselines and AFR have similar interarrival differences and are better than DropTail. This is mainly because that frame drops in DropTail will introduce a sudden increase of interarrival differences. Moreover, we also measure the frame adjustment interval and present the distributions in Figure 15(c). The median adjustment interval of AFR is hundreds to thousands of frames, which is much longer than the response time of frame-rate adjustment (§6.4).

6.3 Parameter Sensitivity

We then evaluate the sensitivity of parameters in AFR and other baselines. We tune parameters of all baselines in §5.2: thresholds for skipping frames for QLen-S and QWait-S, mappings for AFR-QLen and AFR-QWait, ρ for AFR-TX, and W_0 for AFR-Kingman and AFR. We present the ratio of frames with queuing delay $>50ms$ ($P(Q>50ms)$) and the 99th percentile of interarrival time on Cat. (1) traces in Figure 16. The down-left corner indicates the algorithm has a satisfactory trade-off between the queuing delay and the frame rate.

As we can see, AFR outperforms all other baselines in a wide range of settings, achieving a better trade-off between the queuing delay and frame rate. QLen-based algorithms are challenged in achieving ultra-short queuing delay: with the extremest parameters (skipping/decreasing frame-rate as long as queue length is non-zero), QLen-S and AFR-QLen could only achieve a $P(Q>50ms)$ of 2.2‰ and 1.7‰, much higher than other baselines. This follows our analysis in §3.3 that queue length is too coarse-grained as a signal to control the queue with an ultra-short target. Meanwhile, skip-based algorithms could achieve lower queuing delay compared to frame-rate-based algorithms, yet with higher interarrival time. The parameters of all algorithms are tuned according to Figure 16 by aligning the 99th percentile interarrival time.

We also evaluate how different percentiles of queuing delay and total delay are affected by the setting of W_0 in Appendix D.3. The performance of AFR reacts sensitively to the setting of W_0 , indicating that operators could effectively balance the total delay and frame rate by adjusting W_0 . We further evaluate

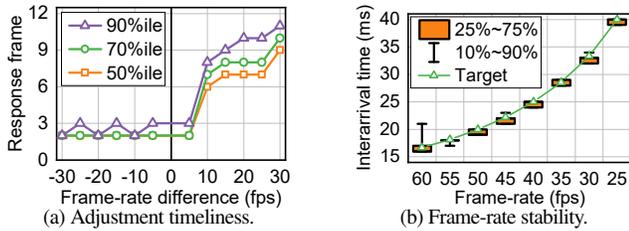

Figure 17: Effectiveness of frame-rate adjustment.

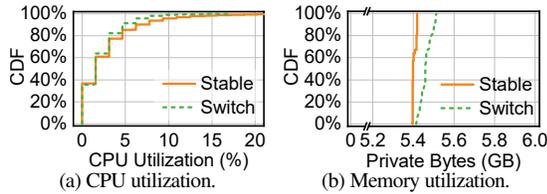

Figure 18: Frame-rate adjustment overhead.

the sensitivity of the discounting factors ξ of the EWMA and EWMV in the transient controller (§4.3) in Appendix D.3, demonstrating how operators should set these parameters to balance between the precision and sensitivity.

6.4 Microbenchmarking

We also benchmark AFR in a testbed of our cloud gaming service.

Effectiveness of frame-rate adjustment. We first measure the responsiveness and precision of frame-rate adjustment at the video encoder. We enumerate all frame-rate switching within {25, 30, ..., 60}fps, and measure how many frames the encoder needs to take to steadily output video streams at the new frame rate. The response time measured by the unit of frame (i.e. *response frame*) is presented in Figure 17(a). For each group of settings, we repeat the experiments 100 times to eliminate the randomness. When decreasing the frame rate, the 90%ile response frames is less than 3 frames, indicating the encoder and gaming application could decrease the frame-rate timely. This could effectively alleviate the overload of the decoder queue. When significantly increasing the frame rate, the frame rate might be slightly delayed to change. This is because the frame rate at the client side follows the bucket effect. Either encoder or the gaming application decreases the frame rate will lead to a decrease of the final frame rate, while the increase of frame rate needs an increase from both components. Even so, the tail response frame is <10 frames, which is much less than the adjustment interval (Figure 15(c)).

We then measure the fluctuation of the frame rate of the output of the streaming encoder. We set the frame rate to several levels as above, and measure the interarrival time between each frame. For each frame rate, we measure the interarrival time for 30,000 frames and present the distribution in Figure 17(b). The interarrival time between frames largely falls around the target frame rate. Therefore, unlike the fluctuating bit-rates in video streaming [42], frame-rate could be precisely controlled by the encoder.

Frame-rate adjustment overhead. We further measure the potential processing overhead of frame-rate adjustment at the edge server. To magnify the overhead, we change the frame rate

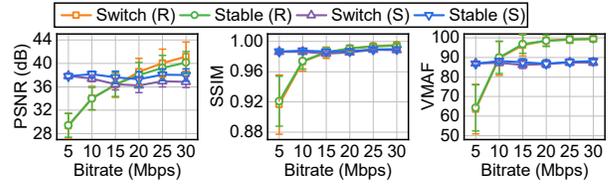

Figure 19: The image quality differences of AFR and the original video tested in a running scene (R) and stable scene (S). The error bar represents the standard deviation.

from 60fps to 30fps and back to 60fps every 6 frames, which is much shorter than the usual adjustment interval. We then measure the CPU and memory utilization of the cloud gaming application and encoder by sampling the CPU processing time and application private bytes with the `typeperf` [66] every 1 second. We measure for 30 minutes to eliminate the randomness. We compare the scenario with a stable frame-rate of 60fps (*stable*) and a frequently switching frame-rate (*switch*) in Figure 18. For CPU utilization, both scenarios have a similar distribution from 0% to 20%. *switch* is a little better than *stable* since producing a lower frame rate takes fewer CPU resources for the gaming application. As for memory utilization, the major memory consumption is from the gaming application. Frame-rate switching slightly increases the utilization of private bytes since frequently resetting the encoder requires allocation of memory. Nonetheless, the increase of memory utilization is less than 1.8% even at the 99%ile, which is negligible and could be even lower in the case of normal frame-rate adjustments.

Image quality degradation. We also investigate the potential image quality degradation caused by AFR. We record two raw videos from games, one in a running scene (R) and another in a standing scene (S). For each video, we switch the frame rate every 100 frames 15 times and measure the video quality for the following 400 frames. We investigate three video quality metrics, peak-signal-to-noise-ratio (PSNR) [2], structural similarity index (SSIM) [76], and video multimethod assessment fusion (VMAF) [51], and present the results in Figure 19. *stable* and *switch* denote the scenarios where the frame-rate remains unchanged or frequently switched. Results demonstrate that frequently switching the frame rate will not affect the video quality: the video quality of two videos on three metrics are comparable in all cases.

6.5 Deployment in the Wild

Finally, we evaluate the performance of AFR by deploying it onto Windows clients of our cloud gaming service, Tencent Start, in one of its production clusters. Before the deployment of AFR, our cloud gaming service follows the frame control strategy in WebRTC (i.e., `DropTail`). To make a clean and controlled comparison, we only present the results from online A/B tests in our production clusters, when all other implementations and settings are kept the same. The A/B test is conducted from January 8, 2021, to January 14, 2021, resulting in 5369 Ethernet sessions and 1467 WiFi sessions. The parameter settings of AFR remain the same as the simulation (§5.2). We randomly enable

Cat. (1)	Q99	Q>50ms	T99	T>100ms	Session
DropTail	54ms	1.11%	101ms	1.03%	7.30%
AFR	22ms	0.51%	80ms	0.68%	5.82%
Cat. (2)	Q99	Q>50ms	T99	T>100ms	Session
DropTail	64ms	1.83%	174ms	3.00%	24.00%
AFR	37ms	0.54%	160ms	2.11%	21.17%

Table 2: Performance of deployment in the wild. Metrics are the 99%ile of queuing delay (Q99), the ratio of frames with Q>50ms, the 99%ile of total delay (T99), and the ratio of the stuttered frame (T>100ms). *Session* is the ratio of sessions with stutter ratio >5%. Cat. (1) and (2) are Ethernet and WiFi on Windows clients.

(or disable) AFR with a probability of 50% for each session, and present the results in Table 2. Similar to the simulation results, the ratio of stuttered frames measured by total delay (P(T>100ms)) in both categories has been improved by 34% and 30%, which significantly improves users’ experiences in interactive streaming. The stuttered sessions (with the same metric as Figure 14(a)) have also been reduced by 17% on average, indicating these users could be alleviated from stuttering streaming experiences. Therefore, the online deployment also demonstrates significant benefits of AFR for high-quality RTC users. AFR has already been deployed onto all production clusters of Tencent Start for over one year, serving thousands of users each day.

7 Discussions

In this section, we discuss the potential limitations of AFR.

Application scenarios. In this paper, we mainly evaluate the performance of AFR on traces or production clusters of our cloud gaming service. However, as we introduce in §1 and §2, the overload of decoder queue generally exists in many high-quality RTC scenarios, such as VR streaming or 4K live streaming, as long as they stream high frame-rate and high bit-rate video onto commercial clients. We evaluate AFR with cloud gaming due to access to the real-world traces and production services X. We leave the deployment of AFR over other scenarios as our future work.

Coexistence of multiple control loops. There are other control loops that work simultaneously in the RTC system. For example, the underlying congestion controller will also control the bit-rate of the video based on network conditions [25]. The video codec will also adjust the quantization parameter based on the scenes to encode [17]. As we discussed in §3.2, these parameters are affected by different causes (network congestion, decoder degradation, scene variation), which are orthogonal to each other. Therefore, the adaption of the frame rate is orthogonal to the other controllers in the RTC system. In §6.5, we evaluate the performance of AFR with all these controllers in our real production in the wild. We leave the coordination of different controllers on the joint optimization over the user’s experience for the future.

8 Related Work

There has been little prior work on the decoder queue for high-quality RTC. We survey the following three aspects.

Frame controls in RTC. As we discussed, besides the *DropTail* mechanism in WebRTC, there are a series of research efforts in the active control of RTC frames. For example, some

work [38, 77, 34] maintains a certain number of in-flight frames based on total delay [77] or frame-level acknowledgement mechanisms [34]. AFR differentiates from them in two aspects. First, the end-to-end control introduces ambiguity in taking effective actions, as discussed in §3.2. AFR takes effective actions to reduce the queuing delay. Second, existing control strategies are based on queue lengths or queuing delay. In contrast, measuring the arrival and service processes in AFR could help high-quality RTC to achieve lower queuing delays. Furthermore, researchers also proposed to co-design the codec and network [35, 34, 79, 75] or even redesign new decoding ASICs [90]. These cannot be accelerated with commercial hardware and are hard to deploy in practice.

Adaptive Bit-rate Control. There have already been a series of research efforts on the optimization of low-latency streaming. Different congestion control [78, 83, 25] or rate adaption algorithms [87, 84] have been proposed to enable the low-latency transport for real-time communications. However, as we discussed above, changing the bit rate without changing the frame rate will not alleviate the load of the decoder queue. Since bit-rate and frame-rate are independent in video streaming, bit-rate adaption is orthogonal to frame-rate adaption and could be integrated with AFR to control the network delay and queuing delay together.

Cloud gaming. As a recently emerging application, cloud gaming also attracts the attention of researchers. Researches include the optimization of the renderer [23, 52, 27] and streaming codec [72], which are independent of the optimization at the transport level. There are also investigations on the user experience of cloud gaming [81, 71, 28], which could be integrated with our work by better customizing the optimization goal. Recent efforts also try to investigate the performance of production-level cloud gaming services from the client side [26], which are limited in scale and completeness. To the best of our knowledge, we are also the first piece of work to investigate the performance of production-level cloud gaming services from the server side, with the scale of tens of thousands of hours of playtime.

9 Conclusion

In this paper, we propose AFR to reduce the queuing delay of the decoder queue for high-quality RTC by dynamically adjusting the frame rate. AFR introduces a stationary controller and a transient controller to respectively mitigate the stationary heavy traffic and contingent arrivals and services. We further evaluate the performance of AFR with trace-driven simulations and deployments in the production clusters. Experiments demonstrate that AFR could significantly reduce the stuttering ratio and tail total delay.

This work does not raise any ethical issues.

Appendices

A Potential Solutions and Concerns

In this section, we discuss why other potential solutions are insufficient to address the problem in this paper, and discuss other concerns of adapting the frame rate during runtime.

A.1 Potential Solutions

Discarding frames or adjusting resolutions. For most widely adopted codecs, dropping one frame or changing the resolution will make the following frames fail to recover the raw pixels of the block because they are differentially encoded by the motion vector to the previous one². This is to utilize the redundant information between frames to reduce the bitrate of the stream. Since key frames do not rely on previous frames, they are usually much larger than other predictive frames (sometimes 10×) [46]. Therefore, given the same bottleneck bandwidth, sending a frame with 10× larger size will take approximately 10× time (tens to hundreds of milliseconds), which drastically increases the delay for the users. Moreover, frequently requesting key frames will degrade the goodput of the streaming and potentially increase the congestion in the network. Therefore, directly dropping delayed frames at the client or frequently changing the resolution will introduce stalls for the subsequent frames and degrade the users’ experiences of high-quality RTC.

Adjusting the bit-rate. Without changing the resolution and frame rate, adjusting the bit rate has a very limited effect in reducing the decoding delay. Generally speaking, resolution, bit rate, and frame rate could be independently set. The display resolution describes the number of distinct pixels in each dimension that

²Recent advances on scalable video coding could partially break the inter-frame dependency, yet degrades video quality with the same bit-rate [69].

can be displayed, and the frame rate represents the number of pictures within one second of video. And the bit rate represents the amount of data used for storing the coded bit-stream. So the higher resolution we set, the more pixels a single picture will have, which could mean a higher definition of the video. And setting a higher frame rate means there will be more pictures per video second to make the video smoother. If we set a higher target bit-rate while keeping other parameters unchanged, the encoder can use more data to represent the pictures to achieve lower possible image distortion with a lower *quantization parameter* [17].

In this case, with the unchanged frame rate and resolution, the decoding procedure is also unaffected. For example, in H.264/AVC, a sequence of macroblocks can be composed of a slice, a picture, therefore, is a collection of one or more slices. Slices are completely independent of each other, and the macroblocks inside a video frame can be reconstructed in parallel. The video decoding has been parallelized using slice-level or block-level parallelism. The resolution will affect how many pixels there are in one frame, and the frame rate determines the tolerable decoding delay for each frame. The parallelized decoder is not significantly affected by the precision of each pixel. We further measure the decoding performance with different bitrates in production in Appendix B.4.

Preset the frame rate and resolution based on client types. An alternative to AFR is that the application checks whether the hardware could reliably decode the video at a certain resolution and frame rate at initialization. This, however, would lead to underutilization on the client side. The decoding capability of hardware is fluctuating over time due to various reasons. For example, we measure the distribution of decoding delay of each user session in Appendix B.5. One-fourth of users will have at least 1% time of a long decoding delay of >18ms, which could result in severe queuing delay, as we illustrated in Figure 6. In this case, if we set the resolution and frame rate based on this tail metric, users will have a much lower resolution and frame rate during most of the time. Therefore, we need to control the frame rate in the runtime to dynamically adapt to the network and decoder dynamics.

Allocating the application with dedicated resources. Another seemingly feasible solution is to bind the application to a certain CPU core or GPU core to avoid the potential fluctuations caused by scheduling. However, we do not have such privileged control on client devices. As a user space application, the controllability over the user’s system is limited. Even if an expert user pins the application to a certain core, for commercial systems such as Windows, pinning does not indicate isolating the core for that application only [14]. The system can only ensure the pinned application to run on that core, but could also schedule other processes if still available. Moreover, since our application is not CPU-intensive most of the time, there would usually be idle resources on the same core where the user binds the application to. Therefore, there could still be the same issue of latency increases *at tail*.

CPU	Release date	Score	Portion

Table 4: Top 5 GPU models of clients in our cloud gaming service.

A.2 Practical Concerns

Since the frame-rate needs to be adjusted at the server, a straightforward concern is whether the frame-rate adaption over the Internet is timely for the stringent delay requirement of high-quality RTC. The measurements in production have two following findings. On one hand, the round-trip network delay is short enough to enable timely feedback: the average round-trip network delay is around 20ms of our cloud gaming service (Appendix B.2). Measurements over other high-quality RTC services (e.g., Google Stadia) have similar results of less than 20ms [26, 57]. On the other hand, the degradation of decoding delay usually lasts for a long time, with a median duration of more than 100 milliseconds (Appendix B.5). Moreover, we also demonstrate that the increase in decoding delay and network delay is hardly correlated (Appendix B.6). Therefore, for high-quality RTC, when the decoder fluctuates, it is timely enough to control the frame rate over the Internet.

B Measurement over Dataset

In this section, we supplement the observations in the main text with measurements in production. The measurement settings follow the details in §5.2.

B.1 User Characteristics

In addition to the distribution in §3.1, we present the top-5 models, with their release dates, benchmark scores, and portion in our users, of CPU and GPU in Table 3 and 4.

B.2 Delay Distributions

Compared to traditional RTC scenarios, the delay distribution for high-quality RTC has some unique features according to our measurements. We present the Cumulative distribution function (CDF) of component delays and the total delay to explore the delay patterns.

First, due to the edge deployments, the network delay in our cloud gaming service is quite small. According to Figure 20, the average round-trip network delay is approximately around 20ms. Even in this case, similar to traditional RTC services, the network delay is accounted for a large part of the total delay, the network delay line closely follows the total delay at the median for all four categories in Figure 20.

However, the tail delay of others component delays like

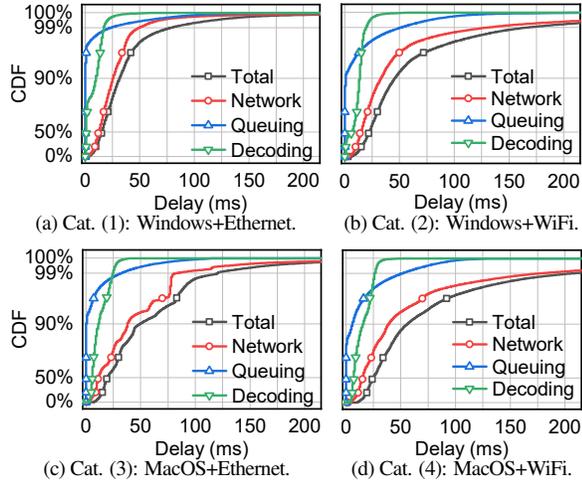

Figure 20: Raw measurements of delays from production.

decoding delay and queuing delay are noticeable under cloud gaming scenarios. For the decoding delay, we can notice that the decoding delay for 1080p frames is 18ms at the 99th percentile. Note that the decoder of all sessions evaluated in this paper has been hardware-accelerated. Therefore, as analyzed in §3.1, the queuing delay is becoming noticeable at the tail. Referring to Figure 20, the 99th percentile of queuing delay can reach 50ms under categories (2) and (4), which could degrade users’ experience for high-quality RTC services. We further present the root cause analysis below in Appendix B.3.

B.3 Root Cause Analysis

The total delay is mainly contributed by the network delay, decoding delay, and queuing delay §3. Therefore, we want to investigate how these three components contribute to the increase in total delay at the tail. For each frame, we denote T as total delay and C as component delay, where the component delay could be the network, decoding, or queuing delay.

To analyze the necessity and sufficiency of the component delay increasing to the total delay at the tail, we then calculate two conditional probabilities between the event of T longer than a certain threshold T_{th} , and the event of C longer than a certain threshold C_{th} :

- $P(C > C_{th} | T > T_{th})$. We want to account for how component delay increasing contributes to total delay under different delayed degrees T_{th} , and this conditional probability is subject to quantify it. If this conditional probability is close to one, there will be great confidence to blame the component delay for contributing C_{th} delay to the total delay to reaching T_{th} .
- $P(T > T_{th} | C > C_{th})$. As the sum of component delays, the total delay should increase when one of the component delays increases. This conditional probability is subject to illustrate this assumption and indicates the probability of total delay reaching the T_{th} under different component delay increasing degree C_{th} .

We calculate the conditional probabilities for three components for different C_{th} and T_{th} , and have the following observations.

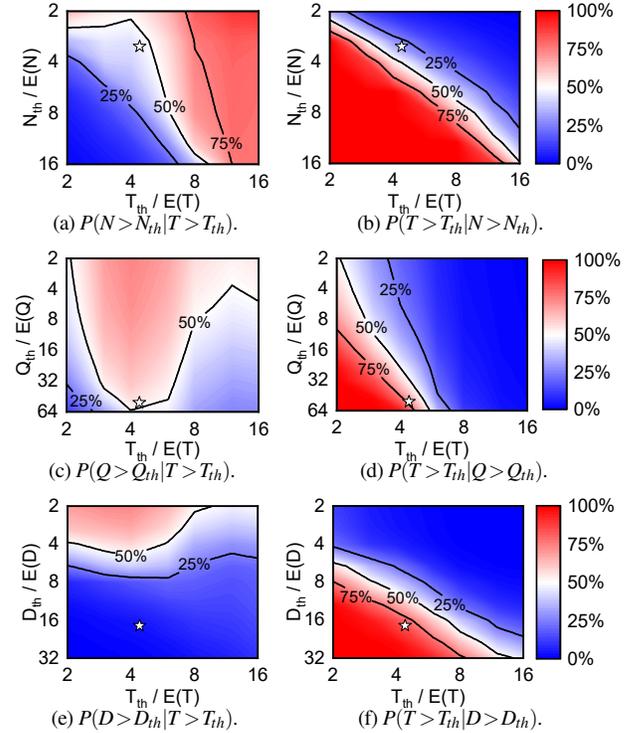

Figure 21: The heatmap of conditional probabilities for wired connections. The horizontal and vertical axes have been normalized by their average values. The star point’s value is recorded in table 5. The down-left corner is 100% since the total delay should always be larger than the component delay.

	Network	Queuing	Decoding
$P(C > C_{th} T > T_{th})$	44.7%	56.6%	4.0%
$P(T > T_{th} C > C_{th})$	29.8%	69.5%	84.2%

Table 5: Conditional probabilities with $T_{th} = 100ms$ and $C_{th} = 50ms$ for wired connections, which accounts for 82% of total users of our cloud gaming service.

Total delay increasing is a reflection of components delay increases. As the sum of the different types of components delay, It’s obvious that no matter what kind of component delay is increasing, the total delay will also increase.

So to find out the sufficiency of total delay increasing, we calculate the conditional probability of $P(T > T_{th} | C > C_{th})$ in right-side of Figure 21. We can notice that for all the component delays, their delay increasing can also mean a higher probability of total delay increasing (75%ile line in the figure is shifting to the right with the component delay increasing). The down-left corner is 100%, because as the sum of all types of component delay, the total delay must be larger than any component delay.

Queuing delay is responsible for delay increases of >100ms. To figure out the necessity of total delay increasing, we calculate the conditional probability of $P(C > C_{th} | T > T_{th})$ in left-side of Figure 21. Our major finding is that with the different order of severity of total delay increasing ($2-16 \times$ of $\mathbb{E}(T)$), the root cause of it is also changing. As we can see, when T_{th} is larger than $8\mathbb{E}(T)$, network delay has a high probability

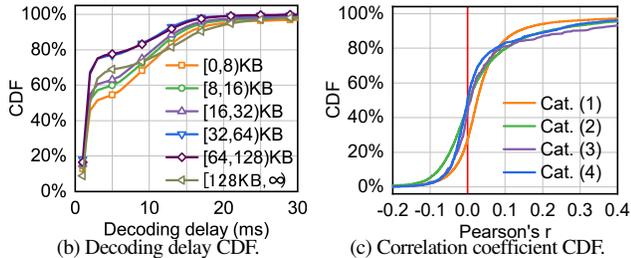

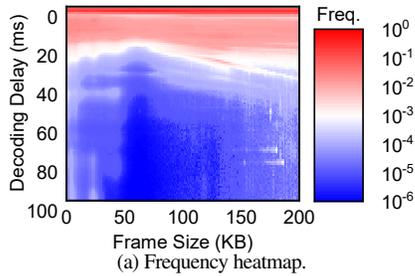

Figure 22: The correlation between the frame size and decoding delay for hardware decoders.

(shaded red) to be blamed. However, when T_{th} is from $3\mathbb{E}(T)$ to $8\mathbb{E}(T)$, queuing delay dominates the most increased events. It illustrates that the queuing delay is responsible for the increase of total delay by around 100ms. Specifically, we present the conditional probabilities for three components with $T_{th} = 100ms$ and $C_{th} = 50ms$ for wired connections in Table 5. As we can see, queuing delay has both high $P(C|T)$ and $P(T|C)$. Indicating that the total delay has a great possibility of reaching 100ms when queuing delay increases to 50ms. And for those video frames that total delay truly getting the 100ms, there will be great confidence to blame the queuing delay for contributing to the majority of delay increasing. So the queuing delay will be the root cause of the increase of total delay to 100ms.

B.4 Decoding Performance

In this section, we explain the reasons behind the ineffectiveness of controlling the service process for eliminating queuing time by adjusting the bit rate. The decoding time of decoders mainly depends on the resolution of the streaming. However, due to the dependency between frames, changing the resolution during the streaming will make the subsequent frames undecodeable and needs to request a new key frame for most codecs [29]. Yet, since the frame size of key frames is usually several times of those of other frames [46], frequently requesting key frames will impose additional overhead on the network and degrade the users' experiences.

Another straightforward solution is to try to accelerate the service process by reducing the bit rate while maintaining the same resolution. With the same resolution and frame-rate options, reducing the bit rate means lesser video data per video frame can carry. We are to investigate whether sending video frames with smaller data sizes is helpful for decoding acceleration. However, according to our measurements on the H.264 decoder, merely changing the bit rate does not significantly reduce the decoding time.

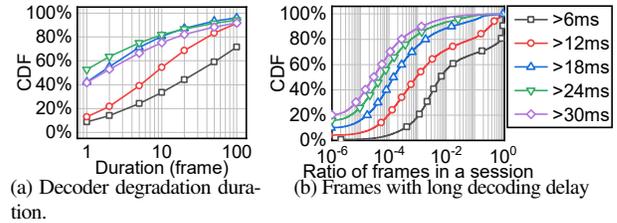

Figure 23: Decoder degradation when filtered with different thresholds for decoding delay.

We measure the relationship between the frame size and decoding time of the dataset described in §5.2. We first present the heat map in Figure 22(a). With the variation of frame size, the distribution of decoding time does not significantly change, where the decoding time of most frame sizes intensively falls around several milliseconds, as shown in the red area at the top of the heat map. To eliminate the frame size variation under the same target bit rate, we split the frame size into different intervals and present the cumulative distribution function (CDF) in Figure 22(b). As the frame size become larger, the $[128KB, \infty)$ the line does not locate in the rightest area (higher decoding delay). And other frame size interval's CDF lines stay together, indicating that the lowering frame size does not help for the decoding time acceleration.

Moreover, we split the dataset into four different categories (Table 1), to demonstrate that reducing frame size will not help decode acceleration under various platforms. We leverage the Pearson correlation coefficient to illustrate the independence, which value of zero can indicate that there is no association between the two variables [70]. Figure 22(c) shows that most of the Pearson's r value is located around zero, indicating the poor association between frame size and decoding delay. Therefore, controlling the service process of encoding bit-rate cannot effectively reduce the decoding time and alleviate the load of the decoder queue.

B.5 Decoder Degradation

Because the queue overhead will be introduced by the mismatch of the rate of two sides of the queue [39], if the decoding speed is not capable of processing the incoming default 60fps, it will be necessary for AFR to change to a lower target frame rate. However, since the client and server are located distant, the frame-rate adjustment request to the server side will need a control loop to take effect on the client side with the updated frame rate. So if the AFR control loop is shorter than the decoder degradation duration, the decoder will be capable of processing a higher incoming frame rate before the AFR requests take effect.

We measure the duration of the decoder degradation level over the traces introduced in §5.2. As we can see in Figure 23(a), for frames with a decoding time of more than 12ms, 50% of them last for more than 10 frames. Under 60fps streaming, considering the average of RTT is close to one frame interval of 16.7ms, and the 90%ile encoder response delay is less than three frames interval §6.4. In this case, lowering the frame rate will be helpful for alleviating the decoder queue even under the control loop delay of AFR. Therefore, AFR is capable of timely adjusting the frame rate to adapt to the decoder degradation. Moreover, the

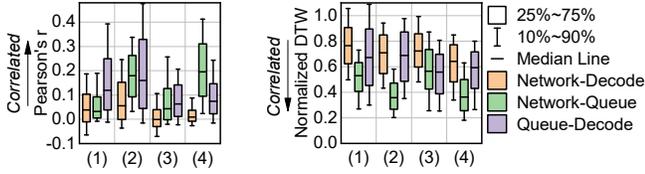

Figure 24: Pearson’s r (left, higher is more correlated) and normalized DTW distance (right, lower is more correlated) between delay components.

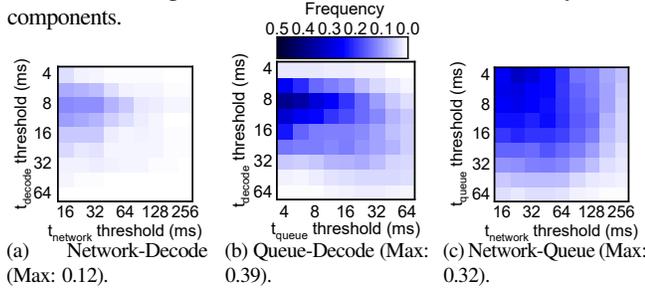

Figure 25: Cramer’s V between different delay components.

AFR can significantly help alleviate the queue overhead under those frames with a long period of decoder degradation and sustain queuing time for waiting for overhead queue elimination.

We further measure the ratio of frames with different decoding delays and present the results in Figure 23(b). Half of the user sessions suffer from a decoding delay of $>12\text{ms}$ for at least 1% frames. This also indicates that the degradation of decoding delay is a general issue among all clients.

B.6 Component Correlation Analysis

The streaming pipeline will be affected by many components, like the networking, decoding, and queuing delays can both cause total delay increases to degenerate the user’s experience Appendix B.3. In this paper, we propose AFR to reduce the tail queuing delay by matching the arrival rate of the decoder queue to the service rate (decoding speed). When decoding delay increases to disable decode frames timely, the AFR will send a frame-rate adjustment request from the client to the server. However, the request and subsequent frames need to be transported through the network. Therefore, a straightforward question is: does the increase of decoding delay affect the network delay to put an extra effect on the AFR control loop? We will figure out this by measuring the independence of those component delays.

We quantify the independence of different component delays with Pearson’s r value [70], dynamic time warping (DTW) [18], and Cramer’s v value [31]. In short, all these metrics demonstrate the poor association between networking and decoding delay, inclining that we could decouple the network and decoder issues and independently control them.

Regarding the Pearson correlation coefficient, the value of zero can indicate that there is no correlation between the two variables [70]. Figure 24 illustrates that for all four categories in Table 1, the Pearson’s r value of networking and decoding are close to zero, indicating a poor correlation between them.

Moreover, the different component delays might be correlated with each other across frames. For example, the decoding delay

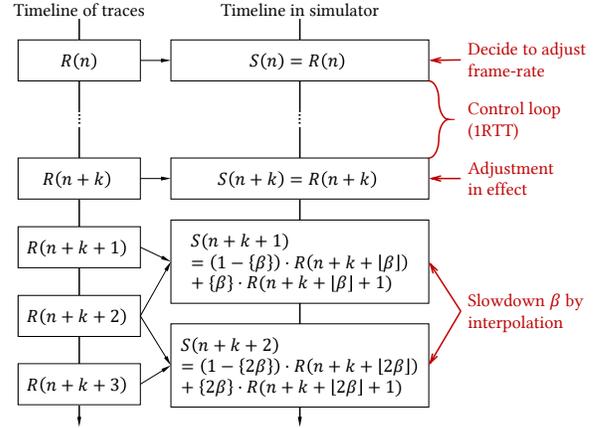

Figure 26: Illustration of frame-rate adjustment in our simulator.

could affect the subsequent queuing delay by its incapacity to decode video frames timely. To measure the correlation across frames, we leverage DTW to calculate the optimal match between two-time series [18]. The DTW algorithm is widely used in many scenarios like sign language recognition and time series clustering [47, 59]. The optimal match calculation under DTW is denoted by the match with minimal cost, where the cost is computed as the sum of absolute differences, for each matched pair of indices, between their values. Therefore, a larger DTW distance can be considered the mismatch between two series to a further extent. According to Figure 24, the normalized DTW distance of network delay to decoding delay under all four categories is large, showing the lack of correlation between them.

The strength of the relationship can also be assessed by Cramer’s V value, which is a metric based on the χ^2 -test but normalized for different data sizes. It indicates how strongly two categorical variables are associated [31]. A Cramer’s V value of ≤ 0.1 can be interpreted as hardly correlated [22]. According to our measurement in Figure 25, we can notice that all the Cramer’s V values of networking and decoding delay are ≤ 0.2 , illustrating the weak association between networking and decoding state. Therefore, according to our measurements before, we can see the independence between networking and decoding delay.

C Simulator Implementation

In this section, we introduce the implementation of our simulator. Specifically, traces are recorded in the following format:

$$R(n) = \left[t_s^{(n)}, \tau_{net}^{(n)}, \tau_{queue}^{(n)}, \tau_{decode}^{(n)} \right] \quad (9)$$

where $t_s^{(n)}$ is the arrival timestamp of the n -th frame, τ_{net} , τ_{queue} , and τ_{decode} are the round-trip network delay, queuing delay, and decoding delay of that frame. The simulator reads the traces frame-by-frame at specific timestamps and measures the current frame rate based on the interarrival time as §4.2. The simulator then dequeues the head frame in the decoder queue when the decoder is available, where the decoding time of each frame is also read from the trace.

When the adaptive frame-rate decides to set the frame-rate

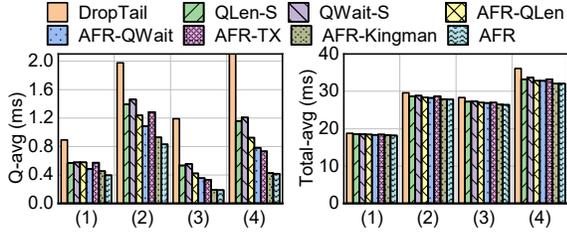

Figure 27: Average queuing delay (left) and total delay (right).

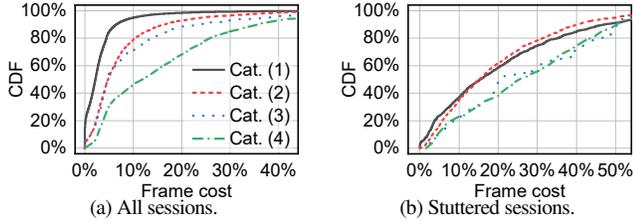

Figure 28: The number of wasted frames when skipping frames instead of adjusting the frame rate for AFR.

to f_{set} , the simulator first reads the current control loop by the round-trip network delay of the current frame $\tau_{net}^{(n)}$. The simulator then calculates the earliest frame $n+k$ that the new frame-rate f_{set} will take in effect:

$$k = \underset{k}{\operatorname{argmin}} \left(t_s^{(n+k)} - t_s^{(n)} \geq \tau_{net}^{(n)} \right) \quad (10)$$

After that, based on the measurement of the current frame-rate f_{cur} , the simulator calculates the slowdown factor $\beta = f_{cur}/f_{set}$, and reads the traces with a slowed-down speed. For example, as shown in Figure 26, When there are frames $R(n+k+1)$ to $R(n+k+3)$ in the original trace, the simulator reads the traces with indices $R(n+k+\beta), R(n+k+2\beta), \dots$. When β is not integer, the simulator interpolates the traces with its neighbor frames ($S(n+k+1)$ and $S(n+k+2)$).

D Supplementary Experiments

D.1 Average Delay

We further measure the average queuing delay and total delay for four traces and present the results in Figure 27. As we can see, the reduction of tail delay of AFR does not sacrifice the average delay on all traces. In contrast, the average delay has also been slightly improved against baselines, due to the improvements at the tail.

D.2 Frame Costs of AFR with Skipping

Besides, as we discussed in §6.4, skipping frames without changing the frame rate from the content generator (e.g., gaming application) would waste the rendering resources of the server. For example, for high-quality RTC, rendering at 60fps would take approximately one time more GPU resources than rendering at 30fps. Therefore, we measure how many frames have been wasted (i.e., frame cost) if we merely skip the frames to approximate the target frame rate without adapting the content generator.

We present the results of all traces in Figure 28. For all traces, adjusting the frame rate could save 3% to 12% frame costs in all traces, saving considerable operating expenses for the service

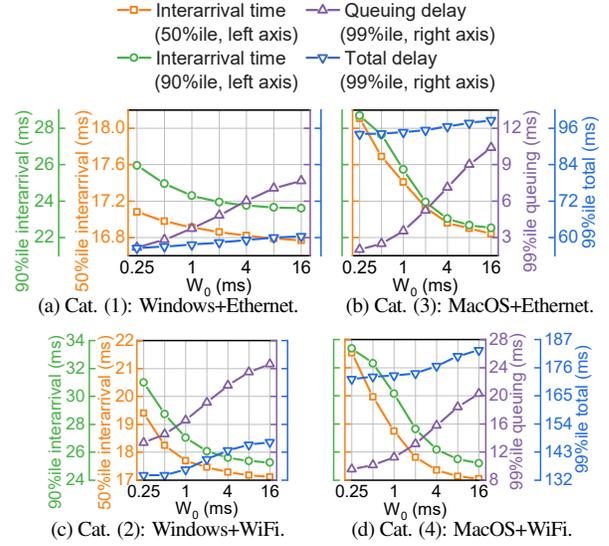

Figure 29: Sensitivity analysis on W_0 on different traces.

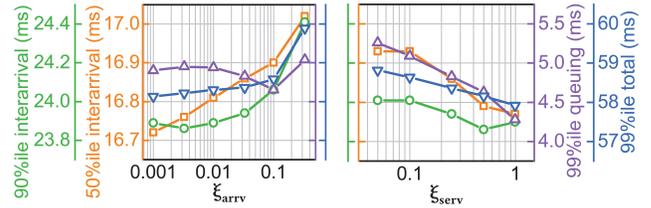

Figure 30: Performance of AFR with different settings of ξ_{arrv} and ξ_{serv} . Y-axes have been magnified compared to Figure 29.

provider since GPU is one of the highest expenses. For stuttered sessions (following the definition in §6.2), the saved frame cost would be even higher.

D.3 Parameter Sensitivity

Long-term control target (W_0) We present the simulation results on the sensitivity of W_0 (in the stationary controller) on different traces in Figure 29. As we discussed in §5.2, a lower W_0 results in a more aggressive queue control yet leads to the degradation of frame rate. We vary W_0 from 0.25ms to 16ms and measure the interarrival time, queuing delay, and total delay. By adjusting W_0 , operators could effectively balance the total delay and frame rate. Therefore, operators could adjust W_0 according to the preferences on total delay and frame rate for different users and games.

EWMA discounting factors (ξ_{arrv} and ξ_{serv}). We also vary the EWMA discounting factors (ξ_{arrv} for the arrival process and ξ_{serv} for the service process). Higher ξ indicates that the EWMA focuses on the recent values more to capture changes, while a lower value indicates more attention to the historical trends. As shown in Figure 30, the performance metrics (including the queuing delay, total delay, and frame rate) are relatively robust to these two parameters. By varying ξ_{arrv} and ξ_{serv} across several magnitudes, most metrics change marginally. For example, the 99%ile of queuing delay changes by 4 \times when varying W_0 (Figure 29) while only changes by less than 15% when varying ξ_{arrv} by three magnitudes (Figure 30). We also observe trends in varying ξ_{arrv} and ξ_{serv} . Lower ξ_{arrv} values will slightly

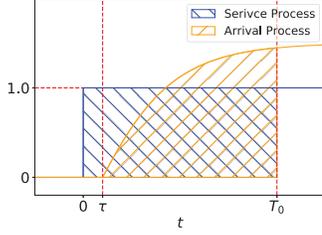

Figure 31: The system begins to control the queue after control-loop delay τ and stabilize the queue at T_0 .

improve the performance of AFR, implying that the long-term behavior of arrival service is more critical. Higher ξ_{serv} also slightly improves the performance, indicating focusing on recent decoding time is helpful. This is because we have already filtered out outlier decoding time. Paying more attention to recent decoding time could make the AFR quickly adjust the frame rate.

E Convergence Analysis

Finally, we provide a detailed analysis of the convergence time during the state transitions of the stationary controller. As introduced in §4.2, let the expectation of queuing delay $E(\tau_{queue}) = W_0$, according to Eq. 1, we have:

$$\mu_a = \frac{\mu_s}{\rho} = \left(1 + \frac{c_a^2 + c_s^2}{2W_0}\right) \mu_s \quad (11)$$

Then we can discuss the *convergence time* of the system. The convergence time here refers to the time at which the stationary controller converges to a stationary state when the service process changes, and the potential accumulated queue during the transition is drained up.

Specifically, without loss of generality, we discuss a simplified case shown in Figure 31: Both the arrival and service process have an average value of zero for $t < 0$, and the service process changes from zero to one at $t = 0$. The arrival rate will gradually respond to the change after a control loop of τ . We want to find the convergence time T_0 where

$$\int_0^{T_0} \mu_a dt > \int_0^{T_0} \mu_s dt \quad (12)$$

In this case, the queue accumulated during the response to the arrival rate will be cleared. We further illustrate the convergence in Figure 31. By substituting Eq. 11, we have:

$$\int_\tau^{T_0} \left(\mu_s + \frac{c_a^2 + c_s^2}{2W_0} \mu_s^2 \right) dt > \int_0^{T_0} 1 dt \quad (13)$$

From the measurement of EWMA in Eq. 5, we have

$$\hat{\mu}_s = 1 - (1 - \xi_\mu)^{t - \tau} \quad (t > \tau) \quad (14)$$

Therefore, let $\gamma = 1 - \xi_\mu$ to simplify the expression, we need to find the minimum T_0 such that:

$$\int_0^{T_0 - \tau} \left((1 - \gamma)^t + \frac{c_a^2 + c_s^2}{2W_0} (1 - \gamma)^{2t} \right) dt > T_0 \quad (15)$$

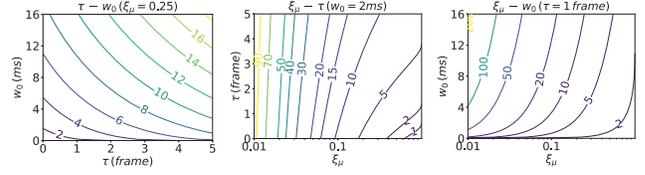

Figure 32: Contour plot of the convergence region of T_0 with different parameters.

By solving the integral in Eq. 15, finally we have

$$W_0 < \frac{c_a^2 + c_s^2}{2} \frac{(\gamma^{T_0 - \tau} - 1)(\gamma^{T_0 - \tau} - 3) + 2(T_0 - \tau) \ln \gamma}{2(\gamma^{T_0 - \tau} - 1) + 2\tau \ln \gamma} \quad (16)$$

For example, when set $c_a^2 + c_s^2 = 2$, we vary the other parameters in Eq. 16 and present the minimum T_0 in Figure 32. In the most general settings of AFR ($\tau = 1$ since the average RTT is around 15ms, $\xi_\mu = 0.25$ as introduced in §5.2, $W_0 = 2$ ms), the stationary controller can converge to the new stationary state within 2 frames. In other settings of the AFR parameters, the stationary controller could also converge and drain the queue within tens of frames, which is much less than the frame-rate adjustment interval of hundreds of frames as evaluated in §6.2.

LemonNFV: Consolidating Heterogeneous Network Functions at Line Speed

Hao Li¹, Yihan Dang¹, Guangda Sun^{1,2}, Guyue Liu³, Danfeng Shan¹, Peng Zhang¹

¹*Xi'an Jiaotong University* ²*National University of Singapore* ³*New York University Shanghai*

Abstract

NFV has entered into a new era that heterogeneous frameworks coexist. NFs built upon those frameworks are thus not interoperable, obstructing operators from getting the best of breed. Traditional interoperation solutions either incur large overhead, *e.g.*, virtualizing NFs into containers, or require huge code modification, *e.g.*, rewriting NFs with specific abstractions. We present LemonNFV, a novel NFV framework that can consolidate heterogeneous NFs without code modification. LemonNFV loads NFs into a single process down to the binary level, schedules them using an intercepted I/O, and isolates them with the help of a restricted memory allocator. Experiments show that LemonNFV can consolidate 5 complex NFs without modifying the native code while achieving comparable performance to the ideal and state-of-the-art pure consolidation approaches with only 0.7–4.3% overhead.

1 Introduction

The past decade has witnessed the flourish of Network Function Virtualization (NFV) research, with the goal of replacing hardware middleboxes with software network functions (NFs) running on commodity servers. Prior research efforts have led to a plethora of NFV frameworks focusing on various aspects, including performance optimization [30, 33, 35, 49], programming models [34, 41], resource management [51, 60], and more recently security [43, 52, 54]. Since there are no conventional and widely-adopted interfaces, these NFV frameworks are unsurprisingly implemented in *heterogeneous* ways, with different libraries (*e.g.*, DPDK [5], netmap [57]), languages (*e.g.*, C, C++, Rust), and abstractions (*e.g.*, Click element [37], BESS module [30]).

NFs built upon these heterogeneous NFV frameworks are not *interoperable*, which exposes two hard choices for users in actual deployment. The first choice is asking operators to learn, deploy, and maintain multiple frameworks to serve different purposes. The second choice is picking one framework and asking the developers to add extra functionalities

by reinventing the wheel. The former choice dramatically increases the cost of operation, and the latter choice requires substantial engineering effort and is error-prone. This reality raises a timely and important question: *can heterogeneous NFs interoperate without modifying the code?*

To answer this question, the first natural candidate solution is using virtualization. Under this model, each NF runs in a virtual machine or a container on one core, and packets are steered across cores to chain multiple NFs. While this approach hides the heterogeneity of NFs under standardized virtualization interfaces, it incurs prohibitive performance overhead when chaining multiple NFs [33, 49]. The overhead stems from three main sources: virtualized components, cache misses, and context switches (details in §2.1). Despite the efforts of various lightweight virtualization techniques [39, 56, 68], these overheads cannot be fully eliminated. As a result, this virtualization approach fundamentally cannot achieve the line speed, one of the key requirements of NFV deployment.

The second candidate solution is using consolidation. This model implements NFs as software modules and runs them in the *same* process. NFs are chained through function calls and scheduled in a *run-to-completion (RTC)* mode, *i.e.*, once a packet is received by an NF, the NF continues processing it until finishes. By eliminating cache miss and context switch overheads, this approach ensures the line-rate processing and has been adopted by existing high-performance NFV frameworks such as Metron [35] and BESS [30]. While consolidation works well for NFs under the same framework, it seems *unlikely* to be applied to heterogeneous NFs without modifying the code due to three key challenges across loading, scheduling, and memory management.

- *How to launch heterogeneous NFs in one process?* Launching NFs written with different frameworks and languages into the same process could result in various conflicts (*e.g.*, dependencies, functions, variables). A potential solution that manually modifying the code to resolve each conflict could be tedious.
- *How to chain multiple NFs with separate control flows within a process?* Each NF has its own control flow

which often includes an infinite loop of packet processing. Chaining these separate control flows requires locating new entry points and correctly schedule them to process packets.

- *How to isolate memory of multiple NFs within a process?* NFs running in the same process share the same stack and heap, without memory isolation. This brings security concerns when chaining multiple NFs from different and possibly untrusted vendors. A previous solution that rewrites NFs with safe programming languages would incur large porting efforts.

In this work, we propose *LemonNFV*, an NFV framework that enables consolidating heterogeneous NFs without modifying the code. To address the above challenges, LemonNFV provides three abstractions for NFs: the compiled binary, the scheduling entry points, and the memory allocation interfaces. The key point of these abstractions is that they (1) are essential and sufficient for making NFs interoperable, and (2) can be easily adopted to NFs without much coding efforts by capturing the natural homogeneity that already exists in all NF implementations. By transforming NFs into such *LEast Modified network functiONs (LEMONs)*, LemonNFV then implements a set of utilities upon those abstractions that load, execute and manage NFs inside a process. Concretely, we make the following contributions in designing LemonNFV.

Loading via LEMON Binary (§4.1 and §4.4). We view each NF as a software module and leverage the standard binary format to load them. The binary hides the complexity of NFs written in different languages and/or with conflicting names. To further enable dynamic chaining and NF migration, we build a *LEMON loader* to specify memory layout and resolve dependency conflicts, both of which are not supported by existing loaders (e.g., `ld.so`).

Chaining via Schedulable I/O (§4.2). We observe that packet I/O could be an ideal scheduling point where an NF's processing logic starts and ends. Based on this observation, we provide unified I/O interfaces as entry points for inter-NF scheduling. These interfaces can replace existing NFs' I/O interfaces, which are usually built on top of several common packet I/O libraries, such as DPDK, `libpcap` and `netmap`. To chain multiple NFs inside one process, we provide a *scheduler* to correctly switch between different NF control flows.

Isolation via Restricted Memory Interfaces (§4.3). We use a *restricted allocator* to set explicit *NF boundaries* by creating private stack and heap for each NF, which can replace the native memory allocation interfaces like `malloc` and its variants. To isolate different NFs in the process, we implement an *isolator* that leverages hardware-aided technique (Intel PKU) to realize efficient intra-process memory isolation¹.

We evaluate LemonNFV with real NFs and traffic (§6). The

¹Currently, our isolation model focuses on memory isolation only and does not support control flow integrity, state sharing and packet isolation as in related works [31, 52, 66]. See §4.3 and §7 for details.

results show that LemonNFV can (1) consolidate 5 complex NFs without code modification – even they are implemented with different frameworks and/or languages; (2) realize comparable performance to the ideal and state-of-the-art consolidation approaches with only 0.7–4.3% overhead of isolation. *Ethics:* This work does not raise any ethical issues.

2 Motivation

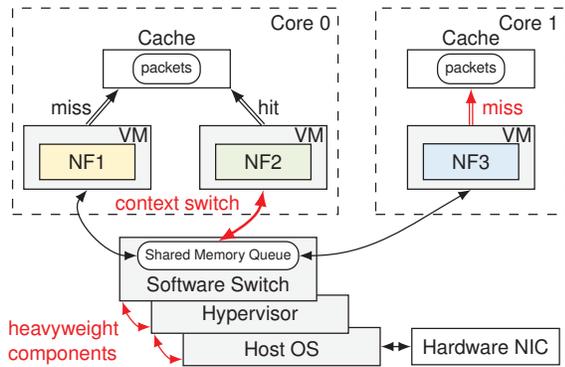

In this section we explain why neither virtualization (§2.1) nor existing consolidation techniques (§2.2) can address the need of heterogeneous NF interoperation.

2.1 Virtualization is Slow

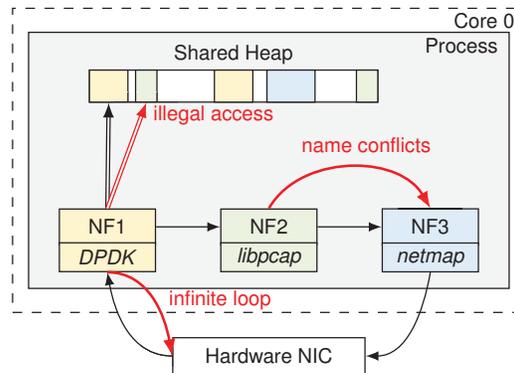

Figure 1a shows the three types of performance overhead incurred by virtualization approaches. (V1) *Heavyweight components:* Packets may need to go through all levels of virtualization components: host OS, VM hypervisor, guest OS and software switch. Each of the components brings a non-negligible overhead since they may run protocol stacks and perform queueing. (V2) *Cache misses:* If the NF instances are deployed on separate cores, passing packets across cores will be inevitable, in which case accessing each packet will become LLC or DRAM bounded. Moreover, passing packets across cores is often achieved by software switches, requiring frequent enqueueing and dequeuing when the NFs send and receive packets. (V3) *Context switches:* Scheduling will happen if there are multiple NF instances pinned to a single physical core, which would result in extra switching overhead.

Researchers have been leveraging the emerging lightweight virtualization techniques to improve the performance of virtualization NFV systems. By reducing full-fledged VMs into more lightweight environments, such as containers [21, 61, 63, 68], unikernels [39, 46, 69], and even processes [40, 42, 56, 76], the virtualization overhead, *i.e.*, V1, is greatly reduced or eliminated, yet still preserving V2 and V3.

In fact, running NFs as separate instances makes it impossible to reduce V2 and V3 at the same time. Pinning instances to dedicated cores (e.g., OpenNetVM [76], NFP [64]) eliminates the overhead of context switches (-V3), but forces packets to be delivered over shared memory and results in L1/L2 cache misses (+V2). On the other hand, compacting instances on a single core (e.g., Quadrant [68], EdgeOS [56]) would reduce the cache misses on packets (-V2), while frequent context switches can lead to much more system calls and TLB misses (+V3). Therefore, we reach a conclusion that virtualization-based NFV frameworks can hardly meet line-rate (*i.e.*, 100/400Gbps) processing requirements because of its inherent overhead.

(a) A virtualization approach that runs NFs as separate instances. Red arrows indicate the major source of overhead, and grey boxes are components that can be optimized out.

(b) A consolidation approach that executes NFs in a single process. Black arrows are the ideal workflow while the red ones signify the obstacles when the NFs are heterogeneous.

Figure 1: The virtualization approach is slow, while the consolidation cannot handle the conflicts between heterogeneous NFs.

2.2 Consolidating Heterogeneous NFs is Hard

Consolidation, on the other hand, avoids all the extra overhead from the virtualization approaches by eliminating the boundaries between NFs [17, 30, 35, 52, 61]. Under this model, the SFC is deployed in one process, *i.e.*, no *VI*, and NF instances are executed in an RTC manner *i.e.*, no *V2* and *V3*, as shown in Figure 1b. However, it introduces even more challenges when trying to consolidate heterogeneous NFs.

Challenge 1: NFs cannot be loaded. NFs are independently developed with different frameworks and abstractions. As such, when putting them together in the same process, they may conflict with each other in terms of dependencies, functions and variables. For example, two NFs may define global data structures with the same name, while simply linking their source code would raise a multi-definition error. Things get more complex if NFs are written in different languages.

Naive solution: A naive solution for loading NFs into a single process includes three time-consuming tasks. First, operators have to check all symbols exposed by NFs to locate the conflicts. Second, they should manually resolve the conflicting symbols, which however is not always a feasible task, considering the conflicts that may happen between closed-source libraries. Third, they need to reconstruct other code with the resolved name, which usually requires deep understanding of the whole NF codebase. Despite the above tedious efforts, manual resolution can never work for the cross-language NFs or dynamic SFC updating without halt.

Challenge 2: NFs cannot be scheduled. The workflow of each NF is driven by an infinite loop of receiving and sending packets, *i.e.*, processing packets after receiving them, and receiving more after sending the processed ones. As a result, an NF will take up a core forever once it starts running, and the downstream NFs in the same process will never be scheduled.

Naive solution: To break the infinite loop inside each NF, one could extract the packet processing logic of each NF, and combine them together to form a synthesized SFC [17, 35,

36]. However, the packet processing logic is closely coupled with NF-specific packet and state abstractions, and combining them results in a large amount of code modification. For example, Snort [10] leverages its unique Data Acquisition Library (DAQ) to receive packets and fill the metadata like timestamp, protocol annotation, *etc.* Such packet abstraction is incompatible with the packet abstraction under Click [37]. As a result, composing a synthesized SFC of Snort→Click requires to transform the packets as well as all metadata from the DAQ abstraction into the Click abstraction, and vice versa for Click→Snort.

Challenge 3: NFs may affect each other. Being in the same process, all NFs share the same stack and heap. In this way, operators are not able to restrict any memory operations of allocation, read and write, and thus lose the control over illegal accesses, *i.e.*, each NF can (unintentionally) modify others' data and make their states inconsistent. For example in Figure 1b, NF1 (yellow) can silently modify the data (red arrow) allocated by NF2 (green).

Naive solution: Consolidation frameworks often choose to trust the NFs under the same process since they come from the same vendor. However, trust cannot be granted when it comes to heterogeneous NFs across vendors. Using safe language, *e.g.*, Rust in NetBricks [52], to rewrite the NFs is a feasible option, but it's not practical given the large body of existing NFs and limited popularity of the safe language. Formal verification on NFs [72, 74, 75] on the other hand requires verification expertise and sometimes also forces NFs to use certain APIs [73].

3 LemonNFV Overview

The heterogeneous NF consolidation is challenging because NFs in the same process share the namespace, the control flow, and the memory. In this section, we introduce the key abstractions for breaking such sharing, and explain why they can be easily adopted without code modification (§3.1). We

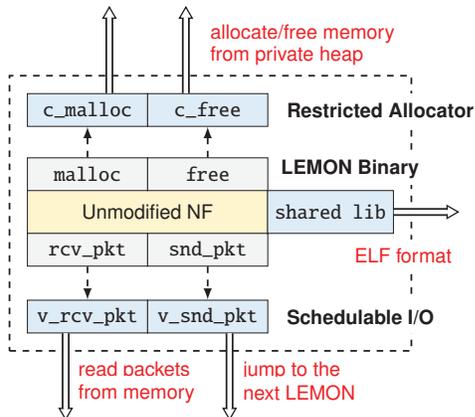

Figure 2: A LEMON with unified abstractions of binary, I/O and memory interfaces. Grey boxes are the common points existed in NFs, and the blue boxes modify/leverage their semantics for providing the unified behaviors (red annotations).

then overview the workflow of LemonNFV that implements a set of utilities upon those abstractions, including the loader, scheduler, isolator and the migration manager, to load, execute and manage LEMONS within the same process (§3.2). We finally discuss the ongoing challenges of LemonNFV (§3.3), which will be addressed in the next section.

3.1 Unified LEMON Abstractions

A LEMON carries an unmodified NF with its own namespace, control flow and memory, each of which could conflict with other LEMONS inside the process. The key challenge here is to decide the proper level to resolve the conflicts. Typical solutions either choose the lowest level for avoiding the code modification, *i.e.*, packaging NFs into OS-level containers, or operate at the highest level for ideal performance, *i.e.*, rewriting NFs' source code, neither of which can fully address our goal.

Instead, LemonNFV aims to resolve such conflicts with three middle-level abstractions: a binary that isolates the namespaces of each NF, a set of I/O interfaces that decouple the packet processing logic from infinite loop, and a set of memory interfaces that restrict the memory operations. These abstractions are high-level enough for resolving the underlying conflicts, while also low-level enough to hide the heterogeneity. In fact, there exists natural homogeneity in all NFs' implementation, and by leveraging it, LemonNFV can equip any NF with the proposed abstractions by a simple interception, *i.e.*, without code modification.

LEMON binary: wrapping the namespace. Simply putting all NFs' code together usually does not compile, because the independent-developed NFs might define variables, functions and dependencies with the same name but different semantics, which would cause name conflicts. Instead of manually wrapping an NF into an isolated namespace, *e.g.*, packing it to a C++ class with private members, we observe that the

compiled binary naturally separates the namespaces of each software module, and the conflicts can be resolved through the symbol resolution process when loading the binary.

Natural homogeneity: ELF is the standard format for executables and shared libraries under Linux, which reveals a chance for LemonNFV to package each NF as a software module without modifying its native code but through a simple recompilation (right part in Figure 2).

Schedulable I/O: creating entry points. The packet processing logic of NFs are usually implemented as an infinite loop, which is not schedulable. Nevertheless, we observe that the I/O behaviors reveal the natural boundaries between NFs. To this end, we design a new set of I/O in substitution for the original, which creates explicit entry points of each NF for scheduling: for the packet receiving function, it could read packets from a shared memory region instead of the physical NIC; for packet sending, it could jump out of the infinite loop after pushing the packets back to specific queues on shared memory, according to the output port of the NF.

Natural homogeneity: NFs are built on a handful of I/O libraries like DPDK and libpcap, which means we can implement the schedulable I/O by only intercepting limited functions of these libraries (lower part in Figure 2).

Restricted allocator: separating memory domains. To realize the isolation requirement, one should create isolated memory regions for each of the NFs, even with the same process. While not all NFs have the compilation support from safe languages like Rust, the feasible solution is to create separate (instead of interleaved) memory domains for each NF, and protect those domains with bound guard [67] or privilege management [14, 53].

Natural homogeneity: All NFs rely on the native allocator, which only provides limited functions like malloc, realloc and free. That is, LemonNFV can override the native allocator with the restricted allocator, which enforces that the dynamic memory allocation in a LEMON takes place in its own heap (upper part in Figure 2).

3.2 LemonNFV Workflow

Having the above unified LEMON abstractions, LemonNFV implements several key components to build, execute and manage LEMONS. As shown in Figure 3, an SFC is a process (dashed rectangle) that runs two types of threads: hypervisor (red) and worker (gray). The hypervisor consists of two components: the LEMON loader that loads LEMONS and intercepts the original allocator and I/O functions, and the migration manager that migrates the LEMON to another worker, SFC, or server. The worker implements the trampolines, which process the packets from the hardware NIC, schedule a chain of LEMONS with virtualized I/O while ensuring their isolation. There is also a LemonNFV controller, relaying the user commands like LEMON loading to the hypervisors, which can be deployed on a remote server.

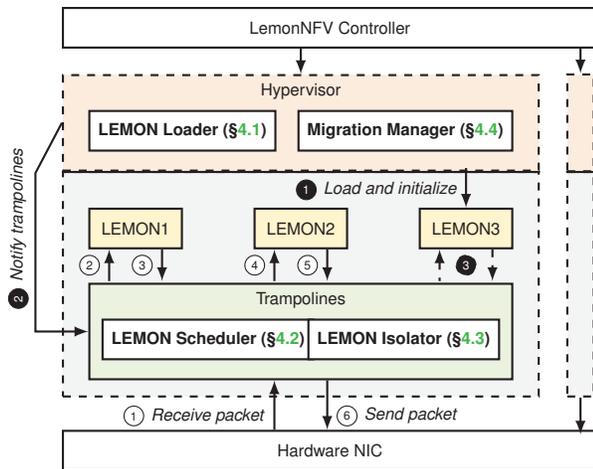

Figure 3: LemonNFV workflow, where a dashed rectangle represents a process (SFC) with two threads: a hypervisor (red) and a worker (grey). ①–⑥ illustrate how a packet being processed; and ①–③ are for runtime SFC changing.

Loading a LEMON. Each LEMON carries an unmodified NF, as well as its dependent libraries and configuration files. To this end, the NF developers are required to recompile the NFs into shared libraries, which only needs a few lines of modification in the make rules (See §6.2). This task can also be done by the operators if the target NF is open-source. Then, the operator should fetch all dependencies of the LEMON, pass their paths to the loader, and specify the total amount of memory needed. With these information, the LEMON loader would allocate the memory, load the code and variable segments, resolve the potential conflicts, and grant the corresponding privileges. The user can then consolidate an SFC by providing the path and interconnection of each LEMON in an interactive terminal.

Chaining and isolating LEMONS. Inside each worker, LemonNFV executes a chain of LEMONS in the RTC way. When receiving a (batch of) packet(s) from NIC (①), the LEMON scheduler in the trampolines will pass the packet to the first LEMON of the SFC, by calling its schedulable packet-receiving function (②). After the processing in LEMON1, the schedulable packet-sending function would transfer the control flow back to the trampolines (③), which would trigger the next LEMON, *i.e.*, LEMON2 (④). When it reaches the end of the chain (⑤), the trampolines send the packet(s) back to NIC (⑥). All of ①–⑥ are done within a single thread, thus will not produce any inter-core communication or thread context switch. When an SFC wants to scale out its performance, LemonNFV can duplicate the worker into more cores, and dispatch the flows using hardware NIC.

The trampolines also ensure the LEMON isolation through above chaining process. Specifically, the LEMON isolator would adjust the memory access privileges of each LEMON, *e.g.*, when executing LEMON2, the memory domains of LEMON1 and LEMON3 should be protected.

Managing LEMONS in runtime. Consider a simple management task that attaching LEMON3 to the end of current SFC. The hypervisor would first load and initialize LEMON3 (①) using the LEMON loader. After that, it will notify the trampolines with the new LEMON, *i.e.*, the packet receiving function of LEMON3 (②). Finally, the trampolines will execute LEMON3 next time a packet leaves LEMON2 (③). Note that the hypervisor is in an individual thread, which means ① can be done asynchronously without halting SFC. ② is also lightweight, as the hypervisor only needs to notify the trampolines with the new entry point, which is a rare operation and would only halt the SFC for a negligible moment.

3.3 Ongoing Challenges

While making the LEMON interoperation a possible vision, LemonNFV is still faced with several practical challenges.

Isolated LEMON namespace. LEMON binary wraps the namespaces of each NF, but the name conflicts between multiple binaries still needs to be resolved. This is the responsibility of the LEMON loader, while the OS-default loader cannot suffice, because it tends to reuse the dependencies for all LEMONS.

Correct LEMON scheduling. Having the schedulable I/O, the LEMON scheduler in the trampolines needs to further address the following concerns for correctly scheduling the LEMONS. (1) how to efficiently switch LEMONS; (2) how to properly execute the logic other than the packet processing, *e.g.*, initialization; and (3) how to correctly handle the complex I/O behaviors like asynchronous Rx and Tx.

Efficient memory isolation. The restricted memory allocator guarantees the separate memory domains for each LEMON. However, it is still unclear how the LEMON isolator restricts the memory accesses to the legal areas. The key challenge here is to isolate those memory domains without compromising too much performance.

Flexible LEMON migration. NF migration is a critical requirement in NFV systems. Even with the help of the LEMON loader, it is still unclear for the migration manager to migrate the LEMONS to other workers, SFCs or even servers. The key challenge here is that the LEMON loader can only handle a LEMON as a whole, while the inner data structures (*i.e.*, NF states) of a LEMON might need to be *partially* migrated to another core or re-accessed in a different process for intra- or inter-server load balancing.

4 Detailed Design of LemonNFV

In this section, we discuss in details how LEMONS are loaded (§4.1), scheduled (§4.2), isolated (4.3) and migrated (§4.4) using the unified abstractions of LEMON.

4.1 Loading the LEMONS

Given an ELF binary, the loader is responsible to allocate the memory for the executable, copy the segments to the corresponding memory regions, resolve the external symbols, and finally call the constructors. While Linux has offered a mature toolchain for loading the ELF file at runtime, *i.e.*, `dl`-family functions, they are ill-suited for serving as the LEMON loader. In the following, we explain the specific requirements when loading a LEMON, and present our solution for the LEMON loader.

Dependency isolation. The OS loader, *i.e.*, `ld.so` with `dlopen`, attempts to reuse the libraries that have been already loaded for saving the memory and improving instruction cache affinity. However, this would cause dirty access of common libraries if multiple LEMONS depend on them.

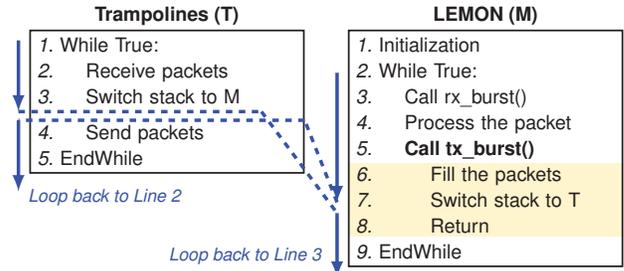

In LemonNFV, the LEMON loader views each NF and its dependencies as a sandbox, and will load the dependencies no matter whether other LEMONS have already loaded them. For example, each LEMON will load its own `libc`, such that they will not share the global variables like `optarg`, so that

Targeted symbol resolution. While loading, lots of functions in LEMONS should be intercepted to the customized versions, *e.g.*, the DPDK I/O to the schedulable I/O, the native `malloc` to the restricted `malloc`. The common solution to this task is `LD_PRELOAD`, which instructs the loader to first lookup the preload libraries when resolving every symbol of the executable. However, `LD_PRELOAD` redirects *all* symbols with the same name, while LEMONS and trampolines should use different versions. For example, trampolines call `rx_burst` to receive packets from NIC, which should not be resolved to the schedulable version as in LEMONS. Besides, LEMONS may depend on different versions of the libraries, and the intercepted functions with the same name also need vary to those semantics.

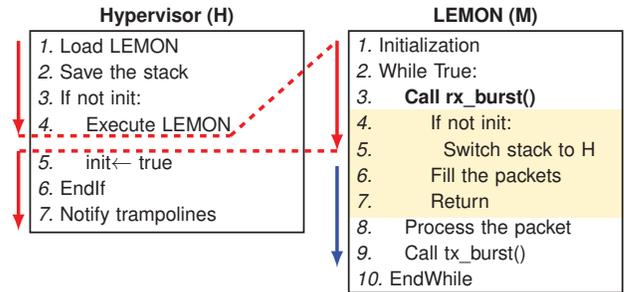

LemonNFV implements a symbol resolution mechanism tailored for loading LEMONS, which allows the trampolines and each LEMON to specify their own preload libraries, enabling different semantics for symbols of the same name.

Consistent loading address. The Linux loader cannot manually specify the loading address. Instead, the recent Linux kernels enable the random address loading, *e.g.*, ASLR [1], mostly due to the security reason. Such random loading would disable the ability of reloading a LEMON, because all pointers in the reloaded LEMON would become invalid. This feature is critical for fault recovery and LEMON migration.

To this end, the LemonNFV process reserves the same virtual address space, which is partitioned into fixed-size *slots*. the LEMON loader would load each LEMON to its *unique* slot, and allocate the fixed address regions for the private stack, heap and dependencies. As a result, all the pointers (expect packet pointers) in a LEMON snapshot would remain valid even being reloaded or migrated to another process.

(a) Scheduling between the trampolines and the LEMON.

(b) Initialization with the hypervisor.

Figure 4: Scheduling LEMONS with the schedulable I/O and private stacks. Solid arrows indicate the executing paths, and dashed lines are the function/stack transitions. The blue paths are executed by the working thread, and the red ones are from the hypervisor thread. Shadowed texts are the pseudocode of `tx_burst` and `rx_burst`.

4.2 Scheduling the LEMONS

A typical NF implementation consists of four stages: (1) the NF initializes its own data structures and hardware; then it starts an infinite loop which (2) receives packets using a function like `rx_burst(pkts)`; (3) processes the packets; and (4) sends the packets out using a function like `tx_burst(pkts)`. The LEMON I/O interfaces unify the way for LEMONS to fetch and send packets, *i.e.*, stage 2 and stage 4. Specifically, the LemonNFV trampolines are responsible to communicate with the hardware NIC. And the “NIC” in the LEMON is actually a memory region that stores the packets. As a result, `rx_burst` should fill `pkts` (the pointers of packets) with the packets from the trampolines; and `tx_burst` should fill `pkts` back to trampolines for the downstream LEMONS.

Having those basic I/O operations, how to schedule the LEMONS such that the packets can flow through them as if they were chained together will be our focus here.

Scheduling LEMONS with schedulable I/O. Each NF has its own control flow, from `main` function to the infinite loop of packet processing. The LEMON scheduler needs to cooperate with those control flows to properly jump into and out from the LEMON execution.

To this end, LemonNFV creates private stack for each LEMON, making its control flow separated from the trampolines and one another. Specifically, LemonNFV allocates a dedicated memory region for each LEMON as its stack, and

the trampolines maintain the corresponding stack pointers (*i.e.*, SP and BP registers). In this way, the LEMON scheduling can be simply implemented as saving the current states of registers (stack pointers and other callee-saved registers) and restoring the previously saved ones of the target LEMON. This process operates purely in the user space, thus incurs much less overhead than the context switch between processes or threads, which would trap into kernel and flush TLBs. We implement the above stack switch logic in the packet sending functions, because each time the NF is sending the current batch of packets out of the NIC, the control flow should move to the next NF in the SFC.

We use Figure 4a to illustrate how the scheduling works. Assume the SFC has only one LEMON, which has processed a batch of packets and is sending them out, *i.e.*, calling (the schedulable) `tx_burst` in Line 5 of M. After filling the packets, the execution stack is saved and switched to the trampolines (from Line 7 of M to Line 3 of T). The trampolines then send the packets to the NIC (Line 4 of T). In the next loop it receives a new batch of packets (Line 2 of T) and schedules the LEMON again (Line 3 of T), which will jump back to Line 7 of M. The LEMON will continue to receive and process the packets from the trampolines, *i.e.*, Line 8–9, 3–4 of M, until it is scheduled out, *i.e.*, `tx_burst` is called again. Any additional logic besides Line 4 (*e.g.*, profiling after sending packets) will also be executed at this moment.

Handling the logic other than packet processing. The hypervisor needs to take care of the LEMON initialization, which, like the packet processing logic, has no explicit boundary in the NF's code. To this end, we view the initialization as the logics from the first line of `main` function to the *very first time* the `rx_burst` is called, which means all preparations for packet processing have been done. We use Figure 4b to depict such process. The hypervisor thread (red path) loads the LEMON, saves its stack and executes the LEMON (Line 1–4 of H). After LEMON is initialized (Line 1 of M), it will eventually call (the virtualized) `rx_burst` (Line 3 of M). For the very first time it is called (*i.e.*, `init==0`), the LEMON should switch back to hypervisor's logic, and the hypervisor will notify the trampolines that the initialization is done. The trampolines will execute the LEMON from the saved stack (Line 6 of M) next time it is scheduled.

Except for the initialization, NFs may also include logic for event logging and runtime configuration. These routines are usually conducted in individual threads. See Appendix A for scheduling a LEMON with such threads.

Complex I/O behaviors. The above scheduling assumes the NFs call the packet I/O in a synchronized way, *i.e.*, receiving (Rx) and sending (Tx) once per batch, while NFs can also invoke less Rx and more Tx (*e.g.*, multicast), or more Rx and less Tx (*e.g.*, packet buffering). The current scheduling is based on Tx, thus can still handle the former case, and we extend the virtualized Rx I/O to deal with the latter. To be

specific, we add a flag in virtualized Rx function to check whether it is called *for the first time in this batch*. If not, the Tx function is not called, which means this LEMON buffers or drops all packets, and blocks the downstream LEMONS. In such case, the trampolines should continue to receive the next batch instead of scheduling the next LEMON, ensuring correctness of NFs that buffer packets (*e.g.*, Reframer [28]).

4.3 Isolating the LEMONS

LemonNFV provides each LEMON with a separate memory domain via the custom allocators, so that the legal region a LEMON can access is bounded. However, achieving this is far from sufficient to isolate each LEMON from each other, because the illegal accesses are only *defined* but not *prevented*. We now discuss how LemonNFV checks illegal memory accesses efficiently. In the following, we first present the threat model of LEMON isolation, then introduce two *software fault isolation (SFI)* techniques to sandbox the memory accesses. After making our design choice, we present how LemonNFV realizes the LEMON isolation in runtime.

Threat model. LemonNFV isolates the SFCs from different tenants with processes. For each process, LemonNFV allocates two virtual functions (VFs), *i.e.*, NICs virtualized by SR-IOV [15], which provide almost the same performance compared to the physical NIC. Given such strict isolation between SFCs, we only need to take care the isolation between LEMONS along the SFC, *i.e.*, the intra-process isolation.

We assume each NF has its own packet processing logic, which are expected to be independent of the others. That is, even in the same process/thread, the data and states of NFs are strictly independent. This assumption disables most communications between NFs, and thus is weaker than NetBricks's threat model that supports state sharing [52]. However, we argue that this assumption is actually aligned with the case when chaining physical middleboxes, where the internal states are unavailable to external NFs, and packets are the only information that can be exchanged between NFs.

We assume the trampolines and hypervisor are written with care, while NFs are written in a negligent way that they might illegally modify the data, *e.g.*, overwrite the state in other NFs or hypervisor. Such bad operations can happen in either NF itself, *e.g.*, `*(bad_addr)=1`, or the libraries it depends, *e.g.*, `memset(good_addr, 0, bad_size)`.

Two design options. The above threat model falls into the SFI area, where the most classical implementation is to check the bound of each memory write [38, 67, 71], *e.g.*, `*p=1` would be modified into `if(p>L&&p<H) *p=1` to ensure p is always within its own memory region (L, H). Its performance is determined by (1) the number of the legal regions, since each instrumentation must check all these regions, and (2) the number of memory access statements, which equals to the number of instrumentation.

Recent studies advocate to leverage hardware-aided techniques to realize SFI [31, 45, 66]. To be specific, they partition the memory into domains, and a certain software module can only access its legal domains. When switching to another software module, this method has to change the legality of the domains. As such, its runtime overhead is mainly determined by the number of domains. Another defect of domain switching is that it restricts the number of domains due to the limitation of hardware.

Our design decision. Bounds checking would incur unacceptable runtime overhead for realizing LEMON isolation for the following reasons. First, the legal regions of a LEMON, *e.g.*, code, stack and heap, are separate, making each instrumentation quite costly. Second, the number of memory access statements could be large for NFs like encryption, which further lowers the performance. To make the performance penalty clear, we implement an extra compiling pass in LLVM that injects bound checking before every memory write at the IR level. We then prototype three typical NFs including NAT, firewall and IDS, and by chaining them into an SFC, we find that the isolated SFC is in average 24% slower than the original one. Such penalty is usually unacceptable for realizing the wire-speed processing.

On the contrary, we find domain switching is quite suitable for LEMON isolation. Recall the threat model that LEMONS do not share states between each other. That is, each LEMON can be packaged into a disjoint domain, such that the number of domain switching is actually the length of SFC, which is fixed and stable no matter how complex a LEMON is. For the limitation on number of domains, it should still be sufficient for LEMON isolation, since the length of SFC is usually small, *i.e.*, less than 10 for most real-world cases [4]. As a result, the domain switching approach is preferred to realize SFI between LEMONS.

Among the others like VMFUNC that require code modification [38, 45], PKU has been viewed as the fastest domain switching approach and requires little modification on existing code [31, 66]. PKU uses the spare four bits in each page table entry to partition memory into 16 domains, and specifies the access restrictions for each domain by a *pkey*. In doing so, the protection can be naturally guaranteed when accessing the page table, and thus incurs *zero extra cost* in runtime. More importantly, the operation of domain-switching, *i.e.*, writing the permissions to *pkeys*, purely works in userspace and only incurs negligible overhead, *i.e.*, less than 100 cycles.

Isolating LEMONS with PKU. Inside the process, LemonNFV specifies one *pkey* for each LEMON. In runtime, when a LEMON is scheduled by the trampolines, LemonNFV enables its *pkey* to grant the access rights to its own domain, *i.e.*, its own stack, heap and data segments, and disables the access to any other domain. Since the switching happens when scheduling LEMONS, the switch logic is embedded into the schedulable I/O for each LEMON.

Consider a simple example with two LEMONS, M1 and M2. The trampolines' domain occupies *pkey0*, and each LEMON (as well as its stack, heap and dependencies), is allocated with one *pkey*, *i.e.*, *pkey1* and *pkey2*, respectively. The packet domain is always readable/writable to trampolines and LEMONS, and thus does not need a specific *pkey* to protect. At runtime, when trampolines are receiving or sending packets, all three *pkeys* are enabled, because trampolines have the full visibility to all domains. Before going into M1, trampolines would disable *pkey0* and *pkey2*. After M1's processing, the schedulable I/O in M1 would enable *pkey2* for M2's processing. After the processing of the last LEMON, *i.e.*, M2, its schedulable I/O will disable *pkey2* and enable *pkey0* to jump back to trampolines. Note that to reduce the domain switching, M1 would directly jump to M2 instead of jumping back to the trampolines. In general, LemonNFV would switch $N + 1$ times for an SFC with N NFs.

4.4 Migrating the LEMONS

NF migration is essential when operators seek a balanced load and/or efficient resource utilization. Existing works realize this feature on top of a fully supervised infrastructure, *e.g.*, OS-level virtualization [12, 44], or through specific migration interfaces, *e.g.*, OpenNF [27]. Without above prerequisites, LemonNFV leverages the standard LEMON binary to empower users to migrate the LEMONS to other cores and machines in an efficient way².

Intra-process LEMON migration. In consolidation approach, it is important that packets should be evenly dispatched to the workers, otherwise the CPU resources are wasted [35]. Due to the dynamics in network (*e.g.*, traffic burst) and resources (*e.g.*, adding a core), such balance is hard to achieve if statically binding packet classes (*i.e.*, a set of flows) to cores. Instead, the NFV framework needs to migrate the packet classes *and* the corresponding NF states to a new core, to balance the working load.

LemonNFV addresses this challenge by relieving the close binding between cores and LEMONS, making the consistent migration possible for any state structures used in LEMONS. To be specific, LemonNFV creates a pool of LEMONS, each of which is dedicated for a packet class. Given the simple fact that both executable code and states are within the LEMON, "migrating the state of packet class P to core C " becomes "letting core C execute the LEMON corresponding to P ".

Figure 5 shows a simple migration scenario, where the operator allocates two cores (C_1 and C_2) to handle three packet classes (P_1 – P_3). In this case, LemonNFV will create three LEMONS (M_1 – M_3) dedicated for P_1 – P_3 , and ensure that cores will always handle the packet classes with their corresponding LEMONS. Assume we want to migrate P_2 to C_2 . The

²The proposed migration schemes are for common load balancing scenarios, while specific migration cases, *e.g.*, migrating an arbitrary flow, balancing a non-splittable flow, are not supported. See §7 for a discussion.

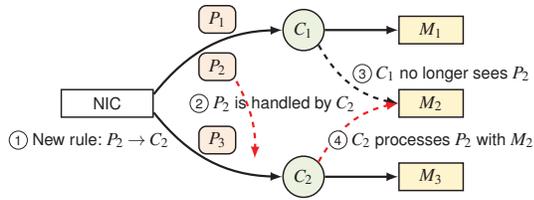

Figure 5: Intra-server LEMON migration. C_1 and C_2 are cores, P_1 – P_3 are three packet classes, and M_1 – M_3 are three identical LEMONS dedicated for P_1 – P_3 .

hypervisor first issues a new rule to the NIC (or modifies the global RSS table [16]), which directs the NIC to tag and send P_2 to the queue binding to C_2 (①). At this point, all packets belonging to P_2 will be handled by C_2 (②), and C_1 cannot see P_2 's packets immediately (③). When C_2 receives the packets of P_2 , it can safely process them with M_2 (④). Since the states of P_2 are always within M_2 , there is no need to synchronize or copy states between cores. However, since each core has a receive queue, there is a minor risk that C_1 still holds a few packets of P_2 after the migration. For this case, we could create a receive queue for each packet class, and let different cores to handle the queue while migration, which would cost little performance [16].

②–④ are natural consequences of ①, meaning that the overhead of migration is essentially the time of rule installation, which only amounts to sub-milliseconds.

Inter-process LEMON migration. Besides the intra-server load balancing, the network-wide load balancing calls for migrating LEMONS across different LemonNFV servers (processes) in runtime. This is done by (1) allocating identical addresses for LEMONS across processes and (2) migrating the snapshots (memory dump) of LEMONS iteratively.

For the first, the LEMON loader has ensured the address consistency across different processes. One concern here is that can a single process provide enough address space, if considering different types of NFs and per-packet-class pool of LEMONS. In fact, modern 64-bit system can easily reserve 96TB of virtual memory (*e.g.*, $0x100000000000 - 0x700000000000$) to support 32768 LEMON instances (6GB memory each), *i.e.*, 128 types of NFs with 256 packet classes, which are sufficient given limited number of popular NFs. Note that this restriction is for the unique LEMONS in *network-wide* servers, and the length of SFC in a single server is still bounded by the physical memory and PKU limitation.

Secondly, LemonNFV needs to realize a packet-lossless migration. In runtime migration, the snapshot is taken after the LEMON losing references over a batch of packets, and is transmitted to its destination. The LEMON loader then loads it into the corresponding slot and modifies the SFC. Since all states are within the LEMON, the migration will not lose any state. However, the cross-machine transmission might be time-consuming due to the large snapshot, resulting in packet losses to the LEMON.

To this end, LemonNFV iteratively copies the snapshot [12].

Specifically, in phase -1, LemonNFV pre-copies the whole snapshot to the target, and uses dirty page tracking [8] to locate that a portion of memory d becomes dirty through this phase. Then in phase 0, LemonNFV only transmits the dirty bytes, and locates the new dirty memory d . When d is getting smaller, the transmission time also decreases, which further reduces d in the next phase. Iteratively, the dirty memory transmission can finish within a negligible time, which is the right timing to route the packets to the new machine. See Appendix B for a detailed implementation.

5 Implementation

We implement a prototype of LemonNFV with 5K lines of C code, including the unified abstractions, *i.e.*, the schedulable I/O and the restricted allocator, and the system components, *i.e.*, the LEMON loader, the LEMON scheduler and the LEMON isolator with PKU. We highlight several key implementations and enhancements in our prototype.

Schedulable I/O. The prototype implements a schedulable version for all I/O functions used by NFs in §6, which includes 28 libpcap [7] and 41 DPDK [5] functions. The user can easily intercept I/O interfaces not included in the prototype by adding functions to the preload libraries when involving new NFs.

Restricted allocator. As mentioned in §3.2, each LEMON should notify its memory budget to LemonNFV. This is to avoid the runtime fault like memory leak: if the customized memory allocator detects that a LEMON exceeds its memory limitation, LemonNFV can unload it before it drains all host memory. Besides, this also enables a simple but effective optimization, *i.e.*, memory pre-allocation, which can largely improve the memory performance in runtime for memory-intensive NFs. To be specific, when a LEMON requires a certain portion of memory, the customized memory allocator pre-allocates all memory in the heap, so that it does not need to make expensive syscalls like `mmap` in runtime.

Fault isolation. §4.3 mainly considers the memory isolation, while the *fault isolation* is also critical for consolidation approaches. Since all NFs are in the same process, a runtime fault, *e.g.*, divided by zero, of a single NF would fail the whole chain. This task is addressable with the help of the trampolines in LemonNFV. First, LemonNFV registers a set of signal handlers for dealing with the runtime fault like SIGABRT, SIGSEGV and SIGILL. Then, once those signals are captured, the trampoline can decide how to prevent the faulty LEMONS from impacting others. In the prototype we simply remove the faulty one and pass the packets to downstream LEMONS. Other policies like restoring a LEMON to its nearest checkpoint can also be implemented based on the above fault capture scheme.

6 Evaluation

In this section, we evaluate the practicality, performance and overhead of LemonNFV with real and synthesized NFs. We are particularly interested in the following questions.

- 1) Can LemonNFV consolidate heterogeneous NFs to obtain high performance without much coding effort? Experiments show that LemonNFV can consolidate real NFs from different frameworks as the virtualization approach, *i.e.*, without modifying native code, and achieve a high-performance SFC as the consolidation approach, *i.e.*, incurring minor overhead between NFs (§6.2).
- 2) Can LemonNFV outperform state-of-the-art NFV systems? Experiments show that LemonNFV is 1.9–2.4× faster than a state-of-the-art virtualization approach, and incurs only 0.7–4.3% overhead compared to a state-of-the-art consolidation approach (§6.3).

6.1 Experimental Setup

Testbed. Our testbed is an x86 machine (24×Intel Xeon 3Ghz, 256GB memory) equipped with a Mellanox CX-6 DX NIC (2-port 100Gbps). Hyperthreading and frequency boosting are disabled in all CPUs, and the host OS is Ubuntu 20.04 with Linux kernel 5.11. We use DPDK 21.05 as the packet I/O for LemonNFV with 32 as the batch size, and enable S-RSS in multi-core experiments.

We prepare two traces for testing: ISP trace from a large service provider that contains majorly TCP flows (8.6M packets, 3.9M active flows, 652 bytes in average) and ENT trace captured from an enterprise network which mostly consists of GTP (UDP) packets (11.2M packets, 462 bytes in average).

Another server with the same NIC replays the traces to the testbed at line rate, serving as the packet generator. The testbed is configured to forward all traffic back to the generator, no matter whether NFs drop them or not. We run each experiment under 100Gbps traffic and record the average value of 20 seconds. Each experiment is then repeated 10 times and the average result is reported.

Real NFs. We consider NFs built upon the fast userspace I/O (DPDK) and kernel I/O (libpcap). We involve three DPDK NFs: an IDS based on Rubik [41] that matches the reassembled payload with snort-like rules; a NAT based on FastClick [17] that is composed of many inherent elements like traffic classifier and ARP querier; and an ACL based on NetBricks [52]. We further involve two libpcap NFs: a connection tracker (CT) based on mOS [34] that tracks the status of TCP connections; and a DPI tool based on nDPI [9] that can identify 170+ L7 applications.

Synthesized NFs. We further choose several synthesized NFs which are feasible to be ported, such that we can fairly compare them under different frameworks. We use NFD [32] to produce four stateful NFs: network address port translator, heavy hitter detector, super spreader detector, and UDP flood

Table 1: The real NFs and the efforts for interoperation.

NF	Framework	Lang.	I/O	CN	CF	CH
IDS	Rubik [41]	C	DPDK	337	31K	2
NAT	FastClick [17]	C++	DPDK	94	331K	2
ACL	NetBricks [52]	Rust	DPDK	401	58K	8
CT	mOS [34]	C	libpcap	325	139K	4
DPI	nDPI [9]	C	libpcap	4498	121K	2

CH: the LOC modified by LemonNFV for interoperation

mitigation. We further extract four NFs from OpenNetVM’s repository [76], including payload scanning, stateless firewall, AES encryption and decryption, which are stateless but computing-intensive.

6.2 Comparing with the Ideals

When interoperating, *i.e.*, chaining, isolating and managing, heterogeneous NFs, we have two ultimate goals: without code modification *and* performance penalty. To this end, we use the real NFs to compare LemonNFV with two ideals, *i.e.*, a virtualization approach that does not modify a single line of code, and a pure consolidation approach that does not incur any performance penalty.

Efforts of interoperating NFs. As shown in Table 1, the real NFs are heterogeneous in many ways including the language, I/O, *etc.* We assume the virtualization approach emulates a full running environment, *e.g.*, with VM or Docker, and thus does not need to modify the real NFs for chaining them. On the other hand, the consolidation approach needs to extract or wrap the NF logic for interoperation.

Intuitively, it would only cost limited coding efforts, since the high-level NF logic is relatively simple and neat, as shown in CN in the table. However, the factual task would cost much more than that number. For example, to implement an NAT in FastClick only needs to write 94 LOC for a Click script, while to interoperate this NF with CT in mOS, one has to dig into the detailed implementation in FastClick *and* mOS, to ensure they have the same packet abstractions, are not conflicting in variable/function names, and do not incur dirty writes on global data structures, *etc.* Things get more complex when porting NFs with different languages, *e.g.*, rewriting a Rust NF into a C/C++ one. Generally, the effort of code reading and writing for consolidating heterogeneous NFs would approach to the numbers shown in CF.

LemonNFV does not modify a single line of native code (*e.g.*, C/C++, Rust) for consolidating these NFs. The only effort we made is to modify the compilation configurations of the NFs, *e.g.*, adding `-fPIC` and `-shared` in `Makefile`, to compile the NF as a shared library instead of an executable, which amounts to a handful of LOC. We also feed the command line arguments, *i.e.*, `argv`, to each LEMON with a configuration file, which also contains minor LOC. CH in Table 1 shows the total number of modified LOC.

Table 2: Performance comparison over real NFs.

	Per-Packet Latency (us)			Throughput (Gbps)		
	Ideal	Docker	LemonNFV	Ideal	Docker	LemonNFV
ISP	0.66	240 (+362×)	0.68 (+3.8%)	22.9	11.6 (-49%)	22.0 (-3.8%)
ENT	0.59	224 (+223×)	0.60 (+2.8%)	18.3	12.7 (-31%)	17.7 (-3.2%)

Performance comparison. We chain the real NFs to conduct a sequential SFC: IDS→NAT→ACL. We do not involve the two libpcap NFs here because the slow packet I/O would significantly enlarge the performance gap between virtualization and other approaches. As a reference, CT and DPI with LemonNFV are 5.6× and 3× faster than their libpcap versions respectively. We consider two performance metrics: the processing time of each packet, *i.e.*, the elapsed time after it entering the first NF and before it leaving the last NF, and the end-to-end throughput.

For virtualization approach, we use Docker containers to carry the NFs. Each container is equipped with one CPU core and two virtual NICs, and the SR-IOV [15] technique ensures the line-rate packet forwarding between Dockers without CPU interventions. Due to the large codebase of real NFs, we do not implement a pure consolidation approach. Instead, we estimate its performance as follows: for the per-packet latency, we simply accumulate the processing time of each single NF; for the throughput, we set up a basic DPDK I/O, and delay each packet for the accumulated processing latency. This should present the performance upper bound of consolidation since interference between NFs (*e.g.*, cache and memory contention) is removed.

Table 2 shows the performance comparison. It can be seen that the Docker approach adds more than 200× latency compared to the Ideal approach. Since those NFs are with high-speed I/O, the major overhead comes from the packet pool in the virtual NIC and DPDK, *i.e.*, V2 mentioned in §2.1. On the other hand, LemonNFV eliminates such overhead and only incurs 2.8%–3.8% overhead, largely resulting from the PKU switch between NFs.

Since Docker uses three separate cores, we also scale Ideal and LemonNFV with three cores for throughput comparison. The results show that Docker is in average 40% slower than Ideal, while the overhead of LemonNFV is just 3.5%. The performance gap between Docker and LemonNFV is narrowed compared to the per-packet latency because the end-to-end measurement includes the I/O latency between the testbed and the packet generator (~100us). Such gap would again enlarge with longer SFC.

Loading and migration. Under LemonNFV, loading a LEMON is essentially loading a shared library, which is fast and predictable. We measure the loading time of all 5 real NFs, and report that the max/average loading time is 28ms/7ms. Note that LEMONS are loaded by the hypervisor in an asynchronous way, so the factual overhead for the SFC can be neglected. As a comparison, booting a container usually takes hundreds of milliseconds [47].

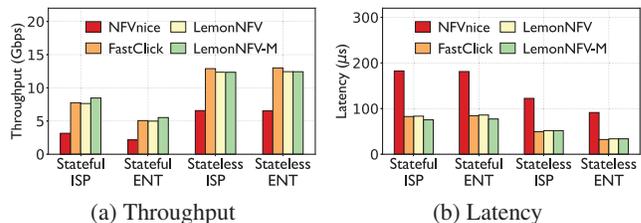

Figure 6: Performance comparison with different SFCs and traces using 4 cores. LemonNFV-M indicates LemonNFV with memory pre-allocation enabled.

We also verify that our inter-process migration can be finished rapidly. We setup two processes on a single server, each of which carries a naive packet forwarding LEMON. The source process then loads IDS in Table 1, runs it for some time, and migrates it to the destination process. Results show that iterative migration copies over 400 dirty pages within 1.2s, and efficiently reduces the total downtime to only 6.9ms.

6.3 Comparing with Existing NFV Systems

We compare LemonNFV with state-of-the-art NFV frameworks. For obtaining higher performance, these frameworks often require developing NFs using specific interfaces. To this end, we port the synthesized NFs to these frameworks and compose two SFCs: Stateful that chains the four stateful NFs from NFD, and Stateless that chains the four OpenNetVM NFs. Performance is the focus of this comparison.

Comparing with NFVnice. We port the synthesized NFs into NFVnice [40], a state-of-the-art virtualization-based approach that deploys NFs inside processes and enables back-pressure between them to minimize wasted work. NFVnice sets a large packet queue (2^{15}) between each NF for higher throughput and less packet loss, which would in turn increase the latency. To this end, we measure the throughput with the default setting, and measure the latency by reducing the queue size to 32 (default batch size). This could represent the ideal performance a virtualization approach can achieve.

Figure 6 shows the comparison of NFVnice and LemonNFV. LemonNFV is at least 88% faster than NFVnice with 55% less latency. Note that besides the four worker cores, NFVnice employs two extra cores dedicated for packet I/O, which, however, has been heavily hindered by the context switches and cache misses when traversing SFCs.

Comparing with FastClick. FastClick [17] is an enhanced version of Click [37] with high-speed I/O, optimized compilation stages, and many useful elements. FastClick is the basis of many state-of-the-art consolidation approaches like Metron [35], RSS++ [16], PacketMill [25] and Reframer [28]. In FastClick, each NF is a C++ object, and chaining NFs is just calling a function of the object. This implementation eliminates all extra overhead between NFs, indicating the ideal performance of a consolidation approach.

Figure 6 shows that LemonNFV is only 1.5% slower than

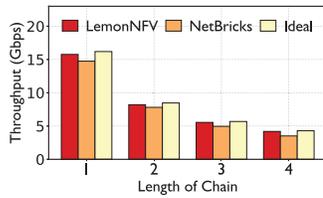

Figure 7: Throughput comparison with NetBricks.

FastClick for Stateful. This demonstrates the end-to-end overhead employed by LemonNFV, including the stack switch, the pkey set, *etc.* The overhead increases to 4.2% for Stateless, because this SFC is more lightweight, making the cost from LemonNFV more significant.

After enabling the pre-allocation, LemonNFV-M even outperforms FastClick by 9.2% in Stateful. This is because NFs in Stateful are memory-access-intensive, such that the pre-allocation would improve the performance significantly. For the similar reason, Stateless performs almost the same with and without this feature.

Comparing with NetBricks. The closest work to ours is NetBricks [52], which also runs SFC in a single thread and provides isolation among NFs. To compare the runtime overhead when hosting NFs, we implement a simple ACL NF using C in LemonNFV and Rust in NetBricks. This NF does not use any complex algorithms and data structures, *e.g.*, hash table, from the standard library, to minimize the performance difference from the language. We chain this NF for several times to measure the scalability, and further involve the pure consolidation, *i.e.*, chaining the C NF by function call, as the ideal approach.

Figure 7 shows that LemonNFV is on average 2.6% slower than Ideal, while NetBricks incurs 11.9% overhead. With a longer chain, the overhead of LemonNFV is stable (always $\sim 2.5\%$), but NetBricks incurs larger overhead (from 8.9% to 18.1%). This is because the overhead of NetBricks mainly comes from the NF logic itself, *i.e.*, checking array bounds with Rust (reportedly a 14% overhead for an LPM [52]), while the overhead of LemonNFV is irrelevant to the NF logic. As a result, though the increasing chain length also increases the number of domain switching, such overhead is still negligible compared to the workload of NF itself. Considering that the example NF is largely simplified, the factual gap between LemonNFV and NetBricks would be much significant in real cases.

Overhead analysis. We quantify the overhead employed by LemonNFV to better understand the performance illustrated above. For each LEMON switching, LemonNFV incurs the following overhead: (O1) switching the memory domain by writing the pkey registers, (O2) switching the private heap, and (O3) switching the private stack to the target domain.

For O1, each domain switching invokes one write to the pkey register, which averages to 82 cycles in both SFCs. O2 is stable and minor (*i.e.*, 9 cycles), because heap switching only changes the base pointer of the heap. For O3, stack switching

needs to save the current context and restore the target. We measure such overhead for each NF switching in Stateful and Stateless and the result averages to only 31 cycles. Note that above overhead is for a whole batch, meaning that the per-packet overhead with default batch size (32) is only ~ 4 cycles for each switching.

As a comparison, virtualization frameworks would be impeded by context switching, cache misses and TLB flushes. To the best of our knowledge, Quadrant [68] has the least overhead by pinning the NF instances on the chain to a single core, which results in a per-packet overhead of ~ 110 cycles. In Stateless with 4 NFs, it will cost 530 more cycles than LemonNFV ($(110 - 4) \times 5$ switching). As the per-packet latency of Stateless is ~ 4000 cycles in LemonNFV, Quadrant is thus $\sim 13\%$ slower in terms of the isolation overhead.

7 Related Work and Limitations

We discuss efforts that relate to or inspire LemonNFV.

NF development. FastClick [17] and BESS [30] can flexibly wire their elements/modules up to the SFC (in an off-line manner). However, those modules must be programmed with specified interfaces, *e.g.*, being inherited from certain base classes. To reduce the overhead between NFs, NetBricks [52] proposes to use a new language, Rust, with a set of domain-specific abstractions for building NFs. However, it is costly to re-implement all existing NFs using such new language. NFD [32] can generate NF code from a high-level behavior model. While this facilitates the porting task, NFD does not make heterogeneous NFs interoperable, and operators are still bound to a specific interface. Nethuns [18] advocates a socket-independent programming abstraction for NFs, trying to unifying the packet I/O, but in turn proposing a new I/O.

Moreover, with LemonNFV, one can directly launch a NF with out-dated I/O, *e.g.*, official NetBricks with DPDK 17.08 [11], or develop a new NF with the simple packet I/O, *e.g.*, libpcap, and get the newest and fast I/O for free.

NF optimizations. OpenBox [19] and SNF [36] optimize the SFC by eliminating the redundancy logics in NFs. Metron [35] goes a step forward by offloading part of the merged logic to programmable switches. PacketMill [25] and Morpheus [50] compiles optimal data structures and control flows for NFs. These optimizations require inner logics of NFs, and thus cannot be borrowed by LemonNFV that views each NF as an opaque box. We see it as an inherent trade-off between the reusability and deep optimizations.

NF execution models. Virtualization approaches are eager to improve the performance [22, 33, 40, 51, 76]. Exploiting the parallelism of NFs is viewed to be a promising direction [64, 77]. However, according to its own results, the parallel approach (NFP [64]) is 16.5% faster than the non-parallel one (OpenNetVM [76]), but 26% slower than the RTC approach (BESS [30]). The factual gap should be larger be-

cause BESS has reached the wire-speed in that results. Quadrant [68] packages NFs into containers and schedules them in a single core to avoid the cache misses, which, however, would cause the thread context switch.

FastClick [17], BESS [30], OpenBox [19] and Metron [35] are pure consolidation approaches, which achieve high performance without isolation. NetBricks [52] is the first consolidation approach that considers the isolation. By reimplementing NFs with a safe language (Rust), NetBricks ensures each instruction cannot access the data beyond its legal scope. However, such operation in Rust is too strict, lowering $\sim 20\%$ throughput compared to native consolidation approaches [52].

Intra-process isolation. Hodor [31], ERIM [66], EPK [29] and CubicleOS [59] leverage Intel PKU to isolate software modules inside the process. LemonNFV is inspired by them and is the first for using PKU to isolate NFs in SFC. However, NFs can change pkey privileges themselves and thus break the control flow integrity or subvert the hypervisor. We see this as the nature of PKU and can leverage methods discussed in existing works to harden PKU-based isolation [20].

Besides memory and fault isolation, previous work has also proposed and enforced packet isolation, which prevents NFs from accessing packets that don't belong to them. Specifically, an NF may tamper packets outside its batch since the packet pool is shared by all NFs, contradicting the isolation among them. To solve this, NetBricks [52] leverages safe language to disable pointer arithmetic, and Quadrant [68] copies packets to cast packets on memory private to each NF. Similarly, LemonNFV can either limit permission on the exact batch using pkeys, or simply copy packets to address this problem.

NF migration. NFV frameworks need to migrate NFs and their states to balance the load across the cores or machines. Previous literatures achieve this feature by adding migration APIs [27, 55], copying states with identical state structures [35], or using centralized state tables [16], all of which require significant code modification to NFs. LemonNFV addresses this need by migrating the LEMON that packages the NF logic and code together. However, each LEMON corresponds to a certain packet class, which means LemonNFV cannot migrate a specific flow [27], or balance the load for a single large (*i.e.*, non-splittable) flow [16].

Limitations. The design of LEMON and LemonNFV does not meet every possible situation in deployment. (1) NFs that do not run as a standalone process (*e.g.*, NFs based on eBPF [3] or partially offloaded to hardware [35]) are not supported due to their fundamental deviation from a LEMON's execution model. (2) LemonNFV enables fast inter-server migration by disabling ASLR, which might be exploited by buffer overflow. Nevertheless, the operator can still migrate the whole LemonNFV process with ASLR enabled by leveraging checkpoint/restore methods (*e.g.*, CRIU [2]), when consolidating untrusted NFs.

LemonNFV requires recompiling NFs from the source

code, which is not always available for off-the-shelf NFs. However, we believe it does not compromise much practicality of LemonNFV because the recompilation (1) still uses the standard compiler (*e.g.*, gcc), not raising concerns of security and inconsistency, and (2) only recompiles the main program, meaning that the original dependencies can be reused. These facts help the NF vendors to re-publish their NFs as LEMONS with a simple recompilation, and the users can directly plug them into LemonNFV.

We emphasize that LemonNFV does not aim to address *all* challenges in NFV. Instead, it tries to shed the light for the NFV world by enabling the ability of heterogeneous NF interoperation. On such basis, approaches like centralized state management [70], NF fault recovery [62], load balancing [16, 58], VNF placement and orchestration [24, 26], *etc.*, could be complementary to LemonNFV.

8 Conclusion

We presented LemonNFV, a novel NFV framework that consolidates the heterogeneous NFs without code modification. We demonstrated the practicality of LemonNFV with 5 real NFs, and evaluated LemonNFV by comparing with state-of-the-arts. The results showed that LemonNFV outperforms the state-of-the-art virtualization approach by $1.9\text{--}2.4\times$, while only sacrifices $0.7\text{--}4.3\%$ performance for isolation compared to the ideal consolidation framework.

Appendix A Multi-Threaded LEMON Scheduling

For a single-threaded LEMON, the hypervisor would initialize it, and the working thread will continue executing it, as shown in Figure 4b. However, a LEMON could create its own threads, which, except for the packet processing threads, could include threads for event logging or user input communication. In the following, we present how LemonNFV cooperates with the multi-threaded LEMONS.

Taking Figure 8 as an example, a LemonNFV process has a hypervisor thread (T_h , red path), and an RTC working thread

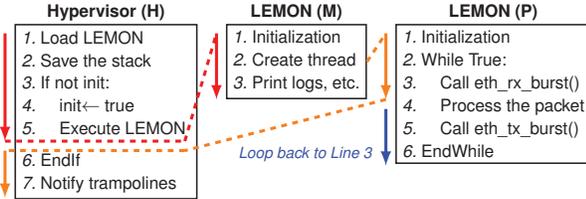

Figure 8: Cooperating with multi-threaded LEMONS. The red path is the (original) hypervisor thread, and the orange path is the newly created packet processing thread. After the LEMON is initialized, the red thread becomes its main thread, and the orange thread becomes the hypervisor thread.

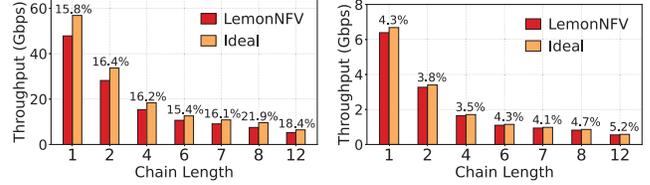

(T_r , blue path). Assume a new LEMON M1 is being loaded into the SFC, which creates a new thread for packet processing (T_p , orange path), and manages that thread in its main thread (T_m). The hypervisor would first execute the main function in T_h , that is, $T_m = T_h$ (Line 5 in H). After creating T_p in T_h (Line 2 in M), the execution in T_p would eventually call the virtualized I/O for the very first time, *i.e.*, the initialization part (Line 3 in P). Then the execution would be switched into the hypervisor stack (Line 6 in H). Note that since T_p is executing the hypervisor logic, this thread now actually plays the role of hypervisor thread. Next, T_p (the new hypervisor thread) would notify T_r that a LEMON is ready to be attached into the SFC (Line 7 in H), and T_r will switch the stack into the packet processing logics of this LEMON next time received the packets (Line 4 in P).

In sum, after loading a LEMON, T_h becomes the management thread of the new LEMON, T_p becomes the new hypervisor thread, and T_r is still the RTC working thread. Note that the LEMON can also use T_m as the packet processing thread, and create a new thread for management. In this case, T_m (T_h) will still be the hypervisor thread. The key here is that there is only one packet processing thread for each LEMON, so the virtualized I/O calls in that thread would eventually guide the hypervisor and trampolines to properly handle it.

Appendix B Dirty Pages Tracking in Inter-Process Migration

In the case of VM, the hypervisor can migrate the running VM to another host without halting it, namely live migration. The key is to capture the dirty pages by changing the accessing rights of the page table entries. For example, Xen implements a shadow page table to the original VM page table [44]. When the hypervisor decides to track memory modifications, the internal page table of the VM is transparently set to read only. That is, memory writes will not trigger a fault, but propagate to the shadow page table, recording the dirty pages during pre-copy stage in the hypervisor. vMotion in VMWare takes a similar approach [12].

Although each LEMON does not have a shadow or an isolated page table, its memory region has explicit boundary.

(a) Lightweight

(b) Heavy

Figure 9: Performance comparison of differently-loaded NFs between their LemonNFV and vanilla DPDK version.

As a result, it is possible to adopt the above method by directly changing the accessing rights of the page table inside a LEMON. To be specific, when migrating a LEMON, LemonNFV first blocks the LEMON and changes the permission of the LEMON’s memory to read only. Then, all the memory writes to the LEMON will trigger a SIGSEGV signal. A pre-registered signal handler would capture this signal, record the address to be written (which pollutes the page), and grant write permission to the corresponding page. Upon completion of the pre-copy stage (*i.e.*, phase -1 in §4.4), the LEMON is set to read only again, waiting for the next iteration.

Experiments on libnids [6], prads [13] and nDPI [9] with real traffic show that after a few iterations, the number of the modified pages eventually converge to 13, 7 and 4, respectively (4KB for each page), which are far lower than the stopping condition of iteration in Xen (<50 pages) and vMotion (<16MB) [23], meaning that the factual migration would only halt the LEMON for a neglected moment.

Appendix C Microbenchmark

In this section we present some additional microbenchmarks of LemonNFV.

As in §6.3, the overhead of LemonNFV is irrelevant to the NF logic, contrast to array bound checking. It’s then worth discussing how this overhead would impact the performance, under various workload and SFC length.

We prepare a light NF (~200 cycles per packet) and a heavy NF (~2300 cycles per packet), packing them as LEMON as well as porting them to DPDK. Under LemonNFV, variable number of identical LEMONS are chained together, while the DPDK version repetitively invokes the packet processing function until chain length is met. Since the vanilla DPDK version does not introduce additional overhead, it is referred to as ‘Ideal’ later as a baseline.

Figure 9 presents the end-to-end throughput under variable chain length and NF workload. We have the following observations and analysis for the results. First, the performance gap between LemonNFV and Ideal is large when the NF is lightweight (17.1% on average across all chain length), but becomes much less significant when the NF is heavy (4.3% on average). This corresponds to our analysis in §6.3 that the overhead of LEMON switching is irrelevant from NF logic. Since real-world NFs are generally more complex and

time-consuming, LemonNFV would be more preferable than isolation methods based on array bound checking.

Second, given the fixed switching overhead, the performance gap should be stable when the chain length increases. This is also verified in Figure 9 when the chain length is under 7. However, the slowdown of LemonNFV grows when the chain length continues to increase. For example, the average slowdown of lightweight NF rises from 16.0% to 20.2% when the SFC is longer than 8. We believe that this is mainly due to cache contention of NFs co-locating on the same core [48, 65]. Compared with virtualization based systems that often run NFs on separated cores, RTC scheduling will be more likely to drain cache and cause performance degradation [78]. We consider it as a feature of RTC and leave better profiling and optimizing cache performance as our future work.

Disaggregating Stateful Network Functions

Abstract— For security, isolation, metering and other purposes, public clouds today implement complex network functions at every server. Today’s implementations, in software or on FPGAs and ASICs that are attached to each host, are becoming increasingly complex, costly and bottlenecks to scalability. We present a different design that disaggregates network function processing off the host and into shared resource pools by making novel use of appliances which tightly integrate general-purpose ARM cores with high-speed stateful match processing ASICs. When work is skewed across VMs, such disaggregation can offer better reliability and performance over the state-of-art at a lower per-server cost. We describe our solutions to the consequent challenges and present results from a production deployment at a large public cloud.

1 Introduction

All major cloud providers implement stateful network functions at their servers. These network functions are essential for network virtualization (e.g., private address spaces [75, 88]), enhanced security (e.g., stateful firewalls [14, 15]), load balancing [56, 87], QoS [62, 68, 92] and cost metering [5, 9, 20].

The key challenges in implementing stateful network functions in a virtualized context are three-fold:

- First, the state that must be maintained and accessed at line-rate can be per flow (for stateful firewalls) or per endpoint (to virtualize IP addresses) and can exceed 100MB for many virtual machines. Programmable switches [24, 25] have small SRAMs and are hence appropriate only in niche cases such as to only support a small subset of all flows [83, 85] or in bare-metal settings where the cloud provider has no access to the servers [41]. The most widely-used NF implementations today combine software in host virtual switches [52, 57, 88] with FPGAs or smart NICs that are directly attached to the servers [6, 58].
- Next, attaching FPGAs and smart NICs to each server is wasteful because these cards must be provisioned to

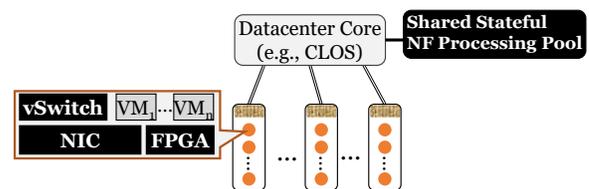

Figure 1: Today, stateful network functions are implemented on-host in virtual switches, NICs and FPGAs shown with a dark background. We propose to disaggregate stateful NFs, i.e., also process them in shared resource pools located elsewhere in the datacenter.

meet the peak anticipated usage at each server but the actual usage is far below the peak most of the time, and on most servers. Moreover, VMs that use networking features which are only supported by the latest FPGA or smartNIC cannot be deployed on older hardware; in turn, this can lead to a sizable waste of non-networking resources.

- Finally, the tail performance is limited today. For example, in the three largest public clouds, we will show that the number of new connections per second a VM can support is well below the NIC capacity and is likely bottlenecked on stateful NFs that are applied on each new connection. Customers who deploy middleboxes in VMs (such as the Palo Alto VM-series firewall [33]) to secure access to their other VMs are forced to deploy many more middleboxes to offset the performance limitations in the provider’s NF processing [35].

We propose to disaggregate the processing of stateful network functions into shared off-host resources pools as shown in Figure 1. Similar to how a customer can pick the CPU or memory for a VM, customers can also now pick a floating network interface (fNIC) which explicitly specifies NF requirements (e.g., # new flows per second, # concurrent flows) as well as the network capacity in Gbps. When deploying a VM, we allocate resources for the fNIC either on-host (that is, on the vswitch and the FPGA), or at an off-host shared resource pool or some combination at both locations.

We call out a few advantages from such a disaggregation

Stateful NF	State at each VM	Computation
Private address spaces [2, 10, 22]	A dictionary that maps customer’s private addresses to the provider’s physical addresses; one entry per remote endpoint that the VM speaks with.	Lookups, adds and deletes into the mapping dictionary
Stateful ACLs [32, 36]	Per ongoing flow that has passed the ACLs, a hashmap containing the flow’s five tuple and the reverse five tuple	Lookups, adds and deletes into the per-flow hash table
Billing [5, 9, 20]	Total bytes, sliced by windows and per billable communicating entity such as a datacenter or a cloud service; also, bursts and peak rates	Multiple counters and sketches
Stateful NATs, load balancers	Per ongoing flow, the new <i>flow</i> to masquerade as.	Lookups, adds and deletes into the rewrite dictionary

Table 1: Some example stateful network functions that are implemented at cloud VMs and the associated state and computation. For more details, see [52, 57, 88].

of stateful NFs. First, we will show that for most of the time most of the VMs require much fewer NF processing capacity than the peak. We can thus reduce cost and power usage by equipping servers with less capable FPGAs or smart NICs and handling all of the spillover load at the shared resource pools. Next, we can deploy VMs which require novel NF processing on any server in the datacenter, including on older hardware, as opposed to restricting to just servers that have the latest FPGAs or smart NICs. As noted above, doing so reduces the fragmentation of non-networking resources. Third, we show how to increase the tail performance for VMs well beyond what is achievable from using the single FPGA or smartNIC that is attached to the host; for example, the number of new connections-per-second a VM can accept may only be limited by its NIC capacity. Doing so reduces cost and eases the deployment of middlebox VMs.

There has been much work on resource disaggregation. Disaggregating stateful NFs is similar in some ways to prior works that disaggregate resources such as memory, storage or GPU [45, 63, 74, 91] but there are a few key differences. One challenge is with regards to implementing a high-performance shared NF resource pool. The pool must simultaneously support large state and high-speed packet processing (e.g., 100s of GBs of states at multi Tbps packet processing rates). Doing so requires coherent access over a large memory at a high-speed. Programmable switches [24, 25] can process at multi Tbps but only have about 1GB of SRAM per switch. We have implemented an appliance which can be thought of as a bag-of-NICs wherein each NIC contains match-processing-unit ASICs that are programmable in P4 as well as a large coherently-accessible memory. Each appliance has 12 NIC cards, each card has a power draw of 75W, 16GBs usable for NF state and can process duplex packets at 100Gbps.

Another novel challenge from disaggregating stateful network functions is that fault tolerance shifts from a fate-sharing mode to a single point of failure. That is, when an FPGA or a smart NIC fails, only the VMs on the corresponding host fail but when an appliance (in the shared NF resource pool) fails the impact is felt by any VM whose fNIC happens to be allocated on that appliance. Naïvely replicating the state of network functions is hard because both primary-backup style replication [44, 51] and Paxos-like protocols [46, 48, 50, 81] queue requests while the state is being replicated. In the case

of stateful NFs, requests can be any packet that changes state and so holding requests at speeds of hundreds of Gbps will require a very large packet buffer. We show how to replicate state *in-line* by ping-ponging packets between the replicas (pairs of programmable NICs) effectively buffering the state-changing requests on the network wires.

To the best of our knowledge, we are not aware of any prior work that disaggregates stateful NFs such as connection tracking firewalls or uses programmable bag-of-NICs appliances or supports in-line state replication. Some works offload specific stateful NFs to top-of-the-rack switches [41, 83, 85, 95] but do not support a rich class of NFs and the memory limit on Tofinos restricts them to only speedup a small subset of flows. Andromeda [52] deploys dedicated software middleboxes to process NFs but does not support stateful NFs citing concerns such as “state loss during upgrade or failure” and “transferring state when offloading”. We discuss other related work in §7. To sum up, our key contributions are:

- We build a case to disaggregate stateful NFs by studying the functions and telemetry at a large cloud provider (§2).
- We present Sirius which disaggregates a rich class of stateful network functions onto pools of P4 programmable NIC cards. We show how to replicate state inline between pairs of nearby cards such that individual card failure does not adversely impact ongoing connections (§3.2). We discuss multiple disaggregation design-points including those that split or migrate the load of a VM across different NF processors (§3.3) and show a programmable NIC implementation that achieves better performance-over-cost than state-of-the-art (§4).
- We report results from a production deployment which, in part, show that when VMs offload onto Sirius, their stateful NF processing capacity improves by about 10×.

2 Background and Motivation

2.1 Stateful Network Functions

Table 1 lists some stateful network functions that are supported by public cloud providers. As the table notes, some NFs must maintain per-flow state whereas others keep state at coarser granularity. Counters and sketches are used to measure network usage for billing and diagnostics [73]. Customers

can also configure (add to) the stateful NFs on their VMs. As exemplars, we discuss two kinds of stateful NFs that are widely used in production but less well known academically.

First, virtual network peering [8, 12, 23] allows VMs in different virtual networks to communicate. Doing so requires all VMs in participating vnets to know how to map a virtual address belonging to any vnet into the corresponding physical address. This mapping must be kept up-to-date whenever VMs are deployed or migrated. Today’s vnet peering implementations cache the map in a stateful layer at VMs [8, 12, 23].

Next, private links [7, 11, 29] let VMs communicate with PaaS services that have public IPs on a more direct path. For example, when a VM in AWS reads from an EBS volume which has a public IP, naïvely, such traffic must go via the cloud egress gateway similar to traffic to any public IP and then turn back towards the cloud store. Private links are more efficient and secure by having such traffic go directly to the cloud storage; a stateful layer at each VM encapsulates the outgoing traffic based on the VMs vnet id and the private IP address of the PaaS service and, in the reverse direction, a stateful layer at the PaaS service remembers which virtual and physical addresses a flow comes from when decapsulating (so-called *stateful decap*) and uses that state to encapsulate packets so that they go back to the appropriate VM.

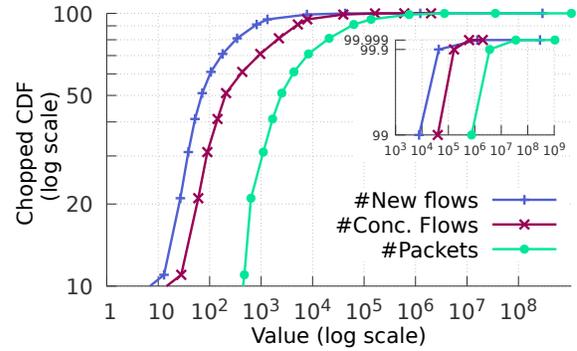

To sum, associated with each VM in the public cloud, providers implement numerous stateful network functions. Among the NFs considered in this paper, the connection-tracking firewalls, NATs and load balancers are the most intensive – they all require per-connection state. The total state to maintain per VM is often large since there can be hundreds of distinct *rules* to apply: one per private link, stateful ACL or vnet peer. NF actions on new connections are often implemented in software due to complexity and ease-of-programmability [52, 57, 88] whereas the per-packet actions are implemented in FPGAs or ASICs [6, 58].

2.2 NF workload at a public cloud

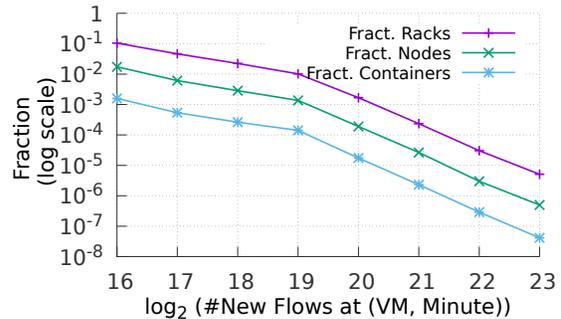

We characterize the usage of network functions at Azure. For each VM and each minute, we obtain the number of newly established flows, the number of active flows and the byte and packet counts. Our results here summarize metrics from a three month period. A typical minute has reports from $O(10^8)$ VMs and $O(10^7)$ nodes. Our key findings are as follows.

Skew in load for NFs: Figure 2a shows that the load for network functions is skewed; we measure load in terms of the number of newly arriving flows which must be verified to be policy compliant, the number of concurrently active flows for which state has to be maintained and the number of packets being exchanged. We see that the median load is multiple orders of magnitude smaller than the peak load. The inset zooms in on values further on the tail.

When the load is skewed, provisioning every host for the

(a) Cumulative distribution function (CDF) of the NF Load at VMs; axes are in log scale and points on the CDF are unique (VM, minute) tuples.

(b) VMs that have high NF load are spread among many nodes and racks.

Figure 2: Characterizing the workload for stateful NFs at a large public cloud; data collected across over 10^8 VMs in a three month period.

Metric	Containers	Nodes	Racks
σ / μ	14.23	5.00	0.67
99th / μ	13.54	10.49	2.52

Table 2: Coefficient-of-variation (=stdev σ / avg. μ) of the number of newly arriving flows per minute at each VM compared to the same metric when rolled up into the nodes or racks that contain the VMs.

peak (e.g., by adding FPGAs or smart NICs), can be costly and most of the NF processing capability remains unused. We aim to provision hosts for the average load and handle the excess load using a disaggregated, logically shared, pool.

Containers with high NF load are spread throughout the network: Figure 2b zooms in on VMs and timewindows (minutes) which report high NF load; the x axes is a logarithmic bin, that is $x = 18$ denotes that the numbers of new flows in a (VM, minute) was in the range of $[2^{17.5}, 2^{18.5})$. The bottom-most line on the figure reports the fractions of distinct containers which exhibit high NF load. If the high-load containers were concentrated into a few nodes and racks, then the fraction of nodes and racks which show high load will be no larger than the fraction of containers. However, the figure shows that highly-loaded containers are spread across many more nodes and racks. The case for other NF load metrics is similar. About 10% of the racks have at least one container which reported over 50000 new connections in a minute.

Variation in NF load: At the granularity of individual VMs, we observe sizable temporal variations in NF load of up to

one order of magnitude larger than the median (see Figure 15). However, the variability appears uncorrelated spatially. That is, the sum of the load of all the VMs in a server or a rack has smaller coefficient-of-variation (see Table 2). Shared pools of NF processing capability thus can be provisioned with smaller peak to average ratios and will be more cost-efficient.

2.3 Characterizing NF Performance

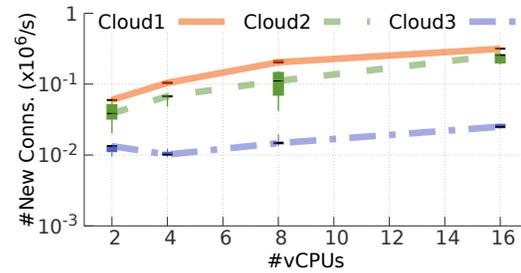

To measure the state-of-art stateful NF performance of public clouds today, we deploy pairs of VMs of different sizes, add a stateful ACL to the *client* VM and initiate TCP connections in an open loop to the other *server* VM. We progressively increase the connection initiation rate and measure the maximum rate that was achieved and the connection establishment latency. Our tool is multi-threaded and asynchronous. We appropriately change various configuration variables and achieve better results than listed in public datasheets [13, 17–19, 34]. Figure 3a shows the maximum number of new connections per second (CPS) achieved by VMs of different sizes on the three largest public clouds today. All VMs are identically configured Ubuntu Linux instances. The variation is over experiment runs likely due to performance interference on the VMs or on the network path; we repeat each point at least ten times. The figure shows that increasing the VM size tends to increase the CPS perhaps because the per-VM networking limits improve [3, 21, 28]. However, the highest CPS across all public clouds and experimented VMs is 0.3M. Figure 3b shows the latency between sending a SYN and receiving a SYN-ACK. In the latency plot, we only use trials where most of the connections succeed to avoid latency cliffs. The figures show that processing the stateful NFs which are deployed in public clouds today represents a sizable bottleneck— there is a sizable latency when establishing new connections and VMs are limited in the number of new connections per second that they can sustain.

3 Disaggregating NF processing in Sirius

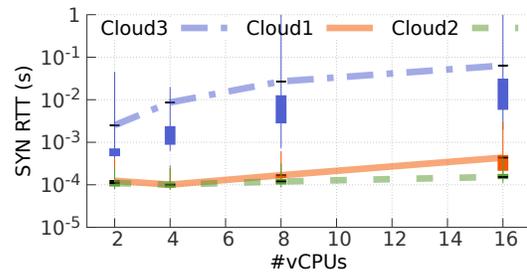

Sirius offers a new API to offload network function processing into pools of appliances that contain custom programmable cards. Each VM or container can specify a floating NIC (fNIC) with requirements on the following dimensions that relate to processing network functions:

- The number of new flows per second (CPS)
- The maximal number of concurrent flows
- Network capacity
- Feature, capability selection and ruleset size

Values for some of these dimensions are already in cloud provider and NVA vendor datasheets [3, 13, 17–19, 21, 28, 34]; Sirius also allows off-the-shelf fNIC sizes that users can pick from (e.g., a *small* fNIC) to help with configuration.

(a) Maximum Connections Per Second achieved.

(b) Latency between sending a SYN and getting a SYN-ACK.

Figure 3: Benchmarking connection establishment rate and latency at different VM sizes on three public clouds. The lines connect the average value, whiskers go from 1st to 99th and boxes go from 25th to 75th percentiles.

We extend our cloud VM allocator [65, 93] to provision fNICs using either resources on the smartNICs that are attached to servers or one or more Sirius appliances. Disaggregation lets VMs be placed on servers that may not locally satisfy fNIC requirements. Allocating fNICs to cards is an instance of the multi-dimensional bin packing problem [61, 86]. A better packing will map more fNICs onto fewer cards. We considered different heuristics and found that heuristic choice improves efficiency only when the fraction of large fNICs (whose resource needs are a substantial fraction of the card capacity) is high. In the rest of this section, we discuss the disaggregated datapath, *inline* state replication and methods to split or move an fNIC’s load between multiple cards. Our design is modular and can work with different implementations of the shared processing pool; in §4, we discuss our P4 programmable cards which in our tests can serve over 3M new connections per second and 16M concurrent connections while processing a rich set of stateful NFs.

3.1 Connectivity and availability

The NF processing pool in Sirius is a collection of appliances. In our prototype, an appliance is a pair of 3U servers with six programmable cards each in PCIe slots. Each card has two 100Gbps QSFP+ connectors and 32GB DRAM.

Reliability, efficiency and flexibility were our key considerations when deciding how to connect Sirius appliances within a datacenter. Adding an appliance to each rack may lead to under-utilization (and fragmentation) since not every rack may have enough demand for NF processing. We also aim for

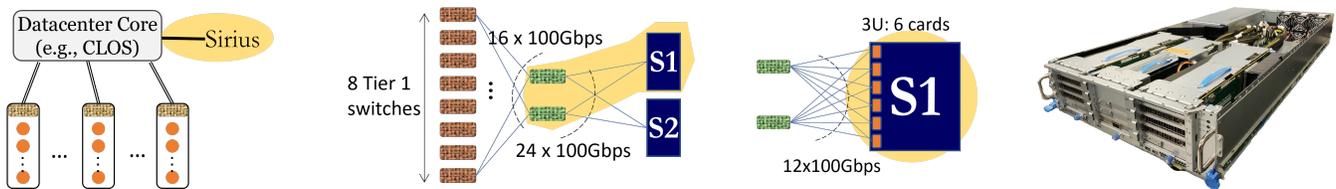

Figure 4: Connectivity diagram. Please read the figures left to right with each subsequent figure fleshing out the portion that is highlighted in the preceding figure. A Sirius appliance can be thought of as a pair of servers labeled S1 and S2 respectively that are connected as shown. Sirius assigns offloaded floating NICs of VMs to the programmable cards in the servers. We deploy more appliances to keep up with the total NF load.

a high level of reliability since NF processing is crucial for security and reachability in public clouds, e.g., for ACLs and private address spaces. Our goal is to ensure that the failure of any one server, card, link or switch must not degrade NF processing capability by a substantial amount. We also aim to independently scale out the NF processing capability as demand increases, e.g., by adding more appliances. Finally, we want VM placement to not be constrained by the availability or lack thereof of NF processing capability; that is, VMs located anywhere in a datacenter should be able to, when needed, use NF processing from the Sirius pool.

We choose to connect Sirius appliances as shown in Figure 4. Our minimum deployment unit is one appliance beneath two top-of-rack (ToR) equivalent switches that connect to the rest of the datacenter network similarly to other ToR switches. Such connectivity also ensures that any VM in any of the racks connected underneath the same CLOS will have equivalent access to Sirius’s appliances thus realizing a large shared NF processing pool. In our experience with Sirius, the primary bottleneck is the NF processing capability and the state on the cards. That is, the number of new flows arriving per second which must be validated and the number of concurrent connections for whom state must be maintained (e.g., in a stateful load balancer). Our measurements show that the added latency incurred by traffic passing through an appliance is small relatively because traffic between randomly placed VMs in the public cloud almost always bounces off a switch in the CLOS tier; in particular, the increase is negligible for north-south traffic (which enters or leaves the datacenter). Finally, the connectivity diagram in Figure 4 preserves access to the NF processing capability under the following conditions.

1. At most one of the two green switches in front of a Sirius server fails.
2. At most one of the two links that connect a given card to the switches fails.
3. At most half of the links that connect the green switches to the red Tier-1 switches fail.
4. At most half of the red switches fail.

The last two conditions above ensure that other racks in the CLOS will have at least one valid path to the green switches. By preserving access to the bottleneck resource, NF processing remains unimpeded and Sirius will still be able to support high rates of new flows per second and concurrent flows.

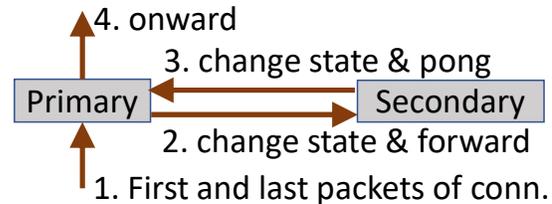

Figure 5: In-line replication of connection state in Sirius by ping-pong’ing packets that change state to both the primary and secondary cards.

3.2 In-line Connection State Replication

To avoid individual card failures from affecting ongoing connections, we duplicate connection state across two programmable cards. A key novel aspect here is that we do so without buffering packets. Due to the very high packet rates that these cards handle, holding packets in the primary card until state is established on the secondary card, as is done typically to replicate state [46, 48, 50, 81], will require very large buffers. We discuss a method that replicates state without any additional buffering by ping-pong’ing the packets of each connection that change state. As shown in Figure 5, for example, SYN’s of a TCP connection which will establish state on the primary card are also forwarded to the secondary card. The secondary card also establishes state for this connection in its local memory and forwards the packet back to the primary. The primary card then transmits the packet to the destination in the usual way. Both cards independently delete the state of connections which remain idle beyond an age out threshold. Besides avoiding additional buffering, such *inline* state replication requires only a small code change to send and process ping-pong messages since the code to check rules and update state can be reused.

Each card pair (primary and secondary) exchanges heartbeats and fails over independently. That is, if the primary misses several heartbeats, the secondary card will receive all of the traffic on fNICs that were assigned to the pair. To achieve such failover, both cards announce BGP routes for the fNICs’ virtual IPs; the primary card announces a shorter AS path than the secondary.¹ At a slower timescale, a different software controller provisions new replicas (e.g., pairs a newly promoted primary with a new secondary card) and schedules bulk state replication (which we describe below).

¹We discuss corner cases in failover in §A.1.

The controller also reduces allocatable appliance capacity if necessary based on the number of cards that are operational. Two control loops at different timescales are commonly used to react to faults [67, 80]; to our knowledge, we are not aware of its use in replicating the state of network functions.

We observe that most of the connection state turns over quickly. For example, a usage stream that has 4M new connections per second and 32M concurrent connections has the average connection lasting 8s. Thus, waiting a bit will allow us to move much less state, which belongs to the long-lived connections, with the trade-off being a small increase in the period for which state is present on only one card.

The goal of our bulk synchronization is to replicate checkpointed state from one card to another quickly. There are multiple ways to implement checkpoints; we append an epoch value to each record in the state and atomically increment the value of the current epoch to take a checkpoint since then all records with a smaller epoch value will belong to the checkpoint.² To copy a checkpoint between paired cards, the ARM cores on the cards move state in batches over a reliable transport. We tradeoff the overhead of copying checkpoints with an increase in the period wherein only one copy of the state exists in the following additional ways: we prioritize moving the state of long-lived connections since other connections may close before needing to be moved and we pace the copy messages so that resource contention (on the memory bus and network) does not adversely affect normal activity.

To sum, replicating connection state between a pair of cards has the following costs and benefits. On the costs, storing each record at two cards halves the total available state that a Sirius appliance can maintain. The NF capacity, say in terms of connections per second that can be handled by an appliance, also halves for the same reason. The connection setup latency increases due to the ping-pong. Also, bulk synchronization, when triggered, uses memory and network bandwidth. On the benefits, the failure of a single card only impacts ongoing connections for the period before traffic failovers onto the secondary card. In-flight connections, that is, connections whose state is not yet present on both cards may only have to retransmit some SYNs (and FINs). To see why, observe that at any of the four steps for a new connection in Figure 5, the failure of either cards at best requires a retransmission.³ Finally, planned card failures can be handled without any impact as so: (X1) promote the secondary and pick a third card to be the new secondary, (X2) take a checkpoint and (X3) initiate bulk synchronization. Upon completion of the bulk synchronization, the old primary card can be taken offline.⁴

²We use a small circular counter to track epoch values.

³We use a poison bit on the record written to the primary card which will be deleted only after the packet pongs back from the secondary to handle failures that may happen after step 2 in Figure 5.

⁴As a proof sketch, note that any new connection that reaches the new primary (old secondary) after X1 will reach the new secondary via the ping-pong method. Furthermore, all state at the time of the checkpoint, X2, will have been reliably copied to the new secondary.

3.3 Dividing NF load appropriately

So far, we have shown that the state for NFs can be maintained in a disaggregated resource pool with high availability. Here, we discuss different design points which divide the NF load between smart NICs that are directly attached to servers and one or more cards in the disaggregated Sirius pool.

3.3.1 Pin fNIC locally or to one card pair

Here, the load of each fNIC is assigned either to the on-server smart NIC or to a pair of cards as discussed in §3.2.

To realize pinning to a card pair, the outgoing packets of an fNIC are encapsulated in an NVGRE tunnel and sent to the chosen primary card in the Sirius pool which applies NFs on the packets and forwards them on to the destination. Traffic in the reverse direction takes an analogous path, first reaching the appliance/card which applies NFs and then forwarded to the VM if appropriate. We implement the encap and decap logic at the smart NICs on the servers.

3.3.2 Disaggregation Cost/ Benefit Analysis

The above design point already leads to substantial cost savings from disaggregation because one appliance can handle the NF load of over 24000 VMs on average. We compute this number as follows. In §6, we will show that each card used by Sirius can process over 16M new connections per second (CPS) with an extensive set of NFs. There are 12 cards per appliance. We assume that each VM has an average CPS load of 4K which is 400× the current median load per Figure 2a and we halve the NF capacity to replicate state as discussed in §3.2. Hence, the cost for the additional switches, cables and the appliance in Figure 4 amortize well. Moreover, regarding peak load and temporal variations, note that these 24000 VMs may be distributed over hundreds of racks and, as we saw in Table 2, the total load over many rack has much lower variability. Thus, Sirius can meet SLOs with much smaller surplus capacity in its disaggregated pools.

3.3.3 Split the load of an fNIC across multiple cards

With the previous design point, the maximum size of an fNIC is limited by the capacity of one card in the Sirius pool. Moreover, as we will show, packing VMs into appliances is less efficient when the size of the balls (i.e., the fNIC size of a VM) becomes close to the size of the bins (i.e., NF capacity in one card). Sirius appliances can also be implemented using diverse hardware and different NFs may be better suited to different hardware. To this end, we aim to split the load of an fNIC across multiple cards or appliances. That is, different portions of the traffic entering or leaving one VM can receive their NF processing at different cards.

Consider splitting the load using a hash function— $\text{hash}(\text{local IP}, \text{remote IP}) \bmod n$, in the encapper, to pick

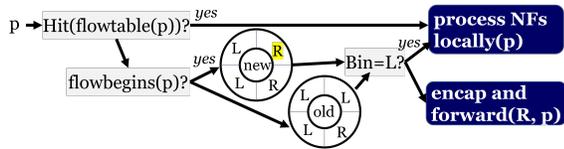

Figure 6: When spilling over NF load, as discussed in §3.3.4, we hash packets into bins and assign the bins to either local (L) or remote (R) NF processing. The figure shows two assignments new and old where the proportion of load that is processed locally is 50% and 75% respectively. When bins are re-assigned, the figure shows how we reduce the state that must be moved by using both bin assignments for a short duration.

from among n different cards. Such a *symmetric hash* ensures that the traffic of a flow in both directions will be processed at the same location which is required by some NFs (e.g., NATs [55]). While this requirement can be met in other ways, symmetric hashing requires no additional state at the encapper and decappers and we use hash functions that are easily implementable in NICs. Next, some NFs require groups of flows to be analyzed at one location. For example, a usage meter or a DDoS detector may want to count all bytes from a VM that leave the datacenter. Our experience is that most such NFs have mergeable actions [39], for example, to compute the total byte count, we can add up the partial sums from different processors. Many sketches (such as hyperloglog [54], count-min [49]) are mergeable with small reduction in accuracy [39, 40]. Finally, when an fNICs traffic is split across multiple NF processors, the ruleset corresponding to the fNIC must be installed at all of the corresponding processors; in practice, doing so adds overhead but is tenable because the total state at the NF processors is dominated by the per-flow state, counters and sketches rather than ruleset size; similarly processing the ruleset dominates the computation at the NF processor over the one-off installation of the ruleset.

3.3.4 Use Sirius as a load spillover

Thus far, all our load allocations have been static. That is, the whole or a portion of an fNICs traffic was allocated statically to the server’s smart NIC or to a Sirius pool. An alternative is to move NF load that cannot be processed locally *dynamically* into a Sirius pool. For example, we may start processing all of the NF load locally on the server’s smart NIC and when the total load nears smart NIC capacity, shed the excess load into the Sirius pool. Doing so will allow cloud providers to offer burstable SLOs on NF processing.⁵ One Sirius appliance can scale to even more VMs compared to the pinned design-point above because only the excess the load of fNICs will be steered to the appliance.

Naïvely supporting such dynamism would require *moving* the state of NFs. For example, if a portion of the traffic that was to be processed on the smart NIC must now spill over

⁵Burstable allocations are already available for CPU and memory. They allow short-duration bursts or price differently the average and peak usage.

into a Sirius pool then the corresponding state of all NFs must move. Intuitively, doing so is complex and our key contribution is to do so efficiently and correctly. First, our design aims to reduce the amount of state that must move to the extent possible. We hash packet headers, partition the resulting hash value into a fixed number of buckets (say 32), and assign different buckets to be processed for NFs at different locations. To move load, we change the bucket assignments; that is, to move 25% of the load from the smart NIC to a Sirius pool, we would reassign a quarter of the buckets that were being processed at the former location to the latter. Instead of moving all of the NF state that corresponds to a moving bucket we move *lazily* as shown in Figure 6. Effectively, newly created state (e.g., state for new connections) immediately reflects the current bucket assignment but for the previously established state, we delay movement by a short period (τ). Connections with duration below τ will not move and we observe that long-lived connections comprise a small fraction of all connections. The trade-off here is that we can rebalance load less frequently (once per τ). Our second idea is that many kinds of state can be re-created at the new NF processing location by just processing packets. For example, stateful ACLs insert the five tuples into a dictionary. The necessary information to create such state – the five tuple – is present in every packet of a flow and so, instead of moving state, we mark and steer packets to their new NF processing location. For state that cannot be recreated in this way, we craft new packets that include the packet header of the original flow and the state and transmit these packet to the new NF processing location. When the new location acknowledges creating the requisite state, the previous processing location deletes its state and load steering will exclusively use the new bucket assignment.

4 Efficient and high-rate NF processing

Thus far, we have discussed how to disaggregate the processing of stateful network functions in public clouds by using cards that (1) support inline replication of state (§3.2), (2) support various disaggregation design points including load splits and state movement (§3.3), and (3) implement a rich set of network functions (Table 1 and §2.1). Any implementation that satisfies these requirements can be used in this design including, for example, software-only or switch-only implementations. Here, we discuss our implementation which uses a specific kind of programmable NIC and compares favorably on functionality, performance and cost.

To process stateful network functions efficiently and at a high rate, we use the P4 programmable card shown in Figure 7 which has two 100 (or 200)GbE QSPF+ connectors, multiple pipelines that are programmable in P4, coherent shared memory, ARM cores for the more complex data plane processing and specialized logic for encryption and compression.

Relative to FPGA-based smart NICs [58], conjoining match-process-units (MPUs) that are programmable in P4

hit in the flow table) is handled by ARM cores. When load balancers are implemented without per-flow state (e.g., using a stateless hash function), any change to the pool of targets will disrupt ongoing flows; for example, a failure in one of the targets will cause the hash function to change from mod- n to mod- $n - 1$ and all flows whose targets change will be disrupted [83]. Recognizing this issue, several large enterprises deploy stateful load balancers which remember per flow the target that the flow was assigned to [56, 83, 85, 87]. Prior work that proposes to accelerate stateful load balancers is limited by on-switch memory, for example, Sailfish [85] uses the Tofino chipset to support a few thousand stateful connections per switch, while the other flows are processed in software and receive no benefits. In our tests, one card can support over 16M concurrent connections and 3M new connections per second. We note a few aspects that help us achieve such performance:

- Although the flow table (in grey on the left in Figure 8) has one entry per ongoing connection, the rewrite table uses indirection and can be significantly smaller in size.
- Our table datastructures allow for more expressive rewrites including changes to the MAC addresses. Thus, we can use a single rewrite table for multiple NFs beyond load balancing (e.g., NVGRE encap [30]).
- We allow partitioning the MPU programs (shown in dark in Figure 8) among multiple pipelines so as to leverage data proximity.
- We divide the table ownership between ARM cores and MPUs to avoid coordinating multiple writers.
- When a new flow arrives for load balance, an ARM core installs entries in the flow and rewrite tables and reinjects the first packet of that flow into the MPU pipelines.

Comparing with recent works [42, 47, 79, 94], two of the P4 pipelines in the DSC (the Ingress and Egress pipelines at the bottom of Figure 7a) resemble reconfigurable match tables (RMT) [42] except that the DSC also has pipeline-local SRAM and not just stage-local SRAM. However, unlike RMT, all of the DSC pipelines can access shared DRAM through coherent caches. The DMA pipelines ({Tx-, Rx-, Sx-}DMA in Figure 7a) are novel and are triggered by timers and doorbells from a programmable scheduler. PANIC [79] addresses chaining offloads and is similar to the DSC which also uses specialized offloads (for crypto, compression and others, see Offloads in Figure 7a). However, while the DSC chains offloads, offloads are not central to the use of DSC in Sirius. FlexCore [94] discusses runtime re-programmability of switches; they add and remove P4 functions on an SN3000 [31] switch with minimal disruption to ongoing activity. We do not discuss re-programmability of the DSC cards in this paper. dRMT [47] pools all of the per-stage memory into shared memory that is accessible to any stage and uses a run-to-completion model wherein a packet is fully handled at one processor (and not in a sequence of match-action stages as in RMT). Our card offers larger shared DRAM instead. While it

is unclear how dRMT’s scheduler, which calculates a static schedule at compile time to guarantee deterministic throughput and latency, generalizes to the case of stateful NFs, the DSC supports stateful NFs more simply by dividing the work between P4 pipelines and ARM cores.

5 Implementation

We have implemented several stateful network functions (including those in Table 1) on the programmable NIC shown in Figure 7 from AMD Pensando. We have also added new code to the smartNICs attached to the hosts in Azure to steer traffic to and from the disaggregated Sirius pool. The resulting system, alongside software controllers to provision and monitor the fNICs, is in public preview at Azure [1].

6 Evaluation

First, in a lab setting using full line-rate traffic generators, we show results for how the programmable NICs used in Sirius handle stateful network functions. We also evaluate key failure scenarios. Next, we report results from Azure wherein fNICs of virtual machines and network virtual appliances are offloaded to Sirius.

6.1 Methodology

Figure 9 shows our three experimental setups. On the left, in a lab, we use a traffic generator that sends and receives packets at hundreds of Gbps. We also mimic failures of the ToR switches, links, and cards to evaluate our state replication.

The other two setups use Sirius’s production deployment in Azure. Figure 9b measures the performance between virtual machines (VMs) and Figure 9c measures the performance of network virtual appliances (NVAs) [13, 18, 33] when deployed on VMs. Here, we compare the default method that the public cloud uses to process stateful NFs versus offloading those NFs onto Sirius. In Figure 9b, we offload the floating NICs of both the VMs onto Sirius. In Figure 9c, we offload the floating NICs of the middlebox VM onto Sirius.

Stateful NFs: For the setup in Figure 9a, each card enforces a large prioritized set of stateful ACLs. As shown in Table 4, each ACL rule is a conjunction of predicates on sets or ranges of source and destination addresses, ports and protocol. Rules apply in priority order and may either accept or deny a connection. Some rules are specific to individual VMs whereas others apply to all VMs in a vnet or subscription. Recall from §2.1 that stateful firewalls maintain per-flow state of all ongoing connections so as to admit traffic in the reverse direction. As discussed in §3.3, the cards also encap and decap the packets to intercede on traffic transparently. For the VM-to-VM setup in Figure 9b, VMs in the public cloud already run many stateful NFs by default, for example, to virtualize

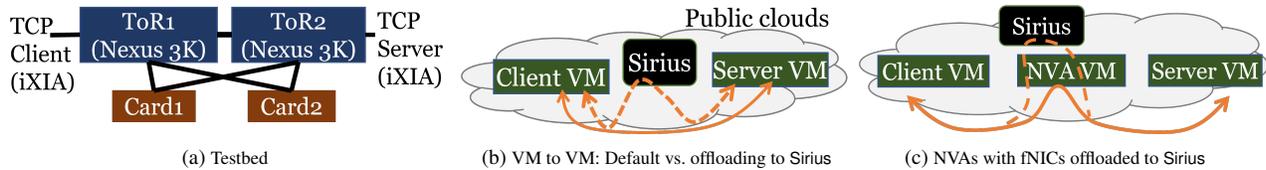

Figure 9: Evaluation setups. On the left is a testbed where we use iXIA breakingpoint [27] to generate traffic of up to 100Gbps. The other two figures depict our experiment setups in Azure. We deploy VMs of different sizes and compare the performance when the Azure-specific stateful NFs are offloaded onto Sirius. On the right we measure the performance of network virtual appliances (such as the Palo Alto VM-series firewall) when using floating NICs that offload onto Sirius.

Granularity of ACL set	#Rules	Total #Conjuncts (prefixes or ranges)			
		Src IP	Dest. IP	Src port	Dest port
fNIC level	202	5102	5102	1021	1021
Subnet level	26	1168	1168	141	141
Subscription	8	394	394	57	57

Table 4: The ACLs for a stateful firewall deployed on the cards in Figure 9a; note: some ACLs are unique per floating NIC whereas others are common across all fNICs in a subnet or an entire subscription.

Resource type	Resource Capacity					
#Cores	2	4	8	16	32	64
Mem. (GB)	8	16	32	64	128	256
NIC Capacity (Gbps)	1	2	4	8	16	30

Table 5: The capacity of various resources for the SKUs used in Figure 9.

their network [2, 10, 22] or to estimate traffic bills [5, 9, 20]. In addition, we insert 1000 prioritized stateful ACLs on the client VM; these ACLs are similar to those in the testbed experiment. For the middlebox experiment in Figure 9c, we configure each middlebox with the reference load specified by the middlebox vendor.

VMs: We evaluate popularly-used Linux Ubuntu SKUs at various public clouds as shown in Table 5. We choose VMs with varying numbers of cores, from 2 to 64 vcpus; the other resources vary roughly proportionally as shown.

Traffic: In Figure 9a, we generate UDP and TCP flows of different sizes at different rates in an open loop using a synthetic traffic generator [27]. This appliance must be physically connected to switches and so, in the public cloud experiments, we use VM-based traffic generators. The Linux network stack cannot generate small TCP connections at high rates, e.g., fewer than 50K zero-byte flows per core [82]. We use the TREX tool instead which, using DPDK, can generate TCP-like connections at much higher rates [37].

6.2 Processing Stateful NFs in Sirius

To sum, the experiment here will show that when supporting a rich set of stateful ACLs (Table 4) the programmable NIC used by Sirius can support up to 3M new TCP connections per second (Figure 10b) and over 50M UDP packets-per-second (Figure 10a). The latency to ping-pong state messages between a card pair is less than 40 μ s (Figure 10c).

In more detail, Figure 10 shows the thruput and latency when the two cards in Figure 9a are set up as a state replicating pair; that is, all state changes for SYNs and FINs are ping-

ponged between the cards as discussed in §3.2. Each datapoint is a several minute experiment and the errorbars show the range of measured values.

Since some stateful NFs are evaluated on every packet, we first measure the maximum number of packets per second (PPS) that our card can support by having the traffic generator send the smallest possible UDP packets at the highest possible rate.⁶ Figure 10a shows that our card supports over 50M packets per second.⁷ Typical packets are larger, e.g., many are MTU-sized, and so our card can process complex stateful NFs at line-rate with a fair amount of headroom.

The end-to-end latency through the card for 64B and 1500B packets is 2.36 μ s and 3.14 μ s respectively.

We also vary the number of concurrent flows which increases the state on the card and can make NF processing more challenging. Figure 10a shows only a modest decrease in PPS up to 64M concurrent flows; state for these many flows uses up most of the 32GB of DRAM on each card.

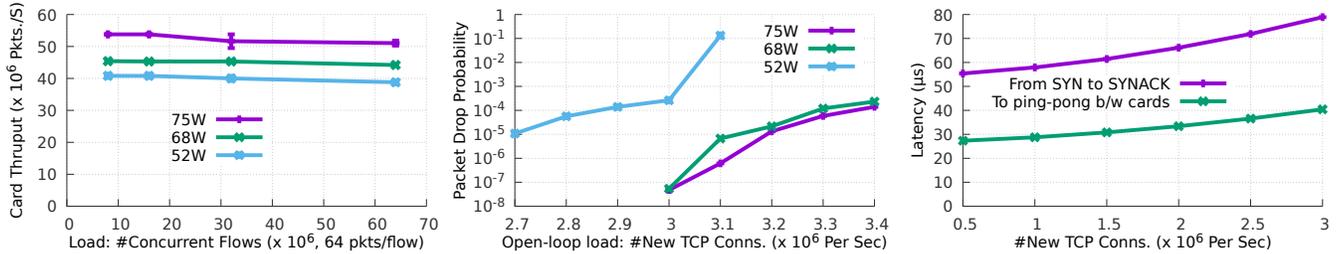

Finally, Figure 10a shows results for low power states of our card wherein we decrease the frequency of the MPU pipelines from their baseline value of 1.5GHz. Observe that we achieve 33% lower power draw with only a 25% drop in PPS. Thus, dynamic power cycling appears viable.

Next, when new connections arrive (or old connections finish) the state maintained in a stateful NF processor must change. To measure the maximum number of new connections per second (CPS) that one card pair can support, we have the traffic generator issue TCP connections in an open-loop with no payload.⁸ Figure 10b shows the packet drop probability (y axes is in log scale) near our desired operating point of 3M CPS. Lower values to the right are better. Since SYN and FIN packets ping-pong between the cards, each card effectively processes twice as many state changes. The remaining packets of the connection, however, only go through the primary card. Also, recall from §4 that only the ARM cores change state and SYNs are reinjected into the MPUs after the ARM cores apply the ruleset. Figure 10b shows that while the 68W power state has very little effect on CPS, the lowest power state (52W) reduces the CPS to about 2.5M. We are not yet sure why and

⁶Each packet is 118B due to VxLAN tunneling with an interframe gap of 12B and the ethernet preamble of 8B [38]. Thus, on a 100Gbps link, the generator issues roughly 90M packets/s.

⁷Per previous calculation, this amounts to 60Gbps.

⁸6 packets per connection: SYN, SYN-ACK, ACK, FIN, FIN-ACK, ACK

(a) The packets-per-second through our card when maintaining different numbers of concurrent flows. (b) The fraction of packets dropped when our card is subject to open loop load, a line for each power state. (c) Latency from sending a SYN to receiving a SYNACK and to ping-pong the SYN between cards.

Figure 10: Card measurements in the lab setup shown in Figure 9a: when applying per connection the thousands of stateful ACLs shown in Table 4, the figures show the throughput in PPS, packet drop probability and latency at different card power levels.

are looking into this issue.

For the CPS test above, Figure 10c measures the latency between sending a TCP SYN and receiving a SYN-ACK and the latency portion that is attributed to ping-pong between cards. The latency is flat at lower CPS load but grows super-linearly at higher demands likely due to queuing at the ARM cores or at reinjection. We note that RPCs can achieve a smaller latency [70, 84] by reusing connections and the latency here is better than that measured at the three clouds in Figure 3b.

6.3 Stateful NFs under faults

For the setup in Figure 9a, we have the traffic generator issue small TCP flows open-loop at the rate of 3M per second. The flows are spread over 16 floating NICs evenly allocated to the two Sirius cards. We examine the impact of three changes:

- (a) planned switchover from Card1 to Card2,
- (b) links between ToR1 and both cards go down and
- (c) Card1 goes down.

For each scenario, we conduct three different experiments each lasting 60s and report average values. Each experiment comprises roughly 180M TCP connections and 1.08B packets. Table 6 shows that none of the flows *broke* as in there were no RSTs or connection time-outs in all three scenarios.

During planned switchover of load, as discussed in §3.2, Card2 advertises itself as the new destination for all of the floating NICs that were mapped to Card1. During the ensuing route reconvergence, the ToR switches drop 0.00316% of the packets and there are no drops at either of the cards. A naïve switchover would cause RSTs on half of the ongoing connections (all conns with state on Card1).

In scenario (b), where ToR1’s links to both cards are down, the net available network capacity in/out of the cards halves but the CPS remains unaffected because, as noted in §3.1, Sirius retains large network capacity to the cards even when half of the connecting links fail. Table 6 shows that recovery here is slower and there are more drops because more routes must reconverge. The cards also see transient drops while their paths move over to ToR2.

Change	#Flow breaks	% of pkts dropped		Recovery Latency
		All	At Cards	
(a) Planned switchover	0	0.00316%	0	1.89ms
(b) ToR1’s links to both cards are down	0	0.00929%	0.0000227%	5.75ms
(c) Card1’s links to both ToRs are down	0	0.00835%	0.0000201%	5.01ms

Table 6: Testing state replication under different fault scenarios in Figure 9a with 3M new TCP flows/s. Note, recovery in milliseconds and the extremely small fraction of packets that were dropped most of which are due to route reconvergence at the ToR switches. The drops at the Sirius cards are all packets that cannot be transmitted because the link to the next hop is down.

Scenario (c) mimics the failure of Card1. Here, the ToRs detect Card1 as being down and route all fNIC traffic on the backup BGP route to Card2. Contemporaneously, Card2 recognizes the failing peer, promotes itself to be the primary, and notifies the Sirius controller asking for a new secondary card. If card state was not replicated, half of all ongoing connections will receive RSTs in this scenario. Table 6 shows that no connections break. Instead, only a few packets are dropped most of which are at the ToRs. A few flows retransmit SYNs and FINs⁹ which may have been lost without completing the pingpong in Figure 5 but none of the connections timeout.

6.4 VM-to-VM: Offloading fNICs to Sirius

Figure 11 shows the maximum connections per second achieved between pairs of VMs for the scenario in Figure 9b. Recall from §6.1 that we use TREX, a DPDK based generator on the VMs to create small TCP connections as many and as quickly as possible. These VMs have the default stateful NFs from public cloud and we add roughly 1000 randomly generated stateful ACLs (see §6.1). The figure shows that most of the VM SKUs, when onboarded on to Sirius, are only limited by the NIC capacity. That is, our tool makes as many connections as possible given the capacity limit of the NIC.¹⁰ The figure shows that with Sirius, one VM pair can achieve

⁹0.0062% and 0.0126% of the TCP flows respectively

¹⁰6 packets per TCP connection each of which is 118 bytes after VxLan encapsulation which translates to 176.5K CPS per Gbps of NIC capacity. NIC capacities of the VMs are as shown in Table 5.

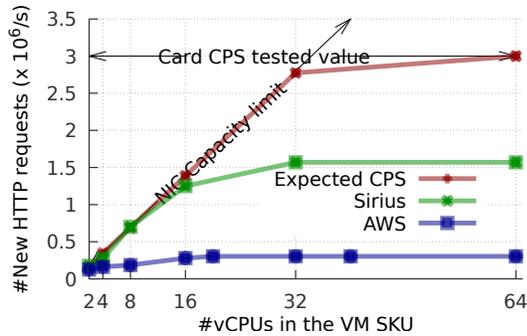

Figure 11: When the floating NIC of a VM is mapped onto the Sirius pool, showing the maximum CPS achieved between pairs of VMs.

over 1.5M connections per second. This value is below the maximum value per card – 3M CPS from Figure 10b– due to inefficiencies we believe in the code that steers fNIC traffic in the Azure smartNIC [58]. The figure also shows the CPS achieved using c5n series instances at EC2 using the same tool, the same configuration and the same guest OS. The lower CPS could be because EC2 employs different stateful NFs at each VM, uses a different NF processing system [6], applies explicit rate limits or some combination of all of the above. Comparing also with Figure 3a, we show that using Sirius a VM can achieve roughly 5× to 10× higher CPS. Further, recall from §3.3 that Sirius can split the load of a VM between multiple cards and so even higher CPS may be achievable.

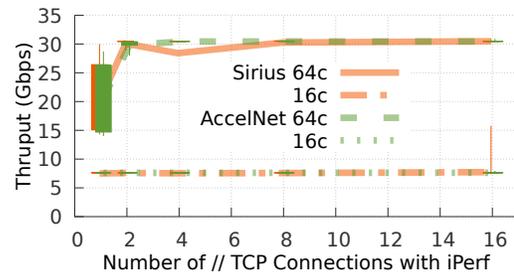

6.5 Measuring the Sirius datapath in Azure

To compare the datapath offered by the Sirius fNICs with the default datapath in Azure, we randomly and repeatedly deploy VMs and measure the latency and throughput on the two datapaths. Each VM in this experiment is equipped with three virtual NICs, one of which is used as the management interface and the other two are configured to use Sirius or AccelNet (the default in Azure) [58] respectively. The results shown are over millions of packets and tens of unique VM pairs.

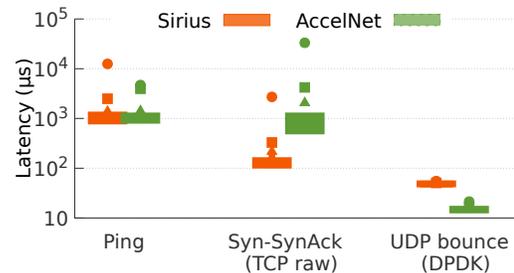

Figure 12a shows that the throughput achieved is nearly identical; with a small number of TCP flows, iPerf [26] can reach the NIC capacity on both of the datapaths.¹¹

Figure 12b shows the latency for three kinds of applications. On the left are applications such as ping, tcping and hping3 which use the traditional in-kernel network stack. Such apps do not see any change in their RTT when using Sirius. Notice that with Sirius the datapath between a VM pair traverses up to two programmable NICs corresponding to the VMs’ floating NICs. However, any increase in the physical length of the network path appears to be masked by the latency added by the guest kernel network stacks. In the middle of Figure 12b is the latency for the custom tool that we used in §2.3 which

¹¹As noted in Table 5, the NIC capacity limits for the 16 and 64 core VMs that we used here are 8Gbps and 30Gbps respectively.

(a) Throughput achieved by iPerf with different numbers of TCP flows. The candlesticks show quartiles (bars) and the min and max values (whiskers) over many pairs of VMs and minutes.

(b) RTT using ping, TCP connections on raw sockets and a DPDK app that bounces UDP packets. In the candlesticks, the bars correspond to quartiles and the whiskers are the 10th and 90th percentiles. The triangle, square and circle above each bar show the 99th, 99.9th, and 99.99th percentile values respectively.

Figure 12: Comparing the datapath of AccelNet [58] with the disaggregated path through Sirius in Azure.

establishes TCP connections on raw sockets. As the figure shows, for such apps Sirius offers a better RTT than AccelNet because although Sirius may have a longer physical path, AccelNet takes much longer to process the stateful NFs for each new TCP connection. A third set of applications, on the right in Figure 12b, achieve very small latency by bypassing both the kernel network stacks (using an optimized DPDK app that we built) as well as the cloud’s stateful NFs (by using UDP packets). As the figure shows, the typical latency for such apps is 15μs and 50μs respectively on the AccelNet [58] and Sirius datapaths. Note also the values on the tail. We conclude that any additional latency due to Sirius will only be visible to a small subset of applications and that for the vast majority of TCP-like traffic Sirius represents a clear improvement.

6.6 Offloading fNICs of middlebox NVAs

For the experiment setup shown in Figure 9c, Figure 13 shows the CPS achieved by traffic through different middlebox VMs. We generate results for Sirius using 32 core VMs as clients and servers of the traffic and offload the floating NIC of the middlebox VM onto Sirius. For all of the public clouds, we pick the best possible CPS numbers from datasheets released by the middlebox vendors [13, 17–19, 34]. The figure shows that using Sirius substantially improves the achievable throughput because the stateful network functions that cloud providers apply by default on the middlebox VM are often

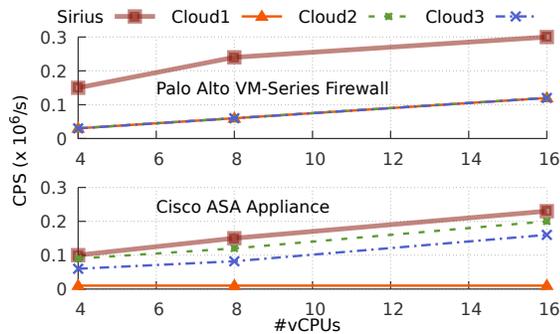

Figure 13: The CPS (# new connections per second) at which traffic can be sent through three different middlebox network virtual appliances on different public clouds and when onboarded onto Sirius.

the limiting factor to middlebox performance.

7 Related Work

The key focus of Sirius is to disaggregate stateful network functions onto pools of programmable NICs which tightly integrate P4-programmable MPUs and general purpose ARM cores with a large coherent memory system. With Sirius, we show how to replicate connection state inline so that individual card failure does not adversely impact ongoing connections (§3.2), discuss multiple design-points which split or migrate the load of a VM across different NF processors (§3.3) and offer an implementation that achieves better performance-over-cost than state-of-the-art (§4).

We are unaware of any prior characterization of the NF load at a large public cloud (§2.2). However, the case for disaggregation based on NF load being skewed across VMs and decorrelated (that is, having smaller variance when considered in aggregates such as at rack-level) is similar to the cases made to disaggregate other resources [59,66,74,78,89,91,96].

The state-of-the-art in processing stateful network functions is either in vswitch software or on programmable FPGAs that are directly connected to the host [6,57,58]. Andromeda [52] processes NFs at dedicated software middleboxes but explicitly states that they do not support stateful functions listing concerns such as ‘state loss during upgrade or failure’, ‘transferring state when offloading’ and ‘ensuring that flows are ‘sticky’ to the hoverboard that has the correct state’ [52]. We address some of these challenges in §3 and to the best of our knowledge are the first to disaggregate the rich class of stateful NFs listed in Table 1 and §2.1.

Offloading stateful network functions is non-trivial since a large amount of memory to maintain state must be accessible at high speeds. SRAMs support switch linerates but are expensive and so we use a bag of NICs architecture with memory coherence. Some prior works offload specific stateful NFs into programmable hardware [41,83,85]; however, they use switches and can only offload only a small subset

of all flows, e.g., top-k by rate [41,83,85]. To compensate, TEA [73] pairs Tofinos with memory on remote servers and uses RPCs to access the remote state. When state is remote, it is challenging to achieve high performance and reliability. Also, Tofinos lack integrated general-purpose cores which forces TEA to build, in P4, a new RPC and a new reliable transport. With Sirius, each card has much larger memory. We replicate state between NICs on nearby servers in one pool and our general-purpose ARM cores simplify the logic. We believe that pairing cards which have tightly-integrated MPUs and ARM cores facilitates richer forms of disaggregation.

Another alternative is to use custom FPGAs with large memory (e.g., Xilinx and Altera). We are unaware of any works that match the performance and power draw of our cards using FPGAs. We believe that (1) P4 programmable MPUs are fundamentally more efficient than FPGAs [43,76,77], and (2) carefully dividing work between MPUs and ARM cores is key for high performance.

We discuss other related work in §C.

8 Conclusion

Stateful network functions are a key cog in today’s public cloud architectures. We disaggregate their processing into a shared pool. Doing so avoids paying for smart-NICs at each server that are provisioned to support peak load, reduces constraints in VM placement and increases performance on the tail. Moreover, we attach this shared pool to the data-center network at the layer off which most packets bounce off in the CLOS and so the latency and bandwidth overhead from packets taking a detour to the shared pool is small. We show a novel and simple solution that replicates connection state between pairs of cards without buffering packets while replicating state. We use NICs that have large memory, P4-programmable match-action pipelines and integrated general-purpose ARM cores. Our results from deployment at Azure show that network usage at VMs can reach NIC capacity even when complex stateful NFs are executed on each new connection and every packet.

A Discussion

A.1 Complications in failover

It is possible for the ToR switches (shown in green in Figure 4), which probe the cards for liveness, to reach different liveness estimates for a card pair. That is, one of the switches can conclude a card is down while the other switch concludes otherwise. Similarly, even though we use multiple heartbeats and there are multiple network paths between a card pair, it is possible that so many consecutive heartbeats are lost allowing one of the cards in a card pair to conclude that the peer is down even though the peer is alive. A *split-brain* happens when different parts of the network assume that different cards (in a card pair) are responsible for an fNIC. Recall that the primary card announces a BGP route with a smaller AS path which helps resolve some of these complications. In addition,

we notify all card role changes to a logically centralized Sirius controller which helps to ensure that *split-brain* cases, were they to happen, do not persist for very long.

A.2 fNIC abstraction guarantees

We statically partition each card’s *capacity*, on the dimensions listed in §3, among the fNICs that are mapped to a card. The capacity values that we use for apportioning (e.g., the last row of Table 7) are slightly smaller than the maximum values that we see in experiments using iXIA traffic generators and a rich variety of network functions in subsection 6.2 and so we do not anticipate performance interference issues at the card.

A.3 Encryption, Traffic QoS

Some aspects such as end-to-end encryption and traffic prioritization can require on-host support. With Sirius, we are exploring how to divide such functions between the disaggregated pool and the smart NIC that is directly attached to the host. For example, the disaggregated pool can perform the more stateful processing such as exchanging keys or determining which queue to assign a flow to so as to meet its priority class or bandwidth limit while the on-host FPGA performs tasks that require less state such as marking or rate limiting queues [90].

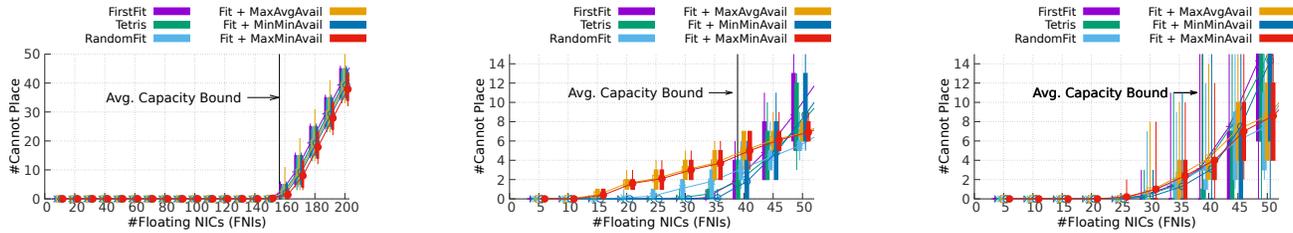

B Additional Results

B.1 Packing floating NICs into Sirius cards

Table 7 shows the sizes of the floating NICs that Sirius offers and the card capacity. A Sirius appliance has 12 cards. We evaluate several vector bin packing heuristics [61, 86] to pack fNICs onto Sirius cards. Our results in Figure 14 show that:

- The optimal choice of a packing heuristic, in terms of packing efficiency, depends on the size distribution of the fNICs and whether or not we split load of an fNIC across multiple cards.
- In some cases, such as when small fNICs dominate the workload, any heuristic can achieve the average capacity bound¹² which assumes that there are no card boundaries and that all resources are in one large pool.
- Splitting the load of an fNIC across cards substantially improves efficiency but also increases state that must be maintained on cards since rulesets belonging to split fNICs must now be deployed on multiple cards. The per flow and per endpoint state substantially dominates the ruleset size however. Nevertheless, we aim to split only fNICs that have large resource needs.

¹²bound = $\min_{\text{resource } r} \frac{\text{total capacity on } r}{\text{avg. FNI load on } r}$

(a) Packing efficiency when the fNICs listed in Table 7 arrive as per the production distribution from §2.2.

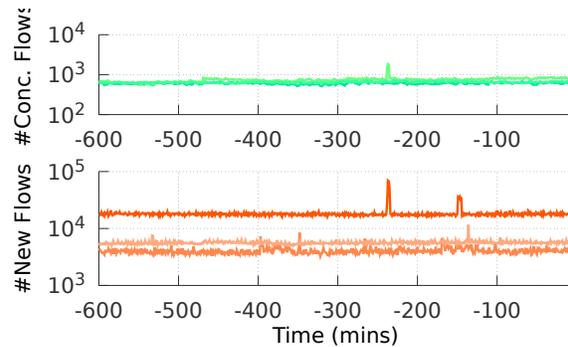

(b) Comparing the packing efficiency when the fNICs listed in Table 7 arrive with an equal probability.

(c) The case of Figure 14b except with the load from each fNIC split evenly across two cards.

Figure 14: Comparing different vector bin packing strategies when mapping floating NICs (granularity of resource allocation for network functions supported by Sirius as listed in Table 7) to a Sirius appliance with 12 cards.

Term	Resource Sizing		
	#New Flows (Millions Per Sec.)	# Concurrent Flows (M)	Throughput (Gbps)
FNI_XXS	0.05	1	5.0
FNI_XS	0.10	1	10.0
FNI_S	0.25	2	12.5
FNI_M	1.00	2	12.5
FNI_L	2.00	4	12.5
FNI_XL	3.00	16	50.0
Sirius card	3.00	16	200.0

Table 7: The resource sizes, along multiple dimensions, that Sirius associates with different kinds of floating NICs. Cloud customers can choose which floating NIC to associate with their VM.

(a) Temporal changes in NF load; showing the total load at three randomly chosen nodes; note: y axes is in log scale.

B.2 Variation in the load for NFs at Azure

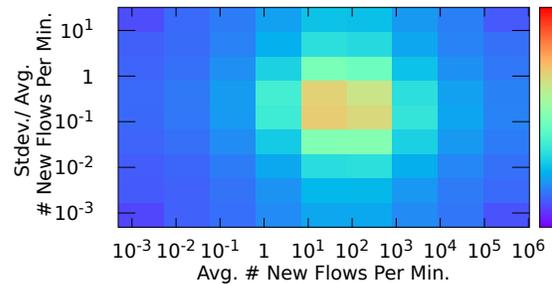

We analyze load variability across all containers in Azure using the same dataset described in §2.2.

Figure 15a shows the temporal variation in the cumulative NF load. The figure shows many short-lived spikes, some of which are larger than $4\times$; note y axes is in log-scale. We also see some innate variability in the steady-state load across these nodes.

Figure 15b is a 2D matrix where each entry represents the number of containers that have the corresponding (x, y) value. The x axes is the average numbers of new flows in each minute. The y axes is the coefficient of variation in the same metric ($=\text{stdev./ avg.}$). Both axes are in log-scale. As well, the number of containers which is shown as a heat plot on the right is also in log scale. The figure shows that most of the containers have between 10 to 1000 new flows per minute and the coefficient of variation is typically between 0.1 and 1. While the variability is high for many containers, containers with more average load appear to only have slightly higher variability and there are no unexpected patterns.

C Additional Related Work

State replication for fault tolerance has received much attention; see [53, 64] for a review. Our method in §3.2 is different from the primary-backup style replication [44, 51] wherein the primary processes requests, forwards state changes to the backup and emits responses after receiving an acknowledge-

(b) Clustering containers based on their average NF load and the coefficient of variability ($=\text{stdev./ avg.}$) of their NF load.

Figure 15: Additional characterization results from the dataset in §2.2.

ment from the backup. Our method is also different from Paxos-like protocols [46, 48, 50, 81] where replicas first agree on an order in which to process requests and then process the requests. The key difference is that both alternatives hold requests while replication is underway. In the case of stateful NFs, requests are packets that change state and so holding requests at speeds of hundreds of Gbps will require a very large packet buffer. To our knowledge, we are unaware of any prior work that ping-pong's packets between replicas which effectively holds the requests on the network wire. Redplane [72] replicates the state between programmable switches and a server-based remote state store but must cope in P4 with route changes that happen between the switches and the server-based store. Our method is simpler and more performant.

For the case of moving state on-the-fly between multiple NF processors, OpenNF [60] is perhaps the first to describe in detail the multiple issues that arise. Their solution however buffers all the packets that arrive while the state is being moved at an SDN controller (e.g., Floodlight [16]) which becomes a scaling bottleneck. OpenNF [60] reports results for $O(100)$ flows (e.g., “a loss-free move involving state for 500 flows takes only 215ms”) whereas each fNIC in Sirius can have many millions of ongoing flows. Similar to Red-Plane [72], StatelessNF [69] and [71] store relevant NF state in an external state store (e.g., in a RAMCloud [69]). As noted above, relative to Sirius (which stores state in a nearby secondary card), we believe that storing state in an external state store has higher intrinsic overheads.

Following the Data, Not the Function: Rethinking Function Orchestration in Serverless Computing

Minchen Yu[†] Tingjia Cao^{‡*} Wei Wang[†] Ruichuan Chen[§]

[†]Hong Kong University of Science and Technology

[‡]University of Wisconsin-Madison [§]Nokia Bell Labs

Abstract

Serverless applications are typically composed of function workflows in which multiple short-lived functions are triggered to exchange data in response to events or state changes. Current serverless platforms coordinate and trigger functions by following high-level invocation dependencies but are oblivious to the underlying data exchanges between functions. This design is neither efficient nor easy to use in orchestrating complex workflows – developers often have to manage complex function interactions by themselves, with customized implementation and unsatisfactory performance.

In this paper, we argue that function orchestration should follow a *data-centric approach*. In our design, the platform provides a *data bucket abstraction* to hold the intermediate data generated by functions. Developers can use a rich set of data trigger primitives to control when and how the output of each function should be passed to the next functions in a workflow. By making data consumption explicit and allowing it to trigger functions and drive the workflow, complex function interactions can be easily and efficiently supported. We present Phomone – a scalable, low-latency serverless platform following this data-centric design. Compared to well-established commercial and open-source platforms, Phomone cuts the latencies of function interactions and data exchanges by orders of magnitude, scales to large workflows, and enables easy implementation of complex applications.

1 Introduction

Serverless computing, with its Function-as-a-Service incarnation, is becoming increasingly popular in the cloud. It allows developers to write highly scalable, event-driven applications as a set of short-running functions. Developers simply specify the events that trigger the activation of these functions, and let the serverless platform handle resource provisioning, autoscaling, logging, fault-tolerance, etc. Serverless computing is also economically appealing as it has zero idling cost: developers are only charged when their functions are running.

Many applications have recently been migrated to the serverless cloud [28, 35, 39, 43, 48, 59, 68, 75, 78]. These applications typically consist of multiple interactive functions with diverse

function-invocation and data-exchange patterns. For example, a serverless-based batch analytics application may trigger hundreds of parallel functions for all-to-all data communication in a shuffle phase [49, 59, 79]; a stream processing application may repeatedly trigger certain functions to process dynamic data received in a recent time window. Ideally, a serverless platform should provide an *expressive* and *easy-to-use* function orchestration to support various function-invocation and data-exchange patterns. The orchestration should also be made *efficient*, enabling low-latency invocation and fast data exchange between functions.

However, function orchestration in current serverless platforms is neither efficient nor easy to use. It typically models a serverless application as a *workflow* that connects functions according to their invocation dependency [4, 11, 21, 24, 34, 51, 53, 66]. It specifies the order of function invocations but is *oblivious to when and how data are exchanged between functions*. Without such knowledge, the serverless platform assumes that the output of a function is entirely and immediately consumed by the next function(s), which is not the case in many applications such as the aforementioned “shuffle” operation in batch analytics and the processing of dynamically accumulated data in stream analytics. To work around these limitations, developers have to manage complex function interactions and data exchanges by themselves, using various approaches such as a message broker or a shared storage, either synchronously or asynchronously [6, 10, 24, 31, 49, 66]. As no single approach is found optimal in all scenarios, developers may need to write complex logic to dynamically select the most efficient approach at runtime (see §2.2). Current serverless platforms also incur function interaction latencies of tens of milliseconds, which may be unacceptable to latency-sensitive applications [46], particularly since this overhead accumulates as the function chain builds up.

In this paper, we argue that function orchestration should follow the flow of data rather than the function-level invocation dependency, thus a *data-centric approach*. Our key idea is to make data consumption explicit, and let it trigger functions and drive the workflow. In our design, the serverless platform exposes a *data bucket abstraction* that holds the intermediate output of functions in a logical object store. The data bucket provides a rich set of data trigger primitives that developers can use to specify *when* and *how* the intermediate

*This work was partially done while the author was at HKUST.

data are passed to the intended function(s) and trigger their execution. With such a fine control of data flow, developers can express sophisticated function invocations and data exchanges, simply by configuring data triggers through a unified interface. Knowing how intermediate data will be consumed also enables the serverless platform to schedule the intended downstream functions close to the input, thus ensuring fast data exchange and low-latency function invocation.

Following this design approach, we develop Pheromone¹, a scalable serverless platform with low-latency data-centric function orchestration. Pheromone proposes three key designs to deliver high performance. **First**, it uses a two-tier distributed scheduling hierarchy to locally execute a function workflow whenever possible. Each worker node runs a local scheduler, which keeps track of the execution status of a workflow via its data buckets and schedules next functions of the workflow onto local function executors. In case that all local executors are busy, the scheduler forwards the request to a global coordinator which then routes it to another worker node with available resources. **Second**, Pheromone trades the durability of intermediate data, which are typically short-lived and immutable, for fast data exchange. Functions exchange data within a node through a zero-copy shared-memory object store; they can also pass data to a remote function through direct data transfer. **Third**, Pheromone uses sharded global coordinators, each handling a disjoint set of workflows. With such a shared-nothing design, local schedulers only synchronize workflows' execution status with the corresponding global coordinators, which themselves require no synchronization, thus ensuring high scalability for distributed scheduling.

We evaluate Pheromone against well-established commercial and open-source serverless platforms, including AWS Lambda with Step Functions, Azure Durable Functions, Cloudburst [66], and KNIX [24]. Evaluation results show that Pheromone improves the function invocation latency by up to 10× and 450× over Cloudburst (best open-source baseline) and AWS Step Functions (best commercial baseline), respectively. Pheromone scales well to large workflows and incurs only millisecond-scale orchestration overhead when running 1k chained functions and 4k parallel functions, whereas the overhead is at least a few seconds in other platforms. Pheromone has negligible data-exchange overhead (e.g., tens of μ s), thanks to its zero-copy data exchange. It can also handle failed functions through efficient re-execution. Case studies of two serverless applications, i.e., Yahoo! stream processing [40] and MapReduce sort, further demonstrate that Pheromone can easily express complex function interaction patterns (*rich expressiveness*), require no specific implementation to handle data exchange between functions (*high usability*), and efficiently support both latency-sensitive and data-intensive applications (*wide applicability*).

¹Pheromone is a chemical signal produced and released into the environment by an animal that triggers a social response of others of its species. We use it as a metaphor for our data-centric function orchestration approach.

2 Background and Motivation

We first introduce serverless computing and discuss the limitations of function orchestration in current serverless platforms.

2.1 Serverless Computing

Serverless computing, with its popular incarnation being Function-as-a-Service (FaaS), has recently emerged as a popular cloud computing paradigm that supports highly-scalable, event-driven applications [8, 18, 22]. Serverless computing allows developers to write short-lived, stateless functions that can be triggered by events. The interactions between functions are simply specified as *workflows*, and the serverless platform manages resource provisioning, function orchestration, autoscaling, logging, and fault tolerance for these workflows. This paradigm appeals to many developers as it allows them to concentrate on the application logic without having to manage server resources [47, 63] – hence the name serverless computing. In addition to the high scalability and operational simplicity, serverless computing adopts a “pay-as-you-go” billing model: developers are billed only when their functions are invoked, and the function run-time is metered at a fine granularity, e.g., 1 ms in major serverless platforms [8, 18]. Altogether, these benefits have increasingly driven a large number of traditional “serverful” applications to be migrated to the serverless platforms, including batch analytics [39, 48, 59, 79], video processing [35, 43], stream processing [28], machine learning [75, 78], microservices [46], etc.

2.2 Limitations of Current Platforms

Current serverless platforms take a *function-oriented* approach to orchestrating and activating the functions of a serverless workflow: each function is treated as a single and standalone unit, and the interactions of functions are separately expressed within a workflow. This workflow connects individual functions according to their invocation dependencies, such that each function can be triggered upon the completion of one or multiple upstream functions. For example, many platforms model a serverless workflow as a directed acyclic graph (DAG) [4, 11, 21, 24, 34, 51, 53, 66], in which the nodes represent functions and the edges indicate the invocation dependencies between functions. The DAG can be specified using general programming languages [4, 21], or domain-specific languages such as Amazon States Language [11, 24]. However, this approach has several limitations with regard to expressiveness, usability, and applicability.

Limited expressiveness. Although the current function-oriented orchestration supports the workflows of simple invocation patterns, it becomes inconvenient or incapable of expressing more sophisticated function interactions, as summarized in Table 1. This is because the current function orchestration assumes that data flow in the same way as how

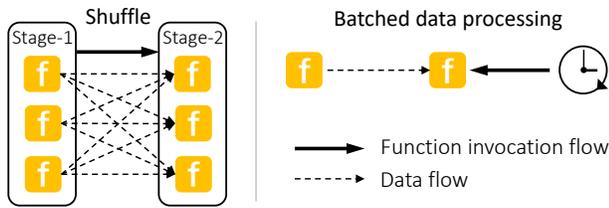

Figure 1: The shuffle operation (left) in data analytics and the batched data processing in a stream (right).

functions are invoked in a workflow, and that a function passes its entire output to others by directly invoking them for immediate processing. These assumptions do not hold for many applications, hence developers resort to create workarounds.

For example, the “shuffle” operation in a data analytics job involves a fine-grained, all-to-all data exchange between the functions of two stages (e.g., “map” and “reduce” stages). As shown in Fig. 1 (left), the output data of a function in stage-1 are shuffled and selectively redistributed to multiple functions in stage-2 based on the output keys. However, the way to invoke functions is not the same as how the output data flow: only after stage-1 completes can the workflow invoke all the stage-2 functions in parallel. In current serverless platforms, developers must manually implement such a complex data shuffle invocation via external storage [49, 59], which is neither flexible nor efficient.

Another example is a batched stream analytics job which periodically invokes a function to process the data continuously received during a time window [40, 73], as shown in Fig. 1 (right). A serverless workflow cannot effectively express this invocation pattern as the function is not immediately triggered when the data arrive, and thus developers have to rely on other cloud services (e.g., AWS Kinesis [7]) to batch the data for periodic function invocations [28–30]. Note that, even with the latest stateful workflow (e.g., Azure Durable Functions [17]), an addressable function needs to keep running to receive data. As we will show in §6.5, deploying a long-running function not only incurs extra resource provisioning cost but results in an unsatisfactory performance.

Limited usability. Current serverless platforms provide various options for data exchange between functions. Functions can exchange data either synchronously or asynchronously via a message broker or a shared storage [6, 10, 24, 31, 49, 66]. They can also process data from various sources, such as nested function calls, message queues, or other cloud services [23].

The lack of a single best approach to exchange data between functions significantly complicates the development and deployment of serverless applications, as developers must find their own ways to efficiently pass data across functions [53] which can be dynamic and non-trivial; thus, reducing the usability of serverless platforms. To illustrate this problem, we compare four data-passing approaches in AWS Lambda: a) calling a function directly (Lambda), b) using AWS Step Functions (ASF) to execute a two-function work-

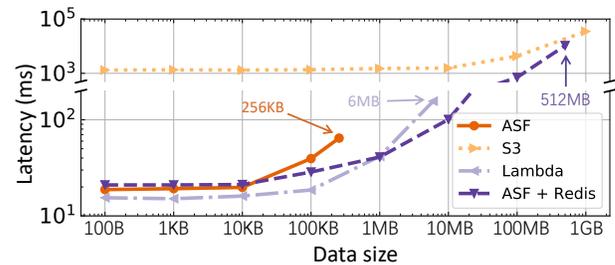

Figure 2: The interaction latency of two AWS Lambda functions under various data sizes using four approaches.

flow², c) allowing functions to access an in-memory Redis store for fast data exchange (ASF+Redis), and d) configuring AWS S3 to invoke a function upon data creation (S3) [32]. Fig. 2 compares the latencies of these four approaches under various data volumes. Lambda is efficient for transferring small data; ASF+Redis is efficient for transferring large data; the maximum data volume supported by each approach varies considerably, and only the S3 approach can support virtually unlimited (but slow) data exchange. Thus, there is no single approach that prevails across all scenarios, and developers must carefully profile the data patterns of their applications and the serverless platforms to optimize the performance of data exchange between interacting functions.

To make matters worse, the data volume exchanged between functions depends on the workload, which may be irregular or unpredictable. Thus, there may be no best *fixed* approach to exchanging data between interacting functions, and developers have to write complex logic to select the best approach at runtime. Developers also need to consider the interaction cost. Previous work has highlighted the tricky trade-off between I/O performance and cost when using different storage to share intermediate data [49, 59], which further exacerbates the usability issue. Altogether, these common practices bring a truly *non-serverless* experience to developers as they still have to deal with server and platform characteristics.

Limited applicability. Existing serverless applications are typically not latency-sensitive. This is because current serverless platforms usually have a function interaction delay of multiple or tens of milliseconds (§6.2), and such delays accumulate as more functions are chained together in an application workflow. For example, in AWS Step Functions, each function interaction causes a delay of more than 20 ms, and the total platform-incurred delay for a 6-function chain is over 100 ms, which may not be acceptable in many latency-sensitive applications [46]. In addition, as current serverless platforms cannot efficiently support the sharing of varying-sized data between functions (as described earlier), they are ill-suited for data-intensive applications [8, 24, 43, 46, 59, 66]. Altogether, the above characteristics substantially limit the applicability of current serverless platforms.

²We use the ASF Express Workflows in our experiments as it delivers higher performance than the ASF Standard Workflows [14].

3 Data-Centric Function Orchestration

In this section, we address the aforementioned limitations of the function orchestration practice in current serverless platforms, with a novel data-centric approach. We will describe how this approach can be applied to develop a new serverless platform later in §4.

3.1 Key Insight

As discussed in §2.2, the current function orchestration practice only specifies the high-level invocation dependencies between functions, and thus has little fine-grained control over how these functions exchange data. In particular, the current practice assumes the tight coupling between function flows and data flows. Therefore, when a function returns its result, the workflow has no knowledge about how the result should be consumed (e.g., in full or part, directly or conditionally, immediately or later). To address these limitations, *an effective serverless platform must allow fine-grained data exchange between the functions of a workflow, while simultaneously providing a unified and efficient approach for function invocation and data exchange.*

Following this insight, we propose a new *data-centric approach* to function orchestration. We note that intermediate data (i.e., results returned by functions) are typically short-lived and immutable [49, 67]: after they are generated, they wait to be consumed and then become obsolete.³ We therefore make data consumption explicit and enable it to trigger the target functions. Developers can thus specify when and how intermediate data should be passed to the target functions and trigger their activation, which can then drive the execution of an entire workflow. As intermediate data are not updated once they are generated [49, 67], using them to trigger functions results in no consistency issues.

The data-centric function orchestration addresses the limitations of the current practice via three key advances. First, it breaks the tight coupling between function flows and data flows, as data do not have to follow the exact order of function invocations. It also enables a flexible and fine-grained control over data consumption, and therefore can express a rich set of workflow patterns (i.e., *rich expressiveness*). Second, the data-centric function orchestration provides a unified programming interface for both function invocations and data exchange, obviating the need for developers to implement complex logic via a big mix of external services to optimize data exchange (i.e., *high usability*). Third, knowing when and how the intermediate data will be consumed provides opportunities for the serverless platform scheduler to optimize the locality of functions and relevant data, and thus latency-sensitive and data-intensive applications can be supported efficiently (i.e., *wide applicability*).

³For data that need durability, they can be persisted to a durable storage.

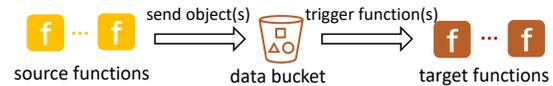

Figure 3: An overview of triggering functions in data-centric orchestration. Source functions send intermediate data to the associated bucket, which can be configured to automatically trigger target functions.

3.2 Data Bucket and Trigger Primitives

Data bucket. To facilitate the data-centric function orchestration, we design a *data bucket* abstraction and a list of *trigger primitives*. Fig. 3 gives an overview of how functions are triggered. A serverless application creates one or multiple data buckets that hold the intermediate data. Developers can configure each bucket with triggers that specify when and how the data should invoke the target functions and be consumed by them. When executing a workflow, the source functions directly send their results to the specified buckets. Each bucket checks if the configured triggering condition is satisfied (e.g., the required data are complete and ready to be consumed). If so, the bucket triggers the target functions automatically and passes the required data to them. This process takes place across all buckets, which collectively drive the execution of an entire workflow.

We design various trigger primitives for buckets to specify how functions are triggered. The interaction patterns between functions can be broadly classified into three categories:

Direct trigger primitive (i.e., Immediate) allows one or more functions to directly consume data in the associated buckets. This primitive has no specified condition, and triggers the target functions immediately once the data are ready to be consumed. This primitive can easily support sequential execution or invoke multiple functions in parallel (fan-out).

Conditional trigger primitives trigger the target function(s) when the developer-specified conditions are met.

- **ByBatchSize:** It triggers the function(s) when the associated bucket has accumulated a certain number of data objects. It can be used to enable the batched stream processing [29, 30] in a way similar to Spark Streaming.
- **ByTime:** It sets up a timer and triggers the function(s) when the timer expires. All the accumulated data objects are then passed to the function(s) as input. It can be used to implement routine tasks [40, 73].
- **ByName:** It triggers the function(s) when the bucket receives a data object of a specified name. It can be used to enable conditional invocations by choice [12].
- **BySet:** It triggers functions when a specified set of data objects are all complete and ready to be consumed. It can be used to enable the assembling invocation (fan-in).
- **Redundant:** It specifies n objects to be stored in a bucket and triggers the function(s) when any k of them are

Table 1: Expressiveness comparison between the function-oriented workflow primitives in AWS Step Functions (ASF) and the data-centric trigger primitives in Pheromone.

Invocation Patterns	ASF	Pheromone
Sequential Execution	Task	Immediate
Conditional Invocation	Choice	ByName
Assembling Invocation	Parallel	BySet
Dynamic Parallel	Map	DynamicJoin
Batched Data Processing	-	ByBatchSize ByTime
k -out-of- n	-	Redundant
MapReduce	-	DynamicGroup

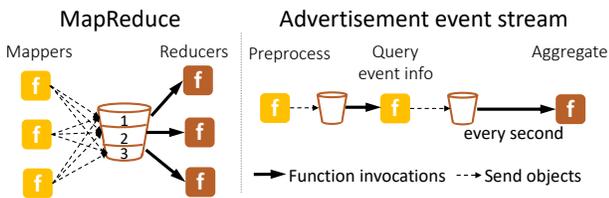

Figure 4: Usage examples of two primitives: DynamicGroup for data shuffling in MapReduce (left), and ByTime for periodic data aggregation in the event stream processing (right).

available and ready to be consumed. It can be used to execute redundant requests and perform late binding for straggler mitigation and improved reliability [50, 60, 69].

Dynamic trigger primitives, unlike the previous two categories with statically-configured triggers, allow data exchange patterns to be configured at runtime.

- **DynamicJoin**: It triggers the assembling functions when a set of data objects are ready, which can be dynamically configured at runtime. It enables the dynamic parallel execution like ‘Map’ in AWS Step Functions [13].
- **DynamicGroup**: It allows a bucket to divide its data objects into multiple groups, each of which can be consumed by a set of functions. The data grouping is dynamically performed based on the objects’ metadata (e.g., the name of an object). Once a group of data objects are ready, they trigger the associated set of functions.

Dynamic trigger primitives are critical to implement some widely-used computing frameworks, e.g., MapReduce (which is hard to support in current serverless platforms as it requires triggering parallel functions at every stage and optimizing the fine-grained, all-to-all data exchange between them [48, 49, 59], see §2.2). Here, our DynamicGroup primitive provides an easy solution to these issues. As shown in Fig. 4 (left), when a map function sends intermediate data objects to the associated bucket, it also specifies to which data group each object belongs (i.e., by specifying their associated keys). Once the map functions are all completed, the bucket triggers the reduce functions, each consuming a group of objects.

We have developed a new serverless platform, Pheromone, which implements the aforementioned data bucket abstrac-

```

struct BucketKey {
    string bucket_; // bucket name
    string key_; // key name
    string session_; // unique session id per request
};

abstract class Trigger {
    // Check whether to trigger functions for a new object.
    vector<TriggerAction> action_for_new_object(
        BucketKey bucket_key);

    // Notify the information of a source function.
    void notify_source_func(string function_name,
        string session, vector<string> function_args);

    // Check whether to re-execute source functions.
    vector<TriggerAction> action_for_rerun(string session);
};

```

Figure 5: Three main methods of the trigger interface.

tion and trigger primitives. The design of Pheromone will be detailed in §4. Table 1 lists all the supported trigger primitives in current Pheromone platform. Compared to AWS Step Functions (ASF), Pheromone supports more sophisticated invocation patterns and provides richer expressiveness for complex workflows. We note that Azure Durable Functions [15] can also achieve rich expressiveness for complex workflows (§6.1). Yet, it fails to achieve the other two desired properties, i.e., high usability and wide applicability (§6.5).

Abstract interface. Pheromone’s trigger primitives are not only limited to those listed in Table 1. Specifically, we provide an abstract interface for developers to implement customized trigger primitives for their applications, if needed. Fig. 5 shows the three main methods of the trigger interface. The first method, `action_for_new_object`, is provided to specify how the trigger’s associated target functions should be invoked. This method can be called when a new data object arrives: it checks the current data status and returns a list of functions to invoke, if any. The method can also be called periodically in a configurable time period through periodic checking (e.g., `ByTime` primitive). The other two methods, `notify_source_func` and `action_for_rerun`, are provided to implement the fault handling logic which re-executes the trigger’s associated source functions in case of failures. In particular, through `notify_source_func`, a trigger can obtain the information of a source function once the function starts, including the function name, session, and arguments; Pheromone also performs the periodic re-execution checks by calling `action_for_rerun`, which returns a list of time-out functions, such that Pheromone can then re-execute them. The detailed fault tolerance mechanism will be described in §4.4. We give an example of implementing a customized `ByBatchSize` trigger primitive via the abstract interface in our technical report [74].

3.3 Programming Interface

Our Pheromone serverless platform currently accepts functions written in C++, with capabilities to support more lan-

Table 2: The APIs of user library which developers use to operate on intermediate data objects and drive the workflow execution.

Class	API	Description
EphemObject	void* <code>get_value()</code>	Get a pointer to the value of an object.
	void <code>set_value(value, size)</code>	Set the value of an object.
UserLibrary	EphemObject* <code>create_object(bucket, key)</code>	Create an object by specifying its bucket and key name.
	EphemObject* <code>create_object(function)</code>	Create an object by specifying its target function.
	EphemObject* <code>create_object()</code>	Create an object.
	void <code>send_object(object, output=false)</code>	Send an object to its bucket, and set the output flag if it needs to persist.
	EphemObject* <code>get_object(bucket, key)</code>	Get an object by specifying its bucket and key name.

```
int handle(UserLibraryInterface* library, \
          int arg_size, char** arg_values);
```

Figure 6: Function interface.

```
1 app_name = 'event-stream-processing'
2 bucket_name = 'by_time_bucket'
3 trigger_name = 'by_time_trigger'

5 re_exec_rules = ([('query_event_info', EVERY_OBJ)], 100)
6 client.create_bucket(app_name, bucket_name)
7 client.add_trigger(app_name, bucket_name, trigger_name, \
8                  BY_TIME, prim_meta, hints=re_exec_rules)
```

Figure 7: Configuring a bucket trigger to periodically invoke a function in a stream processing workflow.

guages (see §7). Pheromone also provides a Python client through which developers can program function interactions.

Function interface. Following the common practice, developers implement their functions through the `handle()` interface (see Fig. 6), which is similar to the C++ main function except that it takes a user library as the first argument. The user library provides a set of APIs (see Table 2) that allow developers to operate on intermediate data objects. These APIs enable developers to create intermediate data objects (EphemObject), set their values, and send them to the buckets. A data object can also be persisted to a durable storage by setting the output flag when calling `send_object()`. When a bucket receives objects and decides to trigger next function(s), it automatically packages relevant objects as the function arguments (see Fig. 6). A function can also access other objects via the `get_object()` API.

Bucket trigger configuration. Developers specify how the intermediate data should trigger functions in a workflow via our Python client. The client creates buckets and configures triggers on the buckets using the primitives described in §3.2. Functions can then interact with the buckets by creating, sending and getting objects using the APIs listed in Table 2.

As an example, we refer to a stream processing workflow [40] as shown in Fig. 4 (right). This workflow first filters the incoming advertisement events (i.e., preprocess) and checks which campaign each event belongs to (i.e., query_event_info). It then stores the returned results into a bucket and periodically invokes a function (i.e., aggregate) to count the events per campaign every second. Fig. 7 gives a code snippet of configuring a bucket trigger that periodically invokes the aggregate function, where a ByTime trigger is

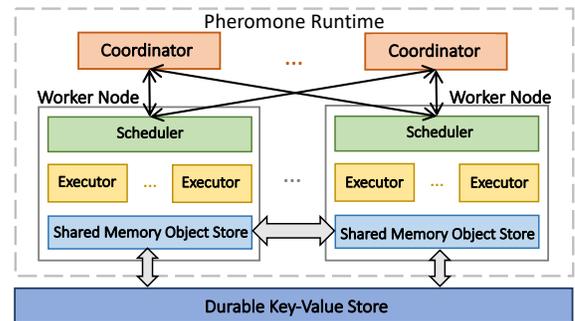

Figure 8: An architecture overview of Pheromone.

created with the primitive metadata that specifies both the target function and the triggering time window (line 4). Developers can optionally specify a re-execution rule in case of function failures, e.g., by re-executing the `query_event_info` function if the bucket has not received `query_event_info`'s output in 100 ms (line 5). We will describe the fault tolerance and re-execution in §4.4. A full script of deploying this workflow is given in our technical report [74].

To summarize, our data bucket abstraction, trigger primitives, and programming interface facilitate the data-centric function orchestration, and enable developers to conveniently implement their application workflows and express various types of data patterns and function invocations. In addition, the unified programming interface also obviates the need to make an ad-hoc selection from many APIs provided by various external services, such as a message broker, in-memory database, and persistent storage.

4 Pheromone System Design

This section presents the design of Pheromone, a new serverless platform that supports data-centric function orchestration.

4.1 Architecture Overview

Pheromone runs on a cluster of machines. Fig. 8 shows an architecture overview. Each worker node follows instructions from a local scheduler, and runs multiple executors that load and execute the user function code as needed. A worker node also maintains a shared-memory object store that holds the intermediate data generated by functions. The object store pro-

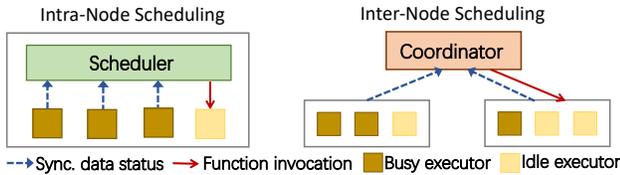

Figure 9: Intra-node (left) and inter-node (right) scheduling.

vides a data bucket interface through which functions can efficiently exchange data within a node and with other nodes. It also synchronizes data that must persist with a remote durable key-value store, such as Anna [71]. When new data are put into the object store, the local scheduler checks the associated bucket triggers. If the triggering conditions are satisfied, the local scheduler invokes the target function(s) either locally, or remotely with the help of a global coordinator that runs on a separate machine and performs cross-node coordination with a global view of bucket statuses.

4.2 Scalable Distributed Scheduling

We design a two-tier, distributed scheduling scheme to exploit data locality and ensure high scalability, enabled by the data-centric approach. Specifically, a workflow request first arrives at a global coordinator, which routes the request to a local scheduler on a worker node. The local scheduler invokes subsequent functions to locally execute the workflow whenever possible, thus reducing the invocation latency and incurring no network overhead.

Intra-node scheduling. In Pheromone, a local scheduler uses bucket triggers to invoke functions *as locally as possible*. The scheduler starts the first function of a workflow and tracks its execution status via its bucket. The downstream functions are triggered immediately on the same node when their expected data objects are put into the associated buckets and ready to be consumed. As no cross-node communication is involved, it reduces the function invocation latency and enables efficient consumption of data objects in a local workflow execution. Fig 9 (left) shows how the local scheduler interacts with executors when running a workflow locally. The executors synchronize the data status (e.g., the readiness of local objects in buckets) with the local scheduler, which then checks the associated bucket triggers and invokes downstream functions if the triggering conditions are met. The low-latency message exchange between the scheduler and executors is enabled via an on-node shared-memory object store.

A local scheduler makes scheduling decisions based on the status of executors. The scheduler only routes function requests to idle executors that have no running tasks, avoiding concurrent invocations and resource contention in each executor (similar to the concurrency model in AWS Lambda [9]). When the executor receives a request for the first time, it loads the function code from the local object store and persists it in memory for reuse in subsequent invocations. In case of

multiple idle executors, the scheduler prioritizes those with function code already loaded to enable a warm start.⁴

Delayed request forwarding from overloaded nodes. If the requests received by a local scheduler exceed the capacity of local executors, the scheduler forwards them to a global coordinator, which routes them to other worker nodes with sufficient resources. Instead of forwarding the exceeding requests immediately, the scheduler waits for a configurable short time period: if any local executors become available during this period, the requested functions start and the requests are served locally. The rationale is that it typically takes little time for executors to become available as most serverless functions are short-lived [64], plus Pheromone has microsecond-scale invocation overhead (§6.2). Such a delayed scheduling has proven effective for improving data locality [77].

Inter-node scheduling. A global coordinator not only forwards requests from overloaded nodes to non-overloaded nodes, but also drives the execution of a large workflow which needs to run across multiple worker nodes that collectively host many functions of the workflow. This cannot be orchestrated by individual local schedulers without a global view.

As Fig. 9 (right) shows, a coordinator gathers the associated bucket statuses of the functions of a large workflow from multiple worker nodes, and triggers the next functions as needed. Each node immediately synchronizes local bucket status with the coordinator upon any change, such that the coordinator maintains an up-to-date global view. When the coordinator decides to trigger functions, it also updates this message to relevant workers, which reset local bucket status accordingly. This ensures a function invocation is neither missed nor duplicated. Note that, some bucket triggers (e.g., ByTime) can only be performed at the coordinator with its global view; here, worker nodes only update their local statuses to the coordinator without checking trigger conditions.

The data-centric orchestration improves data locality in the inter-node scheduling. The coordinator makes scheduling decisions using the node-level knowledge reported by local schedulers, including cached functions, the number of idle executors, and the number of objects relevant to the workflow. It then schedules a request to a worker node with sufficient warm executors and the most relevant data objects.

Scaling distributed scheduling with sharded coordinators. Pheromone employs a *shared-nothing* model to significantly reduce synchronization between local schedulers and global coordinators, thus attaining high scalability. Specifically, it partitions the workflow orchestration tasks across *sharded coordinators*, each of which manages a disjoint set of workflows. When executing a workflow, the responsible coordinator sends the relevant bucket triggers to a selected set of worker nodes and routes the invocation requests to them. A worker node may run functions of multiple workflows. For

⁴Many techniques have been proposed to deal with cold starts of executors [33, 37, 41, 44, 57, 64, 70], which can be applied directly in Pheromone.

each workflow, its data and trigger status are synchronized with the responsible coordinator only. This design substantially reduces communication and synchronization overheads, and can be achieved by running a standard cluster management service (e.g., ZooKeeper [5, 45]) that deals with coordinator failures and allows a client to locate the coordinator of a specific workflow. The client can then interact with this coordinator to configure data triggers and send requests. This process is automatically done by the provided client library and is transparent to developers.

4.3 Bucket Management and Data Sharing

We next describe how Pheromone manages data objects in buckets, and enables fast data sharing between functions.

Bucket management. Pheromone uses an on-node shared-memory object store to maintain data objects, such that functions can directly access them via pointers (i.e., `EpheObject` in Table 2). A data object is marked ready when the source function puts it into a bucket via `send_object()`. The bucket can be distributed across its responsible coordinator and a number of worker nodes, where each worker node tracks local data status while the coordinator holds a global view (§4.2). Bucket status synchronization is only needed between the responsible coordinator and workers, as local statuses at different workers track their local objects only and are disjoint.

Pheromone garbage-collects the intermediate objects of a workflow execution after the associated invocation request has been *fully* served along the workflow. In case a workflow is executed across multiple worker nodes, the responsible coordinator notifies the local scheduler on each node to remove the associated objects from its object store.

When a worker node's local object store runs out of memory, a remote key-value store is used to hold the newly generated data objects at the expense of an increased data access delay.⁵ Later, when more memory space is made available (e.g., via garbage collection), the node remaps the associated buckets to the local object store. In case a data object is lost due to system failures, Pheromone automatically re-executes the source function(s) to get it recovered (details in §4.4).

Fast data sharing. Pheromone further adopts optimizations to fully reap the benefits of data locality enabled by its data-centric design. As intermediate data are typically short-lived and immutable [49, 67], we trade their durability for fast data sharing and low resource footprint. With an on-node shared-memory object store, Pheromone enables *zero-copy* data sharing between local functions by passing only the pointers of data objects to the target functions. This avoids the significant data copying and serialization overheads, and substantially reduces the latency of accessing local data objects.

To efficiently pass data to remote functions, Pheromone

⁵Our current implementation does not support spilling in-memory objects to disk, which we leave for future work.

also enables the *direct* transfer of data objects between nodes. A function packages the metadata (e.g., locator) of a data object into a function request being sent to a remote node. The target function on the remote node uses such metadata to directly retrieve the required data object. Compared with using a remote storage for cross-node data sharing, our direct data transfer avoids unnecessary data copying, and thus leads to reduced network and storage overheads. While the remote-storage approach can ensure better data durability and consistency [24, 65, 66], there is no such need for intermediate data objects. Only when data are specified to persist will Pheromone synchronize data objects with a durable key-value store (see `send_object()` in Table 2).

Note that, Pheromone's data-centric design can expose details of intermediate data (e.g., the size of each data object), therefore we can further optimize cross-node data sharing. For large data objects, they are sent as raw byte arrays to avoid serialization-related overheads, thus significantly improving the performance of transferring large objects (see Fig. 13 in §6.2). For small data objects, Pheromone implements a shortcut to transfer them between nodes: it piggybacks small objects on the function invocation requests forwarded during the inter-node scheduling (see §4.2). This shortcut saves one round trip as the target function does not need to additionally retrieve data objects from the source function. In addition, Pheromone runs an I/O thread pool on each worker node to improve cross-node data sharing performance.

4.4 Fault Tolerance

Pheromone sustains various types of system component failures. In case an executor fails or a data object is lost, Pheromone restarts the failed function to reproduce the lost data and resume the interrupted workflow. This is enabled by using the data bucket to re-execute its source function(s) if the expected output has not been received in a configurable timeout. This fault handling approach is a natural fit for data-centric function orchestration and brings two benefits. First, it can simplify the scheduling logic as data buckets can autonomously track the runtime status of each function and issue re-execution requests whenever necessary, without needing schedulers to handle function failures. Second, it allows developers to customize function re-execution rules when configuring data buckets, e.g., timeout. Fig. 7 gives an example of specifying re-execution rules (line 5). Fig. 5 shows the interface to implement the logic of function re-execution for a bucket trigger (`notify_source_func` and `action_for_rerun`).

Pheromone also checkpoints the scheduler state (e.g., the workflow status) to the local object store, so that it can quickly recover from a scheduler failure on a worker node. In case that an entire worker node crashes, Pheromone re-executes the failed workflows on other worker nodes. Pheromone can also handle failed coordinators with a standard cluster management service, such as ZooKeeper, as explained in §4.2.

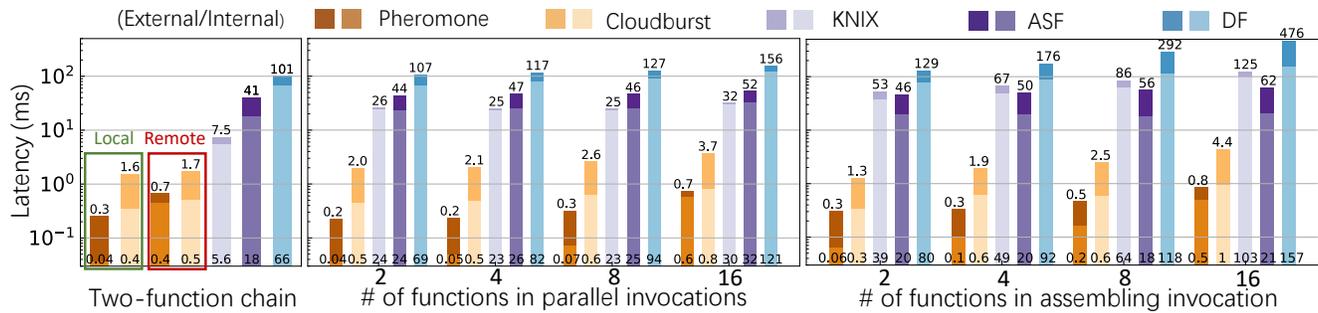

Figure 10: Latencies of invoking no-op functions under three interaction patterns: function chain, parallel and assembling invocations. Each bar is broken into two parts which measure the latencies of external (darker) and internal (lighter) invocations, respectively. The overall latency value is given at the top of the bar, and the internal invocation latency is given at the bottom.

5 Implementation

We have implemented Pheromone atop Cloudburst [66], a lightweight, performant serverless platform. We heavily re-architected Cloudburst and implemented Pheromone’s key components (Fig. 8) in 5k lines of C++ code. These components were packaged into Docker [19] images for ease of deployment. Pheromone’s client was implemented in 400 lines of Python code. Like Cloudburst, Pheromone runs in a Kubernetes [25] cluster for convenient container management, and uses Anna [71, 72], an autoscaling key-value store, as the durable key-value storage. On each worker node, we mount a shared in-memory volume between containers for fast data exchange and message passing. The executor loads function code as dynamically linked libraries, which is pre-compiled by developers and uploaded to Pheromone. The entire code-base of Pheromone is open-sourced at [26].

6 Evaluation

In this section, we evaluate Pheromone via a cluster deployment in AWS EC2. Our evaluation answers three questions:

- How does Pheromone improve function interactions (§6.2) and ensure high scalability (§6.3)?
- Can Pheromone effectively handle failures (§6.4)?
- Can developers easily implement real-world applications with Pheromone and deliver high performance (§6.5)?

6.1 Experimental Setup

Cluster settings. We deploy Pheromone in an EC2 cluster. The coordinators run on the c5.xlarge instances, each with 4 vCPUs and 8 GB memory. Each worker node is a c5.4xlarge instance with 16 vCPUs and 32 GB memory. The number of executors on a worker node is configurable and we tune it based on the requirements of our experiments. We deploy up to 8 coordinators and 51 worker nodes, and run clients on separate instances in the same us-east-1a EC2 zone.

Baselines. We compare Pheromone with four baselines.

1) *Cloudburst*: As an open-source platform providing fast state sharing, Cloudburst [66] adopts *early binding* in scheduling: it schedules all functions of a workflow before serving a request, and enables direct communications between functions. It also uses function-located caches. As Pheromone’s cluster setting is similar to Cloudburst’s, we deploy the two platforms using the same cluster configuration and resources.

2) *KNIX*: As an evolution of SAND [34], KNIX [24] improves the function interaction performance by executing functions of a workflow as processes in the same container. Message passing and data sharing can be done either via a local message bus or via a remote persistent storage.

3) *AWS Step Functions (ASF)*: We use ASF Express Workflows [14] to orchestrate function instances as it achieves faster function interactions than the ASF Standard Workflows [14]. As ASF has a size limit of transferring intermediate data (see Fig. 2), we use Redis [6], a fast in-memory storage service, to share large data objects between functions.

4) *Azure Durable Functions (DF)*: Compared with ASF, DF provides a more flexible support for function interactions. It allows developers to express workflows in program code and offers the Entity Functions [17] that can manage workflow states following the actor model [36, 54]. We include DF to study whether this expressive orchestration approach can achieve satisfactory performance.

Here, Cloudburst, KNIX and ASF focus more on optimizing function interactions of a workflow, while DF provides rich expressiveness. Note that, for the two commercial platforms, i.e., ASF and DF, we cannot control their orchestration runtime. To make a fair comparison, we configure their respective Lambda and Azure functions such that the number of function instances matches that of executors in Pheromone. The resource allocations of each function instance and executor are also maintained the same. In our experiments, functions are all warmed up to avoid cold starts in all platforms.

6.2 Function Interaction

Function invocation under various patterns. We first evaluate the overhead of invoking no-op functions without any

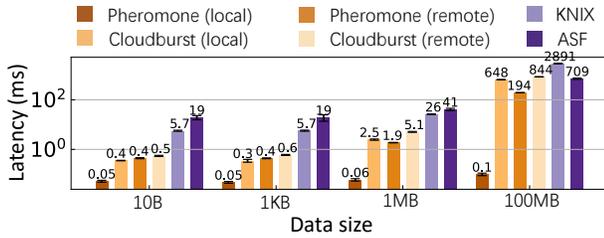

Figure 11: Latencies of a two-function chain invocation under various data sizes.

payload. We consider three common invocation patterns: sequential execution (e.g., a two-function chain), parallel invocation (fan-out), and assembling invocation (fan-in). We vary the number of involved functions for parallel and assembling invocations to control the degree of parallelism. Fig. 10 shows the latencies of invoking no-op functions under these three patterns. Each latency bar is further broken down into the overheads of external and internal invocations. The former measures the latency between the arrival of a request and the complete start of the workflow, and the latter measures the latency of internally triggering the downstream function(s) following the designated pattern. In Pheromone, the external invocation latency is mostly due to the overhead of request routing which takes about 200 μ s [20]. Note that, functions can be invoked locally or remotely in Pheromone and Cloudburst, thus we measure them respectively in Fig. 10. In our experiments, we report the average latency over 10 runs.

Fig. 10 (left) compares the invocation latencies of a two-function chain measured on five platforms. Pheromone substantially outperforms the others. In particular, Pheromone’s shared memory-based message passing (§4.3) only incurs an overhead of less than 20 μ s, reducing the local invocation latency to 40 μ s, which is 10 \times faster than Cloudburst. The latency improvements become significantly more salient compared with other platforms (e.g., 140 \times over KNIX, 450 \times over ASF). When invoking a remote function, both Pheromone and Cloudburst require network transfer, leading to a similar internal invocation latency. Yet, Cloudburst incurs higher overhead than Pheromone for external invocations as it needs to schedule the entire workflow’s functions before serving a request (early binding), thus resulting in worse overall performance.

Fig. 10 (center) and (right) show the invocation latencies under parallel and assembling invocations, respectively. We also evaluate the cross-node function invocations in Pheromone and Cloudburst by configuring 12 executors on each worker, thus forcing remote invocations when running 16 functions. Pheromone constantly achieves the best performance and incurs only sub-millisecond latencies in all cases, even for cross-node function invocations. In contrast, Cloudburst’s early-binding design incurs a much longer latency for function invocations as the number of functions increases. Both KNIX and ASF incur high invocation overheads in the parallel and assembling scenarios. DF yields the worst performance, and

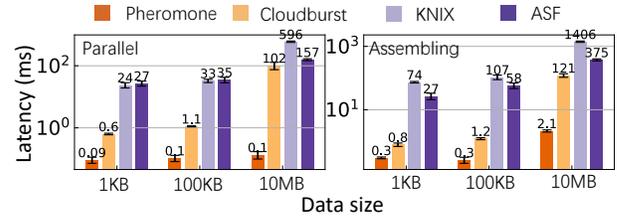

Figure 12: Latencies of parallel (left) and assembling (right) invocations under various data sizes, using 8 functions.

we exclude it from the experiments hereafter.

Data transfer. We next evaluate the interaction overhead when transferring data between functions. Fig. 11 shows the invocation latencies of a two-function chain with various data sizes in Pheromone, Cloudburst, KNIX, and ASF. We evaluate both local and remote data transfer for Pheromone and Cloudburst. For KNIX and ASF where the data transfer can be done via either a workflow or a shared storage (i.e., Riak and Redis), we report the best of the two choices.

For local data transfer, Pheromone enables zero-copy data sharing, leading to extremely low overheads regardless of the data size, e.g., 0.1 ms for 100 MB data. In comparison, Cloudburst needs the data copying and serialization, causing much longer latencies especially for large data objects. For remote data transfer, both Pheromone and Cloudburst support direct data sharing across worker nodes. Pheromone employs an optimized implementation without (de)serialization, making it more efficient than Cloudburst. Collectively, compared with Pheromone, the serialization overhead in Cloudburst dominates the latencies of both local and remote invocations under large data exchanges, which diminishes the performance benefits of data locality: saving the cost of transferring 100 MB data across network only reduces the latency from 844 ms to 648 ms. Fig. 11 also shows that KNIX and ASF incur much longer latencies. While KNIX outperforms ASF when data objects are small, ASF becomes more efficient for passing large data because it is configured in our experiments to use the fast Redis in-memory storage for large data transfer.

We further evaluate the overhead of data transfer under parallel and assembling invocations. For parallel invocation, we measure the latency of a function invoking parallel downstream functions and passing data to all of them; for assembling invocation, we measure the latency between the transfer of the first object and the reception of all objects in the assembling function. Fig. 12 shows the latencies of these two invocation patterns under various data sizes. Similarly, Pheromone constantly achieves faster data transfer compared with all other platforms for both invocation patterns.

Improvement breakdown. To illustrate how each of our individual designs contributes to the performance improvement, we break down Pheromone’s function invocation performance and depict the results in Fig. 13. Specifically, for local invocation, “Baseline” uses a central coordinator to in-

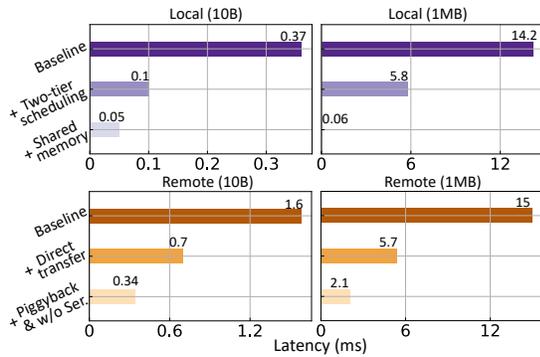

Figure 13: Improvement breakdown for local (top) and remote (bottom) invocations. Each case includes transferring 10 B (left) and 1 MB (right) of data in function invocations.

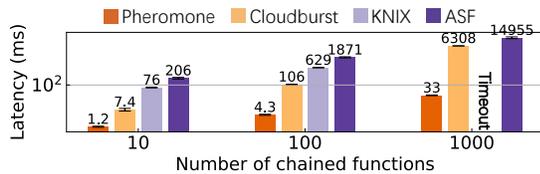

Figure 14: Latencies of function chains of different lengths.

voke downstream functions (i.e., no local schedulers), which is today’s common practice [11]; “Two-tier scheduling” uses our local schedulers for fast invocations on the same worker node (§4.2), where intermediate data objects are cached in the scheduler’s memory and get copied to next functions; “Shared memory” further optimizes the performance via zero-copy data sharing (§4.3). Fig. 13 (top) shows that applying two-tier scheduling can reduce network round trips and achieve up to 3.7× latency improvement over “Baseline”. Applying shared memory avoids data copy and serialization, further speeding up the data exchange especially for large objects (e.g., 1 MB) by two orders of magnitude.

For remote invocation, “Baseline” uses a durable key-value store (i.e., Anna [71]) to exchange intermediate data among cross-node functions; “Direct transfer” reduces the communication overhead by allowing direct data passing between nodes (§4.3), where raw data objects on a node are serialized into a protobuf [27] message and then sent to downstream functions; “Piggyback & w/o Ser.” further optimizes the data exchange by piggybacking small objects on forwarded function requests and eliminating serialization (§4.3). As shown in Fig. 13 (bottom), direct data transfer avoids interactions with the remote storage and improves the performance by up to 2.6× compared with baseline. The piggyback without serialization further speeds up the remote invocations with small (10 B) and large (1 MB) objects by 2× and 2.7×, respectively.

6.3 Scalability

We next evaluate the scalability of Pheromone with regard to internal function invocations and external user requests.

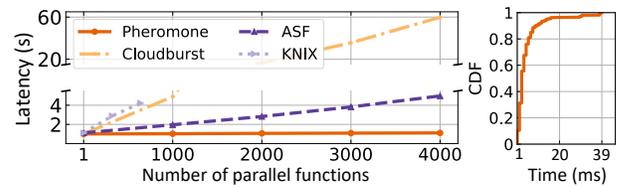

Figure 15: End-to-end latencies with various numbers of parallel functions (left), and the distribution of function start times when executing 4k functions in Pheromone (right).

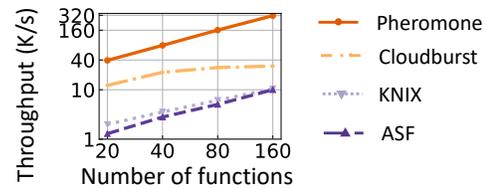

Figure 16: Request throughput when serving requests to no-op functions under various numbers of functions or executors.

Long function chain. We start with a long function chain that sequentially invokes a large number of functions [76]. Here, each function simply increments its input value by 1 and sends the updated value to the next function, and the final result is the total number of functions. As shown in Fig. 14, we change the number of chained functions, and Pheromone achieves the best performance at any scale. Moreover, Cloudburst suffers from poor scalability due to its early-binding scheduling, causing significantly longer latencies when the number of chained functions increases; KNIX cannot host too many function processes in a single container, making it ill-suited for long function chains; ASF incurs the longest latencies due to its high overhead of function interactions.

Parallel functions. Fig. 15 (left) evaluates the end-to-end latencies of invoking various numbers of parallel functions, where each function sleeps 1 second. We run 80 function executors per node in Pheromone and Cloudburst. Pheromone only incurs a negligible latency in large-scale parallel executions, while ASF and Cloudburst incur much higher latencies, e.g., seconds or tens of seconds. KNIX suffers from severe resource contention when running all workflow functions in the same container, and fails to support highly parallel function executions. To further illustrate Pheromone’s behavior in parallel invocations, Fig. 15 (right) shows the distribution of function start times, where Pheromone can quickly launch all 4k functions within 40 ms.

User request throughput. Fig. 16 shows the user request throughput when serving requests to no-op functions using various numbers of executors. We configure 20 executors on each node in Pheromone and Cloudburst. We observe that Cloudburst’s schedulers can easily become the bottleneck under a high request rate, making it difficult to fully utilize the executor’s resources; KNIX suffers from a similar problem that limits its scalability. While ASF has no such an issue, it

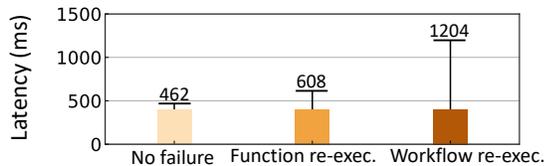

Figure 17: Median and 99th tail latencies of a four-function workflow with no failure, function- and workflow-level re-executions. The numbers indicate the tail latencies.

leads to low throughput due to its high invocation overhead (Fig. 10). Compared with these platforms, Pheromone ensures better scalability with the highest throughput.

6.4 Fault Tolerance

We evaluate Pheromone’s fault tolerance mechanism (§4.4). We execute a workflow that chains four sleep functions (each sleeps 100 ms), and each running function is configured to crash at a probability of 1%. Fig. 17 shows the median and 99th tail latencies of the workflow over 100 runs using Pheromone’s function- and workflow-level re-executions after a configurable timeout. In particular, the timeout is configured as twice of the normal execution, i.e., 200 ms for each individual function and 800 ms for the workflow. We also include the normal scenario where no failure occurs. Compared with the common practice of workflow re-execution, Pheromone’s data-centric mechanism allows finer-grained, function-level fault handling, which cuts the tail latency of the workflow from 1204 ms to 608 ms, thus significantly reducing the re-execution overhead.

6.5 Case Studies

We evaluate two representative applications atop Pheromone: Yahoo’s streaming benchmark for advertisement events [40], and a data-intensive MapReduce sort.

Advertisement event stream processing. This application filters incoming advertisement events (e.g., click or purchase), checks which campaign each event belongs to, stores them into storage, and periodically counts the events per campaign every second. As shown in Fig. 1 (right) and discussed in §2.2, the key to enabling this application in serverless platforms is to periodically invoke a function to process the events accumulated during the past one second.

In Pheromone, this is straightforward by using the `ByTime` primitive (§3.3 and Fig. 7). This application can also be implemented easily in DF by using an addressable Entity function for aggregation [16]. However, it is non-trivial in ASF and we have to resort to a “serverful” workaround: one workflow does the regular “filter-check-store” for each event and sends the event ID to an external, serverful coordinator; a separate workflow is set up to get triggered every second by the accumulated event IDs sent from the external coordinator, so that

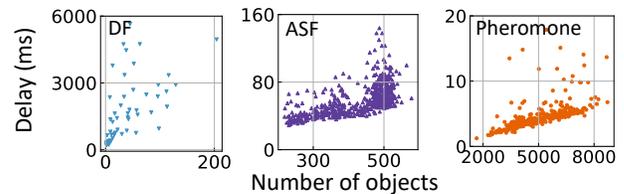

Figure 18: Delays of accessing the accumulated data objects in the advertisement event stream processing. Lower delays and more objects are better.

it can access and count the associated events per campaign.

Fig. 18 compares the performance on Pheromone, ASF, and DF. We measure the delays of accessing accumulated data objects (i.e., advertisement events), where the lower delays and more objects are better. For DF, data are not accessed in batches, and thus we measure the queuing delay between the reset request being issued and the Entity function receiving it. We use up to 40 functions in all these platforms. DF results in a significant overhead with high and unstable queuing delays, as its Entity function can easily become a bottleneck. Among the three platforms, Pheromone performs the best: it can access substantially more accumulated data objects in a much smaller delay. In summary, Pheromone not only simplifies the design and deployment for such a stream processing application, but also delivers high performance.

MapReduce sort. We next evaluate how Pheromone’s data-centric orchestration can easily facilitate MapReduce sort, a typical data-intensive application. We have built a MapReduce framework atop Pheromone, called Pheromone-MR. Using the `DynamicGroup` primitive, Pheromone-MR can be implemented in only 500 lines of code, and developers can program standard mapper and reducer [2] without operating on intermediate data (§3.2). We compare Pheromone-MR with PyWren [48], a specialized serverless analytics system built atop AWS Lambda. Compared with Pheromone-MR, PyWren is implemented in about 6k lines of code and supports the map operator only, making it complicated to deploy a MapReduce application: developers need to explicitly transfer the intermediate data via a shared storage (e.g, Redis) to simulate the reducer, and carefully configure the storage cluster for improved data exchange. Even with these optimizations, PyWren still suffers from limited performance (and usability).

We evaluate the performance of Pheromone-MR and PyWren with MapReduce sort over 10 GB data, where 10 GB intermediate objects are generated in the shuffle phase. We allocate each Pheromone executor and each Lambda instance the same resource, e.g., 1 vCPU. We also configure a Redis cluster for PyWren to enable fast data exchange. We measure the end-to-end latencies on Pheromone-MR and PyWren using various numbers of functions, and break down the results into the function interaction latency and the latency for compute and I/O. The former measures the latency between the completion of mappers and the start of reducers. For PyWren,

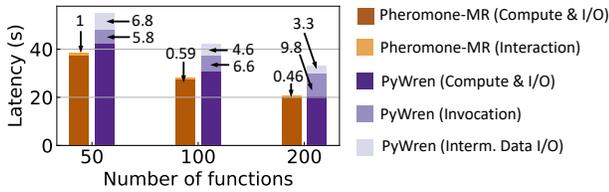

Figure 19: Latencies of sorting 10 GB data using various numbers of functions on PyWren and Pheromone-MR. The latency is broken down into: the interaction latency (for PyWren, the invocation and intermediate data I/O), and the latency for compute and I/O. The numbers indicate the former.

the interaction latency consists of two parts: 1) the invocation latency of triggering all reducers after mappers return, and 2) the I/O latency of sharing intermediate data via Redis. As shown in Fig. 19, running more functions in PyWren improves the I/O of sharing intermediate data, but results in a longer latency in parallel invocations. Compared with PyWren, Pheromone-MR has a significantly lower interaction latency (e.g., less than 1s), thus improving the end-to-end performance by up to $1.6\times$.

We note that, the limitations of AWS Lambda make PyWren less efficient. First, because Lambda does not support large-scale map by default [13], it needs to implement this operation but in an inefficient way which incurs high invocation overheads. Second, Lambda has a limited support for data sharing, forcing developers to explore an external alternative that incurs high overheads even though using a fast storage (i.e., Redis). Unlike AWS Lambda, Pheromone supports rich patterns of function executions while enabling fast data sharing, such that developers can easily build a MapReduce framework and achieve high performance.

7 Discussion and Related Work

Isolation in Pheromone. Pheromone provides the container-level isolation between function invocations, while functions running on the same worker node share in-memory data objects (§4.3). Commercial container-based serverless platforms often do not co-locate functions from different users to enhance security [1]. In this setting, functions on the same worker node can be trusted; hence, it is safe to trade strict isolation for improved I/O performance. We notice that current serverless platforms have made various trade-offs between performance and isolation. For example, AWS Lambda runs functions in MicroVMs for strong isolation [33]; KNIX isolates a workflow’s functions using processes in the same container for better performance [34]; recent work proposes lightweight isolation for privacy-preserving serverless applications [52]. Pheromone can explore these different trade-offs, which we leave for future work.

Supported languages. Pheromone currently supports functions written in C++, but it can be straightforward to sup-

port other programming languages. Specifically, Pheromone’s executor exposes data trigger APIs (Table 2) and interacts with other system components, and can serve as a proxy for functions written in different languages. That being said, Pheromone’s optimization on fast data exchange via shared memory may not apply to all language runtimes – only those allowing the direct consumption of byte arrays without (de)serialization, e.g., Python ctype, can benefit from zero-copy data sharing. The other Pheromone designs are still effective regardless of language runtimes.

Data exchange in serverless platforms. Data exchange is a common pain point in today’s serverless platforms. One general approach is to leverage shared storage to enable and optimize data exchange among functions [38,42,43,49,56,58,59]. One other approach is to exploit data locality to improve performance, e.g., by placing workflow functions on a single machine [46,51,53,65–67]. Moreover, OFC [55] and FaaS^T [61] provide the autoscaling cache for individual applications. Shredder [80] and Zion [62] push the function code into storage. Wukong [39] enhances the locality of DAG-based parallel workloads at the application level. Lambda [67] makes the intent of a function’s input and output explicit for improved locality; however, it does not provide a unified programming interface for expressive and simplified function interactions, and its performance is heavily bound to Apache OpenWhisk [3,51].

8 Conclusion

This paper revisits the function orchestration in serverless computing, and advocates a new design paradigm that a serverless platform needs to: 1) break the tight coupling between function flows and data flows, 2) allow fine-grained data exchange between functions of a workflow, and 3) provide a unified and efficient approach for both function invocations and data exchange. With this data-centric paradigm, we have designed and developed Pheromone, a new serverless platform which achieves all the desired properties, namely, rich expressiveness, high usability, and wide applicability. Pheromone is open-sourced, and outperforms current commercial and open-source serverless platforms by orders of magnitude in terms of the latencies of function invocation and data exchange.

Acknowledgments

We thank the anonymous reviewers and our shepherd, Yiyang Zhang, for their insightful comments that helped shape the final version of this work. We also thank Yuheng Zhao for his help in experiments, and Chenggang Wu for his valuable feedback at the early stage of this work. This work was supported in part by RGC GRF Grants 16202121 and 16210822. Minchen Yu was supported in part by the Huawei PhD Fellowship Scheme.

Abstract

Standalone orchestrators simplify the development of serverless applications by providing higher-level programming interfaces, coordinating function interactions and ensuring exactly-once execution. However, they limit application flexibility and are expensive to use. We show that these specialized orchestration services are unnecessary. Instead, application-level orchestration, deployed as a library, can support the same programming interfaces, complex interactions and execution guarantees, utilizing only basic serverless components that are already universally supported and billed at a fine-grained per-use basis. Furthermore, application-level orchestration affords applications more flexibility and reduces costs for both providers and users.

To demonstrate this, we present Unum, an application-level serverless orchestration system. Unum introduces an intermediate representation that partitions higher-level application definitions at compile-time and provides orchestration as a runtime library that executes in-situ with user-defined FaaS functions. On unmodified serverless infrastructures, Unum functions coordinate and ensure correctness in a decentralized manner by leveraging strongly consistent data stores.

Compared with AWS Step Functions, a state-of-the-art standalone orchestrator, our evaluation shows that Unum performs well, costs significantly less and grants applications greater flexibility to employ application-specific patterns and optimizations. For a representative set of applications, Unum runs as much as 2x faster and costs 9x cheaper.

1 Introduction

Serverless computing offers a simple but powerful abstraction with two essential components: a stateless compute engine (Functions as a Service, or FaaS) and a scalable, multi-tenant data store [27]. Developers build applications using stateless, event-driven “functions” which persist states in shared data stores. This abstraction allows users to leverage scalable data center resources with fine-grained per-invocation billing and frees them from server administration.

While serverless platforms originally targeted simple applications with one or a few functions, this paradigm has increasingly proven useful for more complex applications composed of many functions with rich and often stateful interaction patterns [19, 20, 25, 26, 40]. Unfortunately, building such applications using the basic FaaS is challenging. Event-driven execution makes depending on the results of multiple previous functions and therefore fan-in patterns difficult. At-least-once execution guarantee that is typical for FaaS functions complicates end-to-end application correctness as non-deterministic functions may pass inconsistent results downstream. Finally, the lack of higher-level programming interfaces for expressing inter-function patterns hinders application development.

Standalone orchestrators are recently introduced into the serverless infrastructure to support such complex applications (§2.1). Cloud providers commonly offer serverless orchestrators as a service [3, 6, 22, 23], though users may build custom orchestrators and deploy them in separate VMs or containers alongside their functions [19, 20, 38]. These orchestration services provide higher-level programming interfaces, support complex interactions and ensure exactly-once execution.

Though often internally distributed, standalone orchestrators operate as *logically centralized* controllers. Developers provide a description of an execution graph—nodes in the graph represent FaaS functions and edges represent invocations of a function with the output of one or more functions—and the orchestrator drives the execution of this graph by invoking functions, receiving function results and storing application states (e.g., outstanding invocations and function results) centrally.

Centralization simplifies supporting stateful interactions—e.g., an orchestrator can run fan-in patterns by simply waiting for all branches to complete before invoking an aggregation function. Similarly, an orchestrator can ensure that applications appear to execute exactly-once by choosing a single result from multiple executions for each function invocation.

However, standalone orchestrators have important drawbacks for both serverless providers and serverless users. As an additional service that is critical to application performance

and correctness, a standalone orchestrator is expensive to host and use. User-deployed orchestrators risk under-utilization and do not benefit from serverless’ per-use billing. Provider-hosted orchestrators are multi-tenant and can thus multiplex over many users to improve resource utilization and amortize the cost. However, they still incur the costs of hardware resources and on-call engineering teams. These costs may be affordable for large platforms but can be a significant burden for smaller providers.

Furthermore, standalone orchestrators preclude users from making application-specific trade-offs and optimizations. While the interface and implementation of an orchestrator might efficiently support the needs of many applications, it cannot meet all applications’ needs, resulting in a compromise familiar from operating systems [9, 13], networks [17, 39], and storage systems [21, 28].

For example, applications that need orchestration patterns not supported by the provider-hosted orchestrator have to either compromise performance by using less-efficient patterns or first repeat the hard work of building, deploying and managing their own custom orchestrator. A video processing application that encodes video chunks and aggregates results of adjacent branches in parallel has to compromise performance if the orchestrator only supports aggregating results of all branches.

Similarly, applications that consist entirely of deterministic functions, such as an image resize application for creating thumbnails or an IoT data processing pipeline for aggregating sensor readings, can tolerate duplicate executions without weakening correctness. However, with a standalone orchestrator that always persists states to ensure exactly-once execution, this application would incur the overheads of strong guarantees regardless.

In this paper, we show that additional standalone orchestrators for serverless applications are unnecessary. Furthermore, we argue that application-level orchestration is better for both serverless providers and developers. It is better for developers as it affords applications more flexibility to implement custom patterns as needed and apply application-specific optimizations. It is better for providers as it obviates the need to host an additional complex service and frees up resources such that providers can focus on fewer, core services in their serverless infrastructure. Moreover, application-level orchestration built on top of existing storage and FaaS services in the serverless infrastructure can benefit automatically from improvements to cost and performance to these services.

To support these arguments, we present Unum, an application-level serverless orchestration system. Unum provides orchestration as a library that runs *in-situ* with user-defined FaaS functions, rather than as a standalone service. The library relies on a minimal set of existing serverless APIs—function invocation and a few basic data store operations—that are common across cloud platforms. Unum introduces an intermediate representation (IR) language to

express execution graphs using only node-local information and supports front-end compilers that transform higher-level application definitions into the IR.

A key challenge in Unum is to support complex stateful orchestration patterns and strong execution guarantees in a *de-centralized* manner. Our insight is that, scalable and strongly consistent data stores, already an essential building block of serverless applications, address the hardest challenge of orchestration: coordination. Using such data stores, we show that an application-level library running *in-situ* with user functions can orchestrate complex execution graphs efficiently with strong execution guarantees.

At a high level, Unum relies on the FaaS scheduler to run each function invocation *at least* once and consistent data store operations to coordinate interactions and de-duplicate extra executions of the same invocation. Unum uses checkpoints to commit to exactly one result for a function invocation and ensures workflow correctness despite duplicate executions of non-deterministic functions. Unum fan-ins use objects in a consistent data store as coordination points for aggregating branches. Both require generating globally unique names for nodes and edges in the execution graph *locally* (using only information available at each node) as well as cleaning up intermediate data store objects in a timely manner.

Our implementation of Unum (§4) includes a compiler for AWS Step Functions’ description language, enabling Unum to run arbitrary Step Function workflows. We show that Step Function workflows compiled to Unum execute with the same execution guarantees as running natively using the Step Functions orchestrator.

Moreover, while performance and cost are difficult to compare objectively with existing black-box production orchestrators—both are influenced by deployment and pricing decisions that may not reflect the underlying efficiency or cost of the system—Unum performs well in practice (§5). We find that a representative set of applications run faster and cost significantly less with Unum than Step Functions (Table 2). We also demonstrate that Unum’s IR allows applications to run faster by using application-specific optimizations and supporting a richer set of interaction patterns.

2 Background & Motivation

The basic serverless abstraction is simple and quite powerful. Developers build “functions”, typically written in a high-level language and packaged as OS containers or virtual machines, which run short computations in response to a platform event. Events include storage events (e.g., the creation of an object) or HTTP requests. The platform can scale resources for each function to respond to instantaneous bursts in events and developers are absolved from capacity planning and resource management tasks.

This simple abstraction can be used to compose many simple applications with one or a few functions. For example, developers can chain functions for data pipelines using triggers. In trigger-based composition [10] each function in a chain invokes the next asynchronously or writes to a data store configured to invoke the next function in response to storage events. Alternatively, developers might use a “driver-function” [40] to drive more intricate control-flow logic. A driver function acts as a centralized controller that invokes other functions, waits for their outputs, and invokes subsequent functions with their outputs.

Such ad-hoc approaches work “out-of-the-box”, that is, they require no additional platform provided infrastructure. However neither is well suited to complex applications with 10s or 100s of functions [20, 35]. Trigger-based composition can only support chaining of individual functions or fan-out from one function to multiple, but cannot, for example, fan-in from multiple functions to one. Moreover, trigger-based composition scatters control-flow logic across each function or in configured storage events, making development unwieldy when application complexity grows.

On the other hand, driver functions concentrate control flow in a single function and support arbitrary composition. However, most serverless platforms impose modest runtime limits on individual functions, and thus driver functions restrict the total runtime of applications. Furthermore, driver functions suffer “double billing” since they are billed for the entire call-graph execution despite spending most time idly waiting for callees to return.

Finally, both ad-hoc approaches require developers to handle function crashes, retries and duplicate invocations gracefully [1, 7, 8, 14]. Application typically want to ensure “exactly once” semantics [10, 11, 24, 25, 40] for an entire call-graph, but failures and multiple invocations of individual functions can subvert this goal without careful consideration.

2.1 Standalone Orchestrators

A common solution to address the needs of complex serverless applications is to introduce a workflow orchestrator that provides a high-level programming interface with support for a rich set of patterns (e.g., branching, chaining, fan-out and fan-in) [3, 6, 19, 20, 22, 23, 38]. Many cloud providers offer serverless orchestrators as a service [3, 6, 22, 23] or users can build custom orchestrators [19, 20, 38] and deploy them in VMs alongside their functions.

Similar to driver functions, orchestrators operate as *logically centralized* controllers. They drive a workflow by invoking its functions and hosting application states such as function outputs and outstanding invocations.

However, different from driver-functions, orchestrators are standalone services. Orchestrators are not limited by function timeouts and can be arbitrarily long-running [4]. Moreover, as standalone services, orchestrators are often internally dis-

tributed and employ techniques such as replication and sharding to provide strong execution guarantees, fault-tolerance and scalability. For example, orchestrators can ensure that workflows appear to execute exactly-once by choosing one result for each function invocation, even if FaaS engines only guarantee at-least once execution. Orchestrators can also persist or replicate states during execution so that in face of orchestrator failures, applications do not lose executions or retry from the beginning.

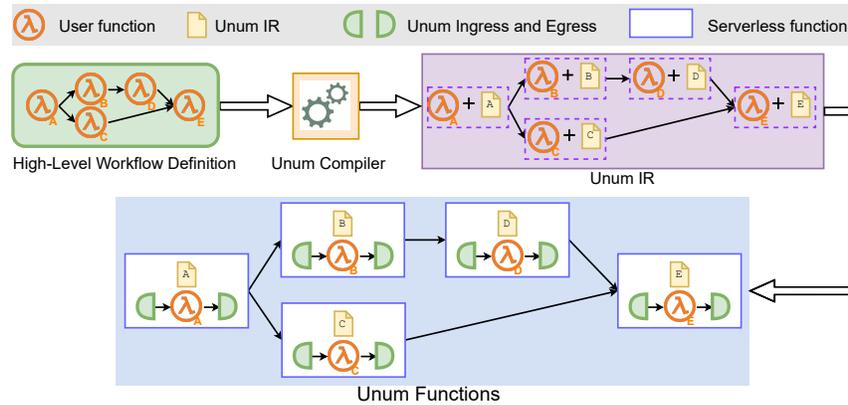

While orchestrators are able to address the needs of complex serverless applications, introducing a new standalone service has significant drawbacks. Building performant, scalable and fault-tolerant multi-tenant systems is hard and orchestrators introduce yet-another potential performance and scalability bottleneck. Indeed, we find that, in practice, production systems limit end-to-end performance for highly-parallel applications (§ 5).

Moreover, hosting such services is expensive. Deploying a custom orchestrator per user risks under-utilization as it cannot multiplex over many users and users pay even when the orchestrator is not actively in use, breaking the fine-grained billing benefit of serverless. Provider-hosted orchestrators are multi-tenant and can amortize this cost. But they still incur engineering expenses as they require teams on-call. Indeed, we find that provider-hosted orchestrators cost developers significantly and dominate the total cost of running applications (§ 5).

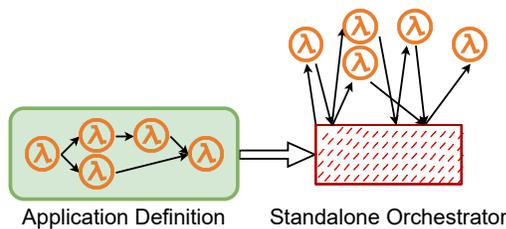

Lastly, provider-hosted orchestrators preclude users from making application-specific optimizations. Each provider typically offers just a single orchestrator service option. While the interface and implementation of the orchestrator might efficiently support many applications, it cannot meet all applications’ needs, resulting in a compromise familiar from operating systems [9, 13], networks [17, 39], and storage systems [21, 28]. Indeed, we find that provider-hosted orchestrators force applications to compromise performance by using less-efficient patterns (§ 5).

3 Design

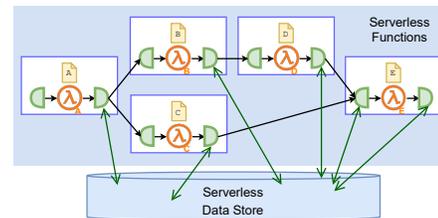

Unum is an application-level orchestration system that supports complex serverless applications without a standalone orchestrator. It does so by decentralizing orchestration logic in a library that runs in-situ with user-defined FaaS functions and leverages a scalable consistent data store for coordination and execution correctness. By removing standalone orchestrators, Unum improves application flexibility and reduces costs. Importantly, Unum does this while retaining the expressiveness and execution guarantees (§3.3) of standalone orchestrators.

(a) Serverless workflows form directed graphs. Unum partitions the graph into an intermediate representation where each function is embedded with an Unum configuration that encodes how to transition to its immediate downstream nodes. Developers package user function, Unum config and Unum’s runtime library (a pair of ingress and egress components) together to create “unumized” functions.

(b) A typical standalone orchestrator operates as a logically centralized controller that drives the execution of applications by invoking functions, receiving function results and storing application states

(c) At runtime, Unum orchestration logic is decentralized and runs in-situ with the user functions on an unmodified serverless platform. For coordination and checkpointing, Unum relies exclusively on a standard data store of choice, such as DynamoDB or Cosmos DB.

Figure 1: Unum’s Decentralized Orchestration. Unum partitions orchestration logic at compile time and a Unum runtime runs in-situ with user functions to perform only the orchestration logic local to its node.

3.1 Architecture

Figure 1a depicts how developers run serverless workflows using Unum. Developers write individual functions and describe the workflow using a high-level workflow language, such as Step Functions’ expression language. An Unum front-end compiler uses these to extract portable Unum IR for each node in the graph and “attaches” it to the function (e.g. by placing a file containing the IR alongside the function code). A platform-specific Unum linker “links” each function with a platform-specific Unum runtime library.¹ Developers deploy each linked function along with its IR to the FaaS platform.

Each Unum workflow begins with an “entry” function. Invoking this function (e.g. using an HTTP or storage trigger) starts a workflow. Moreover, admission control rules for the workflow, such as access control and rate limiting, are implemented by setting appropriate rules on this entry function. For example, a workflow can be invoked by a particular principal

¹Since functions are typically written in dynamic languages, the Unum library source code is placed alongside the function and dynamically imported, rather than statically linking an object file

if the entry function is exposed to that principal.

The runtime library is composed of an ingress and egress component that run before and after the user-defined function and unwrap and wrap the results of the function in Unum execution state, respectively (Figure 2). The ingress component coalesces input data from each incoming edge (e.g. in a fan-in), resolves input data if passed by name rather than by value, and passes the input value to the function. The egress component uses the function’s result to invoke the next function(s), enforces execution semantics using checkpoints, performs coordination with sibling branches in fan-in, and deletes intermediate states no longer needed for the workflow, executing the workflow in-situ with the functions, in lieu of a centralized orchestrator (Figure 1c).

3.2 Unum Intermediate Representation

Similar to many standalone orchestrators, Unum applications are modeled as directed execution graphs where nodes represent user-defined FaaS functions and edges represent function invocations (incoming edges) with the output of one

Invoke (Fn)	Queue a single invocation of a function.
Map (Fn)	Queue one function invocation for each element in the current function's result.
FanIn (Set, Size, Fn)	Queue a fan-in to a function using the provided coordination set object and size.
Pop	Pops the top frame of the execution state stack (passed via Unum requests).
Next	Increments the current execution state frame's iteration counter.
CreateSet (Name)	Creates a coordination set object in the data store with the provided name.

Table 1: Unum intermediate representation instructions.

or more other functions (outgoing edges).

An Unum graph may include fan-outs, where a node's output is used to invoke several functions or split up and "mapped" multiple times on the same function. Each such branch may be taken conditionally, based on the output value or dynamic states of the graph. Execution graphs may also contain fan-ins, where the outputs of multiple nodes are used to invoke a single aggregate function. Cycles are also supported and each iteration through a cycle is a different invocation of the target function.

The Unum intermediate representation (IR) is designed to encode directed execution graphs in a way that both allows decentralization of orchestration and is low-level enough to support application-specific patterns.

Each function's IR includes the function's name and a sequence of instructions (Table 1). Instructions direct the runtime to invoke functions and operate on Unum metadata passed between functions (Figure 2).

The egress component, which receives the function's user-code output, executes the IR and uses it to determine which next steps to take. An invocation can be protected by a conditional—a boolean expression that operates on the invocation request and the current function's output. Unum's IR provides three kinds of invocations:

- **Invoke** simply invokes the named function using the current function's output.
- **Map** treats the current function's output as iterable data (e.g. a list) and invokes the named function once for each item in the output.
- **FanIn** invokes the named function using the current function's output along with the outputs of all other func-

```

struct InvocationRequest {
    data: Vec<DatastoreObjectName>,
    workflowId: String,
    fanOut: Stack<FanOut>,
}

struct RequestData {
    reference: DatastoreObjectName,
    value: Option<Value>
}

struct FanOut {
    index: usize,
    size: usize,
    iteration: usize,
}

```

Figure 2: An Unum request wraps function outputs with metadata that allows function invocations to be named uniquely and assists in coordinating fan-ins. Unum IR instructions can reference and modify this metadata.

tions fanning into the same node. Fan-in requires coordination among multiple functions and is described in detail in §3.4.

When multiple invocations occur, either using multiple instructions or a single Map invocation, each of the invocations adds a fan-out frame to the invocation request's fan-out stack. This allows different invocations of the same function to be differentiated for naming (§3.6) and to coordinate fan-in (§3.4).

The IR also includes instructions for manipulating the Unum request data and an instruction that creates a new coordination set, typically for use in later nodes to coordinate fan-in (§3.4) or garbage collection (§3.5).

This IR is sufficient to represent basic patterns, as well as more complex fan-in patterns (described in §3.4).

Chain & Fan-out. Unum encodes passing the output of a function to one (chain) or multiple (fan-out) subsequent functions, simply, with one or more calls to the Invoke instructions.

Map. Applications may perform the same operation on each component of a function's output. For example, an application may unpack an archive of high-resolution images in one function and perform compression on each of the images. Unum's Map instruction invokes the same Fn for each element of a function's output.

Branching. Applications may need to invoke different functions based on runtime conditions (e.g., the output of a function). For instance, an application may first validate that a user-uploaded photo is a valid JPEG. If it is, it invokes, e.g., one of the patterns above, otherwise it notifies the user of the error. Unum's invocation instructions are optionally protected by a conditional expression that has access to the function output and execution metadata (Figure 2).

3.3 Execution Guarantees Using Checkpoints

FaaS functions only provide weak execution guarantees. Functions can fail mid-execution and be retried. Even in the absence of failures, one function invocation may result in more than one execution because most FaaS engines only ensure at-least-once execution. This is problematic for applications whose functions are non-deterministic because a single workflow invocation can produce multiple *diverging* outputs.

An important benefit of orchestrators is strong execution semantics such that applications appear to execute *exactly-once* even if individual functions in the application run multiple times. Because standalone orchestrators are logically centralized, guaranteeing exactly-once is conceptually straightforward: the orchestrator can choose a single result from executions of the same invocation and use it as input for all downstream functions. At the end of the workflow, the result is consistent with an execution of the workflow where each function invocation executed exactly-once.

A key challenge for Unum is to provide the same semantics without centralizing orchestration. Moreover, because failures and, thus, retries are the exception, not the rule, Unum should provide these semantics without expensive coordination—function instances should be able to proceed without blocking in the common, fault-free case.

Unum leverages two key insights to achieve these semantics. First, it is correct for different executions of the same function invocation to return different results as long as Unum ensures downstream functions are always invoked with exactly one of those results. Second, a workflow’s output is *correct* even if a function is invoked more than once, as long as the invocations uses the same input, since additional, but identical, invocations are indistinguishable from additional executions.

The Unum library employs an atomic `create_if_not_exists` operation in the serverless data store to *checkpoint* exactly one execution of each function invocation. The egress component of the Unum library attempts to write the result of the function to a checkpoint object in the data store. If such a checkpoint already exists, a concurrent or previous execution of the invocation must have already completed and the operation will fail. To invoke downstream functions, the egress component *always* uses the value stored in the checkpoint, rather than the result of the recently completed function. Essentially, Unum “commits” to result of the first successful executions of invocations.

Data stores need to be strongly consistent to support `create_if_not_exists`. It is important that a later attempt to create an existing checkpoint fails and the slower execution can read the existing checkpoint.

As a further optimization, the ingress component in the Unum library checks for the checkpoint object before executing the user-defined function. If the object exists, it bypasses the user-defined function and passes the checkpoint value

```
def ingress(self, function):
    ...
    result = datastore_get(self.checkpoint_name):
    if result:
        self._egress(result)
    else:
        self.egress(function.handle())

def egress(self, result):
    ...
    if not datastore_atomic_add(self.checkpoint_name, result):
        result = datastore_get(self.checkpoint_name)
    self._egress(result)
    ...

def _egress(self, result)
    for f in next_functions:
        faas.async_invoke(f, result)
```

Figure 3: Pseudo-code showing Unum’s checkpointing mechanism. As different executions of a function may return different results, Unum’s egress component checkpoints the first successful execution using an atomic add data store operation. All subsequent executions will use this committed value rather than the result their own execution returned.

directly to the egress component to invoke downstream functions. This is not necessary for correctness but helps reduce computation that we know will go unused.

Note that the exactly-once guarantee does not automatically extend to applications with external side effects, i.e. functions that directly call external services. In such cases, retries can lead to unexpected results if the effects are not idempotent. This issue is well known, and independent of the orchestrator architecture (centralized vs. decentralized). Thus, we consider the question of how to control such side effects to be orthogonal and beyond the scope of this paper. However, Unum does not preclude applications from using libraries, such as Beldi [40], that can solve this problem.

3.3.1 Fault Tolerance

Another source of multiple executions is retrying failed functions. Retries in Unum rely on FaaS engines’ error handling support. All popular FaaS engines provide error handling so that applications do not just crash silently without a way to react to failures. Common mechanisms include “automatic retry” that re-executes the same function [7, 14, 32, 34] or failure redirection that triggers a pre-configured error-handler function [29, 33]. Unum can work with either mechanism.

The Unum error handler is part of Unum’s standard library and is triggered in a separate FaaS function after an application function crashes. The error handler simply retries the crashed function by invoking it again. As part of the orchestration library, the error handler is assumed to be bug-free and relies on the FaaS scheduler to execute at least once.

Unum’s checkpointing mechanism ensures that while faults may occur at any point during the execution of a function’s

user code or the Unum library, and while downstream functions may be invoked multiple times by different executions of the same invocation, a single value is always used to invoke downstream functions.

If there is a fault after the user code completes but before creating the checkpoint, user code result is ignored (indeed, never seen) by other executions and another execution's value will be used to invoke downstream functions. If the “winning” function crashes after creating a checkpoint, and before invoking some or all downstream functions, other executions will use the checkpoint value to invoke downstream functions. Finally, even if multiple executions invoke some or all downstream functions, execution guarantees are still satisfied as these invocations will have identical inputs.

3.4 Fan-in Patterns

In fan-in patterns, the results of multiple nodes are used to invoke a single head node. Such patterns are a particular challenge for decentralized orchestration because invoking the target function cannot happen until all branches complete, but there is no standalone orchestrator to wait for this condition. Designating one of the tail nodes as the coordinator would address this directly. However, there is no guarantee that branches for a fan-in complete soon after each other, incurring a potentially large resource cost to do virtually no work, and risk exceeding platform-enforced function timeouts. Moreover, functions typically cannot communicate with each other directly, so it is not obvious how other branches would notify this coordinator of their completion.

Unum, instead, leverages the same insight as checkpoints—the data store provides strong consistency that can serve as a coordination point. Rather than designating a single branch function as the coordinator, all branches are empowered to invoke the fan-in function once all other branches have completed. To determine this condition, branches in a fan-in add the name of their checkpoint object to a shared “Set” in the data store. Any branch that reads the set with size equal to the total number of branches invokes the target function using all the branches' checkpoints as input.

Importantly, functions do not wait for any other to complete. As long as all functions complete eventually (in other words, they run at-least once), *some* function will read a full set and invoke the fan-in target function. More than one function may observe this condition, resulting in multiple invocations, but these invocations will be identical and are handled as spurious executions of the same invocation (§3.3).

In order to perform this coordination, branches must know the branching factor—the size of the set. The `FanIn` instruction includes this size, which is either specified explicitly, or using a variable from the invocation request, commonly the fan-out size.

Similar to checkpoints, the set data structure for coordination requires the data store to be strongly consistent. Updates

to a set must be immediately visible to other branches otherwise the downstream fan-in function may ever be invoked. Moreover, the data store must support data structures that can implement a “set” abstraction.

Fan-in supports enable more patterns that commonly arise in applications:

Aggregation. After processing data with many parallel branches, applications commonly want to aggregate results. For example, to build an index of a large corpus, the application might process chunks in parallel and then aggregate the results. Aggregation is a common pattern to join back multiple parallel functions, by invoking a single “sink” function with the outputs from a vector of functions.

Fold. `fold` sequentially applies the same function on the outputs of a vector of source functions, while aggregating with the intermediate results of running the function so far. For example, a video encoding application might encode chunks in parallel and then concatenate the results in order: concatenating chunk 1 and 2, then concatenating chunk 3 to chunk [1–2], and so on. `fold` is an advanced pattern that is not supported by all existing systems (e.g., AWS Step Functions do not support `fold`) but is expressible in Unum.

3.5 Garbage Collection

Both checkpointing and fan-in require storing intermediate data (e.g., checkpoints and coordination sets) in the data store. These intermediate data is only temporally useful and grows with each invocation. This poses a garbage collection challenge. Deleting them too early can compromise execution guarantees while deleting too late incurs storage costs.

Checkpoint Collection. A checkpointing node does not know when *its* checkpoint is no longer necessary. If it deletes its checkpoint immediately after invoking subsequent functions, it may crash and the FaaS platform may re-execute it, yielding a potentially inconsistent result. However, downstream nodes know that once they have committed to a value by checkpointing, previous checkpoints are no longer necessary to ensure their own correctness. Once a node has committed to some particular output, future invocations, even with *different* inputs will produce the same output, as the node will *always* use the checkpointed value.

Note that a duplicate execution that checkpoints after the previous checkpoint is garbage collected has the same semantics as a separate invocation. It may result in multiple outputs from the workflow, though each output is still consistent with an execution of the workflow where each function was invoked exactly-once. Any GC policy, no matter how conservative, might lead to multiple executions if the FaaS platform could execute duplicates of a function invocation after an arbitrarily long time in the future.

Therefore, Unum collects checkpoints by relaxing the constraint that nodes always output the same value. Instead, they must only output the same value until all subsequent nodes

have committed to their own outputs. This means that, in non-fan-out cases, once a node checkpoints its result, it can delete the previous node’s checkpoint.

Fan-outs are more complicated because deleting the checkpoint must wait until all branches have committed to an output. Unum repurposes the same set-based technique from fan-in to collect checkpoints in fan-out cases as well. The originating node of a fan-out creates a set for branches to coordinate when to delete its checkpoint. Branches add themselves to the set after checkpointing their own value. Any node that reads a full set deletes the parent’s checkpoint as well as the set. This guarantees that the parent’s checkpoint is deleted and ensures that all branches have first checkpointed.

Note that it is possible for one of the branches to re-execute *after* the set has been deleted. This is safe because it is the origin of the fan-out that creates the set, so a branch’s attempt to add itself to a, now, non-existent set will simply fail.

Fan-in Set collection. Deleting sets used for fan-in works much like removing checkpoints—the target node of a fan-in deletes the set once it has generated a checkpoint. However, who *creates* the set?

If each branch in the fan-in creates the set if it doesn’t already exist, a spurious execution of one of the branches *after* the fan-in target removes the original set will create a new one that is never deleted (because it never fills, and thus the target function is never invoked again). To avoid this, Unum places the responsibility to create the set on the node that originates the *fan-out* at the same level as the target node.

3.6 Naming

Much of Unum’s functionality relies on unique naming. A workflow invocation must be named to differentiate it from other concurrent invocations of the workflow; functions must be named to invoke them; different invocations of functions must have different names to uniquely name invocation checkpoints and coordination sets for fan-in.

Each workflow invocation has a unique name that is passed through the execution graph. The name is either generated in the ingress to the first function using, e.g., a UUID library or, when available, is taken from the FaaS platform’s invocation identifier for the first function. This enables functions to have different names when invoked as part of a specific workflow invocations. The function’s name is either user-defined or determined by the FaaS platform (e.g. the ARN on AWS Lambda) and determined at “compile-time” (i.e. when generating Unum IR).

However, this is not sufficient as functions may be invoked multiple times in the same workflow due to map patterns—which invoke the same function multiple times over an iterable output—and cycles. Moreover, invocation names must be determined using local information only. Once running, each function only has access to it’s own code (including the IR) and metadata passed in its input. Nonetheless a partic-

ular invocation must be able to determine its own name for checkpointing as well as, if it is part of a fan-in, the name of downstream invocations to coordinate with other branches.

As a result, Unum names function invocations using a combination of the global function name, a vector of branch indexes and iteration numbers (taken from the Unum request fan-out stack) leading to the invocation, and the workflow invocation name. Function names are global and the remaining items are propagated by Unum in invocation arguments.

During a fan-out pattern (multiple scalar invocations or a map invocation), a branch index is added to a list in the next functions’ input. If the next function is an ancestor of the current function (a cycle), an iteration field in the input is incremented. Note that a single iteration field is sufficient even if there are nested cycles since it is only important that different invocations of the same function have *different* names, not that the iteration field is sequential. Thus, a monotonically increasing iteration field is sufficient.

We note that the format of this name is not significant and, importantly, it need not be interpretable. It must only be deterministic and unique for its inputs. For example, a reasonable implementation could serialize the inputs and take a cryptographic hash over the result, guaranteeing uniqueness (with very very high probably) while preventing names from growing too large to use as object names.

4 Implementation

We implement a prototype Unum runtime that supports AWS and Google Cloud. We also implement a front-end compiler that transforms AWS Step Function definitions to Unum IR. Currently our runtime only supports Python functions and is itself written in 1,119 lines of code. The Step Functions compiler is 549 lines-of-code.

Implementing the runtime primarily requires specializing high-level functionality the IR depends on for a particular FaaS platform and data store. The FaaS platform must support asynchronous invocation and the data store must be strongly consistent with support for atomic creation and set operations.

Importantly, we choose data stores and primitives that only incur per-use costs and scale on-demand. For example, we use DynamoDB in on-demand capacity mode, rather than provisioned capacity mode, and avoid long-running services such as a hosted Redis or cache. As a result, Unum incurs fine-grained costs only when performing orchestration (e.g., per-millisecond Lambda runtime costs to execute the Unum library, per-write DynamoDB costs to create checkpoints).

4.1 AWS Lambda & DynamoDB

Asynchronous invocation in Lambda is natively supported. In particular, the Lambda `Invoke` API is asynchronous when passed `InvocationType=Event`. In the event of a crash, we use Lambda’s `Failure Destination` [29] to redirect the fault to

an error handler function which runs just the Unum runtime. The error handler checks if the failed function should be retried (e.g., based on the Step Function definition [15]) and if so, retries the function by explicitly invoking it again.

DynamoDB organizes data into tables, with each item in a table named by a key. Within tables, items are unstructured by default. Our implementation of Unum uses a single table for each workflow. Each item in the table corresponds to a checkpoint, or a coordination set for fan-in or garbage collection.

DynamoDB supports atomic item creation by passing the conditional flag `attribute_not_exists` to the `put_item` API call. We use this for creating both checkpoint blobs and coordination sets. DynamoDB supports set addition natively using the `Map` field type. In particular, we use update expressions to atomically set a named map element to true. As an optimization, we use the `ALL_NEW` flag when adding to a set to atomically get the new value after a set in a single operation.

4.2 Google Cloud Functions & Firestore

Google Cloud Functions (GCF) do not have an asynchronous invocation API. Instead, we allocate function-specific pub-sub queues and subscribe each function to its respective queue. Unum then asynchronously invoke a function by publishing the input data as an event to the function's queue.

GCF supports automatic retry for asynchronous functions [34]. In the event of a crash, the Unum runtime in the retry execution checks if the failed function should be retried and if so, retries the function by explicitly invoking it again.

Firestore organizes data into logical collections (which are created and deleted implicitly) containing unstructured items, named by a unique key. Similar to DynamoDB, we use a separate collection for each workflow. Atomic item creation is supported using a special `create` API call, which only succeeds if the key does not already exist. Firestore supports an `Array` field type which can act as a set by using the `ArrayUnion` and `update` operation, which atomically sets the field to the union of its existing elements and the provided elements. The `update` operation always returns the new value data.

5 Evaluation

Unum argues for eschewing standalone orchestrators and, instead, building application-level orchestration on unmodified serverless infrastructure using FaaS schedulers and consistent data stores. In this section, we evaluate how well application-level orchestration performs, reduces costs, and improves application flexibility. In particular, we focus our performance evaluation on whether decentralization comes at a reasonable overhead compared with standalone orchestrators.

Specifically, we answer the following questions:

1. What overhead does Unum incur in end-to-end latency and what are the sources of Unum's overheads?
2. How much does it cost to run applications with Unum and what are the sources of costs compared with Step Functions?
3. How well does Unum support applications that Step Functions cannot support well?

Though we evaluate the applications running on both AWS and Google Cloud, we focus our discussion on our AWS implementation with Lambda and DynamoDB, because it runs on the same serverless infrastructure as Step Functions.

5.1 Experimental setup

We run all experiments on AWS with Lambda and DynamoDB, and on Google Cloud with Cloud Functions and Firestore. All services are in the same region (`us-west-1` on AWS and `us-central-1` on Google Cloud). All functions are configured with 128MB of memory except for ExCamera where we use 3GB of memory to replicate the setup in the original paper [19, 20]. DynamoDB uses the on-demand provisioning option that charges per-read and per-write [12]. To avoid performance artifacts related to cold-starts, we ensure functions are warm by running each experiment several times before taking measurements.

All but one application were originally written as Step Function state machines. For Step Function experiments, we ran them directly with the "Standard" configuration [37], which provides similarly strong execution guarantees as Unum [16]. For Unum experiments, we first compiled the Step Functions definitions to Unum IR, linked the functions with the Unum runtime library and finally executed them as lambdas or Google Cloud functions. The notable exception is our Unum and Step Functions implementations of ExCamera, which differ due to a limitation in the Amazon State Language. As a result, the more efficient Unum implementation is written directly in Unum IR instead of compiled from the Step Functions definition (§ 5.4).

5.2 Performance

Unum's performance overhead results from the Unum runtime logic run in each function as well as API calls to data stores and FaaS engines. We characterize these overheads by measuring the latency to execute various patterns consists of `noop` functions as well as end-to-end performance of real applications. Overall we find that Unum performs comparably or significantly better than Step Functions in most cases owing to higher parallelism and a more expressive orchestration language, with modest slow downs in the remaining cases due to implementation deficiencies.

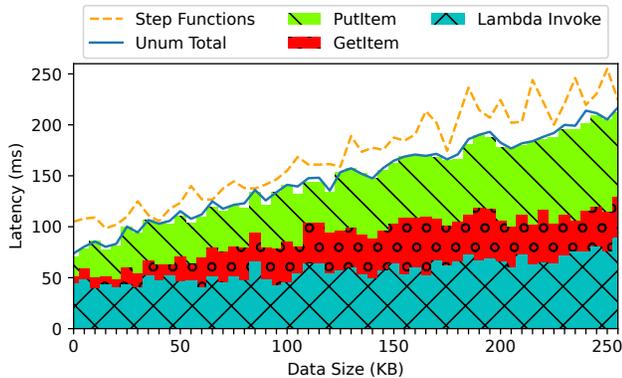

Figure 4: An orchestrator incurs a latency on each transition between functions. Unum’s overhead is due to storage operations to ensure exactly-one-result semantics, Lambda invocation API overhead to enqueue the next function to run, and additional Unum runtime code in the function instance itself for the orchestration logic.

5.2.1 Chaining

For the simple chaining pattern, the Unum runtime performs a storage read to check whether a checkpoint already exists, a storage write to checkpoint the function’s result, and an asynchronous function invocation to initiate the next function in the chain.

Figure 4 shows time to perform each of these operations for different result sizes. As expected, storage operations are slower when checkpointed results are larger, but the total overhead from the Unum runtime operations is consistently lower than an equivalent Step Function transition.

The Unum implementation of the IoT pipeline application benefits from this difference, with the Unum version running 1.9x faster than the Step Functions version (Table 2).

5.2.2 Fan-out and fan-in

Fan-out requires the same number of storage operations as chaining and similar orchestration logic, but the Unum runtime performs an additional asynchronous invocation at the source function for each branch. For fan-in patterns, each source branch performs an additional storage read to determine if it is the final branch to execute, and only the final branch performs the asynchronous invocation of the target function.

Figure 5 shows the latency of a fan-out followed by a fan-in at varying branching degrees for both Unum and Step Functions. At low branching degree, Unum incurs a modest overhead (up to 200ms) relative to Step Functions. We believe this is mostly due to our implementation initiating each branch invocation sequentially. However, at higher branching degrees (as low as 20 branches), Step Functions limits the number of outstanding fan-out branches [30] while Unum is limited only

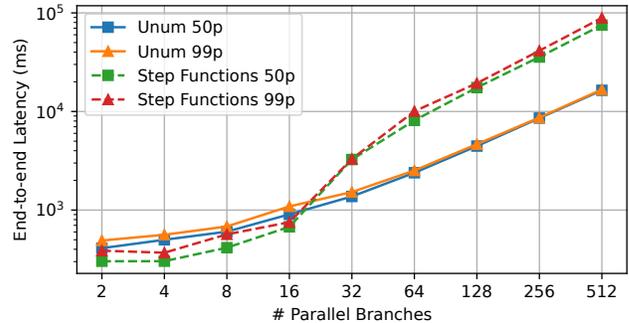

Figure 5: End-to-end latency of a fan-out and fan-in pattern with increasing branching degree. Unum is slower at lower branching degrees but significantly outperform Step Functions at moderate and high branching degree.

by Lambda’s scalability, resulting in over 4x lower latency with 512 branches.

These differences manifest in real workloads as well. Word-count is highly parallel (with 262 parallel mappers and 250 reducers) and performs over 2x faster on Unum than on Step Functions (Table 2).

Although it may not be the case that standalone orchestrators fundamentally have to impose limits on the number of outstanding function invocations, this example shows that it is at least not trivial to ameliorate the constraint. On the other hand, as a library, Unum is free from the need to design and implement yet-another service that supports parallel applications well, but can instead provide as much parallelism as FaaS schedulers and data stores permit. FaaS schedulers and data stores already support highly-parallel applications well, and Unum’s performance will improve automatically when these underlying services further improve.

5.3 Cost

One of the main attractions of building applications on serverless platforms is fine-grained and often lower cost. In particular, because resources are easy to reclaim, applications are charged only for resources used to respond to actual events. Thus, the *cost* of orchestration matters as well as performance.

The source of costs for Unum and Step Functions is quite different. Step Functions imposes a cost to developers for each workflow transition [5], such as each branch in a fan-out. This abstracts the underlying, likely shared, costs to run the Step Functions servers, persist states and checkpoint data. Conversely, Unum incurs costs directly from those services. In particular, compute resources for executing orchestration logic is charged per-millisecond such as Lambda runtime cost [2] and storage for persisting states is charged per read and write such as DynamoDB reads and writes [12].

On AWS, Unum is much cheaper than Step Functions—AWS’s native orchestrator. For a basic transition in a chaining

App	Latency (seconds)			Costs (\$ per 1 mil. executions)		
	Unum-aws	Unum-gcloud	Step Functions	Unum-aws	Unum-gcloud	Step Functions
IoT Pipeline	0.12	0.81	0.23	\$12.38	\$6.3	\$112.02
Text Processing	0.52	3.56	0.55	\$60.42	\$31.7	\$225.29
Wordcount	408.88	484.12	898.56	\$13,433.67	\$11,727.3	\$18,141.19
ExCamera	84.52	122.63	98.42	\$62,684.29	\$51,617.2	\$114,633.13

Table 2: Application latency and costs comparison between Unum and Step Functions. Running applications on Unum is 1.35x to 9x cheaper than on Step Functions. Furthermore, Unum is faster than Step Functions especially for workflows with high degrees of parallelism.

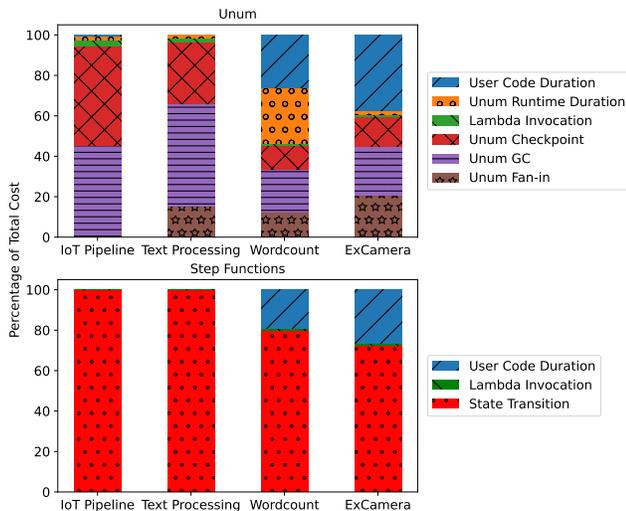

Figure 6: Step Functions state transitions dominate the total costs for all applications (99.5% in IoT Pipeline, 99.4% in Text Processing, 80.0% in Wordcount, 72.2% in ExCamera). While Unum runtime cost is also the majority, it accounts for a smaller portion of the overall costs (95.7% in IoT Pipeline, 97.8% in Text Processing, 72.5% in Wordcount and 61.0% in ExCamera).

pattern, Step Functions charges \$27.9 per 1 million such transitions. On the other hand, Unum costs, for 1 million transitions, (1) \$0.42 for ~200ms extra Lambda runtime to execute orchestration library code, (2) \$2.79 for 1 DynamoDB write to checkpoint, (3) \$0.279 for 1 DynamoDB read to check checkpoint existence, and (4) \$2.79 for 1 DynamoDB write to garbage collect the checkpoint. In total, a basic transition in Unum is about 4.4x cheaper than the provider-hosted orchestrator on the same platform (\$27.9 vs \$6.279).

Table 2 shows the cost to run each of the applications we implemented in the `us-west-1` region. Unum is consistently, and up to 9x, cheaper than Step Functions for the applications we tested.

Figure 6 shows the cost to run each application using Unum broken down to each component: data store costs for writing and reading checkpoints, data store costs for writing coordina-

tion sets, data store costs for deleting checkpoints and writing coordination sets for garbage collection, Lambda invocation, and Lambda CPU-time for both the Unum runtime and user function. Storage costs, using DynamoDB, are the largest portion of overall cost and costs for writing to DynamoDB is the majority². This includes writing checkpoints, writing to coordination set (either for fan-in for garbage collection) and deleting checkpoints for garbage collection.

Of course, developer-facing pricing is only a proxy for *actual* costs of hardware and human resources. However, it is clear that, in practice, Unum’s costs are reasonable and, in fact, often lower than Step Functions. This suggests that at least applications that currently run on Step Functions could afford to run using Unum instead.

Furthermore, services that Unum builds on—FaaS schedulers and data stores—are core multi-tenant services that likely multiplex over a larger audience of applications than orchestrators for greater economies of scales. These services typically have enjoyed long periods of improvement already to make them efficient. Unum’s design obviates the need to host yet-another service which frees up resources such that providers can focus on fewer core services in their serverless infrastructure.

Moreover, Unum automatically benefits from improvements to the underlying infrastructure and pricing schemes. For example, Azure’s Cosmos DB provides similar performance and consistency guarantees to DynamoDB but charges 5x less to perform a write operation (the dominant cost of Unum’s data store operations).

5.4 Case Study: ExCamera

ExCamera [20] is a video-processing application designed to take advantage of high burst-scalability on Lambda using custom orchestration. We compare our Unum implementation with three others: (1) the original hand-optimized ExCamera using the `mu` framework, (2) an implementation using a generalized orchestrator (`gg`) by the same authors, and (3) an optimized Step Functions implementation we wrote.

Both `gg` and `mu` employ standalone orchestrators to proxy inter-function communications, store application states and

²Writes in DynamoDB cost about an order-of-magnitude more than reads

invoke lambdas. However, mu uses a fleet of long-running identical lambdas where all application code is co-located and raw video chunks are pre-loaded, whereas gg lambdas are event-driven, task-specific and cannot leverage pre-loading. The application logic, though, is identical for gg ExCamera and mu ExCamera. Unum’s ExCamera replicates the application logic from gg and mu. However, the Step Functions ExCamera implementation must serialize the encode and re-encode stages because Step Function’s Map pattern requires all concurrent branches to complete before any fan-in starts (Figure 7).

5.4.1 Performance

Using the same experimental setup as the prior work (i.e., encoding the first 888 chunks of the sintel-4k [31] video using 16 chunks per batch and Lambdas configured with 3GB of memory), Unum is 7.1% faster than gg [19] and 10.5% slower than the original, hand-optimized ExCamera (Table 3). The original authors attributes the slower performance of gg ExCamera to the lack of pre-loading which is likely also the reason for Unum’s slower performance.

But different from gg, Unum executes orchestration in a decentralized manner while gg has a standalone coordinator on EC2. The reduced number of network communications likely explains why Unum is slightly faster.

Comparing with Step Functions, Unum’s design allows the flexibility to implement ExCamera’s original application pattern where tasks start as soon as their input data becomes available, whereas the Step Functions implementation had to use the less-efficient Map pattern without the flexibility to add new orchestration patterns easily. As a result, the Unum ExCamera enables more parallelism between branches and is 16.7% faster than Step Functions.

5.4.2 Cost

Unlike Unum, neither gg nor mu aimed to reduce the cost of running serverless applications and neither discussed costs in detail. Nevertheless, there are several important factors in comparing Unum with gg and mu in relation to costs.

First, similar to Step Functions, gg and mu both rely on standalone orchestrators. Thus, the fundamental costs difference is also similar, namely Unum’s use of storage vs gg’s and mu’s use of VMs. mu’s orchestrator consists of a coordinator server as well as a rendezvous server [20], while gg’s only has a coordinator server [19]. In the mu authors’ experiments, they used a 64-core VM (m4.16xlarge) as the rendezvous server. Neither mu nor gg specified the instance type of its coordinator server. However, the cost of the rendezvous server, at the time of writing, is \$3.20 per hour, or approximately \$2352 per month.

Furthermore, standalone orchestrators must separately consider fault-tolerance in case of orchestrator failures. Most

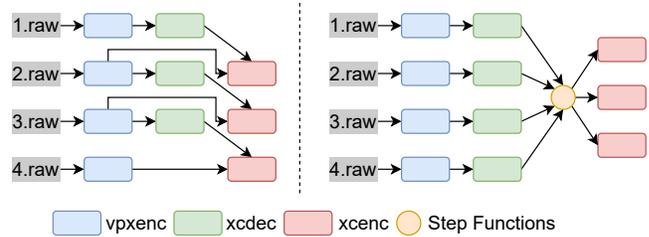

Figure 7: Unum ExCamera replicates the application logic from gg and mu where the re-encode stage (xcenc) of a branch can start immediately when the previous branch completes decoding (xcdec) and my own branch completes the initial encoding (vpxenc). Step Functions provides a Map pattern [30] for parallel workloads. However, branches in Map must be identical and Map does not support data dependencies between branches. As a result, to ensure previous branches’ xcdec have completed, all branches must first finish and fan-in to Step Functions before starting the xcenc step, essentially serializing the stage.

ExCamera Implementation	Latency (seconds)
Original	76
Unum-aws	84
gg	90
Step Functions	98

Table 3: ExCamera performance. Unum is 7.1% faster than gg [19] and 10.5% slower than the hand-optimized implementation.

commonly, fault-tolerance is achieved by running multiple coordinating instances (replicas) of the service. As a result, production deployments of mu and gg would likely cost more.

Lastly, deploying an orchestrator per application or per user limits the ability to amortize costs through multi-tenancy. A provider-hosted orchestrator, such as Step Functions, can achieve larger economies of scale by serving many users concurrently with a single deployment.

6 Related Work

Serverless Workflows. Many systems have recognized the need to augment serverless computing with support for composing functions to build larger and more complex applications. AWS Step Functions [3] defines serverless workflows as state machines using a JSON schema. Google Workflows [23] uses a YAML-based interface to list steps in a workflow sequentially and allows jumps among steps. Azure Durable Functions [6] uses a “workflow-as-code” approach, similar to driver functions, where the workflow logic is written in a programming language (e.g., C#, Python).

In all of these systems, orchestration is performed by a

standalone orchestrator. The nature and location of this component varies: in AWS Step Functions [3] and Google Workflows [23], it is provided by a cloud service that is separately hosted and billed. In Azure Durable Functions [6], it is an extension of the serverless runtime, and uses the same billing. In contrast to all of these, Unum proposes a novel **decentralized orchestration strategy** and runs entirely on unmodified serverless infrastructure without adding any new services or new components.

Kappa [41] addresses the lack of coordination between function and function timeout limits when executing large applications. Similar to Durable Functions, it also exposes a high-level programming language interface. Cloudburst [36] uses a specialized key-value store to enable low-latency execution of serverless functions. Users can express workflows as static DAGs and an executor program runs the DAG by passing data and coordinate via the key-value store. ExCamera [20] proposes the mu framework which uses a long-running coordinator to command a fleet of lambdas, each of which executes a state machines where user functions are the states. gg [19] proposes a thunk abstraction where each thunk executes as a deterministic lambda and expresses data dependencies between thunks as DAGs. gg uses a standalone coordinator to receive thunk updates and lazily launch thunks when their inputs become available.

Similarly, the above systems rely on a standalone orchestrator program. As the orchestrator program is not itself executing in a hosted environment, progress is not guaranteed when its host crashes. Also, progress is not checkpointed (except in Kappa), so workflows must restart from the beginning in that situation. In contrast, Unum relies only on a basic, highly available serverless platform. Thus, it guarantees progress under all faults, including the orchestrator. And Unum checkpoints each function result to minimize redundant computations when handling faults.

Beldi [40] and Boki [25] are two recent systems that provide exactly-once execution and transactions to stateful serverless applications. Both extend transactional features to specific application side effects supported by the system (e.g., DynamoDB writes). Developers use Beldi or Boki’s library in user code when writing to a supported data store (e.g., DynamoDB) such that writes are executed only once. In comparison, Unum does not change how developers write user code and does not extend exactly-once guarantee to side effects in user code. Instead, Unum treats user code as a black box and ensures exactly-once semantics on a workflow-level. However, Unum users who want to ensure exactly-once when writing to DynamoDB can additionally use Beldi or Boki in their user code.

Programming Interface. Most serverless workflow systems require developers to write workflows with specialized interfaces. Some uses a declarative approach that defines workflows using JSON or YAML schemas (e.g., AWS Step Functions [3], Google Workflows [23]). Others allow expressing

workflow as code (e.g., Durable Functions [6], Kappa [41], Fn Flow [18]).

Unum does not propose a new frontend for defining workflow. Instead, Unum aims to support any existing frontend that explicitly or implicitly expresses a directed graph where nodes are functions and edges are transitions between functions. Developers using Unum can choose the frontend that they prefer.

7 Discussion & Limitations

Unsupported applications. Unum supports a superset of applications that can be expressed using Step Functions, but there are applications that do not fit Unum’s constraints. In particular, Unum only supports statically defined control structures. For example, Durable Functions expresses workflows dynamically as code and allows the developer to use arbitrary logic to determine what the next workflow step should be at runtime. This is not currently possible with Unum.

Measurement error. Due to the opaque design, implementation and pricing of production workflow systems, such as Step Functions, comparisons in our evaluations are limited in their explanatory power. In particular, we use the current *price* of Lambda, DynamoDB, and Step Functions as a proxy for the *cost* of providing these services. Of course, prices may be either lower or higher for a particular service than the underlying cost.

Code Complexity. While Unum affords users more flexibility, application-level orchestration increases code complexity for developers. Coordination and exactly-once execution require careful design and implementation to function correctly in a decentralized manner. Introducing application-specific optimization also needs additional developer efforts than using off-the-shelf patterns from provider-hosted orchestrators.

8 Conclusion

We designed and implemented Unum, an application-level, decentralized orchestration system that runs as a library on unmodified serverless infrastructure without requiring additional services. Our results show that basic serverless components—function schedulers and consistent data stores—are sufficient abstractions for building complex and fault-tolerant serverless applications. Moreover, Unum affords applications more flexibility, reduces costs and performs well compared with standalone orchestrators with similar execution guarantees.

Enhancing Global Network Monitoring with *Magnifier*

Abstract

Monitoring where traffic enters and leaves a network is a routine task for network operators. In order to scale with Tbps of traffic, large Internet Service Providers (ISPs) mainly use traffic sampling for such global monitoring. Sampling either provides a *sparse view* or generates *unreasonable overhead*. While sampling can be tailored and optimized to specific contexts, this coverage–overhead trade-off is unavoidable.

Rather than optimizing sampling, we propose to “magnify” the sampling coverage by complementing it with mirroring. *Magnifier* enhances the global network view using a two-step approach: based on sampling data, it first infers traffic ingress and egress points using a heuristic, then it uses mirroring to validate these inferences efficiently. The key idea behind *Magnifier* is to use *negative* mirroring rules; *i.e.*, monitor where traffic should *not* go. We implement *Magnifier* on commercial routers and demonstrate that it indeed enhances the global network view with negligible traffic overhead. Finally, we observe that monitoring based on our heuristics also allows to detect other events, such as certain failures and DDoS attacks.

1 Introduction

Monitoring transit traffic in Internet Service Provider (ISP) networks is difficult: most operators do not know precisely where traffic enters or leaves their infrastructure. This inability to correlate traffic network-wide makes it hard—if not downright impossible—to detect network-wide problems. As a consequence, operators occasionally learn about routing issues in their own network only via customers calling or opening up tickets.

Operators could use control-plane data to identify where traffic enters and leaves an ISP network; however, that is insufficient. Traffic towards the same destination is often load-balanced between multiple egresses; traffic from the same source prefix often enters via multiple ingresses; importantly, in case of failures or attacks, traffic may not follow the control

plane. Data-plane measurements are thus necessary for accurate flow-level information. Unfortunately, such measurements are hard to scale with the Tbps of traffic crossing ISP networks nowadays.¹ Two common techniques to collect data-plane measurements are packet sampling and traffic mirroring. Both have advantages and disadvantages, making them suboptimal for detecting traffic ingresses and egresses.

Sampling-based approaches such as NetFlow [12] or sFlow [30] provide good coverage at the expense of precision and correctness. Often only a few flows are sampled, and even fewer are sampled at both the ingress and egress. We confirmed this by analyzing a 5-minute slice of NetFlow data (1/1024 sampling rate) extracted from *all* border routers of a Tier-1 ISP in Europe. The slice contains around 40 million flows, where a flow corresponds to packets sharing the same source and destination subnet as well as the same source and destination port. After discarding flows from/to the ISP-owned prefixes, we found that over all sampled transit flows, only 22% are sampled at both their ingress *and* egress, while 41% (resp. 37%) of flows are sampled only at the network ingress (resp. egress). Hence, a traffic matrix such as shown in Fig. 1a locates only 22% of sampled flows; we waste the information from all other sampled flows.

Mirroring-based approaches [33,39] provide high precision and *correctness* at the expense of scalability. Suppose we would mirror all traffic at network border routers. In that case, we could easily enhance packets sharing the same source and destination subnet with their ingresses and egresses, but that would double the network’s traffic. Besides packet mirroring, techniques based on sketches [22] or in-band telemetry [25,26] also excel at gathering precise information but can only do so for a specific share of the traffic.

In this work, we ask ourselves whether we can combine the benefits of sampling and mirroring to mitigate their respective drawbacks. We answer this question positively and present

¹For example, Deutsche Telekom’s IP network has a transit capacity exceeding 30 Tbps and reports up to 10 Tbps of IP traffic on average (3500 PB/month). Source: <https://globalcarrier.telekom.com/business-areas/internet-content/ip-transit>

*The CRediT statement for this work is available in Appendix A.

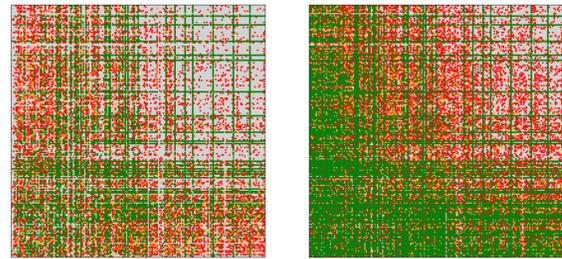

Magnifier, a system that enhances the global network view obtained via sampling using a two-step approach. First, we **infer the ingress and egress of flows** using a heuristic: packets that are “close” in the IP space tend to be routed similarly. This intuition has already been used successfully in other contexts, e.g., to scale heavy-hitter detection using counters [25]. Assuming this holds, we search for the largest IP subnets for which packets appear to enter the network via the same ingress (resp. exit via the same egress) according to the sampling data available. We call these subnets *sentinels*. Fig. 1b shows the sentinel heuristic applied to our Tier-1 NetFlow data, which immediately magnifies the view: not only do we observe more flows for certain ingress–egress pairs (red to green), but we also reveal pairs which were not visible at all in the NetFlow-based matrix (Fig. 1a).

Naturally, this heuristic is not perfect; as sampling is sparse, we may lack important information to correctly identify ingress or egress points, or traffic may simply be rerouted over time. Thus, in a second step, we use **mirroring to validate the inferred ingresses and egresses**. To avoid mirroring a lot of traffic, the key idea is to install mirroring rules where we do *not* expect traffic; i.e., if we infer that subnet s always enters via router R , we install a mirroring rule for s in all ingress routers, except R . In practice, this leads to little mirrored traffic because sentinels are most often correct. Thanks to mirroring, *Magnifier*’s ingress/egress inferences are **guaranteed correct**, which is a key feature of our design and an essential difference from other monitoring tools. Mirrored traffic reveals inference errors or traffic shifts in sub-seconds, which allows *Magnifier* to maintain a correct network view.

The main limitation of *Magnifier* is the number of mirroring rules to install, which, naively, is about one mirroring rule per sentinel on all border routers. For networks forwarding traffic which covers most of the IP space, this vastly exceeds the mirroring capabilities of today’s routers. We thus investigate different strategies to cap the number of rules installed while harnessing most of *Magnifier*’s benefits.

Contributions

- We design *Magnifier*, a network monitoring system that combines sampling with mirroring to enhance the global view on traffic ingresses/egresses (e.g., Fig. 1) while providing correctness guarantees.
- We implement *Magnifier* [3], run it on Cisco Nexus 9300 switches, and demonstrate that *Magnifier* increases the network view coverage with only limited traffic overhead and inference errors using real traffic traces (§ 6).
- We discuss (§ 4.2) and evaluate (§ 6.2.2) different strategies to scale *Magnifier* to large ISP networks by capping the number of mirroring rules required to e.g., the top 1k sentinels while maintaining most of *Magnifier*’s benefits.
- We observe that, even without mirroring, changes in the number of found sentinels create an interesting signal for other monitoring applications, such as failure detection or DDoS protection (§ 6.4).

(a) NetFlow-based matrix. (b) *Magnifier*’s matrix.

Figure 1: By inferring ingress or egress points of sampled flows, *Magnifier* significantly improves the network-wide coverage (Fig. 1b) compared to using sampling only (Fig. 1a). These inferences are guaranteed correct by (the absence of) mirrored packets. Dots represent the number of flows observed from an ingress router (x -axis) to an egress router (y -axis). Grey indicates no flow, red one flow, orange up to 4 flows, and green 5 or more flows. Data source: NetFlow samples from a large Tier-1 ISP.

2 Overview

This section introduces the problem statement (§ 2.1) and *Magnifier*’s main building blocks (§ 2.2). Finally, we illustrate *Magnifier*’s behavior on a simple example (§ 2.3).

2.1 Problem statement

Can we combine the benefits of sampling and mirroring to design an *easy-to-deploy* system that produces *accurate, complete* and *timely* ingress/egress observations in ISP networks, where an “observation” consists of an IP subnet for which we know the correct ingress and egress points?

Ease of deployment The system should be usable in today’s networks with no need for new or specialized hardware.

Accuracy The system should correctly infer subnets’ ingress and egress points.

Completeness The system should generate observations for the largest possible portion of the IP space.

Timeliness The system should update observations in real-time based on newly-collected information; that is, information is processed quicker than it is collected.

2.2 Building blocks

Magnifier extends the coverage of ingress/egress observations using a two-step approach (Fig. 2): based on sampled data, it first *infers* the missing traffic ingress and egress points, then it *validates* these inferences using mirroring.

Inference *Magnifier* cross-correlates the sampled flows to identify IP subnets that are consistently routed via the same ingress or egress routers. For example, suppose we observe *all* sampled flows for a source prefix p enter via ingress router A . *Magnifier* learns that p is an implicit tag for “ingress A ”, which

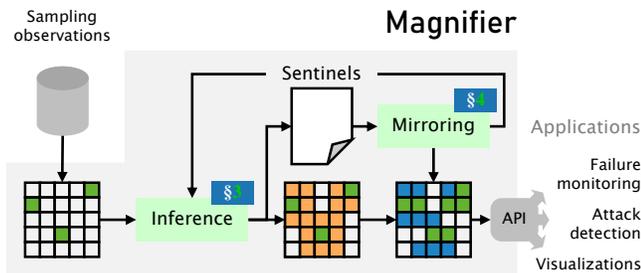

Figure 2: *Magnifier* uses sampled data to infer sentinels that predict IP subnets’ ingress or egress points. *Magnifier* then validates sentinels at runtime using packet mirroring. This way, we can greatly extend the coverage of traffic ingress/egress observations usable by many applications.

enables to map any sampled flow sourced by p as entering via A —even if observed on a different router.

In addition, *Magnifier* leverages the hierarchical nature of the IP space: packets that are “close” in the IP space tend to be routed similarly. Thus, *Magnifier* searches for the largest IP subnets that share the same tags and postulates that all the IPs in these subnets are routed via the same ingresses or egresses. We call these largest subnets *sentinels*. Sentinels significantly extend the coverage of ingress/egress observation (compare Fig. 1). However, these sentinels may be incorrect; sampling may have missed important information, or traffic may simply be re-routed over time. Therefore, *Magnifier* uses mirroring to validate them at runtime.

Validation The key idea behind *Magnifier* is to validate the sentinel inferences using *negative mirroring*; i.e., to deploy mirroring rules where we expect traffic *not* to go. Negative mirroring is efficient because sentinels are often correct in practice; therefore, we mirror only a little traffic. Fundamentally, this guarantees that *Magnifier*’s outputs are correct; all prefixes covered by sentinels either have correctly identified ingress/egress or carry no traffic. Otherwise, traffic is mirrored, which provides additional observations and allows *Magnifier* to maintain and improve its accuracy over time.

Optimization The main limitation of *Magnifier* lies in the number of mirroring rules that can be activated simultaneously on one router. By aggregating subnets together, sentinels effectively limit the number of mirroring rules that must be deployed, but this remains a constraint for large ISP networks. *Magnifier* supports multiple rule deployment strategies to respect a given rule budget per router while optimizing for different properties (e.g., IP space coverage).

2.3 Illustrative example

While mirroring rules generate additional traffic, they are essential to *Magnifier*, illustrated with an example (Fig. 3): p_0 to p_7 are eight /24 prefixes belonging to the same /21; most of the traffic comes from p_0 , with sporadic traffic from other prefixes. Let’s assume that we only sample traffic from p_0 ,

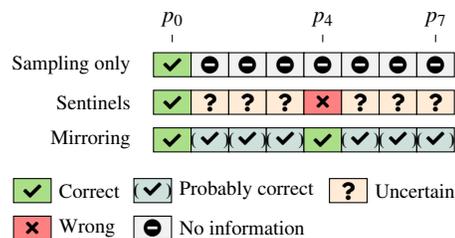

Figure 3: Sampling provides information about the sampled prefixes only. The sentinel inference extends the coverage, but it is uncertain and can make wrong assumptions without any means to detect them. With mirroring, these inferences can be validated, leading to either correct or probable inferences.

which enters at ingress A . One can hypothesize that all p_0 traffic enters via A , but nothing can be said about p_1 to p_7 .

Since no sampled packet contradicts this hypothesis, we infer that all eight /24 enter via A ; the whole /21 is a sentinel for ingress A . This inference is, however, uncertain for seven /24 prefixes without any data. Some traffic from p_4 enters via another ingress, but as long as we do not sample p_4 traffic, we will not detect the wrong inference.

We now use mirroring to validate the sentinel: all routers except A mirror packets for the /21. At first, no packet is mirrored: this indicates either that the sentinel is indeed correct or that there is no traffic *at all* on prefixes that would enter via another ingress. Thus, for the seven prefixes without sampling data, *Magnifier* concludes that the ingress is “probably A ”.

Finally, ingress router B mirrors packets coming from p_4 . *Magnifier* now learns that the /21 sentinel was incorrect. We recompute sentinels, which leads to two /22 sentinels, one for A and one for B . Once the corresponding mirroring rules are installed, *Magnifier* confirms that p_0 and p_4 enter via A and B respectively, and that p_1 to p_3 (p_5 to p_7) probably enter via A (resp. B) as we would otherwise observe mirrored packets.

Conclusion The mirroring rules are essential to validate the sampling-based inferences. Once active, *Magnifier* *guarantees* that the inferences are either correct or that prefixes for which they are wrong do not carry any traffic at all.

3 Ingress & egress identification

In this section, we define the notion of “sentinels” and present an efficient algorithm to find them (§ 3.1). We then discuss sentinel subnet size tradeoffs (§ 3.2) and finally show how *Magnifier* uses these sentinels to match ingress and egress observations in sparsely sampled data (§ 3.3).

3.1 Sentinel search and definition

Definition A sentinel is an *IP subnet* which always enters or leaves the network via *one* network device. Therefore, a sentinel identifies this device whenever a flow from/towards

Algorithm 1 Sentinel search algorithm

```
start ← starting subnet size
end ← ending subnet size
table[IP, device] ← search IPs and network devices
sentinels ← {}
for start ≤ S ≤ end do
  table[IPnew] ← ((IP >> (32 - S)) << (32 - S))
  aggregated ← table.groupby(IPnew)[device]
  result[n] ← numique(aggregated[device])
  sentinels += (result[n] == 1)
  table -= sentinels
end for
return sentinels
```

the IP subnet is observed *somewhere* in the network. As an example, if flows towards 1.2.3.0/24 *only* leave the network via egress router R, we say that 1.2.3.0/24 is an egress sentinel for R. Note that a single sentinel can cover numerous flows.

Types We can distinguish four types of sentinels depending on which IP address we look at (source or destination) and which traffic direction is identified by them (ingress or egress). For example, we can speak about ingress source sentinels. However, unlike specified differently, the remaining sections will only focus on two types of sentinels (i) ingress source sentinels (abbreviated as *ingress sentinels*); and (ii) egress destination sentinels (abbreviated as *egress sentinels*). Currently, *Magnifier* only considers IPv4 sentinels, but *Magnifier* can be applied to the IPv6 address space as well.²

Search algorithm *Magnifier*'s sentinel search algorithm takes flow samples as input. They contain, among others, the identifier of their origin router and the packet source and destination IP addresses. In addition, we define a start and end subnet size over which the algorithm searches for unique subnets to reveal sentinels. Algorithm 1 highlights the main sentinel search steps. The for loop iterates from the start to the end subnet size. In each iteration, we extract the corresponding subnets from the IP addresses of the collected flow samples. All flows belonging to the same subnet are aggregated. If one aggregate only contains samples from the same device, *Magnifier* has found a sentinel, removes the samples from further search iterations, and eventually returns the sentinels.

3.2 Sentinel subnet sizes

Algorithm 1 returns a subnet as a sentinel as soon as it only contains flow samples from one device. However, it is also possible that a smaller subnet would cover all these samples. Fig. 4 shows a simple example. The network forwards traffic from three different /24 subnets. We collect samples from the

²Current IPv6 allocation strategies (e.g., <https://www.ripe.net/publications/docs/ripe-738#5>) are favorable for *Magnifier*. The same AS tends to be allocated large IP blocks that we can use as sentinels.

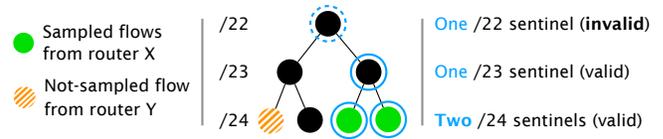

Figure 4: The sentinel amount and coverage depend on the subnet size. The “largest” /22 sentinel is invalid, whereas one /23 sentinel or two /24 sentinels are valid.

two green /24 subnets (ingress router X). Unfortunately, we do *not* sample a packet from the orange /24 subnet (ingress router Y). Algorithm 1 would return the corresponding /22 subnet as an ingress sentinel. After installing corresponding mirroring rules (§ 4.1), *Magnifier* will detect that this sentinel is invalid as it contains flows from two different ingress routers (X and Y). If we would search for smaller subnets, we could either return one valid /23 sentinel or two valid /24 sentinels.

This simple example shows a fundamental tradeoff between the subnet size of found sentinels, the number of sentinels, and their validity. In general, sentinels based on smaller subnets are more likely to be valid but require more mirroring rules to be validated. Experimentally, we find that starting at /16 and ending at /24 yields good performance; starting at bigger sizes does not help as we rarely see such big prefixes in BGP, and it is unlikely that they are unique to a single ingress/egress, while /24 is the smallest globally routed prefix size [35]. As a consequence, the search sizes also influence the number of required validation mirroring rules (§ 4.1) and, therefore, the required router resources.

3.3 Sentinel-based ingress & egress detection

Magnifier uses the found sentinels in two ways. First, for each sentinel type, it tracks the number of sentinels found per device in the network. § 6.4 shows that the number of sentinels is rather stable and changes can reveal unexpected network behavior. The second use case exploits the uniqueness property of sentinels. Let’s assume we have found a (valid) egress sentinel for router X. For each flow towards the sentinel’s subnet—no matter if we observe a corresponding packet on an ingress or another device—we instantaneously know that it will leave the network over X. Similarly, we can identify flow ingresses based on ingress sentinels. *Magnifier* uses this information as input for its ingress/egress observations.

4 Mirroring-based validation

In this section, we explain how *Magnifier* uses traffic mirroring to validate the ingress and egress sentinels produced by the sentinel search algorithm (§ 4.1). To ensure that *Magnifier* can adhere to an operator-given budget of mirroring rules, we introduce two different rule deployment strategies and discuss additional optimization possibilities (§ 4.2).

4.1 Validating found sentinels with mirroring

Magnifier uses *negative* rules to validate the sentinels it finds. Negative rules are placed on devices that are *not* expected to see matching traffic. For instance, to validate that an ingress sentinel belongs to ingress I , *Magnifier* places negative mirroring rules mirroring traffic for the sentinel's source subnet at all ingress routers except I . The negative mirroring rules will never generate any packets if the sentinel is valid. For invalid sentinels or sentinels which become invalid over time (e.g., a forwarding change), the mirrored packets inform *Magnifier* immediately, and we can update our inferred ingress or egress observations. *Magnifier* then includes the mirrored data in the next sentinel search to find better sentinels.

ACL-based mirroring *Magnifier* relies on existing features such as ERSPAN [9] to mirror traffic from a router. Depending on the router model and capabilities, there are different ways to define the mirrored traffic. We can temporarily mark packets (i.e., [39]) or directly assign a list of subnets to the mirroring session. We use so-called Access Control Lists (ACLs) in all these cases. An ACL is a list of subnets that matches on the forwarded traffic and defines the mirrored traffic. Our “mirroring rules” are entries in an ACL.

Deployment and activation of mirroring rules To deploy its mirroring rules, *Magnifier* interacts with a Python script that runs directly on the router CPU. Via its arguments, *Magnifier* tells the script the mirroring rules to add to the ACL. The script uses e.g., Cisco's Python API [6] to perform the changes. However, naively adding entries to an ACL that is already connected with an active ERSPAN session can result in unexpected mirroring behavior for at least two reasons: (i) adding new entries takes some time and *Magnifier* cannot predict at which point in time a new mirroring rule is active; (ii) the Ternary Content Addressable Memory (TCAM) region which handles the ACLs/mirroring rules is limited. *Magnifier* handles (i) by pre-deploying inactive mirroring rules and (ii) with techniques explained in § 4.2.

To pre-deploy mirroring rules, *Magnifier* first adds entries to an ACL that is not yet active, i.e., connected with an ERSPAN session. The ACL entries do not yet take space in the TCAM. Once the ACL contains all mirroring rules, another script activates the entire ACL, simultaneously enabling all mirroring rules. In practice, *Magnifier* always iterates between *two* ACLs. One is currently actively mirroring traffic while the other one is populated. Once the second ACL is ready, we switch between them. Due to this deployment strategy, *Magnifier* is not negatively influenced by frequently changing mirroring rules/sentinels (see § D.4) as we always activate a new pre-deployed ACL. Furthermore, this only affects the mirrored traffic; *Magnifier* does not impact the production traffic.

Magnifier can also add a parameter to the scripts which defines how long an ACL should be active. The script will then automatically, i.e., without any external interaction, deactivate the mirroring rules once the defined timeout expires.

4.2 Limiting the amount of mirroring rules

The amount of mirroring rules which a single router can support is limited. Not only is the entire TCAM limited, other features (e.g., traffic engineering) use the same memory space and compete with *Magnifier*'s mirroring rules. For this reason, *Magnifier* supports multiple deployment strategies to adhere to an operator-given budget of mirroring rules. In the following paragraphs, we describe two strategies, but network operators can easily define their own sorting algorithm to control which mirroring rules they deploy first.

Deployment based on sentinel size The first strategy maximizes the sentinel IP space covered by mirroring rules. As each mirroring rule is connected to a sentinel with a specific subnet size, *Magnifier* first orders all sentinels of an ingress or egress based on their subnet size. *Magnifier* then iterates through all network border routers in a round-robin fashion and deploys mirroring rules for the sentinel with the biggest subnet (i.e., the subnet which covers the most IP space). This process ends if either the mirroring rule budget is reached or every mirroring rule is deployed.

Deployment based on sentinel activity The second strategy prioritizes the most active (amount of sampled packets) subnets/sentinels. In other words, we make sure that the inferred ingress or egress points for the most active subnets are validated by mirroring. To this end, *Magnifier* iterates through all border routers in a round-robin fashion and first deploys mirroring rules for the sentinels that are based on the largest number of sampled packets. Random packet sampling—by design—favors large, active flows. Therefore *Magnifier* indirectly deploys mirroring rules for the most active subnets. We evaluate both deployment strategies in § 6.2.2 and § D.3.

Network-specific optimizations *Magnifier* further reduces the amount of mirroring rules using network-specific knowledge. For example, some ISP border routers only connect to customers, and the operator knows exactly which IP addresses belong to them. That limits the possible source addresses entering the ISP over these ingresses (assuming no IP spoofing). On these devices, *Magnifier* does not need to install mirroring rules which belong to IP subnets outside of the customer's prefixes as we should never receive contradicting traffic.

5 *Magnifier*'s controller

Magnifier's controller collects and combines the sampled and mirrored packets, finds new sentinels, deploys and activates the corresponding mirroring rules, and uses the newest data to generate accurate and up-to-date ingress/egress observations. This section first explains how the different pieces work together before introducing *Magnifier*'s API. § B contains details about *Magnifier*'s controller placement.

Controller design *Magnifier*'s control flow works in iterations that align to the system component with the longest runtime.

As various tests on real hardware show, this is usually the time it takes to deploy mirroring rules on the routers. Fig. 5 shows the entire process. *Magnifier* uses the collected sampled and mirrored data in iteration $N-2$ (and optionally $N-3$ or older iterations) to compute sentinels and their mirroring rules. Based on the operator given rule budget, *Magnifier* sorts the sentinels according to the deployment strategies in § 4.2. While iteration $N-1$ is running, *Magnifier* pre-deploys the newly computed mirroring rules on the routers. As soon as *Magnifier* deploys the last rule (or once we reach the defined iteration time), it switches to iteration N and activates the pre-deployed mirroring rules after deactivating the old ones. Finally, *Magnifier* uses the collected sampled and mirrored data and the inferred ingress and egress points from the newest sentinels to compute accurate and up-to-date ingress/egress observations.

***Magnifier*'s API** *Magnifier*'s API supports four distinct primitives. First, `enhance_subnet(S)` returns the available ingress and/or egress data related to subnet S . Second `get_interfaces()` returns the relationship between sentinels and their interfaces. *Magnifier* can infer the corresponding interfaces based on sampling data and/or the observed MAC addresses in mirrored packets. Third, `get_matrix()` generates the most up-to-date ingress/egress matrix. Each cell contains the number of observed packets and bytes (reported by sampled packets) for an ingress/egress observation. In addition, a validity bit indicates inferences that are currently validated with mirroring rules. Finally, `get_counts()` outputs the number of found sentinels per device grouped by sentinel type. In § 6.4 we use this API call to detect network problems based on data from a real Tier-1 ISP.

6 Evaluation

This section evaluates *Magnifier* in detail. After introducing the evaluation setup (§ 6.1), we first focus on *Magnifier*'s performance in simulation and on real hardware devices in our lab (§ 6.2). Afterward, we perform a detailed comparison with the Everflow system (§ 6.3) before we highlight that *Magnifier* also works with data from a real ISP (§ 6.4).

6.1 Evaluation setups, datasets, and metrics

Setups We evaluate *Magnifier* in a simulation setup without any resource constraints and a lab setup on real hardware with its corresponding limitations. Our lab setup contains two Cisco Nexus 9300 switches (C93108TC-FX) [10], and a larger Nexus 7009 switch (N7K-C7009) [8]: an older³ but more resourceful model that we use for benchmark experiments.

We illustrate the lab setup in Appendix § D.1. We establish four parallel connections between the two Nexus 9300 switches, each emulating a network ingress. The first switch receives and samples the traffic using sFlow (sampling rate

³Released in 2011 and no longer sold.

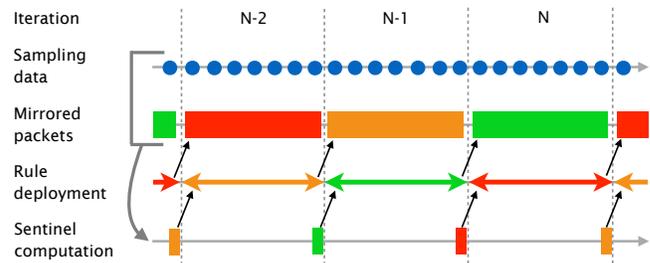

Figure 5: *Magnifier*'s control flow works in iterations based on the mirroring rule deployment time. Rules for sentinels based on $N-2$ are deployed in $N-1$ and active in iteration N .

1/4096⁴). It then forwards to the second switch, which mirrors the traffic according to the configured rules. *Magnifier*'s controller runs on a server and collects sampling and mirroring data. As these switches are limited to 512 mirroring rules, we used a fixed budget of 500 rules per emulated ingress point.⁵ Unless otherwise specified, *Magnifier* prioritizes sentinels according to the activity ordering (§ 4.2).

Our simulation setup is an idealized version of the lab setup. It instantaneously starts mirroring for any prefixes, has unlimited memory space for mirroring rules, and removes rules after their first mirrored packet. The simulator is written in Python and publicly available [3]. Unless specified differently, we always consider *Magnifier*'s iterations to be 60s long. For the N -th sentinel computations, we take sampling and mirroring data from iterations $N-1$ and $N-2$ (see Fig. 5).

We focus on ingress sentinels in the evaluation, *i.e.*, source IP prefixes unique to one ingress. However, the results also apply to egress sentinels. For example, BGP selects the best route for each prefix that is assigned to a single egress. *Magnifier* identifies (part of) these prefixes as egress sentinels (§ 6.4). As a result, one major problem is how to split traffic over different ingress points: *Magnifier*'s performance depends on the assumption that prefixes close in the IP space get routed similarly. We study this dependency using three IP space to ingress mappings: *random* (least favorable for *Magnifier*), *static*, and *permuted* (most favorable). The *random* approach splits the *destination* IP space into n^6 equal slices and assigns one destination IP slice to each ingress point; as a result, source IPs are randomly assigned to one ingress, and this assignment changes frequently. The *static* approach assigns each source /24 prefix *statically* to one random ingress point; however, close IP space is still distributed over different ingresses. Finally, *permuted* splits the *source* IP space into n equal slices and permanently assigns each slice to one of the n ingresses. Then we permute a fixed percentage of /24 source prefixes by moving them to different ingresses. This way, we preserve most of the existing IP structure. A *permuted* 0% assignment results in a perfect mapping for *Magnifier*.

⁴The highest configurable rate on this model; we get the *most* samples.

⁵The four emulated ingresses share the budget. We use TCAM carving [7] to increase the space for our mirroring rules to 2048 (by taking it from other features) to enable the original budget (512) per ingress.

⁶Lab: 1st: 0.0.0.0/2; 2nd: 64.0.0.0/2; 3rd: 128.0.0.0/2; 4th: 192.0.0.0/2

Datasets We use two datasets: one actual packet trace based on CAIDA data and NetFlow samples from a Tier-1 ISP.

The packet trace is based on a 2018 CAIDA trace [4] (1.5 billion packets; one hour long), adjusted to be used in both our setups: (i) We modified the packet MAC addresses to match the lab setup. (ii) We added random payload bytes (removed from CAIDA traces) to match the specified packet sizes. (iii) We moved all destination IPs from 224.0.0.0/4 to a different /4 prefix as this prefix is reserved for IP multicast and led to unexpected packet forwarding on the switches. Replaying the trace at normal speed using `tcpreplay` [16] exhibited anomalies (packet loss and delays). Therefore, we slowed the replay by 10x, resulting in an average of 45k packets per second. Our simulations also use normal and faster speeds to emulate increasing traffic load.

The second dataset contains sampled (rate 1/1024) NetFlow data from all border routers (more than 100) belonging to a large Tier-1 ISP in Europe. The dataset spans over one hour of peak time in the evening of a weekday in 2018. The IP addresses are anonymized by replacing source and destination IPs with the best matching prefix from the full BGP table or the corresponding /24 prefix, whichever is more specific.

Metrics We use the following performance metrics and report the mean over 60 iterations (30 for 2x replay speed).

Coverage Quantifies the amount of traffic for which the ingress point is *correctly* identified. We consider both per-prefix coverage—*i.e.*, the number of /24 covered—and per-packet coverage—*i.e.*, the percentage of covered packets from the input trace.

Mirrored traffic volume Quantifies the overhead in terms of mirrored traffic, as a percentage of the total traffic.

Mirroring rule space Quantifies the number of mirroring rules (ACL entries).

Deployment speed Quantifies how long it takes to either add new mirroring rules or deactivate an installed rule.

6.2 *Magnifier*'s performance

This section details *Magnifier*'s performance. We first show that *Magnifier* greatly enhances the prefix coverage compared to sampling only (up to 80x) and that the ingress points are validated with mirroring rules. This is achieved while mirroring less than 0.3% of traffic. We then analyze methods to limit the number of mirroring rules required. Finally, we confirm that *Magnifier* runs and performs well on real hardware.

6.2.1 Coverage and mirrored traffic volume

We first use our simulation setup to evaluate *Magnifier*'s coverage in different scenarios.

Setup We use our simulation setup and the CAIDA dataset. We vary the trace replay speed (traffic load) and compare the coverage achieved by *Magnifier* by using sampling only. We compute sentinels, install mirroring rules at the start of

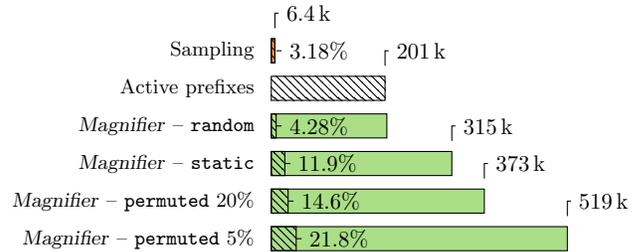

Figure 6: Amount of covered /24 source prefixes by *Magnifier* and sampled data assuming unlimited mirroring resources. 32 border routers, 1/1024 sampling rate, and real replay speed.

each iteration, and compute their coverage values at the end unless mirrored traffic invalidated them. Only these count to the shown coverage values (mean over all iterations).

Per-prefix results Fig. 6 shows the per-prefix coverage with 32 border routers, 1/1024 sampling rate, and real-time replay speed. Sampling covers $\approx 6.4k$ of the active /24 prefixes in the trace, for which we could consider the corresponding ingress point as identified, although without any confirmation that it is valid for all packets belonging to the /24 prefix.

By contrast, we immediately see that *Magnifier* enhances these inferences for all different prefix-to-ingress mappings in at least two ways. First the number of covered /24 prefixes increases to $\approx 200k$ (random), $\approx 315k$ (static), $\approx 370k$ (permuted 20%) and $\approx 520k$ (permuted 5%) respectively. Second, *Magnifier* covers prefixes that are currently active in the CAIDA traces (dashed boxes). The active prefixes increase from $\approx 4\%$ (random) up to $\approx 20\%$ (permuted 5%).

These observations highlight two principles of *Magnifier*: (i) our sentinel heuristic greatly enhances the prefix coverage around sampled data; and (ii) *Magnifier* remains a data-driven system. It has difficulties covering active prefix space that is not sampled using sentinels of reasonable sizes—hence the small % of active prefix coverage (Fig. 6, stripes).

Even more important, for every sentinel validated by mirroring rules, *Magnifier* immediately reports if an ingress inference is no longer valid or enhances new flows (which get active over time) with ingress information. These results are more visible in the per-packet coverage analysis.

Per-packet results Fig. 7 shows the per-packet coverage (left) and mirrored traffic volume (right) with 32 border routers and a 1/1024 sampling rate for varying replay speeds and traffic-to-ingress assignment strategies.

The left plot shows that *Magnifier* achieves an increasing per-packet coverage from $\approx 20\%$ (random) up to $\approx 80\%$ (permuted 5%) which can be surprising given the lower active prefix coverage (Fig. 6). This is explained by the nature of the CAIDA trace, which contains a small number of heavy-hitters and a lot of /24 source prefixes that only carry a few packets. 10% of source /24 IP prefixes account for more than 90% of the packets in 60s trace data (§ D.2). Hence, *Magnifier* often samples and covers these prefixes with sentinels.

These results nicely show the different trade-offs of our assignment strategies. For `random`, the ingress of packets is constantly moving, which makes it difficult to find valid sentinels, while at `permuted 5%`, the assignments are static and *Magnifier* can often find large sentinels which cover a lot of packets. The “real” coverage value is somewhere in between.

To compare, Fig. 7 also contains two sampling-based inferences (without *Magnifier*’s enhancements). The violet line near zero represents a lower bound. We only infer the ingress for the sampled packets. As an upper bound, we consider all the sampled packets in the `permuted 5%` assignment and naively assume that a single sampled packet immediately reveals the ingress point for all other packets belonging to the same source /24 prefix. Note that we can only plot these values because we have the full ground truth data from the CAIDA trace. An operator would *not* know if these inferences are correct. For bigger traffic loads, the upper bound is better than *Magnifier*’s per-packet coverage. This is due to invalidated sentinels: *Magnifier* searches for large sentinels based on sampled packets, likely to come from heavy-hitter flows. Suppose a non-sampled /24 prefix covered by that sentinel is mapped to a different ingress and carries even only one packet. In that case, it triggers a mirroring rule and invalidates the entire sentinel, and *Magnifier* loses all its coverage.

The right plot in Fig. 7 shows a low percentage of mirrored traffic for all assignment strategies (between 0.3% and 0.01%). As expected, a `random` assignment often leads to invalid sentinels and thus more mirrored packets.

Finally, we observe that larger traffic loads yield better performance. With more traffic, *Magnifier* collects more samples per iteration, computes more accurate sentinels, and achieves better coverage and less mirrored traffic. We show additional results in § D.3: Performance decreases with the number of routers in the `random` case—as the previously discussed mapping strategy gets worse—but remains nearly unaffected in the `static` and `permuted` cases (Fig. 15). Moreover, more sampled packets (higher sampling rate) result in better input data and thus performance improvements (Fig. 16).

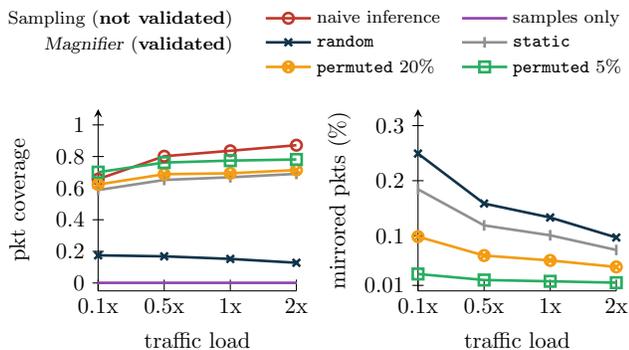

Figure 7: Amount of covered packets and mirrored traffic for different assignment strategies and inferences based on sampled packets only. 32 border routers and 1/1024 sampling rate.

Conclusion *Magnifier* greatly increases the per-prefix coverage compared to sampling (up to 80×) while validating all ingress points with mirroring rules. *Magnifier* achieves this while mirroring less than 0.3% of traffic and translates into a per-packet coverage of up to 80%.

6.2.2 Impact of limited mirroring budget

We now show that *Magnifier* also performs well when limiting the number of mirroring rules installed per router.

Setup We use the same setup as before and compare the coverage achieved by *Magnifier* with different bounds on the number of validated sentinels for two sentinel selection strategies (§ 4.2): `activity` (covering most sampled packets) & `size` (largest subnet sizes). The number of validated sentinels is an upper bound for the number of mirroring rules required per router; in the worst case, all sentinels belong to one router, resulting in one rule per sentinel on *all* the other routers.

Results Fig. 8 compares *Magnifier*’s per-packet coverage achieved with different numbers of validated sentinels: 500, 1k, 5k and unlimited; using the same settings as in Fig. 7. We show results for the `permuted 5%` (left) and `static` (right) assignment strategy, additional plots can be found in § D.3.

More validated sentinels achieve a higher coverage and generate more mirrored traffic. The top `size` sentinels have the highest chance of being invalidated by un-sampled prefixes and generate more traffic than their `activity` counterparts.

The `activity` selection achieves much better per-packet coverage than `size`, which is expected since `activity` prioritizes sentinels covering the most active prefixes. As the trace contains many heavy-hitters (previous discussion), even as few as 500 sentinels are enough to yield good packet coverage. Note that for 0.1× traffic load in the top left plot, the number of sentinels is smaller than 5000, resulting in the same coverage

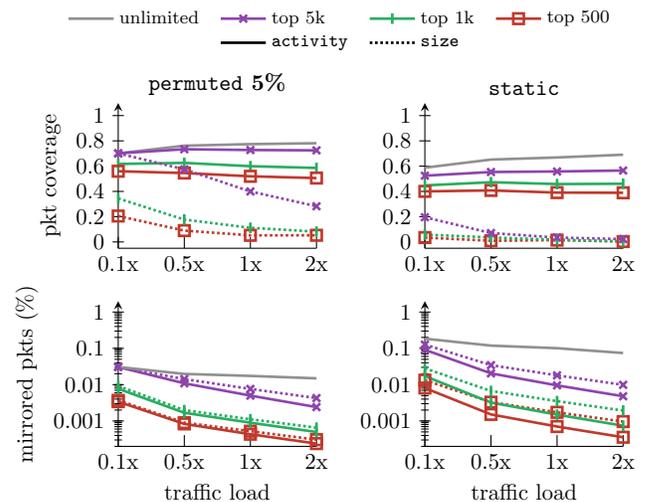

Figure 8: Coverage and mirrored traffic amount for different top sentinels ordered by activity or size.

Technique	Covered /24 prefixes
Sampling	6.4k
[activity] top 500 static	4.1k
[activity] top 500 permuted 5%	29.4k
[size] top 500 static	9k
[size] top 500 permuted 5%	47.3k

Table 1: Covered /24 source prefixes by *Magnifier* and sampling only considering the top 500 sentinels (activity and size ordering) in the static and permuted 5% assignments.

values for activity and size. We also see that the activity coverage values remain more or less constant even if the traffic load increases which is not the case for size.

The size selection favors sentinels centered around sparse samples in a relatively empty prefix space; this results in a low per-packet coverage (Fig. 8), but in a large per-prefix coverage (Table 1). As we can see, activity really prioritizes sentinels around a few selected prefixes resulting in fewer covered prefixes than sampling (static assignment). However, a size ordering can easily exceed the number of covered prefixes by up to seven times, even if we only take the top 500.

Conclusion *Magnifier*'s performance is maintained when limiting the deployed mirroring rules. The top 1k activity sentinels are sufficient to achieve up to $\approx 50\%$ packet coverage while mirroring less than 0.05% of traffic (static case).

6.2.3 Comparison with the lab setup

We now show that our hardware-based results match the simulation ones, validating *Magnifier*'s performance in practice.

Setup We use our lab setup (Nexus 9300 switches), which has two main differences from the simulation: we only have 500 mirroring rules per router, and there are delays to install and delete rules. We use the random assignment strategy and fill the 500 mirroring rules with the top 500 activity sentinels. For a fair comparison with the simulation, we consider iteration times of 60s. *Magnifier* needs ≈ 20 s to install all mirroring rules and then activate them. Afterward, we start to delete the rules which mirror packets. We compare this with the corresponding simulation results *i.e.*, 4 border routers, 1/4096 sampling rate, and $0.1 \times$ replay speed.

Results Fig. 9 shows the amount of covered /24 prefixes for sampled data only and the validated sentinels. We first notice that the coverage for sampled packets in our simulation (297) is slightly higher than on the switches (268). This can be explained by the different setups. All four ingress routers run on one Nexus 9300 (§ 6.1), which is not transparent to the sFlow-based sampling unit. Therefore, we get random packet sampling over all the traffic while the simulation performs packet sampling for each ingress device independently. This also shows in the achieved coverage values using the top 500 activity sentinels: ≈ 10.4 k prefixes in the simulation, ≈ 8.7 k prefixes on the hardware. We also have to consider that

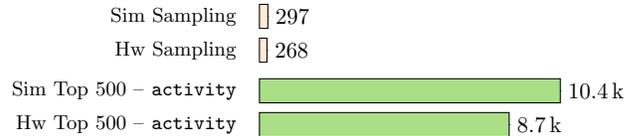

Figure 9: Covered /24 source prefixes by *Magnifier* and sampled data in simulations and on Nexus 9300 switches. random assignment, 1/4096 sampling rate, and $0.1 \times$ replay speed.

we need additional time to deploy the mirroring rules on the switch. Thus, a few more sentinels get invalidated compared to the simulations; and no longer count to the coverage values. The packet coverage values (not shown) are also comparable between the simulation (17.0%) and the hardware (16.1%).

Finally, we evaluate the percentage of mirrored traffic. We notice that the deactivation of active mirroring rules works well. In the worst case (active rules mirror for the entire 60s), *Magnifier* would mirror 2.3% of the overall traffic. This value is reduced to 1.4% if we start to deactivate rules. However, we are still above the optimal simulation results (less than 0.1%), where we can deactivate mirroring instantaneously.

Conclusion The hardware results closely follow our simulations regarding achieved coverage. However, *Magnifier* needs more time to install and deactivate mirroring rules, resulting in additional mirrored packets. To reduce the amount of mirrored traffic, operators can use existing hardware features to rate-limit the mirrored traffic on the switch [11].

6.2.4 Micro-benchmarks

We now perform micro-benchmarks on the hardware switches to assess (i) how many mirroring rules each device supports, how long it takes to (ii) deploy them, and (iii) deactivate them.

Results—Mirroring rule space With the default configuration of the Nexus 9300 switch, we can deploy 512 rules and up to 2048 in the current lab setup (TCAM carving [7]). On the Nexus 7009, we can deploy ≈ 32 k rules using one TCAM bank and ≈ 128 k rules if we chain all four TCAM banks together.

Results—Rule deployment time We measure how long it takes to deploy a set of mirroring rules on our two devices. During our tests, we realized that deploying the rules over multiple parallel sessions between *Magnifier* and the switches is beneficial. Four parallel sessions worked well for us. Table 2 shows the mean deployment times over ten measurements each. They include the session setup and round-trip time between *Magnifier* and switch. We see that the deployment time is not strictly linear in the number of rules. We conjecture that caches and buffers allow deploying a small number of rules quickly, but this no longer works for larger number of rules. We also see that the (newer) Nexus 9300 switch needs less time than the Nexus 7009. We can deploy 2000 rules in ≈ 18 s, which matches our observations in § 6.2.3 (500 rules for 4 ingresses on one device). We expect that the rule deployment time will continue to decrease with more powerful/newer devices.

Number of rules	100	500	1000	2000	5000
Nexus 9300	3.5s	5.5s	8.4s	17.8s	112s
Nexus 7009	2.6s	7.5s	21.7s	74.9s	475s

Table 2: Mirroring rule deployment times.

Note that even if we cannot activate 5k+ rules on the Nexus 9300 switch with the current TCAM carving (§ 6.1), we can still deploy them. Overall, these results confirm *Magnifier*’s design (Fig. 5) which aligns the iterations to the rule deployment time. Especially as the sentinel computation time is negligible (≈ 1 s on the CAIDA trace.)

Results—Rule deactivation time We finally measure the rule deactivation time on the Nexus 9300 switch. We generate 100 ping probes per second and deactivate a matching mirroring rule as soon as we receive the first mirrored probe. The deactivation time is the difference between the timestamp of the first and last mirrored probe, including the round-trip (≈ 0.5 ms) and session setup time between switch and controller. This setup is representative of an ISP deployment where close, dedicated control servers could quickly deactivate rules (§ B). We repeated the experiment ten times. The mean deactivation time is 1.65 s (min: 1.62s, max: 1.73s). In the worst case, we would receive a burst of traffic for ≈ 1.7 s. The amount of mirrored packets can be further reduced by rate-limiting the mirrored traffic directly on the switch; we expect this would *not* affect *Magnifier*’s performance, as a single mirrored packet is enough to invalidate a given sentinel.

Conclusion Our tests show that hardware switches can contain thousands to tens of thousands of mirroring rules, which is more than sufficient for *Magnifier*. Mirroring rules can be deactivated quickly (≈ 1.7 s), which limits the risk of bursts of mirrored traffic. The rule deployment is the most time-consuming operation (≈ 20 s for 2k rules). As a result, we can adjust the number of deployable mirroring rules (number of validated sentinels) by changing *Magnifier*’s iteration time.

6.3 Comparison with Everflow

We compare *Magnifier* with Everflow [45] which is a monitoring tool designed for debugging datacenter networks. Like *Magnifier*, Everflow randomly samples packets (using mirroring rules). In addition, it also mirrors *all* TCP SYN, FIN, and RST packets. As far as we know, the Everflow code is not available. Therefore, we reimplemented the relevant features and integrated them into our simulation framework (see § C).

Setup We use our simulation setup and the CAIDA dataset, 32 border routers, a sampling rate of 1/1024 (for both systems), and we vary the trace replay speed. We compare the performance of *Magnifier*, and Everflow on the *static* and *permuted 5%* traffic-to-ingress mappings.

Results Fig. 10 shows the per-packet coverage and mirrored traffic of both systems. We consider three different approaches: (i) “Everflow sampling only”, where we rely only on Everflow’s

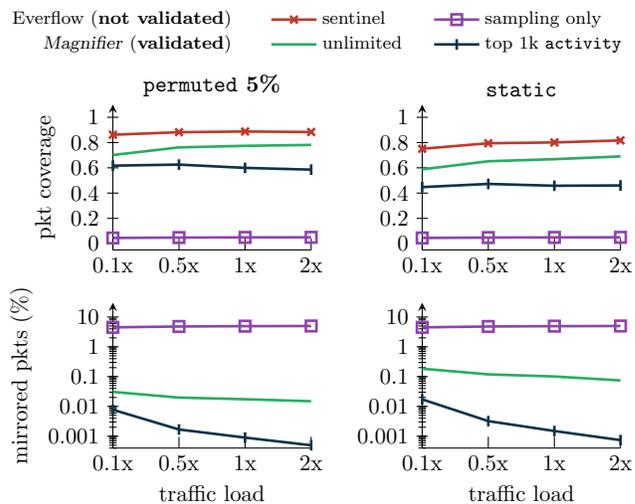

Figure 10: Comparison of coverage and mirrored traffic for *Magnifier* and Everflow under different traffic loads.

sampled packets to compute the ingress points; (ii) “Everflow sentinel”, where we use the sentinel idea on top of Everflow’s sampled packets; and (iii) “*Magnifier* unlimited” and “top 1k activity”, where we report *Magnifier*’s coverage for all and the 1k most active sentinels.

We first look at the coverage values (top plots in Fig. 10). Everflow’s sentinel approach shows the best—although not validated—coverage values with up to 88% in the permuted 5% case. This is due to Everflow’s sampled TCP flag packets. We do not reach 100% as traffic in some /24 prefixes is neither randomly sampled nor does it contain any TCP flags. These prefixes can invalidate found sentinels. Note again that the ground-truth data from the CAIDA trace allows us to compute these values. Everflow does not deploy any validation mirroring rules and does *not* know about the sentinel’s validity. *Magnifier* follows closely with $\approx 80\%$ (unlimited) and $\approx 60\%$ (top 1k) coverage as we only have randomly sampled packets as input. Despite that, *Magnifier* manages to reach good coverage values, with validation from mirroring. Both systems’ coverage values decrease in the more difficult *static* approach. For completeness, we also show Everflow’s coverage if we only consider the sampled packets. This results in a poor packet coverage, although on a higher level than the “sampling only” line in Fig. 7 given that Everflow additionally also samples all TCP packets with SYN, FIN, and RST flags. These coverage values are constant between both assignment strategies as we observe the same TCP flag packets and roughly the same random samples.

Everflow’s increased coverage has a high cost in the amount of mirrored traffic (lower plots in Fig. 10). Everflow generates the randomly sampled and TCP flag packets as mirrored traffic by design. *Magnifier* however, only generates targeted mirrored packets to validate found sentinels. If a sentinel is valid, it does not mirror any traffic. This is visible in the corresponding fraction of mirrored traffic.

Everflow constantly mirrors $\approx 5\%$ of all traffic while *Magnifier* is more than one magnitude lower ($\approx 0.1\%$ of all traffic at real-time replay speed in the static case). This value decreases even further if we only consider the most active sentinels. We again observe that Everflow mirrors roughly the same amount of packets for both assignment strategies.

Conclusion Everflow yields better coverage but generates more mirrored traffic, which is more than one order of magnitude higher than *Magnifier*. Unlike Everflow, *Magnifier* validates the inferred ingress points, informing the controller as soon as a sentinel is no longer valid. In contrast, Everflow might need to wait a long time before receiving a mirrored packet indicative of an ingress point change, especially for long-running flows that do not often have TCP flags. In terms of mirroring rules, Everflow only needs around 20 of them [45]. *Magnifier* needs more mirroring rules but also uses them for *validation*—something that Everflow cannot achieve.

6.4 Sentinels in Tier-1 dataset

We now validate the practicality and benefits of sentinel-based monitoring by evaluating *Magnifier* on Tier-1 ISP data.

6.4.1 Existence of sentinels

Setup We divide our Tier-1 dataset into 30s slices over which we compute sentinels and report the number of found ingress and egress sentinels. We only have sampling data available. Thus, we can only *approximate* the number of sentinels that would be found if *Magnifier* was deployed with mirroring.

Results We find a median of 145k egress sentinels and a median of 174k ingress sentinels. The lower and upper quartiles are within 1.4k around the median values in both cases.

We observe that we find more ingress than egress sentinels. This results from the typical forwarding behavior observed in an ISP: traffic from each of the ISP customers, which own specific prefixes, tends to enter via a single ingress point, which leads to a high number of ingress sentinels. At the same time, most ingress traffic goes to few popular destinations, which leads to few egress sentinels. We also see that the number of (ingress and egress) sentinels is stable over time, as shown by the small quartile ranges.

Conclusion We confirm that we find sentinels based on real sampling data from a Tier-1 ISP network. Furthermore, the number of sentinels is stable over time; this suggests that large changes in sentinel numbers can be used as a signal to detect various network events, which we discuss next.

6.4.2 Per-device sentinel changes

Setup We divide our Tier-1 dataset into 30s slices over which we compute sentinels using *Magnifier*, focus on the number of sentinels found per border router, and search for large changes in the number of sentinels over consecutive slices.

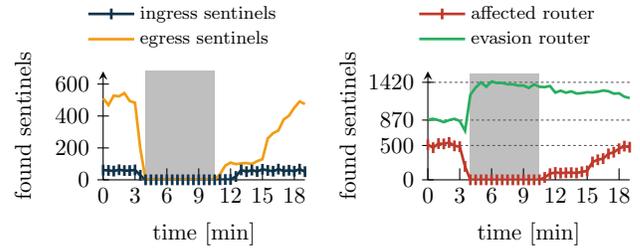

Figure 11: A temporary router outage (gray block) decreases the number of found sentinels (left) while we see similar increases on a close router (right).

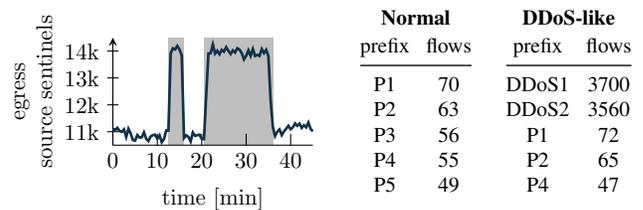

Figure 12: A sudden burst of egress source sentinels (left) is likely to result from a DDoS-like event (right).

Results Fig. 11 shows the number of sentinels found following a single border router outage. As expected, *Magnifier* finds no more sentinels for the affected router. More interestingly, *Magnifier* also detects where the affected traffic was re-routed during the outage, as shown on the right: the number of egress sentinels of a geographically-close router increases shortly after and closely matches the number of lost sentinels.

Fig. 12 (left) shows a router with a burst of *egress source* sentinels (traffic from a given subnet exiting via a unique egress point) while no other router shows a matching decrease. Thus, we observe a sudden burst of packets from “new” source IPs towards a few destinations (table, right), indicating a possible Distributed Denial of Service (DDoS) attack. During this event, the egress traffic volume increased by less than 8%, which is less pronounced than the clear increase in sentinels. *Magnifier* also identifies the ingress of more than 75% of the “attack” flows via their ingress sentinels. Existing volumetric DDoS detection systems could use this information to block the DDoS traffic at the network ingress.

Conclusion Changes in the number of found sentinels reveal interesting network events. Operators could analyze the collected sampling data this way, even if they do not have the resources to deploy mirroring. With mirroring, *Magnifier* detects such changes in sub-seconds, long before similar events are visible in sampled flow data or SNMP counters.

7 Related work

Sampling-based network monitoring Many systems use NetFlow [12], J-Flow [27], sFlow [30] or related flow extraction tools for network measurements. Sampling suffers from a fundamental trade-off between coverage and accuracy. For

example, Teixeira et al. [37] use NetFlow data to detect egress changes due to BGP hot-potato routing but are limited by the collected ten-minute bins. In addition, Cunha et al. [13] uncover measurement artifacts in two J-Flow implementations.

Consequently, several works aim to improve sampling by optimizing the collection process. Estan et al. [14] propose router software updates to dynamically adapt the NetFlow sampling rate depending on the available traffic and memory amount. FlowRadar [21] uses flow sets to count flow observations in multiple array cells, then combines and decodes these counters centrally. Similarly, Flowyager [34] introduces Flowtrees, an efficient data structure to store flow information. These approaches are all limited by the sampling information. A key difference of *Magnifier* is to further improve the network visibility by leveraging mirrored traffic.

Mirroring-based systems Several monitoring systems use mirroring, which provides accurate visibility over a subset of the traffic, flows, or devices. Stroboscope [39] supports query-based monitoring under a strict budget of mirrored traffic. Everflow [45] provides the possibility to mirror some packets of every flow, e.g., by mirroring packets with special TCP flags or debug header bits. Planck [33] takes a radical approach and mirrors all traffic over a single router port, which provides detailed insights but can also overload the network devices. Mirroring has also been used for troubleshooting [41], SDN monitoring [1], on in-network analysis [38, 42].

Mirroring suffers from three problems: (i) the flows of interest must be known in advance; (ii) it is limited by the routers' mirroring capacity, and (iii) it generates a potentially high volume of traffic. *Magnifier* mitigates these problems by leveraging sampling to derive the mirroring rules to deploy and uses negative mirroring to limit the traffic overhead.

In-network monitoring There has been many recent proposals for performing in-network monitoring based on in-band telemetry (e.g., [2, 18, 25, 26, 31]) or sketches (e.g., [5, 19, 22, 43, 44]). Both approaches boil down to implementing highly efficient data structures to gather traffic statistics, e.g., packet counts. The main limitation is that these approaches depend on software-defined or P4-programmable hardware, which is not commonly deployed in ISP networks nowadays. Moreover, these approaches provide precise information, but over specific queries only; setting and collecting counters to track ingress and egress points of an arbitrarily large number of IP prefixes is hard to scale. Negative mirroring addresses this: while *Magnifier*'s inferences are correct, there is no traffic nor compute overhead—only TCAM usage. Packets that do get mirrored provide exact information—i.e., source and destination IP—which allows for quick and precise reactions.

Detection of ingress/egress *Magnifier* is designed to detect traffic ingress/egress points, which has been previously studied: Feldmann et al. [15] provide foundation work for detecting different flow types in ISP networks as well as the ingress and egress of observed flows. To achieve good results, they

need per-flow measurements on the ingress and up-to-date forwarding tables of the routers in the network, which are both costly to obtain. Mahajan et al. [23] use algorithms similar to our sentinel idea to build so-called “aggregates”, a collection of packets with a common property, to free congested links. However, it is unclear how they extract the traffic to build the aggregates or validate their assumptions. Peng et al. [29] run a change point detection algorithm to detect changes in the number of new IP addresses, which is a good metric to detect (the ingress) of DDoS attacks. Most of these systems lack the global ingress/egress view that *Magnifier* provides.

Traffic matrix estimation Soule et al. [36] compare different techniques based on bias and variance properties. They show that direct measurements are required to reduce bias, which is an expensive process. Papagiannaki et al. [28] observe that the node fanout, e.g., how traffic from an ingress is distributed towards different egresses, is stable over time. *Magnifier* confirms and leverages this behavior: sentinels are stable over time, which creates a valuable monitoring signal (§ 6.4). With mirroring, *Magnifier* also quickly detects changes and updates its traffic matrix estimation. OpenTM [40] uses a different approach, based on active polling of every source-destination pair, which is very precise but does not scale to large networks. Malboubi et al. [24] addresses the special case of SDN networks, which limits the system's applicability. Pingmesh [17] frequently generates pings to compute latency matrices. By contrast, *Magnifier* does not require active measurements and runs on traditional routers, which makes it easy to deploy.

Monitoring frameworks Several monitoring frameworks support rich sets of queries, e.g., [20, 32, 42]. In particular, Flowyager [34] is similar to *Magnifier* as it builds primarily on sampling. The downside of these frameworks is their complexity and extensive storage and computational resource requirements. By contrast, *Magnifier* focuses on performing ingress/egress monitoring with little overhead.

8 Conclusion

Precise observations of traffic ingress and egress points are difficult to generate in large ISP networks. In this paper, we show how *Magnifier* combines the global view of sparsely-sampled flow observations with precise, targeted information from mirrored traffic. *Magnifier* enhances observed flows with validated ingress and egress points and scales to the largest ISP networks while only generating a small amount of mirrored traffic. *Magnifier*'s outputs can also help monitor outages or detect volumetric DDoS attacks.

Acknowledgments

We would like to thank Paul Stark and Derk-Jan Valenkamp for their great help with the hardware-based evaluation. Many thanks as well to Tibor Schneider for his support with TikZ.

B Magnifier’s controller placement

Magnifier needs a central controller to build its network-wide ingress/egress view. As we heavily depend on sampled flow observations, it makes sense to co-locate *Magnifier* with the e.g., already existing, central collector of the sampling data. In large ISP networks, with routers around the globe, we can deploy additional sub-controllers that start and stop the mirroring rules and collect mirrored packets. More precisely, the main controller is needed to compute new sentinels and builds the final ingress/egress observations. It delegates mirroring to the sub-controllers which autonomously handle the deployment, activation and deactivation of rules while reporting back any mirroring-based observations.

C Everflow implementation

Following a few more details to our Everflow reimplementation in our simulation setup.

Everflow uses packet mirroring to produce its random packet samples. The paper [45] explains that Everflow mirrors based on a fixed number of bits in the IP identification header field (IPID). As an example, selecting 10 random bits in the IPID field will result in random packet sampling of 1 out of $2^{10} = 1024$ packets. However, this assumption is only true if the values in the IPID fields are more-or-less uniformly distributed. Taking our CAIDA trace as an example, we see that we have a huge number of packets which set the IPID field to zero. Depending on how we select the bits in the IPID field, we might get way more or less sampled packets than expected. For this reason, we implemented the random packet sampling aspect of Everflow in our simulation code by taking every n-th packet observed on a device, e.g., every 1024th packet in the previous example.

Additional to the implemented mirroring techniques (random packet sampling and TCP flag packets), Everflow also supports mirroring of packets with a special debug bit. As this was not relevant for a direct comparison with *Magnifier*, we did not implement this feature in our simulation code. The same holds for Everflow’s controller, storage and reshuffler components.

D Additional evaluation results

This appendix section first illustrates the lab setup used to evaluate *Magnifier*. We then analyze the used CAIDA trace in more detail. Afterward, we show additional evaluation results focused on *Magnifier*’s performance. We conclude with additional plots comparing *Magnifier* with Everflow.

D.1 Magnifier lab setup

Fig. 13 illustrates the lab setup we used to evaluate *Magnifier*. We establish four parallel connections between the two Nexus

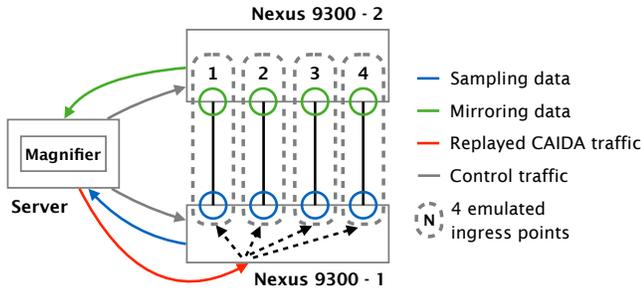

Figure 13: Two Nexus 9300 switches emulate four network ingress points. The traffic is replayed and sampled on the first switch, then forwarded to the second, which mirrors packets.

9300 switches, each emulating a network ingress. The first switch receives and samples the traffic using sFlow (sampling rate $1/4096^7$). It then forwards to the second switch, which mirrors the traffic according to the configured rules. *Magnifier*'s controller runs on a server and collects sampling and mirroring data. As these switches are limited to 512 mirroring rules, we used a fixed budget of 500 rules per emulated ingress point.⁸

D.2 CAIDA data analysis

Fig. 14 shows a CDF of the amount of packets observed per source /24 in 60s of our CAIDA trace used in the evaluation. 60s represent one iteration at real-time replay speed. As we can see we have a very small number of heavy hitters which carry most traffic as well as a huge number of /24 prefixes which only contain a few packets. Roughly 10% of all /24 prefixes contain more than 90% of all the packets.

A lot of the /24 prefixes with very low packet counts are most likely DDoS attack traffic (e.g., TCP SYN packets). We decided to keep these packets in the trace as a real ISP network could also observe similar packet distributions in their transit traffic.

D.3 Additional Magnifier plots

This section contains additional plots which evaluate *Magnifier* in terms of packet coverage and mirrored traffic.

Fig. 15 shows the performance results if we consider an increasing number of border routers (from 4 to 64). For *random* and *static* traffic assignment we notice that the coverage slightly drops while we see an increased amount of mirrored traffic. However, this is not true for the *permuted* assignment strategies. *random* and *static* distribute the packets to their ingress points based on equal slices of the *destination* IP space. If we have more border routers, we also have additional slices

⁷The highest configurable rate on this model; we get the *most* samples.

⁸The four emulated ingresses share the budget. We use TCAM carving [7] to increase the space for our mirroring rules to 2048 (by taking it from other features), to enable the original budget (512) per ingress.

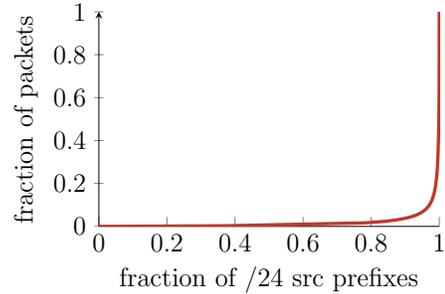

Figure 14: A CDF plot of the amount of packets observed per source /24 prefix in 60s (one iteration at real speed) in our CAIDA trace.

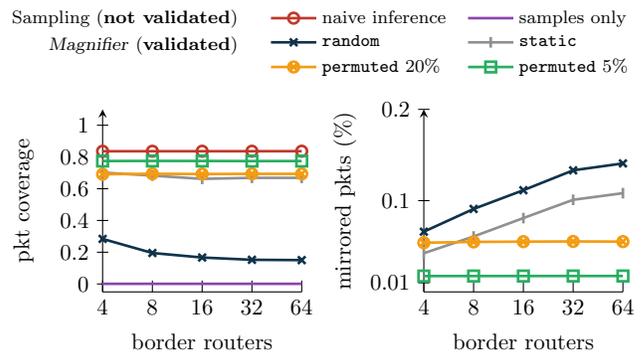

Figure 15: Simulation results for coverage and mirrored traffic when *Magnifier* runs with different amounts of border routers. CAIDA traces replayed at real speed, sampling rate $1/1024$.

and close IP space is distributed over multiple ingresses which leads to the observed drop in coverage. This is not true for the *permuted* cases, where we always permute a fixed number of source /24 prefixes to different ingresses.

Fig. 16 considers different sampling rates. As expected, if we have fewer samples as input *Magnifier* can cover fewer packets and also produces fewer mirrored packets as it finds fewer sentinels to begin with. We observe this behavior for all traffic assignments.

Finally, Fig. 17 shows the missing assignment strategies (*random* and *permuted 20%*) if we consider different amounts of top sentinels (*activity* and *size* ordering). Following the results in Fig. 8, the *activity* strategy provides better coverage than *size* and a lower amount of mirrored traffic.

D.4 Stability of sentinels

Following, we evaluate how many sentinels change between simulation iterations.

Setup We use the results from our simulations with 32 border routers, real traffic speed and various traffic-to-ingress assignments (sampling rate $1/1024$). The results show mean values over 60 iterations.

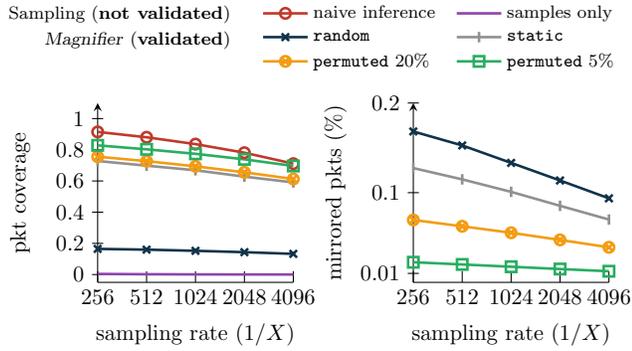

Figure 16: Simulation results for coverage and mirrored traffic when *Magnifier* runs with different sampling rates. CAIDA trace replayed at real speed, 32 border routers.

Results Table 3 shows the amount of changed sentinels for different amounts of deployed sentinels (based on activity and size ordering) for random, static and permuted 5% traffic assignment. We first observe that we have to change fewer sentinels if we base the ordering on sentinel activity. More active sentinels are often also stable over longer periods of time which means that we find them consistently. We see a different behavior for the ordering based on size. Here nearly all sentinels change between iterations. The largest sentinels are often based on sparse samples located in empty prefix space. That means, we might not be able to find the same big sentinel between multiple iterations if the covered flows are no longer visible (e.g., in the sampled data).

As expected, the number of changed sentinels also depends on the difficulty of the traffic assignment. In the *random* case, ingress assignment changes frequently even during a single iteration. That means we often find new sentinels in the following iteration. For *permuted 5%*, the assignment is much more stable and we can always keep around 50% of all sentinels between iterations.

	# sentinels	random	static	permuted 5%
activity ordering	Top 100	84	50	35
	Top 500	406	292	220
	Top 1000	836	610	466
	Top 5000	4487	3662	2769
size ordering	Top 100	94	87	45
	Top 500	472	453	224
	Top 1000	950	918	461
	Top 5000	4817	4698	2776

Table 3: Number of changed sentinels between iterations for different assignment and sentinel ordering strategies.

Conclusion The top sentinels often change between iterations, however *Magnifier* is not really impacted by that. As we describe in § 4.1, *Magnifier* works with two ACLs and switches between them. While one is active, the other one gets populated.

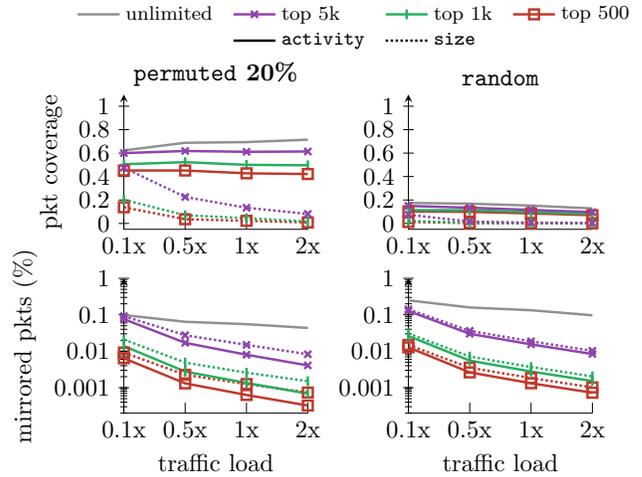

Figure 17: Simulation results for coverage and mirrored using different amount of top sentinels according to a activity and size ordering. We show the *random* and *permuted 20%* traffic assignment strategies (compare with Fig. 8). The plots show values for different traffic replay speeds of the CAIDA trace with 32 border routers and sampling rate of 1/1024.

The frequent sentinel changes between iterations are therefore not a big problem as we anyway need to build a completely new ACL.

D.5 Additional comparison with Everflow

In this section we show additional comparison plots between *Magnifier* and Everflow. Fig. 18 shows different number of ingress routers while Fig. 19 considers varying sampling rates. For both figures we show the results for *permuted 5%* and *static* traffic assignments. Everflow’s packet coverage and amount of mirrored packets show only small reactions to the different ingress routers and/or sampling rates. Everflow’s mirrored packets mainly contain packets due to TCP SYN, FIN or RST flags. The randomly sampled ones contribute only in a small amount. As a result, changes in the sampling rate (Fig. 19) have more impact on *Magnifier* than on Everflow. *Magnifier*’s performance is tightly related to the amount and distribution of the randomly sampled packets.

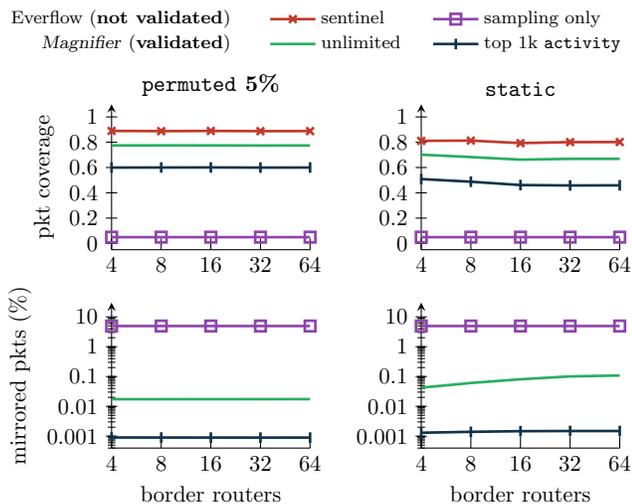

Figure 18: Comparison of coverage and mirrored traffic for *Magnifier* and *Everflow* for different amounts of border routers. We show the *static* and *permuted 5%* traffic assignment. We replay the CAIDA trace at real speed and use a sampling rate of 1/1024.

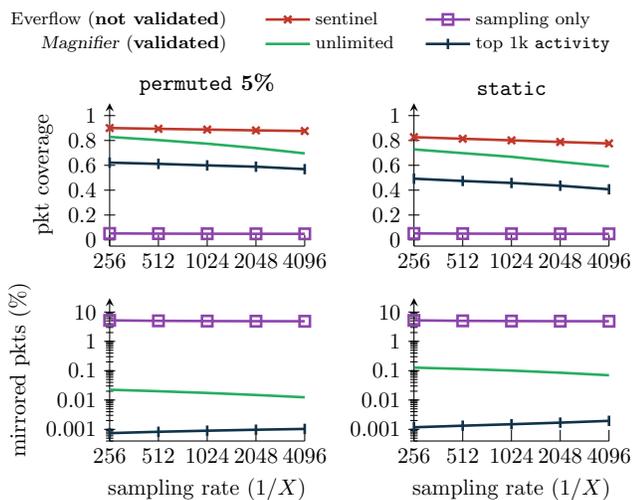

Figure 19: Comparison of coverage and mirrored traffic for *Magnifier* and *Everflow* for different sampling rates. We show the *static* and *permuted 5%* traffic assignment. We replay the CAIDA trace at real speed and distribute traffic over 32 simulated ingresses.

NetPanel: Traffic Measurement of Exchange Online Service

Abstract

Global cloud applications are composed of thousands of components. These components are constantly generating large volumes of network traffic, which is a major cost of cloud applications. Identifying the traffic contributors is a critical step before reducing the traffic cost. However, this is challenging because the measurement has to be component-level, cost-effective, and under strict resource restrictions. In this paper, we introduce NetPanel, which is a traffic measurement platform for the Exchange Online (EXO) service of Microsoft. NetPanel fuses three data sources, namely IPFIX, Event Tracing for Windows (ETW), and application logs, to jointly measure the service traffic at the component level, where each component is owned by a service team. NetPanel uses several schemes to reduce the measurement overhead.

NetPanel has been in operation for more than one year. It has been used to profile network traffic characteristics and traffic cost composition of EXO. With the insights obtained through NetPanel, we have saved millions of dollars in network resources. The overhead of running NetPanel is relatively small, which requires less than 1% CPU and disk I/O on production servers and less than 0.01% of EXO computation cores to process the data in our big-data platform.

1 Introduction

Cloud applications, such as Exchange Online (EXO), are composed of thousands of components running on hundreds of thousands of servers, developed and maintained by engineers from many different teams. In EXO, one component is a module that performs a specific function, as an entire or part of a process. The Internet Information Services (IIS) [4] based proxy, running on frontend (FE) servers, routes traffic for different components such as REST [23], EWS [5] and MAPI [6]. The traffic of each component is owned by a specific engineering team. These components are sending tremendous traffic across data centers, which incurs great costs. Any defect in a single component may lead to widespread traffic flood.

Furthermore, due to the massive number of components, the limited shared bandwidth could be easily drained by low-priority traffic. In these cases, customers could suffer from long latency or even connection loss [7, 9, 12, 14]. For example, an incident caused by anomalous traffic was reported by Azure [2] on June 14th, 2021 where some customers received errors when performing service management operations. The root cause was high CPU consumption and request timeouts caused by an unexpected surge in internal traffic. The issue was mitigated by adding rules to block internal traffic on a subset of backend servers.

Cloud application owners have built plenty of monitors for incidents and performance regressions [1, 3, 20]. Such monitors are typically based on availability or latency metrics, which are insensitive to traffic issues. Therefore, there is still undesired traffic caused by various reasons, such as code bugs or misconfigurations. Over time, these hidden bugs become extremely difficult to trace as everyone takes them as necessary bandwidth requirements. Unnecessarily more capacity planning budget is therefore needed in subsequent years. The extra cost will be millions of dollars per year given the application scale. For example, in one case, we caught a configuration error that nearly quadrupled its peak traffic. In another case, we found that one service was sending requests globally, while these requests can actually be handled within a location. These cases will be detailed in Section 5.2. Although there is existing work to detect anonymous traffic bursts [29, 31, 39, 44], few have provided insights for continuous traffic optimization. There is a body of work on misconfiguration detection [51, 53] and safe deployment [34], but their solutions are not specially designed for traffic-related issues. In particular, some traffic issues can only be identified through long-term continuous monitoring.

While it is vital to continuously monitor the traffic flow for a cloud application, the dynamic and heterogeneous nature of a global cloud application makes this difficult. An efficient traffic monitoring system for cloud applications must satisfy the following requirements:

- (1) **The measurement should provide component-level**

results. To efficiently identify the owner of the traffic, component-level measurement is required. A component is typically owned by a single engineering team. Researchers have been exploiting network measurement tools such as IPFIX/Netflow in the last decade [22, 37, 55] to gain insights into the network traffic in large-scale cloud infrastructures. These approaches operate on network routers, so they cannot identify components at the application layer. Server network analysis tools [8, 11, 36, 43] can observe the traffic sent by each process. However, multiple components can share a single process. These tools cannot distinguish the traffic emitted by components sharing the same process.

(2) The size of daily measurement results should be small (in GB). To draw an effective conclusion on traffic observation, engineers need to query data over a long period of time. In addition, there are cases where successive interactive analysis is needed, such as the case we discuss in Section 5.2.1. A user query response should be returned within a few seconds. On the other hand, global cloud applications are constantly generating a vast amount of traffic logs. For instance, the size of IPFIX data is more than 10TB per day. Event Tracing for Windows (ETW) [11] data and application logs are in PB. Directly joining PB and TB data at a daily frequency is impractical due to resource constraints. Directly running queries on these log data imposes huge data processing costs and unacceptable query latency.

(3) The collector in production environment should run under strict resource restrictions. Cloud applications such as EXO provides high Service Level Agreements (SLA) [13] to the customers. Therefore, the service has strict restrictions in terms of the resource used by any single component on the servers to ensure a quick response to customer requests. To collect event logs, ETW needs to run on the servers by the side of service components. Pulling all the network metrics from ETW regularly is prohibited in the production environment because it will exhaust the CPU and disk I/O on the production servers.

To address the aforementioned challenges, we design NetPanel, a cost-effective continuous traffic profiling tool for EXO. NetPanel takes three data sources, including IPFIX, ETW, and application logs. We fuse these data sources to jointly provide component-level measurement results. We reduce the data size with feature translation, data splitting, and data aggregation to keep all measurement results at several GB per day, which will be detailed in Section 4. To reduce the resource consumption of ETW, we only retain the data for the top k ports obtained from IPFIX.

NetPanel has been safeguarding the network traffic of EXO for more than 1 year. It brought us valuable insights into our traffic and helped us save millions of dollars per year. We introduce 4 real-world cases in Section 5.2. NetPanel runs with negligible impact on our production servers (less than 1% increase in CPU and disk IO). The data processing cost for our big-data platform is also minor given the scale of

Roles	Abbr.	Functionality
Frontend	FE	Connects with customers and routes customer requests
Backend	BE	Stores mailboxes, delivers emails, and provides site resilience
Active Directory	AD	Holds and queries customer metadata

Table 1: Server roles and their functionalities.

EXO (less than 0.01% of EXO cores). For a query for data in a 60-day period, the response can be returned within 30 seconds.

Our key contributions and insights in this work are summarized as follows:

- We discuss the requirements and challenges of measuring the traffic for a global scale application, i.e., EXO. We show that telemetry data should be attributed to an organizational structure, such as a team of engineers, to actually drive cost reduction. Moreover, daily data size should be small enough to provide insight into how traffic data changes over time.
- We present our novel traffic measurement design which fuses IPFIX, ETW, and application logs to achieve component-level measurement. We demonstrate that, with proper data volume reduction, it is feasible to join data sources across routers and servers. We show that cross-validating data for integrity is feasible and crucial.
- We share our observations on traffic characteristics of EXO in production environment. Specifically, we figure out that heavy hitters (top ports/components) are stable in EXO, and this feature can be used to reduce data volume. We also demonstrate how NetPanel can help reduce traffic costs through real-world case studies.

We believe that the experience of operating NetPanel provides valuable guidance to other cloud applications on how to monitor and optimize their network traffic.

2 Background

This section introduces the EXO service traffic and explains how these traffic flows are generated. Then, we share the measurement tools available in EXO and their capabilities.

2.1 EXO Service Traffic

EXO operates in numerous datacenters around the world. There are hundreds of thousands of servers all over the world serving its enormous user community. The servers are categorized into three server roles: frontend routing proxy (**FE**), backend mailbox (**BE**), and directory (**AD**), as summarized in Table 1. FE servers, which sit behind load-balancers, serve customer requests over direct connections. AD servers hold information about users, mailboxes, and other customer metadata. BE servers provide storage for mailboxes and are responsible for the delivery of emails to/from mailboxes. Multiple

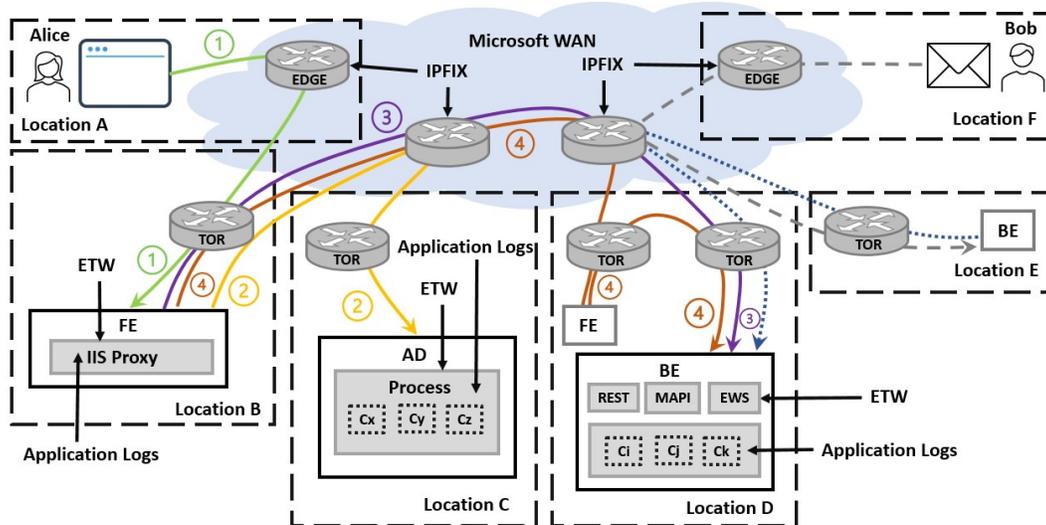

Figure 1: EXO traffic overview. When Bob sends an email to Alice, replication occurs, and Alice later reads the email replica. During the email-reading process, 6 Internal Long-haul traffic flows and 2 Internet traffic flows are generated.

copies of mailboxes are geographically-dispersed to provide high availability and site resilience. Each role of servers (i.e., FE, AD, or BE) hosts a group of services in order to provide functionalities as designed.

EXO servers communicate with each other when serving customers. We divide EXO traffic into two types: *WAN* traffic and *Metro* traffic. The WAN traffic goes through routers in WAN; and the rest, namely Metro traffic, travels within datacenters in the same location. We are particularly interested in the WAN traffic because it costs more than 90% of the annual bill. There are two subtypes of WAN traffic. The first is the traffic between EXO servers and user clients (Internet traffic) and the other among EXO servers (Internal Long-haul traffic). Internet traffic is responsible for around 10% of WAN traffic and Internal Long-haul traffic takes the rest.

The Internal Long-haul traffic are assigned to different priority tiers, *Tier 0* and *Tier 1*, by Bandwidth Broker [52]. Tier 0 is of higher priority with higher Quality of Service (QoS). Tier 1 traffic has a lower priority, and it is routed through sub-optimal paths and is dropped by routers first when congestion occurs.

2.2 How EXO Traffic Generated?

We use a typical scenario shown in Figure 1 to describe how the traffic is generated in EXO. In this scenario, Bob uses the Desktop client to send an email to another user Alice. Alice then reads her email through a web client. Bob in Location F sends the email to Alice’s mailbox in Location E. The mailbox is replicated to Location D for high availability. These are annotated by the gray dashed line and the blue dotted line

in Figure 1. Later, Alice reads her email from the mailbox. There are 4 steps in this email-reading process, detailed as follows:

Step 1: Alice uses the web client in Location A to send a request to the closest FE server. In this example, we assume the closest FE server resides in another Location B.

Step 2: The FE server talks to an AD server in Location C to query which BE server knows where the active copy of Alice’s mailbox is hosted. In this case, the BE server in Location D is returned by the AD server.

Step 3: The FE server queries the BE server in Location D to ask which BE server hosts Alice’s mailbox. In this example, the BE server in Location D happens to host Alice’s mailbox, so it responds with itself.

Step 4: The FE server in Location B forwards the request to another FE server in Location D and that FE server in Location D will further transfer the request to the BE server in Location D. The mailbox’s response is returned to Alice in the opposite direction along the paths of Step 1 and Step 4.

During the email-reading process, the traffic in Step 1 and the traffic from FE to the web client in the mailbox’s response is Internet traffic because the FE server is talking to an external client outside of Microsoft. The traffic in Steps 2 and 3, and the traffic from the FE in Location B to the FE in Location D in Step 4 is Tier 0 traffic because the source and destination EXO servers are in different locations. In Step 4 (the orange arrow in Figure 1), the traffic between FE servers is Tier 0 traffic, while the traffic between FE and BE servers in Location D is Metro traffic. We use the example shown in Figure 1 only to explain the generation of Tier 0 traffic. Most

of the traffic would be Metro traffic when the servers involved are in the same location.

The replication traffic, represented as the blue dotted line in Figure 1, is Tier 1 traffic. Tier 1 traffic mostly consists of background traffic that does not serve user activities and therefore does not have rigorous latency requirements. Typical cases include: (1) data replications for high availability; (2) non-urgent mailbox migrations; (3) uploading logs.

In the example in Figure 1, Alice’s request first hits the FE server in Location B (step 1), then is routed to the FE server in Location D (step 4), and finally reaches the BE server in Location D (step 4). The request is served by the REST [23] component on the BE server. In this situation, only the application logs of the FE servers capture this long-haul traffic between the two FE servers (Location B ⇒ D). The components on BE servers in Location D, such as REST [23], MAPI [6], and EWS [5], are behind the FE proxy in the same location. As a result, the BE servers are unaware if the request originates from another location. Sometimes, multiple components on one BE server may even share the same process. Therefore, server network analysis tools [8, 11, 36, 43] are insufficient to provide component-level traffic measurements. In summary, application logs are necessary to perform component-level traffic measurements.

2.3 Traffic Measurements

There are two kinds of traffic measurement methods available in our data centers: *on-router* and *on-server* measurements.

One of the commonly used on-router measurements is flow monitoring [26, 35, 41]. There are two standards, i.e., Netflow [21] and IPFIX [15], that have been used for years. Flow monitoring samples packets with a certain probability and aggregate them into flows. A flow is a sequence of packets with the same IP 5 tuples (*src./dst. addresses, src./dst. ports, and protocol*). Flows are uploaded to a centralized storage.

When measurements are made on the servers, common toolkits include Tcpdump [8] and Event Tracing for Windows (ETW) [11]. Tcpdump is a well-known library that provides powerful packet analysis capabilities on Linux, while Windows uses ETW to collect system network events. These tools can monitor the traffic usage of all processes on a machine.

We annotate these measurement schemes in Figure 1. IPFIX collects traffic data on WAN routers. ETW collects system network events and provides traffic statistics for processes on servers. We further add application logs, which are generated within the services and are owned by different teams for debugging purposes. Application logs are request-focused. For a specific request, application logs record the timestamp, the component that serves the request, the local server name, the remote server name, the latency, the request and response content size, the remote port, etc.

We summarize the measurement capabilities of the three schemes in Table 2. TimeStamp, IP, Port, Process, and Traffic

	Timestamp	IP	Port	DSCP	Process	Component	Traffic Size	Request Size
IPFIX	✓	✓	✓	✓	✗	✗	✓	✗
ETW	✓	✓	✓	✗	✓	✗	✓	✗
App logs	✓	✓	✓	✗	✓	✓	✗	✓

Table 2: Available Measurement Methods

Size are general definitions. TimeStamp, an IP pair (source and destination), and a Port pair identify a unique flow. Process is the information of processes that are sending and receiving the traffic. We need a Differentiated Services Code Point (DSCP) tag [18] because Bandwidth Broker uses it for traffic QoS classification. Packets with different DSCP tags are classified into different priority tiers. IPFIX covers IP, port, and DSCP but cannot cover the process and component information which are available only on servers. ETW can further measure processes, but cannot cover the exact component as discussed in our example in Sec. 2.2. Application logs contain the request and response content sizes of components but not counting the sizes of the packet headers. In addition, application logs do not capture packet loss or retransmission. In conclusion, we need to fuse IPFIX, ETW, and application logs to achieve component-level measurement.

3 Motivation and Design Goals

In this section, we state our motivation to design NetPanel and further define the goals to be met for our design along with the challenges to be resolved.

3.1 Motivation

In the EXO service, many components are working together to serve customers. These components send large amounts of traffic globally, which is very expensive. The large cost has motivated the application owner to understand the current traffic, reduce the traffic cost, and ensure there is no traffic waste. Furthermore, when a development team adds a new feature to reduce their traffic, they also need a tool to validate the traffic change of their component. Before NetPanel, each team only monitors their own request amount, leading to an isolated and incomplete view, which makes it hard to motivate traffic optimization efforts, verify data correctness, and detect traffic-related issues. On the other hand, without component-level information, it is non-actionable even if anomalous traffic is detected. With the increasing complexity of modern global-scaled software, this requirement becomes more and more urgent, which motivates us to build NetPanel.

3.2 Design Goals and Challenges

The design of NetPanel has to meet the following goals and address the corresponding challenges.

Goal-1: The measurement should provide component-level results. The overall EXO traffic should be divided into

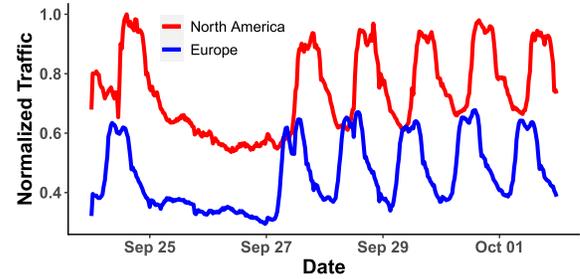

various components. EXO runs on hundreds of thousands of machines of three server roles. Machines of the same server role hold the same set of components. A component is owned by an engineering team. As long as the component’s traffic is identified, the engineering team can take action to optimize its cost. NetPanel should provide the capability to establish the mapping between the components and their traffic flow.

Recent measurement works [33,45,46,48,54] are on-router measurements, so they cannot support measurement at component granularity. Traffic Refinery [19] identifies the component flows by inspecting DNS queries and manually specifying matches between components and their IP prefixes. This does not work in EXO because it assumes that each IP must correspond to at most one component. However, in our case, an IP can be shared by many components at the same time. Google uses Bandwidth Enforcer (BwE) [32] to allocate bandwidth at task granularity. A task may contain multiple processes, and therefore, BwE cannot be used to monitor the bandwidth for components sharing a process. NetPanel addresses this challenge by leveraging application logs to fill in the component property. We will describe how to jointly consider the three data sources, i.e., IPFIX, ETW, and application logs, to recover component-level traffic throughout Section 4.

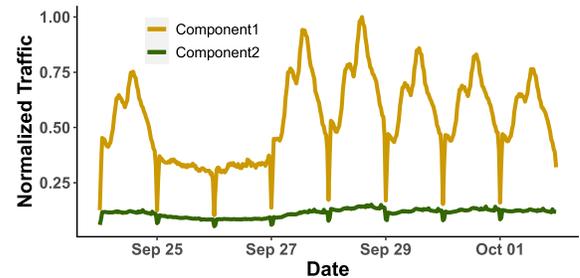

Goal-2: The daily measurement result size should be small (in GB). In EXO, IPFIX generates several TB of data every day, while the daily application log in PB. After compression, the data size will be reduced to $\sim 10\%$. However, IPFIX data is more than 10TB per day, so the data size will still be too large after compression. To draw an effective conclusion on traffic, engineers usually have to do consecutive analysis over long time intervals and compare the results. The system should provide quick responses to user queries and consume few resources. From our experience, we need to limit the result size to several GB per day, so that analysis over a long time interval is allowed.

The data used for analysis should cover a continuous time interval of at least several weeks to overcome the dynamic nature of network traffic. Figure 2a shows the traffic variation in EXO over a time interval of more than one week in North America and Europe. The traffic volume highly aligns with user activities, with more traffic during working hours and much less at night and on weekends. The valley values are nearly half of the peak values. The large fluctuation rate is likely to override the traffic change introduced by a new feature if we make queries only over a short time interval of a few hours. Moreover, different components can have different traffic patterns. We show the traffic patterns of two components in Figure 2b. The traffic of Component 1 fluctuates greatly, while that of Component 2 is relatively stable.

Many approaches have been proposed to reduce the data size. However, they cannot satisfy our requirements for different reasons. IBM cloud [39] is dealing with a 2.35TB log each day, but their approach only reports anomalies without any details on current and historical traffic usage. Analysis

(a) All geographical regions have fluctuations between day-time and night but follow a similar weekly pattern. The valley values could be half of the peak values.

(b) Different components have various traffic patterns.

Figure 2: Huge variations in time and components domain.

farm [47] proposes a cloud log analysis platform and aggregates IP addresses to IP-groups. We achieve something similar with feature translation (detailed in Section 4.2.1), but this alone would only reduce the data size to hundreds of GB per day. Anwar et.al. [16] claim to reduce the data size by up to 80% using different sampling frequencies and storage aggregation for different metrics. In our case, we collect only one metric but the data size must be reduced thousands of times. NetPanel addresses the challenge with multiple steps, which will be introduced in Section 4.2.

Goal-3: The collector in the production environment has to run under strict resource restrictions. The data collector has to run continuously in the production environment. There are strong resource restrictions (CPU, memory, disk I/O, etc.) for measurement tools in order to reserve as many resources as possible to serve user requests. The resource consumption of the collectors has to be very small.

We abandoned pulling all network metrics from ETW in the EXO production environments because of performance issues. In EXO, every single component should use no more than 5% CPU. It is restricted to log no more than 32MB of data on local disks every five minutes. Running ETW and writing all the metrics to the local disk exceeds the limit as shown in Section 6.1. The ETW data size for a single day is in PB. NetPanel reduces ETW collectors’ resource consumption by only recording the traffic data of the top k ports. This greatly reduces the log size as well as the computation resource and disk I/O throughput. We explain how the top k ports are

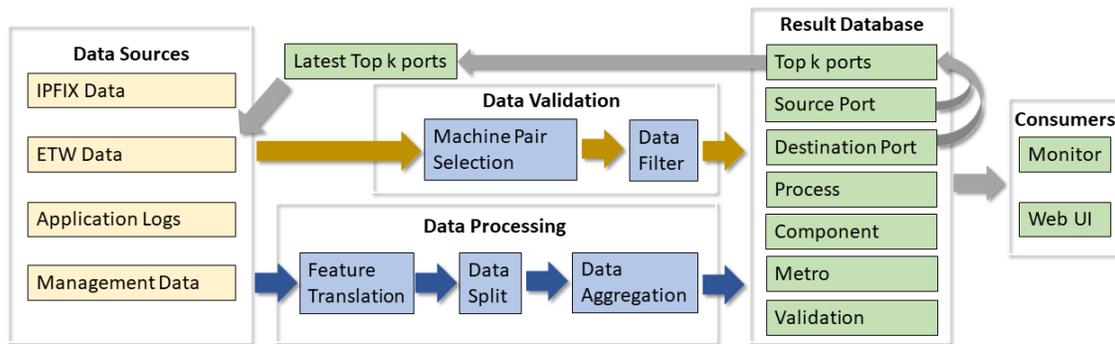

Figure 3: NetPanel Architecture Overview.

identified in Section 4.2.2.

4 System Design

Figure 3 shows the overview of our design. The data sources include IPFIX, ETW, application logs, and management data. There are two separate pipelines in the system. The first one (blue arrows) is responsible for reducing the data size while preserving important attributes. The second one (yellow arrows) is used to cross-validate the data from IPFIX and ETW to ensure data integrity.

The output of both pipelines is fed into the result database. The result database is a light-weighted database that can respond to web services as well as user queries in near real-time. We use Azure Data Explorer (Kusto) [10] for the result database. The result database contains tables for different features. The schema of the tables is available in Table 3. We use port tables in the result database to derive the top k ports with the largest traffic volume and use them as a filter for ETW collectors to reduce their resource consumption in the production environment (grey arrows). We also set up a monitoring service to help component owners detect anomalies and continuous upticks in their traffic usage. A WebUI is provided for traffic data visualization.

4.1 Data Sources

Before NetPanel, EXO deployed a background packet trace monitor on its servers to provide network statistics such as throughput, RTT, etc. However, without component-level information, this background tracking is not adequate to drive owners to optimize their traffic. This experience drives us to choose a different set of data sources for NetPanel.

NetPanel takes three measurement inputs: IPFIX, ETW, and application logs. The data is uploaded to COSMOS [38] on an hourly basis. COSMOS is a Hadoop-like distributed data storage and processing platform. We convert different types of data into a uniform format like Table 2. In addition to the measurement data, NetPanel also takes in management

data. The management data contains the mapping between an IP address and its location and server role. The management data is uploaded daily because it is relatively static.

NetPanel handles the three data sources independently. IPFIX data size is more than 10TB per day. ETW and application logs data sizes are several PB per day. It is too expensive to directly join the three data sources based on shared features (i.e., TimeStamp, Port, IP, and Process). We thus process the raw data independently and only store aggregation results in the result database as detailed in the next section.

4.2 Data Processing

The data processing pipeline consists of three consecutive steps. (1) Feature translation: translate the raw information of the traffic data into a set of features. (2) Data split: divide the traffic data associated with source-destination port pairs into two separate views, i.e., source-port view and destination-port view. (3) Data aggregation: aggregate the traffic data into various feature tables.

4.2.1 Feature Translation

In Microsoft, different services occupy different blocks of IP ranges, so we use IP addresses¹ to retrieve EXO traffic. Then, we use management data to translate machine IPs into locations and server roles. The server role is among AD, FE, and BE. Location is the metropolitan area where the server locates. This translation reduces the storage requirements from trillions of IP pairs to millions of feature pairs.

We translate location pairs to Rate-Regions. Location pairs are only used to get the prices of traffic flows. A longer distance implies a higher price. We thus use a new feature called Rate-Region to replace the location pair of a flow. Azure charges Microsoft internal services a unified price (\$/Mbps) for the flows traveling a geographical continent or an ocean, like North America, Europe, Atlantic, etc. There are only

¹The IP addresses here are all Microsoft IPs.

Table	Data Source	Schema - Keys	Schema - Value (Bytes)
Source/Destination-Port	IPFIX	TimeStamp, ServerRole, RateRegion, Port, DSCP	TrafficSize
Process	ETW	TimeStamp, ServerRole, RateRegion, Port, Process	TrafficSize
Component	Application logs	TimeStamp, ServerRole, RateRegion, Port, Process, Component	RequestSize

Table 3: Columns in result tables.

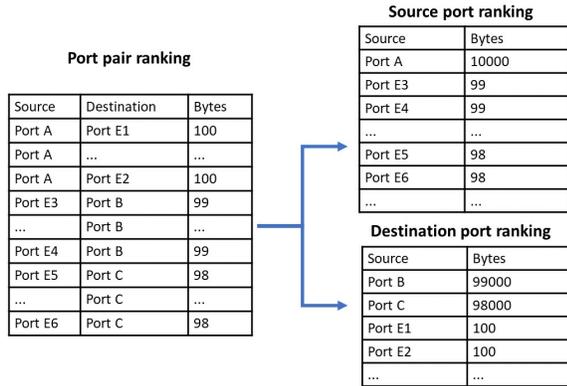

Figure 4: Split the port pair view into the source-port view and the destination-port view, separately. Port Es are ephemeral ports. Well-known ports A, B, and C pop up in the ranking list after the split.

about 10 Rate-Regions. Translating location pairs to Rate-Regions reduces the data size by $\sim 99.1\%$. We note that the feature translation does not hinder traffic debugging. One component is deployed on all machines of the same role. In case we detect anomalous traffic for one component in a Rate-Region, engineers can randomly pick a server in that Rate-Region and start the debugging from there.

4.2.2 Data Split and Aggregation

We aggregate the raw data based on the source port and destination port, separately, ranked based on the traffic volume. This results in two views: the source-port view and the destination-port view, which have two benefits: (1) significantly reduces the table size, i.e., from $O(\# \text{ source port} \times \# \text{ destination port})$ to $O(\# \text{ source port} + \# \text{ destination port})$; (2) helps pop up “well-known” ports in ranking because the traffic of ephemeral ports will converge to relatively smaller numbers than the traffic of “well-known” ports after aggregation. An example of port view splitting is shown in Figure 4.

Once we have identified the “well-known” ports, we take an additional step to filter the ephemeral ports in the source-port table and destination-port table. For every single time slot, we aggregate all ports that contribute less than 1% of the total traffic to one record and mark it with a special tag. Recall that our goal is to reduce overall traffic cost, the threshold of 1% is small enough. We will show in Section 5.1.1 that a

handful of ports dominate the traffic usage. The outputs are streamed into Kusto on a daily basis.

We aggregate the records from different data sources to obtain different feature tables. The schemas of these tables are shown in Table 3. We generate the Process table from ETW data, the Component table from application logs, and the Source-Port table and Destination-Port table from IPFIX data. We aggregate the TimeStamp with 5-minute intervals. Traffic-Size is aggregated with sum operation for all the records with the same key. For example, the tuple of $\langle \text{TimeStamp}, \text{ServerRole}, \text{RateRegion}, \text{Port}, \text{DSCP} \rangle$ is the key for the Source-Port table. The TrafficSize in the Source/Destination-Port table and the Process table is the sum of network traffic while the RequestSize of the Component table is the sum of request/response content sizes, excluding packet headers.

4.3 Data Validation

As a global-scale system, there are many factors that result in data corruption such as broken hardware and data loss. During the development of NetPanel, we experienced a partial data loss of the IPFIX data due to the data collector pipeline change. In fact, data missing issues are non-trivial to detect due to the vast amount of data being processed. NetPanel resolves the problem by cross-validating the results obtained from its multiple data sources.

The key idea is to cross-validate the ETW data and IPFIX data because the traffic size captured with ETW should match that with IPFIX. However, because IPFIX does packet sampling while ETW captures all traffic, we need to recover IPFIX data before comparing them. The recovery function is shown in Eq. (1). We do not validate the traffic size using application logs, because they only capture the content sizes without the request headers.

$$IPFIXBytes = \frac{(PacketSize + HeaderSize) * PacketNumber}{SamplingRate} \quad (1)$$

PacketSize, PacketNumber, and SamplingRate are available from the IPFIX data. Note that we add the ethernet header length (i.e., HeaderSize) to PacketSize to get the actual ethernet frame size on the wire. Based on the law of large numbers, we believe that: Given a machine pair that continuously send a lot of traffic to each other, an effective estimation of IPFIX should be close to ETW data. We conducted an experiment to validate our recovery approach. The result shown in Figure 5

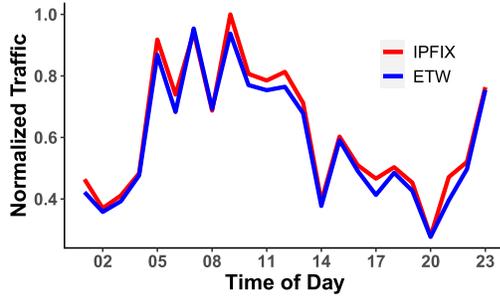

Figure 5: Recovered traffic for a single pair of machines in one day from IPFIX matches the traffic from ETW.

can confirm that the recovered IPFIX traffic size matches the ETW measurement precisely.

We selected the top 1000 pairs of machines in EXO that send the most traffic in a day for data validation. Machine pairs are re-selected daily as machine pairing relationships may change when machines become online or offline. After selecting the machine pairs, we insert their IPFIX data and ETW data into the validation table. Direct data comparison could be done with queries to the validation table. Data validation is done on a daily basis.

4.4 Result Database

The result database contains the Source-Port table, the Destination-Port table, the Process table, and the Component table. These tables are used to analyze traffic for component owners. A validation table is stored for data integrity checks. A top k ports table is created based on the Source-Port table and Destination-Port table. It picks the top k ports in both tables. These top k ports will be used as filters for the ETW collector in the future.

NetPanel uses the latest top k ports as a filter for the ETW collector to save production resources. These top k ports are usually obtained last day. IPFIX and Application Logs have been deployed in our environment for a long time. These data collectors have been optimized to guarantee no impact on SLA. ETW collector is a newly added collector running on production servers. As we will show in Section 6.1, directly collecting all ETW records will result in tens of times the CPU and disk IO usage. We must reduce ETW collector’s resource consumption on production servers. With the observation in Section 5.1.1 that the top 10 ports cover more than 94% of the traffic and stay stable over weeks. We decide to use the Top-k algorithm as a filter in the ETW collector to reduce the data to be collected and thus reduce its resource consumption.

4.5 Component Traffic Estimation

We built a web UI to provide engineers with a convenient way to analyze the traffic. The dashboard shows component-level

traffic like shown in Figure 2b (in Section 3). If the component monopolizes a process, its traffic could be directly obtained from the Process table as described in Table 3. Otherwise, we calculate its traffic in an approximated fashion. The details are presented in Algorithm 1.

```

Input: Component C
Output: Traffic size of Component C per second
1 if Process Contains C then
2   | return Process[C]
3 else
4   | P = Component C’s RemotePort
5   | PortTraffic = Source-Port[P] + Destination-Port[P]
6   | return  $\frac{Component[C,P]}{Component[*P]} \times PortTraffic$ 
7 end

```

Algorithm 1: Calculation Algorithm

If a component shares a process with other components, we have to estimate its network traffic following Line 4 to 7. In Line 4, we first find the port P used by component C with the Component table. Then, in Line 5, we calculate the total network traffic of this port P with the Source-Port table and Destination-Port table. In Line 6, Component[* , P] is the total request/response size of all components (* is the wildcard) going through port P. Component[C , P] is the request/response size of Component C going through port P. We use the ratio of Component[C , P] and Component[* , P], and the PortTraffic of P to estimate the TrafficSize of component C. The underlying assumption is that different components suffer from similar packet loss patterns (i.e., similar retry rate) and the packet header size is proportional to the payload size.

4.6 Monitoring

Aside from the dashboard, we also create monitors on the Source-Port table and Destination-Port table in the result database to safeguard the overall traffic usage of EXO. We now support two types of monitors, one to capture the static trend and the other to capture the dynamic change-points.

We use Mann-Kendall trend test [25] to obtain the static trend and use LinkedIn’s Greykite [27] to capture dynamic change points. The static trend monitor could help us find feature roll-out that potentially generates sub-optimal traffic. The dynamic change-points monitor could discover sudden bursts in traffic. These sudden bursts are usually caused by code regression or configuration errors.

5 Production Results

We used NetPanel to support traffic analysis in EXO. In this section, we share the observed traffic characteristics and use case studies to show the effectiveness of NetPanel.

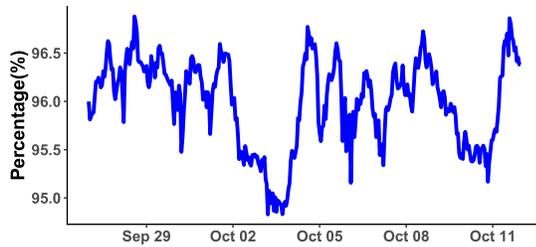

Figure 6: Traffic percentage taken by the top 10 ports. The percentage stays stable during the half-month observation.

5.1 Traffic Overview

Recall that there are two tiers of traffic in Sec. 2.1. To use Tier 1 traffic, the owner team must register a specific port. All traffic to or from that port is labeled with a Tier 1 DSCP tag. The registration prevents other components from using the same port. Therefore, all Tier 1 traffic through that port is used exclusively by a single component. In the following, we only discuss the characteristics of Tier 0 traffic.

5.1.1 Several ports dominate the overall traffic

From the Source-Port and Destination-Port tables, we observe that several top ports contribute to most traffic usage. Figure 6 shows the percentage of total traffic generated by the top 10 ports over half a month period. The lowest value during this period is 94.8%. This result confirms that the Top-k ports filter algorithm could cover at least 94% of the total traffic for ETW collector when $k = 10$. Furthermore, the list of top ports remains unchanged during our observation. This observation supports us to use the latest top k ports obtained as a filter for the ETW collectors as described in Section 4.4. The concentrated traffic distribution at a few top ports saves us a lot of traffic optimization work. We can focus on a small number of ports when we want to reduce network traffic costs. We engage the partner teams that use these ports instead of calling every team in EXO.

5.1.2 Several components dominate the traffic of a top port

When multiple components share the same port (as in Figure 1 REST and EWS share the same port), there are many contributors to the port traffic. We analyze the traffic distribution for top ports. We show the traffic contribution of the top 5 components for the top 2 ports separately in Figure 7, labeled as A and B. For both ports, the contribution of the 6th component is less than 5%. Investigation into lower-ranked components does not have a significant benefit in reducing overall traffic usage. With the help of NetPanel, engaging with a few partner teams is usually enough to optimize the traffic of a top port. For example, when we want to reduce the traffic

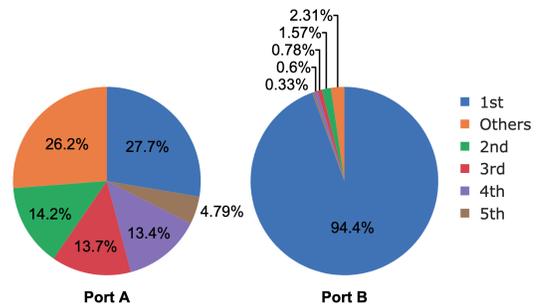

Figure 7: Component-level traffic distribution for the top 2 ports.

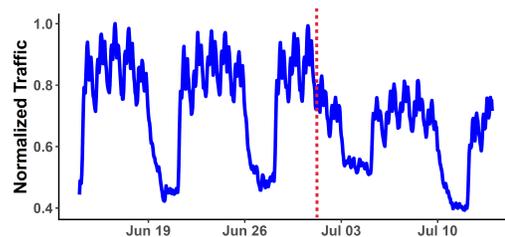

Figure 8: The traffic with destination port A decreased by 20% after switching from external to internal endpoint. The vertical dotted line indicates the recover time.

for Port A, we only need to engage the owners of the top 5 components.

5.2 Case Studies

In this section, we show how we use NetPanel to refine the WAN traffic for EXO. We present 4 cases where we leveraged NetPanel for: (1) service traffic optimization; (2) legacy traffic discovery; (3) anomaly traffic burst detection; and (4) WAN feature validation. These actions save millions of dollars per year for EXO.

5.2.1 Service Traffic Optimization

In this case, we introduce how we use NetPanel to identify sub-optimal traffic and optimize the utilization of network resources. NetPanel provides long-term data visualization. This makes it easy for the application to identify its major traffic contributor. After engaging the owning team, it is easy to make a conclusion on whether the traffic is necessary.

During our investigation of the traffic composition of EXO, we discovered that the Tier 0 traffic from our BE servers to port A on FE servers is too large. Because EXO has optimized the internal service endpoint (URL) to serve requests with the nearest FE server, we expect that there should be little Tier 0 traffic from BE to FE. We then used the Component table to find the main contributors. We identified that a component

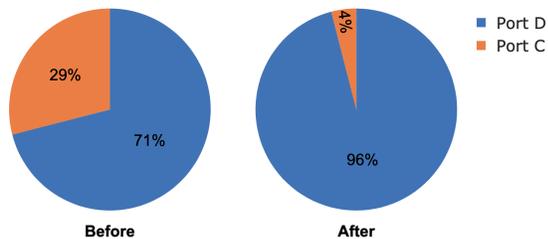

Figure 9: The ratio of the traffic from Port C to the traffic from Port D before and after the fix.

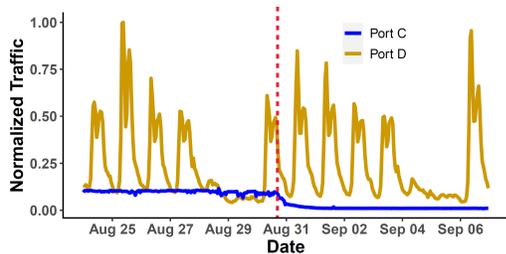

Figure 10: Traffic volume change with source port C and source port D after the removal of legacy code. The vertical dotted line indicates the change time.

that is used to extract plain text content from different formats of documents in emails took up most of the traffic. Then, we contacted the owning team and figured out that the component was using an external service endpoint. It had no control of where the requests were sent to and thus caused massive Tier 0 traffic worldwide. After identifying the issue, we worked together with the owning team to change to use an internal service endpoint so that this component could serve its requests within a single location. This action saved millions of dollars per year. The traffic change is shown in Figure 8. The traffic with destination port A decreased by 20% after the change. Prior to NetPanel, it relied heavily on code reviews to prevent such cases. This manual approach was likely to lead to omissions.

5.2.2 Legacy Traffic Discovery

There is another case where NetPanel helped discover legacy traffic and its source code. As the system grows, the source code becomes overwhelming. The work to remove outdated settings and services is necessary. However, it turns out that it is hard to discover legacies while do not break anything. We figured out there was one component on BE machines that was sending traffic to certificate authorities to validate some certificates that had been retired. We started from the continuous unexpected high traffic volume from port C in the NetPanel Source-Port table. According to our knowledge, EXO had finished the migration from Port C to Port D, so there should be very little traffic from port C, but massive

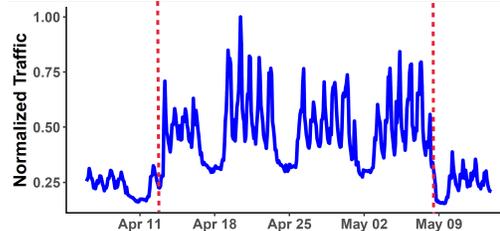

Figure 11: Traffic volume change of the log uploading service during the configuration error. The vertical dotted lines indicate the start time and the end time, respectively.

traffic from port D. The left pie chart in Figure 9 shows the ratio of the traffic from port C to the traffic from port D. The traffic from port C is 42% of the traffic from port D, which is much higher than our expectation. We used NetPanel to find the suspicious component and its owning team. After reaching out to the team, they investigated the issue and removed the legacy code. After the fix, the ratio of the traffic from port C to the traffic from port D became much smaller, where the traffic from port C was reduced to 4.2% of the traffic from port D, as shown in the right pie chart of Figure 9. The traffic of both ports during the fix is shown in Figure 10. After the removal, the traffic with source port C dropped to lower than 10% of the original traffic. That fix led to a savings of inbound capacity in the Gbps for Microsoft.

5.2.3 Anomaly Traffic Burst Detection

This case shows how we leverage NetPanel to detect an anomaly traffic burst caused by a configuration error. Some configuration errors at the application level may cause abnormal network behaviors. For example, a configuration error may cause the component to keep sending requests to an endpoint and thus leads to a traffic burst. These bugs are hard to detect unless the affected machines get so hot and break critical services [28]. In NetPanel, the change in request volume can be detected. When anomalies are reported by NetPanel, we could contact the component owner to debug the issue.

Figure 11 visualizes the traffic change during a configuration error for one component in EXO. An engineer accidentally changed a log uploading compression algorithm to an older version. The decrease in compression rate led to an increase in the total data volume sent to the log center and eventually hit the throttling limit. However, the component had a retry mechanism and kept sending data. This resulted in nearly quadruple the traffic volume sent during peak hours. The error was detected late after the change rolled out worldwide and drove a dramatic increase in traffic volume. We caught this abnormal burst and contacted the owner to dig into their component. After rolling back the change, the abnormal traffic disappeared and the traffic dropped back to the previous level. Without NetPanel, the problem could only be

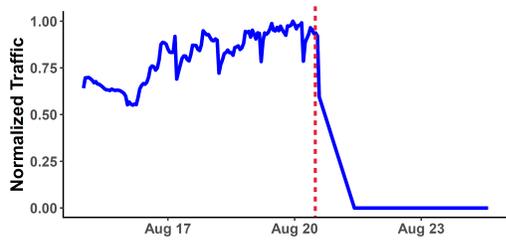

Figure 12: The volume change of Tier 0 traffic sent to registered ports after RWA devices support QoS Policy. The vertical dotted line indicates the change time.

discovered until the availability of the affected component is severely impacted, which would take a much longer time to fix the error and waste much more bandwidth.

5.2.4 WAN Feature Validation

This section introduces how NetPanel triggers a feature validation on newly deployed devices. When a new type of device starts to be deployed in the network, it may miss some functionality. Regional WAN Aggregator (RWA) is a kind of core router recently added to the Azure Network that sits on the top of datacenters and is responsible to connect the datacenter network to the backbone WAN. In this case, the newly deployed RWA devices do not support the QoS policy. They ignore the DSCP tag and treat all traffic with Tier 0 priority. NetPanel helped fix the bug at an early stage and avoid purchasing tens of millions of dollars in redundant capacity.

Bandwidth Broker routes traffic with different priorities. Our replication service has registered ports on the Bandwidth Broker service to lower the priority of non-urgent replications to Tier 1. However, from NetPanel data, we found that these ports have a significant amount of traffic classified as Tier 0. Together with the owning team, we picked a machine pair and captured packets on routers along the routing path. We found that the RWA device on the path does not support the QoS policy. Even though only 2 locations had RWA devices deployed at an early stage, this fix already saved several million dollars each year. If RWA devices were deployed worldwide, the value of this fix would be tens of millions of dollars per year. As shown in Figure 12, the Tier 0 traffic for those registered ports dropped to zero after the fix. NetPanel builds a map between components and ports, which makes it easy for component owners to monitor the priority tier of its traffic. Once any bug is introduced on the routing plane, they could discover and fix it quickly.

6 Evaluation

In this section, we evaluate the overhead of NetPanel in two categories: overhead inside and outside the production en-

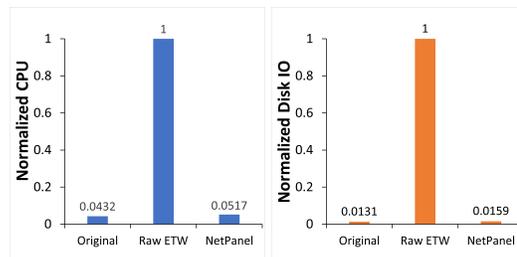

Figure 13: Normalized CPU and Disk IO usage on a BE machine when only services are running, when raw ETW is running, and when NetPanel is running.

vironment. The production environment serves customer requests and thus has strong restrictions on resource consumption, while the restrictions on overhead outside the production environment are more relaxed.

6.1 Overhead in the Production Environment

Figure 13 shows our evaluation of NetPanel overhead in the production environment. We ran the test on a single server. The overhead of NetPanel in the production environment is introduced by the ETW collector, which has extremely high CPU and disk IO consumption. If we enable ETW fully on machines, it will occupy $25\times$ more CPU and $77\times$ more disk IO compared to those when ETW is disabled. When we deploy NetPanel on production machines, less than 1% rise of the total available CPU and disk IO are observed because of retaining only top ports as mentioned in Section 4.4. It saves 99.1% CPU and 99.7% Disk IO compared with Raw ETW.

6.2 Overhead outside the Production Environment

The overhead outside the production environment includes two parts: data storage and computation. These are the overhead of processing and storing data in the big-data platform.

6.2.1 Data Storage

Table 4 shows the ratio between result data and raw data using our approach. The result size is 0.00361% of the origin for IPFIX, 0.00076% for ETW, and 0.00003% for application logs. The daily result sizes of all three data sources are in GB and are close to each other. The huge difference in the ratios is caused by the huge difference in the size of the original data. ETW data is much larger than IPFIX because it does not perform data sampling and covers Metro traffic (traffic within a location). Application log data is even larger because a machine pair could send multiple requests in one connection. The log data contains many extra columns for debugging.

Data	Size Ratio	Daily Calculation
IPFIX	0.00361%	1.1 hours
ETW	0.00076%	2.5 hours
Application Logs	0.00003%	6.8 hours

Table 4: Result data size ratio (compared to the raw data) and calculation time.

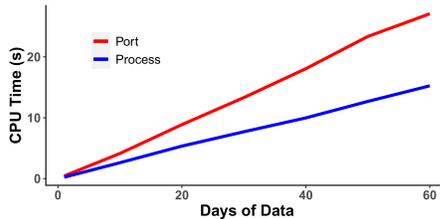

Figure 14: The CPU time for a query on a port and a query on a process increase linearly with the days of data. It takes 27 CPU seconds to get the 60 days of traffic for a port, and 15 CPU seconds to get the 60 days of traffic for a process.

6.2.2 Computation

The computational overhead consists of two parts. The first part is the overhead of background data processing and validation pipelines. The jobs run every day. The second part is the overhead of user queries.

We show the computational overhead for NetPanel’s data processing and validation pipelines in Table 4. We use less than 0.01% of our production computation resources to process the data. It takes 1.1 hours to process IPFIX data, 1.6 hours to process ETW data, and 6.8 hours to process application logs every day. The validation pipeline takes around 1.5 hours. The tight resource restriction leads to a long calculation time. We make this trade-off because the goal of NetPanel is to support the reduction of traffic costs in the long run, and therefore a delay of hours is acceptable.

It typically takes no more than 30 seconds for NetPanel to respond to a user query for the traffic of a set of specific ports or processes over months. We show the CPU time NetPanel needs to respond to a user query in Figure 14. The CPU time is proportional to data size. The actual waiting time is usually much smaller than the CPU time because multiple CPUs can calculate the result in parallel. The overall overhead of user queries is usually negligible.

7 Related Work

EXO runs on Azure architecture, further details of Azure architecture are shown in [30]. Gunawi [24] provided a summary of 597 cloud outages from 2009 to 2015. Ardelean [17] used Gmail as an example to analyze the performance of cloud applications. They studied the dynamic nature of cloud

applications in short time intervals. There are multiple efforts to minimize the cost of operating data centers. Cascara [42] tried to optimize the edge cost. Yang et. al. [50] scheduled the bulk transfer among datacenters. ROTOS [49] designed an optical DCN architecture to improve power efficiency.

Large investments have been made in data-center monitoring. There is a body of work on server monitors for Linux and Windows [8, 11, 36, 43]. Trumpet [36] is a monitor that processes every packet at line rate on end-hosts and tests the presence of user-specified network events. PathDump [43] designs a server stack to retrieve metadata from arrived packets on edge devices to help debug network issues. Monitoring data-center networks has been a hot topic for years. Commonly used protocols include IPFIX/Netflow and sFlow [15, 22, 37]. A detailed review [26] of the general flow monitoring technique is provided. In recent years, researchers have refined flow monitoring for different purposes [33, 40]. To monitor all the flows without sampling, FlowRadar [33] encodes per-flow counters at switches and leverages the computing power at the remote collector to perform decoding. To handle the large-scale challenge of data-centers, many have turned to query-based solutions, including Stroboscope [46], OFRewind [48], and PacketScope [45]. Stroboscope [46] mirrors millisecond-long traffic slices on routers according to user queries to monitor network forwarding behavior including traffic paths, one-way delays, and load-balancing ratios. IBM [29] uses HTTP logs to detect component failure and provide reports over the last 48 hours when an anomaly is detected.

8 Conclusion

The vast amount of network traffic generated by the components in cloud applications consumes significant resources. It is vital to identify the composition of network traffic to reduce the cost. Component-level measurement is needed to drive the traffic optimization effort for systems developed by a large number of teams. NetPanel analyzes the network traffic for EXO at the component level and at a low cost. One primary challenge is caused by the huge amount of measurement data. We design several schemes to reduce the data size without losing fidelity. We discuss real cases where NetPanel is applied to save millions of dollars per year. We believe that the insights we gained during the design and operation of NetPanel provide valuable experience in traffic measurement and reduction of other cloud applications.

DOTE: Rethinking (Predictive) WAN Traffic Engineering

Yarin Perry¹, Felipe Vieira Frujeri², Chaim Hoch¹, Srikanth Kandula², Ishai Menache², Michael Schapira¹, and Aviv Tamar³

¹Hebrew University of Jerusalem, ²Microsoft Research, ³Technion

Abstract— We explore a new design point for traffic engineering on wide-area networks (WANs): *directly* optimizing traffic flow on the WAN using only *historical* data about traffic demands. Doing so obviates the need to explicitly estimate, or predict, future demands. Our method, which utilizes stochastic optimization, provably converges to the global optimum in well-studied theoretical models. We employ deep learning to scale to large WANs and real-world traffic. Our extensive empirical evaluation on real-world traffic and network topologies establishes that our approach’s TE quality almost matches that of an (infeasible) omniscient oracle, outperforming previously proposed approaches, and also substantially lowers runtimes.

1 Introduction

To meet the constant rise in traffic, service providers invest huge effort into traffic engineering (TE)—optimizing traffic flow across their backbone WANs [11, 22, 24, 28, 37, 39, 57], which interconnect their datacenters with each other and with external networks. The production state-of-the-art involves periodically solving a (logically centralized) optimization problem to determine how to best split traffic across network paths. Changes to TE configurations are realized using software-defined control of network hardware [11, 22, 24, 35, 38, 39].

A key challenge for WAN TE is uncertainty regarding future traffic demands. The standard approach for contending with this is twofold. For time-sensitive traffic, providers measure application-specific usage data from switches (e.g., using sampled netflow or ipfix counters) and attempt to *predict* future usage. For bandwidth-hungry, scavenger-class traffic [22], providers deploy so called agents/shims in the OS of hosts from which traffic originates. These agents explicitly signal applications’ traffic demands to “brokers” that, in turn, aggregate demands, relay them to the centralized optimizer, and enforce the resulting rate allocations [22, 24].

Both of the above approaches for handling traffic uncertainty have drawbacks. Demand predictions can naturally be erroneous and, more importantly, there is an objective mismatch between the loss functions to predict future traffic demands (e.g., mean-squared-error, L1 norm error) and the *end-to-end objective* of producing high-performance TE configurations. For example, mean-squared-error would weight error in *any demand* equally, yet errors on demands that are

more problematic to carry on a given topology will exert a disproportionately large effect on TE quality. The other approach – brokering and explicitly specifying demands – entails nontrivial operational overheads, including changes to end-hosts and applications. This can increase the lag experienced by application requests (which is why this approach is used in practice only for bandwidth-hungry, scavenger-class traffic [22]).

The demand uncertainty challenge is further amplified for *customer-facing traffic* (web, images, e-mails, videos, etc.), which constitutes a large and growing share of the total traffic traversing some providers’ backbones. For such traffic, which originates in unmodified apps or clients, brokering in the host OS is not applicable. Moreover (see §2.1), such traffic exhibits high variability and is difficult to predict accurately.

We explore a new design point for WAN TE: training a TE decision model on *historical* data about traffic demands to *directly* output high-quality TE configurations. We present the *DOTE* (Direct Optimization for Traffic Engineering) TE framework. *DOTE* applies *stochastic optimization* to *learn* how to map recently observed traffic demands (e.g., empirically-derived traffic demands from the last hour) to the next choice of TE configuration. Using *DOTE*, providers need only *passively* monitor traffic to/from datacenters and do not have to onboard applications onto brokers. Directly predicting TE outcomes that optimize TE performance also resolves the objective mismatch between demand prediction and TE performance, yielding TE outcomes that are more robust to traffic unpredictability. We show how *DOTE* can scale to handle large WANs and real-world traffic by harnessing the expressiveness of deep learning.

We evaluate *DOTE* both analytically and empirically. Our theoretical results establish that if the TE optimization objective satisfies desirable convexity/concavity properties, *DOTE* *provably* converges to the optimum. We prove that this is indeed the case for standard TE optimization objectives such as minimizing the maximum-link-utilization (MLU) [8, 14, 27], maximizing network throughput [4, 22, 24, 37], and maximizing concurrent-flow [11, 29].

Our empirical evaluation compares *DOTE*, in terms of both quality and runtimes, to TE with explicit demand estimates from end-hosts, demand-prediction-based TE, demand-oblivious TE, deep-reinforcement-learning-based TE, and more. Evaluating data-driven TE schemes like *DOTE* requires substantial empirical data regarding traffic conditions

for both training and performance analysis. We conduct a large-scale empirical study using both publicly available datasets and historical data from Microsoft’s private WAN. These datasets span months of traffic demands at few-minutes granularity, amounting to tens of thousands of demand snapshots. Our evaluation covers small (10s of nodes) and large (100s of nodes) WANs, different types of traffic (including inter-datacenter and customer-facing), and different TE optimization objectives. To facilitate reproducibility, our code is available at [2].

Our evaluation results show that:

- ***DOTE* achieves TE quality almost matching that of an infeasible oracle with perfect knowledge of future demands.** Across all evaluated network topologies, traffic traces, and considered TE objectives, *DOTE* compares favorably to all other evaluated TE schemes. We also demonstrate *DOTE*’s robustness to changes in traffic conditions and to network failures.
- **By invoking a DNN for the online computation of TE configurations, *DOTE* achieves runtimes 1-2 orders of magnitude faster** than solving a linear program (LP), even for large WANs, matching the gains from recent proposals for fast (approximate) LP optimizations [4,40]. Our approach thus also holds promise for expediting decision making for TE.

We view our investigation of direct optimization for WAN TE as a first step and discuss current limitations of our approach that we hope future research can address.

This work does not raise any ethical concerns.¹

2 Motivation and Key Insights

2.1 Inter-DC vs. Customer-Facing Traffic

Enterprise WANs carry traffic between the provider’s own datacenters (e.g., geo-replication of datasets, newly computed search indices) as well as traffic traversing the backbone towards/from customers (e.g., web traffic, videos).

To motivate our direct optimization approach, we present analyses of traffic on Microsoft’s production WAN. Figure 1(a) plots the standard deviation in *inter-datacenter traffic* demands, normalized by the mean, across 11 consecutive weeks, for the pair of datacenters with the highest average demand. Demands are collected at 5-minute granularity. Similarly, Figure 1(b) plots the normalized standard deviation in *customer-facing traffic* demands over 4 consecutive weeks for the pair of nodes with the highest average demand. Observe the substantial difference; in the inter-datacenter traffic trace, demands are *significantly* less variable.

¹In particular, the measured traffic demands, used in our evaluation, are aggregate counters between pairs of datacenters at the granularity of minutes (or coarser). They do not contain user IP addresses or packet contents.

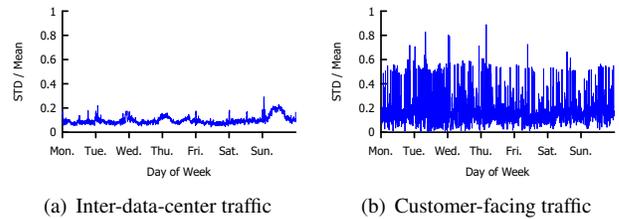

Figure 1: Variability in traffic demands for inter-datacenter traffic and customer-facing traffic across different weeks.

High variability in customer-facing traffic demands can accrue from different sources, e.g., (1) flash-crowds that may cause a surge in search requests, e-mail volume, etc., (2) congestion on the WAN’s peering links with ISP networks, and (3) route changes and outages that cause traffic to ingress or egress the WAN at different sites. We have observed that customer-facing demands can exceed $100\times$ the average value for extended stretches of time. Thus, customer-facing traffic is harder to accurately predict than inter-datacenter traffic. See Figure 10(a)–Figure 10(b) in the appendix for differences in demand-prediction accuracy between the above discussed two traffic traces.

To summarize: for customer-facing traffic, which is a large and growing share of overall WAN traffic, not only is direct inference of traffic demands by the host OS infeasible, but accurate demand prediction also appears elusive. We seek a method that can achieve nearly optimal TE outcomes even for the unpredictable traffic demands.

2.2 Demand Prediction vs. Direct Optimization

We illustrate key insights underlying *DOTE* using the example in Figure 2(a). Each of nodes *A* and *B* wishes to send traffic to node *D*, and can do so either via its direct link to *D* or its 2-hop path to *D* through node *C*. All link capacities are 1. Every fixed time interval (say, 5 minutes), the TE system must determine, for each of the two source nodes, *A* and *B*, traffic splitting ratios specifying which fraction of its demand is forwarded along each of its assigned two paths to *D*. *A* and *B*’s traffic demands for each time interval are drawn (i.i.d) at the beginning of each time interval from a *fixed* probability distribution: with probability $\frac{1}{2}$ node *A*’s demand is $\frac{5}{3}$ and node *B*’s demand is $\frac{5}{6}$ and with probability $\frac{1}{2}$ node *B*’s demand is $\frac{5}{3}$ and node *A*’s demand is $\frac{5}{6}$. The TE system has no a priori knowledge of the realization of the traffic demands; splitting ratios must be determined before actual traffic demands are revealed.

Demand-prediction-based TE and its shortcomings. A natural solution is training a predictor on empirical data containing past demands for *A* and *B* to predict the combination of demands closest (in expectation) to the realized combination of demands (e.g., in terms of mean-squared-error), and then

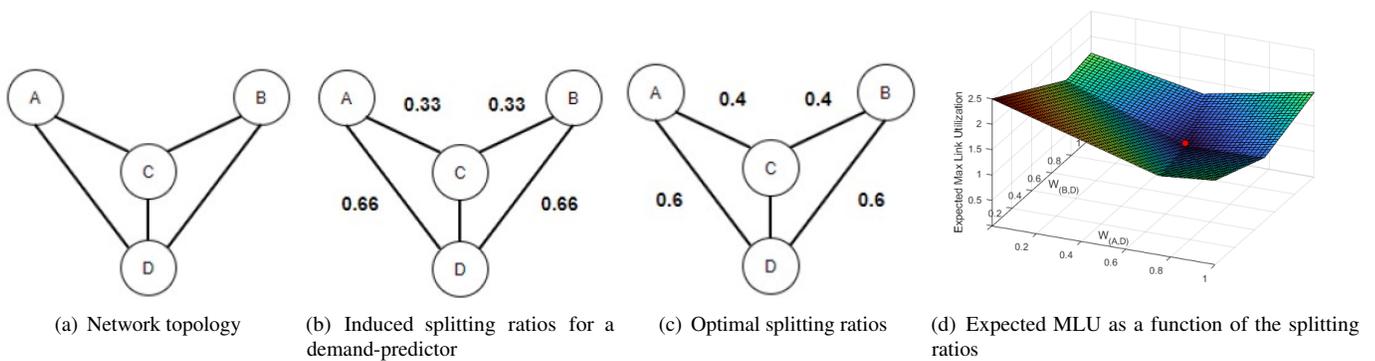

Figure 2: Simple WAN TE example

performing global optimization with respect to the predicted demands. In our simple example, this leads to the predicted demand-combination being $(\frac{5}{4}, \frac{5}{4})$ and the induced splitting ratios presented in Figure 2(b). Under these splitting ratios, *regardless* of the realization of the demands, either link (A, D) or link (B, D) will carry more traffic than its capacity can accommodate. In the optimal solution shown in Figure 2(c), however, *regardless of the realized demands, no link carries more traffic than its capacity can support*.

Of course, instead of predicting a single demand-combination, one could have predicted a *probability distribution* over the traffic demands and optimized splitting ratios with respect to that. This entails two nontrivial challenges, which are significantly amplified for large WANs and real-world traffic: (1) We must impose a specific structure on the probability distribution to be predicted (e.g., Gaussian, bimodal), which might not be a good fit for actual WAN traffic. This is particularly true when there hidden correlations between demands (as in our example); (2) Optimizing an LP with respect to a distribution over *multiple* demand-combinations can be prohibitively time consuming for large WANs.

On direct optimization of traffic splitting ratios and why it might do better. An alternative approach, which avoids presuppositions regarding the traffic, and also LP optimizations, is training a decision model on past realizations of A and B 's traffic demands to *directly* output traffic splitting ratios that are close to the global optimum. This approach can outperform the demand-prediction-based approach in scenarios where traffic is volatile and hard to predict but a certain configuration of splitting ratios performs well on most traffic realizations. Directly inferring the splitting ratios also obviates the need for solving an LP to optimize splitting ratios with respect to predicted traffic. As our evaluation results in §4 show, this significantly accelerates TE runtimes for large WANs. In our example, after sufficient training, the model is expected to learn the splitting ratios in Figure 2(c) (the unique

global optimum). Indeed, *DOTe*, which is a manifestation of this approach, quickly converges to this global outcome.

Exploiting convexity/concavity for direct optimization of splitting ratios via gradient descent. A key insight is that for classical TE optimization objectives, the function mapping splitting ratios to *expected* performance scores satisfies desirable properties, namely, *convexity/concavity*. This facilitates utilizing elegant direct optimization methods, like (stochastic) gradient descent, circumventing explicit demand prediction.

To illustrate this, we consider the classical TE objective of minimizing maximum-link-utilization (MLU). We visualize in Figure 2(d) the impact of different choices of splitting ratios on MLU, i.e., the maximum ratio, across all network links, between the traffic traversing a link and the link capacity. x-axis values specify the fraction of A 's traffic sent on the direct path (A, D) . Since A only has two available paths, this value also uniquely determines the fraction of A 's traffic sent on the indirect path (A, C, D) . Similarly, y-axis values specify the fraction of B 's traffic sent on (B, D) and so also on (B, C, D) . z-axis values represent the *expected* MLU for different choices of splitting ratios for A (x-axis) and B (y-axis) for the underlying demand distribution described above. For instance, the scenario where A and B send all of their traffic on (A, D) and (B, D) , respectively, is captured by $w_{(A,D)} = 1$ (x-axis) and $w_{(B,D)} = 1$ (y-axis), and the derived expected MLU is $\frac{5}{3}$ (z-axis). Indeed, in this scenario, regardless of which of the two demand combinations is realized, the traffic injected into either link (A, D) or link (B, D) will be $\frac{5}{3}$ x its capacity. The *unique* global minimum for MLU, in which no link capacity is exceeded, is achieved for $w_{(A,D)} = 0.6$ and $w_{(B,D)} = 0.6$ (the red dot in Figure 2(d), which corresponds to the splitting ratios in Figure 2(c)).

As seen in Figure 2(d), the expected MLU exhibits a desirable structure—*convexity* in the traffic splitting ratios. This suggests the following procedure for converging to the optimum: start with *arbitrary* splitting ratios, and adapt the splitting ratios in the direction of the steepest slope of the (ex-

pected) MLU (i.e., the opposite direction of the *gradient* with respect to the splitting ratios) until converging to the global minimum. We show (in §3.3) that the convexity of the expected MLU extends to *any* network topology, *any* choice of network paths (tunnels), and *any* underlying demand distribution, and so, this elegant optimization procedure is guaranteed to converge to the global optimum in general.

2.3 TE as Stochastic Optimization

How to estimate the gradient of the expected MLU? Executing gradient descent on the *expected* MLU requires repeatedly evaluating the gradient for different traffic splitting configurations. However, *exact knowledge of the gradient is impossible without exact knowledge of the underlying demand distribution*. Once again, the specific structure of the TE setting gives rise to opportunities for effective optimization. We show how the gradient can be closely approximated from data samples of past realizations of the demands. Our approach builds on the following two observations that, while illustrated using our toy example, generalize to arbitrary network topologies, tunneling schemes, and distributions over traffic demands (see §3).

- **For any realized demand-combination, the MLU gradient with respect to these specific demands can be expressed in closed form.** Suppose that the realized demands in our simple example are $\frac{5}{3}$ for A and $\frac{5}{6}$ for B . The MLU as a function of A 's splitting ratios, $w_{(A,D)}$ and $(1 - w_{(A,D)})$, and B 's splitting ratios, $w_{(B,D)}$ and $(1 - w_{(B,D)})$, can be expressed as:

$$\max\left\{\frac{5}{3}w_{(A,D)}, \frac{5}{3}(1 - w_{(A,D)}) + \frac{5}{6}(1 - w_{(B,D)}), \frac{5}{6}w_{(B,D)}\right\}$$

(i.e., the maximum load across the links (A,D) , (C,D) , and (B,D) , respectively²). This representation of the MLU for the realized demands as a convex function of the splitting ratios enables deriving a closed form expression of the (sub)gradient of the MLU³, as shall be discussed in §3.

- **Averaging over the MLU gradients for past realized demands closely approximates the gradient of the expected MLU.** Exact knowledge of the underlying probability distribution over demands is elusive in most real-world scenarios. Hence, the gradient of the *expected* MLU for a given configuration of splitting ratios cannot be precisely derived. However, this gradient can be well-approximated by averaging over the gradients for

²Observe that the load on (A,C) and (B,C) is always dominated by the load on (C,D) , and so we disregard these links.

³Note that even though this function is not differentiable for all inputs due to the maximum operator, the subgradient always exists and can be explicitly derived.

realized demands at those splitting ratios. In our example, deriving the expected MLU gradient for specific traffic splitting ratios for A and B can be achieved by sampling sufficiently many past realizations of A and B 's demand-combinations, deriving the MLU gradient with respect to each such realized demand combination (at these splitting ratios), and averaging over these.

Why is reinforcement learning (RL) not a good fit? (Deep) RL methods have been applied to many networking domains, including routing [54]. Similarly to *DOTe*, RL approaches to TE also replace explicit demand prediction with end-to-end optimization, mapping recent traffic demands to TE configurations [54]. However, while RL can be applied to essentially any sequential decision making context, RL suffers from higher data-sample complexity, notorious sensitivity to noisy training, and a brittle optimization process that necessitates painstakingly sweeping hyperparameters [21]. A key observation underlying *DOTe* is that WAN TE exhibits a desirable structure that gives rise to opportunities for much simpler and more robust optimization, rendering RL an “overkill”.

2.4 Harnessing Deep Learning

In our simple example, traffic demands were repeatedly drawn from the *same* probability distribution. Real-world traffic exhibits intricate temporal (hourly, diurnal, weekly), and other, patterns. To pick up on such regularities, the TE system could take into account the recent history of observed traffic demands (e.g., traffic demands from the last hour). However, there are infinitely many possible recent histories of traffic demands the TE system might observe. To address this, *DOTe* trains a deep neural network (DNN) to *approximate the optimal mapping from traffic histories to TE configurations*, exploiting the capability of DNNs to automatically identify complex patterns in large, high-dimensional data (§3.4). *DOTe* builds on recent developments in large-scale optimization, namely, the ADAM stochastic gradient descent optimizer [30], to accommodate efficient training on extensive empirical data (10s of thousands of traffic demand snapshots in our experiments).

3 Direct Optimization for TE (*DOTe*)

Below, we present our model for WAN TE with uncertain traffic demands, which extends the classical WAN TE model. We then delve into the the *DOTe* stochastic optimization framework, provide theoretical guarantees, and discuss how *DOTe* can be implemented in practice.

3.1 Modeling WAN TE

Network. The network is modeled as a capacitated graph $G = (V, E, c)$. V and E are the vertex and edge (link) sets,

respectively, and $c : E \rightarrow \mathbb{R}^+$ assigns a capacity to each edge.

Tunnels. Each source vertex s communicates with each destination vertex t via a set of network paths, or “tunnels”, P_{st} .

Traffic demands. A demand matrix (DM) D is an $|V| \times |V|$ matrix whose (i, j) ’th entry $D_{i,j}$ specifies the traffic demand between source i and destination j .

Optimization objective. To simplify exposition, we first describe *DOTTE* for the case of one classical TE objective: minimizing maximum-link utilization (MLU) [9, 13, 17]. We discuss other optimization objectives (maximum network throughput and maximum-concurrent-flow) in §3.5.

TE configurations. We focus on how traffic should be split across a given set of tunnels so as to achieve the optimization objective. *DOTTE* is compatible with any tunnel-selection method. We discuss an extension that incorporates data-driven tunnel selection in §5.

Given a network graph and demand matrix, a TE configuration \mathcal{R} specifies for each source vertex s and destination vertex t how the $D_{s,t}$ traffic from s to t is split across the tunnels in P_{st} . Thus, a TE configuration specifies for each tunnel $p \in P_{st}$ a value x_p , where x_p is the fraction of the traffic demand from s to t forwarded along tunnel p (and so $\sum_{p \in P_{st}} x_p = 1$).

Given a demand matrix D and TE configuration \mathcal{R} , the total amount of flow traversing edge e is $f_e = \sum_{s,t \in V, p \in P_{st}, e \ni p} D_{s,t} \times x_p$. The objective is minimizing the maximum link utilization induced by \mathcal{R} and D , $\max_{e \in E} \frac{f_e}{c(e)}$, which we will refer to as MLU and represent as $\mathcal{L}(\mathcal{R}, D)$. WAN operators seek to reduce the MLU to keep more headroom open for unplanned failures and traffic spikes. Typically, operators spend to increase link capacities when MLU exceeds a threshold value, and so reducing MLU can reduce CAPEX [14, 27].

In this work, we aim to select TE configurations without a priori knowledge of the traffic demands. To do so, we augment the above model as follows:

WAN TE under traffic uncertainty. Time is divided into consecutive intervals, called “epochs”, of length δ_t . δ_t is determined by the network operator (e.g., at some large service providers [22, 24], δ_t is a few minutes). At the beginning of each epoch t , the TE configuration $\mathcal{R}^{(t)}$ for that epoch is decided based only on the history of *past* demand matrices and TE configurations. We also assume that the demand matrix is fixed within an epoch and can be approximately estimated after the fact.⁴ Such periodic changes to TE configuration reflect the current practice in private WANs [22–24].

After selecting the TE configuration $\mathcal{R}^{(t)}$ for epoch t , the demand matrix D_t is revealed. To minimize MLU, the goal for direct optimization is to devise a TE function $\pi(D_{t-1}, \dots, D_1)$

⁴For e.g., by sampling ipfix (or equivalent) data at each node in the WAN, as is done in production in SWAN [22] and B4 [24]. This data contains source and destination nodes and volume of bytes exchanged. Alternatively, traditional ISP backbones use network tomography on measured link usage data (see, e.g., [46, 58]).

that, for every $t > 0$, maps the history of DMs from the previous $t - 1$ time epochs to a TE configuration $\mathcal{R}^{(t)}$ for the upcoming time epoch t so as to minimize $\frac{1}{T} \sum_{x=1}^T \mathcal{L}(\mathcal{R}^{(x)}, D_x)$, where T represents the length of time in which TE configurations are computed according to π .

To reason about WAN TE in the presence of traffic uncertainty, we assume that the demand matrix D_t at each epoch t is generated from some probability distribution. We also make the following two assumptions, which are fundamental to any data-driven approach to WAN TE. First, we assume that there is some sufficiently large $H > 0$ such that the finite window of H recent historical observations of DMs is sufficient for informing the decision of the next TE configuration. (Our empirical results in §4 suggest that $H = 12$ suffices for attaining high performance on our datasets.) Formally, we model the demand matrix D_t as generated according to an unknown H -Markov process with transition probabilities such that $P(D_t | D_{t-1}, \dots, D_{t-H}) = P(D_t | D_{t-1}, \dots, D_1)$. Second, we assume that the probability of observing a particular sequence of H DMs in the training data and during real-time system execution is the same. This formally translates to the Markov process being in a steady state. Let $P(D_{t-1}, \dots, D_{t-H})$ denote the Markov process’ stationary distribution, which determines the probability for any specific H -long recent history of DMs. The expected MLU for a TE configuration \mathcal{R} at epoch t is therefore $\mathbb{E}_{D_t} [\mathcal{L}(\mathcal{R}, D_t)]$, where the expectation is with respect to the (unknown) probability distributions $P(D_{t-1}, \dots, D_{t-H})$ and $P(D_t | D_{t-1}, \dots, D_{t-H})$ defined above.

3.2 The *DOTTE* TE Framework

DOTTE leverages stochastic optimization to compute a TE function $\pi_\theta(D_{t-1}, \dots, D_{t-H})$, parametrized by θ , which maps the H -long recent history of DMs to the TE configuration for the next time epoch, $\mathcal{R}^{(t)}$. If the TE function is sufficiently expressive, there should exist parameters that closely approximate the optimal TE function. As we shall discuss in §3.4, in *DOTTE*, π_θ is realized by a deep neural network (DNN), and the parameters θ correspond to the DNN’s link weights. We thus consider the optimization problem of seeking parameters θ for which the following expression is minimized: $\mathbb{E} [\mathcal{L}(\pi_\theta(D_{t-1}, \dots, D_{t-H}), D_t)]$, where the expectation is with respect to choosing t uniformly at random from $\{1, \dots, T\}$, and the probability distributions $P(D_{t-1}, \dots, D_{t-H})$ and $P(D_t | D_{t-1}, \dots, D_{t-H})$ defined above. Observe that by the linearity of expectation and the above equation, $\mathbb{E} [\mathcal{L}(\pi_\theta(D_{t-1}, \dots, D_{t-H}), D_t)] = \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{D_t} [\mathcal{L}(\mathcal{R}^{(t)}, D_t)]$, which is precisely our optimization objective in *DOTTE*.

The training data for *DOTTE* is a trace of historical DMs, consisting of N sequences of DMs of the form $\{D_1^i, D_{t-1}^i, \dots, D_{t-H}^i\}$, where each sequence consists of $H + 1$ DMs and captures a specific realization of a H -long history of DMs and the subsequent realized DM. We assume that

these N observations of DM sequences are sampled i.i.d. from $t \in [1, \dots, T]$, $P(D_{t-1}, \dots, D_{t-H})$ and $P(D_t | D_{t-1}, \dots, D_{t-H})$.⁵

DOTE executes *stochastic gradient descent* (SGD) [51] to optimize the parameters θ by sequentially sampling m -sized mini-batches of data, where each data point in the mini-batch is drawn from the data uniformly at random. For each mini-batch of sampled data points, the parameters θ are updated as follows:

$$\theta := \theta - \alpha \frac{1}{m} \sum_{i \text{ in batch}} \nabla_{\theta} \mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i)),$$

where α is a step size parameter and $\nabla_{\theta} \mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i))$ is the gradient of the loss function with respect to θ . Our realization of stochastic optimization in *DOTE* follows the ADAM [30] method, which incorporates momentum and an adaptive step size.

A closer look at *DOTE*'s parameter update step. Recall that our objective is to reach a performant TE configuration with respect to the *expected* loss (MLU). The success of *DOTE*'s SGD is thus crucially dependent on *DOTE*'s ability to well-approximate the gradient with respect to the expected loss. Unfortunately, in most real-world TE environments, exact knowledge of the underlying distribution over traffic demands is unattainable. To address this, *DOTE*'s parameter update step (see above) incorporates the expression $\frac{1}{m} \sum_{i \text{ in batch}} \nabla_{\theta} \mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i))$. As discussed above, each sequence of $H+1$ demand matrices $\{D_t^i, D_{t-1}^i, \dots, D_{t-H}^i\}$ in the batch is assumed to be independently drawn from the underlying stationary distribution of the Markov process. Hence, $\frac{1}{m} \sum_{i \text{ in batch}} \nabla_{\theta} \mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i))$ is an *unbiased* estimate of the gradient of the expected loss, and closely approximates the gradient of the expected loss for a large enough m . Approximating the gradient of the expected loss in this manner is termed Sample Average Approximation (SAA) in stochastic optimization literature [51]. Relying on unbiased stochastic gradients for SGD guarantees convergence to a *global* optimum with respect to the *expected* loss [49] when the loss function is concave (as in our context, see §3.3).

We are left with the challenge of deriving $\frac{1}{m} \sum_{i \text{ in batch}} \nabla_{\theta} \mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i))$. An important technical observation is that each data point i in the batch, $\mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i))$ is a composition of *differentiable* computations. *DOTE* capitalizes on this for calculating the gradient $\nabla_{\theta} \mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i))$ in closed form via backpropagation. We revisit this point in §3.4.

⁵When the data is a long trace of historical DMs, the samples are not necessarily independent. However, we assume that the mixing time of the Markov process is fast enough such that correlations between the data samples are negligible. This is a common assumption in time series prediction.

3.3 Analytical Optimality Results

We prove that, for a *perfectly expressive* TE function, i.e., when the TE function can be *any* mapping from demand histories to TE configurations, and in the limit of infinite empirical data sampled from the underlying Markov process' stationary distribution, *DOTE* attains optimal performance. In practice, we relax both assumptions: in *DOTE*, we sample from a large, but *finite*, dataset of historical demands, and use a *parametric* model (specifically, a neural network) to map from the set of possible histories to valid TE configurations. Our theoretical result below, however, establishes that our approach is *fundamentally sound*, and so high performance in practice can be achieved by acquiring sufficient empirical data and employing a sufficiently expressive decision model (e.g., a deep enough neural network). Our empirical results in §4 corroborate this.

For the sake of analysis, we assume that the set of possible history realizations, which we denote by \mathbf{H} , is finite. Let $\pi : \mathbf{H} \rightarrow \mathbf{R}$ denote a mapping from history to TE configuration⁶. We consider an idealized stochastic gradient descent (SGD) algorithm that, at each iteration k samples a *single* data point $D_t, D_{t-1}, \dots, D_{t-H}$ from the probability distributions $P(D_{t-1}, \dots, D_{t-H})$ and $P(D_t | D_{t-1}, \dots, D_{t-H})$, and updates $\pi_{k+1} = Proj\{\pi_k - \eta v_k\}$, where $v_k \in \partial \mathcal{L}(\pi_k(D_{t-1}, \dots, D_{t-H}), D_t)$ denotes the subgradient of the objective function, and *Proj* denotes a projection onto the simplex for each (s, d) pair. The final output after K iterations is $\bar{\pi} = \frac{1}{K} \sum_{k=1}^K \pi_k$. Let $\bar{\mathcal{L}}(\pi) = \mathbb{E}[\mathcal{L}(\pi(D_{t-1}, \dots, D_{t-H}), D_t)]$ denote the expected MLU of a TE function, and let $\pi^* \in \arg \min_{\pi} \bar{\mathcal{L}}(\pi)$ denote the optimal TE function. We prove the following theorem:

Theorem 1. *For any $\epsilon > 0$, there exists $\eta > 0$ and finite K such that $|\mathbb{E}[\bar{\mathcal{L}}(\bar{\pi})] - \bar{\mathcal{L}}(\pi^*)| \leq \epsilon$, where the expectation is w.r.t. the sampling by the algorithm.*

The proof of Theorem 1, which crucially relies on the convexity of the MLU objective, appears in Appendix B.

3.4 Scalability and Real-World Traffic

Direct TE optimization aims at computing a mapping from the history of recent traffic demands to a TE configuration that optimizes expected performance for the next demands. A key insight is that with real-world traffic, one may expect certain *patterns* in this mapping; for example, if two histories of traffic conditions are very similar, their corresponding optimal TE configurations should also be similar. However, measuring and explicitly quantifying such similarities is nontrivial. Our approach is to exploit deep neural networks, which have demonstrated remarkable success in identifying complex patterns in high dimensional data, for this task.

⁶Note that we dropped the subscript θ in π , as in our analysis we consider the space of all possible TE configurations, and not a specific parametrization.

DOTE employs a DNN to realize the TE function $\pi_{\theta}(D_{t-1}, \dots, D_{t-H})$. Specifically, *DOTE*'s DNN maps an input of H (12 in our experiments) most recent DMs into an output vector specifying the splitting ratios across tunnels for all source-destination pairs. In our implementation of *DOTE*, we use the popular Fully Connected DNN architecture. See Appendix E for a formal exposition of how the DNN's output and the realized DM are fed into the loss function to derive the induced MLU. Importantly, the sequence of steps for mapping the DNN output to the MLU value $\mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i))$ involves only *differentiable* computations; the loss as a function of the TE configuration is a composition of a max and a linear function, and the neural network is differentiable by design. Hence, the gradient $\nabla_{\theta} \mathcal{L}(D_t^i, \pi_{\theta}(D_{t-1}^i, \dots, D_{t-H}^i))$ can be calculated in closed form via backpropagation. In our implementation, the Pytorch [41] auto-differentiation package is used to calculate the gradients.

3.5 On Maximum and Concurrent Flow

We next explain how *DOTE* extends to two other central TE objectives: maximizing network throughput [18, 22, 24, 25] (maximum multicommodity flow) and maximum concurrent-flow [11, 29, 48].

TE configurations for flow maximization. TE objectives that capture different notions of flow maximization require that the outputs of the TE mechanism satisfy strict capacity constraints. To address this, we revise our definition of TE configuration \mathcal{R} from §3.1: for each source-destination pair $s, t \in V$, \mathcal{R} now specifies (1) traffic splitting ratios x_p over the paths (tunnels) $p \in P_{st}$ (as in §3.1), (2) for each path (tunnel) $p \in P_{st}$, a “cap” $\omega_p \geq 0$. ω_p represents the maximum permissible flow between s to t along the path p (enforced via rate limiting). \mathcal{R} must satisfy that no link capacity is exceeded (*regardless of the realized demands*), i.e., that for each link $e \in E$, $\sum_{s,t \in V, p \in P_{st}, e \ni p} \omega_p \leq c(e)$. A TE configuration \mathcal{R} and demand matrix D induce, for each tunnel p a flow $f_p(\mathcal{R}, D) = \min\{x_p \times D_{s,t}, \omega_p\}$. The total flow between s and t is thus $f_{st}(\mathcal{R}, D) = \sum_{p \in P_{st}} f_p(\mathcal{R}, D)$.

The maximum-multicommodity-flow and maximum-concurrent-flow objectives. In maximum-multicommodity-flow [18, 22, 24, 25], the performance objective $\mathcal{L}(\mathcal{R}, D)$ is to compute, for a given demand matrix D , a TE configuration \mathcal{R} that maximizes the expression $\mathcal{L}(\mathcal{R}, D) = \sum_{s,t \in V} f_{st}(\mathcal{R}, D)$ (the total network throughput). For a TE configuration \mathcal{R} and demand matrix D , let $\alpha(\mathcal{R}, D)$ denote the maximum value $\alpha \in [0, 1]$ for which at least an α -fraction of each $D_{s,t}$ is routed *concurrently*, i.e., such that for all $s, t \in V$, $f_{st}(\mathcal{R}, D) \geq \alpha D_{s,t}$. The goal in maximum-concurrent-flow is to compute, for an input DM D , the TE configuration \mathcal{R} for which $\mathcal{L}(\mathcal{R}, D) = \alpha(\mathcal{R}, D)$ is maximized. Relative to maximum-multicommodity-flow above, the maximum-concurrent-flow objective enhances fairness. Practical TE

systems [22, 24] use a sequence of optimizations wherein they employ different objectives for different priority classes. For example, they may use maximum-multicommodity-flow or minimizing MLU for high priority traffic and maximum-concurrent-flow for scavenger-class traffic.

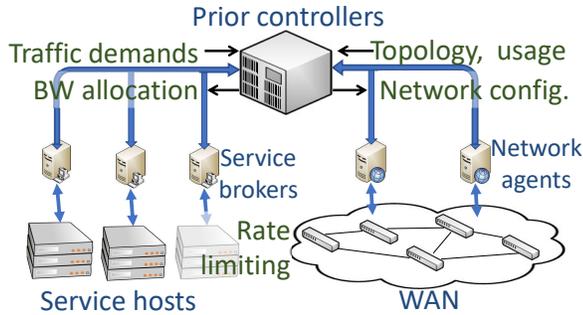

***DOTE* for maximum-multicommodity-flow and maximum-concurrent-flow.** Adapting *DOTE* to the above two flow-maximization objectives is accomplished along the lines described in §3.4. In particular, a DNN is again utilized to map the recent observations of DMs to the next TE configuration. Recall from the above discussion that the (revised) TE configuration consists of both traffic splitting ratios across tunnels and a “flow cap” for each tunnel. In our design, the DNN outputs $w_p \geq 0$ for each tunnel p . The w_p 's are used to derive traffic splitting ratios and flow caps as follows. We set $\omega_p = \frac{w_p}{\gamma}$, where $\gamma = \max\left(\max_{e \in E} \frac{\sum_{p: e \in p} w_p}{c(e)}, 1\right)$. Observe that this guarantees that no link capacity can be exceeded even if each tunnel p carries its maximum permissible flow ω_p (i.e., that $\sum_{s,t \in V, p \in P_{st}} \omega_p \leq c(e)$). We then set the traffic split share on tunnel p to simply be its proportional weight: $x_p = \frac{\omega_p}{\sum_{q \in P_{st}} \omega_q}$. Since the objective is now *maximizing* a performance metric, *DOTE* now involves stochastic gradient *ascent*.

Optimality via stochastic quasi-concave optimization. In Appendix B, we prove the analogues of Theorem 1 for maximum-multicommodity-flow and for maximum-concurrent-flow, establishing *DOTE*'s optimality for these two objectives. Similarly to Theorem 1 (for MLU), this implies that with sufficient training data and a sufficiently expressive decision model, *DOTE* attains near-optimal TE configurations. Our evaluation results for maximum-multicommodity-flow and for maximum-concurrent-flow exemplify this (§4.3).

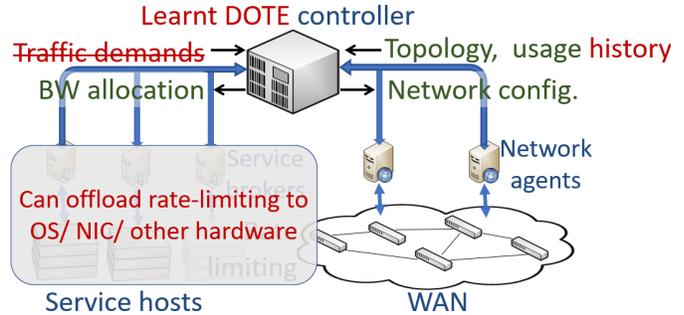

Our proofs for maximum-multicommodity-flow and for maximum-concurrent-flow are considerably more subtle than that of Theorem 1, as both objectives are not concave (the analogue of convexity for maximization problems). Instead, we show that the average maximum-multicommodity-flow / maximum-concurrent-flow score of a TE configuration over any set of DMs is *quasi-concave*. This result, which may be of independent interest, allows us to leverage the analytical arguments in [20] to show convergence of a suitable stochastic gradient ascent algorithm to the global optimum, and bound the number of required iterations.

3.6 Realizing *DOTE*

Figure 3 illustrates key differences between *DOTE* and prior software-defined WAN TE schemes. One key difference is the use of historical traffic demands and a learnt controller instead of running an optimization solver, leading to substantial decrease in deployment overheads and runtimes. In particular, bandwidth brokers are no longer needed to estimate application demands. Furthermore, rate allocations can, if necessary, be enforced by piggy-backing on novel traffic

(a) Architecture of prior SD-WAN TE schemes [22, 24].

(b) DOTE with differences shown in red.

Figure 3: Illustration of the key differences from previous SD-WAN TE schemes.

shaping techniques that are deployed in modern cloud servers at the OS-level as well as in NIC/FPGA offloads [1, 12, 43, 47].

Training DOTE. Since DOTE’s decision model is trained *offline* on historical data, its operational model can be periodically replaced by a model trained in the background on more recent and up to date data, to gracefully adapt to *planned* changes in WAN topology (adding capacity, planned addition/removal of nodes or links) and to temporal drifts in traffic demand distributions. Our evaluation results (§4) indicate that DOTE produces high performance TE configurations even weeks after being deployed, and even if the network topology changes during this time (e.g., due to failures). This provides ample time for training substitute TE functions (a process that requires less than a day on large networks for our empirical datasets without code and hardware optimizations).

Handling network failures. Tunnelling protocols (e.g., MPLS) identify tunnels with failed nodes/links. A traditional approach in TE to rerouting traffic around failed tunnels is to let traffic sources redistribute traffic proportionally among their remaining tunnels [22, 24, 39, 52].⁷ We incorporate this simple approach into DOTE and evaluate its effectiveness in §4, showing that it achieves high resiliency to failures. We discuss other possible approaches in §5.

4 Evaluation

Using actual traffic demands from three different production WANs (Abilene, GEANT, and Microsoft’s WAN), we ask the following questions: (1) How does DOTE compare against an omniscient oracle with perfect knowledge of future demands? (2) How does DOTE compare with state-of-the-art prediction-based TE [4, 22, 24, 36, 40], demand-oblivious TE [8, 32], and RL-based TE [54]? (3) Can DOTE support different TE objectives (e.g., MLU [8], maximum-multicommodity-flow [4, 22, 24])? (4) How long does DOTE take to train and to apply online at each solver activation? (5) How does DOTE perform under network faults and drift in traffic patterns?

⁷Traffic split (0.6, 0.3, 0.1) becomes (0, 0.75, 0.25) if the first path goes down.

	#Nodes	#Edges	Length	Granularity
Abilene	11	14	4.5months	5 min.
GEANT	23	37	4 months	15 min.
PWAN	O(100)	O(100)	O(1) months	minutes
PWAN _{DC}	O(10)	O(10)	O(1) months	minutes
GtsCe	149	193	Synthetic	
Cogentco	197	243		
KDL	754	895		

Table 1: Datasets used to evaluate DOTE

4.1 Methodology

Datasets: Data-driven TE is best evaluated on *real-world* datasets; we use the production topology and the traffic demands from GEANT [53], Abilene [3], and PWAN, a private WAN at Microsoft. Traffic traces were collected at a few-minute granularity over several months. We also use three topologies (GtsCe, Cogentco and KDL) from Topology Zoo [31] with synthetic traffic (generated using the gravity model [8, 45]). Table 4 lists the topology sizes and traffic demands. Nodes in these WAN topologies are datacenters, edge sites, or peering points. Traffic on PWAN includes both traffic between datacenters and traffic to/from end users. To better understand how DOTE performs for each traffic class, we consider a subset—PWAN_{DC}—which only contains large datacenters and the traffic between them. For each WAN, we use the earlier 75% of demand matrices (DMs) for training and the later 25% DMs as the test set.

Tunnel choices are k -shortest-paths, edge-disjoint paths, and SMORE trees. More specifically, we use (1) Yen’s algorithm for k -shortest-paths, with $k = 8$ per commodity (pair of nodes), (2) edge-disjoint shortest-paths where, for each commodity, we iteratively compute a shortest-path in the network and remove all links on that path from consideration until no more paths exist for that commodity, and (3) tunnels from SMORE [37] generated using Yates [36].

Comparables to DOTE include: (1) **Omniscient oracle**, which is an optimization with perfect knowledge of future demands and bounds the quality of *any* WAN TE scheme. (2) **Demand-prediction-based TE** methods [4, 22, 24, 36, 40], which are in production today [22, 24]. We consider a rich

WAN	Online Lat. (s)		Precomp. Lat. (s)		
	<i>DOTE</i>	LP	<i>DOTE</i>	COPE	Oblivious
Abilene	0.0005	0.02	1800	180	1
PWAN _{DC}	0.003	0.05	1200	7200	15
Geant	0.002	0.04	2400	10800	180
PWAN	0.2	1	36000	> 345600	~ 86400

Table 2: Comparing the online latency (to compute a TE configuration for a demand matrix) as well as the precomputation latency (to train models, to compute demand-oblivious configurations, etc.) for various TE schemes. 8 shortest paths are used per demand across all WANs and TE schemes.

collection of possible predictors of future demands: linear regression, ridge regression, random forest, DNN models, and autoregressive models (§C). (3) **RL-based WAN TE** [54], which leverages a neural network of the same size as *DOTE*'s (see below). (4) **Demand-oblivious TE** [8], which optimizes the *worst-case performance* over *all* traffic demands. (5) **SMORE** [37], which picks source-rooted trees for worst-case demands but adapts splitting ratios over the chosen trees based on *predicted* future demands. (6) **COPE** [55], which enhances demand-oblivious schemes by also optimizing over a set of predicted traffic demands.

Metrics: Our TE quality metric is the ratio between the value obtained by the evaluated TE scheme and the performance obtained by the omniscient oracle, which has perfect information about future traffic demands. We consider three TE objectives: minimize maximum link utilization (MLU) [8, 14, 27], maximize multicommodity flow [4, 22, 24, 37] and maximize concurrent-flow [11, 29]. Note that this ratio is ≥ 1 for MLU (because lower max-link utilization is better) and ≤ 1 for the other metrics (because carrying more flow is better). We refer to the relative gap from 1 as the *optimality gap*. We also measure the runtimes (latency) of the evaluated TE schemes on the same physical machine.⁸

DNN architecture: Unless otherwise specified, results for *DOTE* use five fully connected NN layers with 128 neurons each and $ReLU(x)$ activation except for the output layer which uses $Sigmoid(x)$. For different TE objectives, *DOTE* uses a similar architecture with small changes. We chose this architecture because it empirically outperformed other investigated architectures.

Infrastructure and code: We ran our experiments in cloud VMs and made use of cloud ML training systems. To enable further research, we have released our code at [2].

Fault model: To examine TE behaviour under network faults, we randomly bring down a certain number of links (e.g., 1 to 20 while ensuring network is not partitioned), and compare the performance of *DOTE* (see *DOTE*'s failure-recovery scheme at the end of §3.6) and alternatives with an omniscient oracle with perfect knowledge of both future failures and future traffic demands.

⁸VM with 8 vCPUs and 256GB RAM.

4.2 Comparing *DOTE* with Other TE Schemes

TE quality. Figure 4 compares *DOTE* with the other TE schemes described in §4.1, with the exception of SMORE (to be discussed in §4.3). The values plotted here are the maximum link utilization (MLU) normalized by that of the omniscient oracle with perfect knowledge of future demands. The figure shows results on four different topologies. Each candlestick shows the distribution of MLUs achieved on the various demand matrices with the boxes ranging from 25th to 75th percentile and the whiskers going from minimum to maximum value. The figure also plots values achieved at various other percentile values. We note a few findings.

- First, optimizing for *predicted* demands can lead to poor TE quality (see results for GEANT and PWAN). Note that the y axis is in log scale. A value of $y = 2$ indicates that the link most utilized by the TE scheme is twice as utilized as the most utilized link in the optimal solution (produced by the oracle). Optimizing with respect to predicted demands performs well only on Abilene and PWAN_{DC}, where the traffic demands are predictable. These results are for a linear-regression-based predictor that outperforms all other considered predictors on our real-world traffic datasets (see Appendix C).
- Next, we observe that the RL-based TE scheme [54] has extremely poor TE quality even on Abilene. This could be due to the infamous training complexity of RL.
- Third, demand-oblivious TE [8] results in somewhat decent TE quality on GEANT but not on any of the other WANs. This could be because optimizing *worst-case* performance across *all* possible demands fails to take advantage of the specific characteristics of real-world traffic demands.
- Fourth, COPE [55], which explicitly accounts for historically observed demands, significantly outperforms demand-oblivious TE. The key issue with COPE is its extremely high runtimes. Our analysis (see Table 2 and discussion below) suggests that COPE's applicability does not extend beyond topologies with tens of nodes.
- Finally, note that *DOTE* achieves TE quality that is almost always significantly better than the alternatives' and nearly as good as the omniscient oracle's. The difference in TE quality is especially stark at the higher percentiles. Relative to the compared TE schemes, *DOTE* offers MLU up to 25% better at the median and 170% better at the 99th percentile.

Runtimes. Table 2 presents a comparison of runtimes across TE schemes. The table presents the latency of applying each TE scheme to a new demand matrix and, wherever appropriate, the required precomputation time. Demand-oblivious schemes [8] and COPE [55] do not change the TE configuration online but involve very long precomputation latency and require very large memory. *DOTE* performs both precompu-

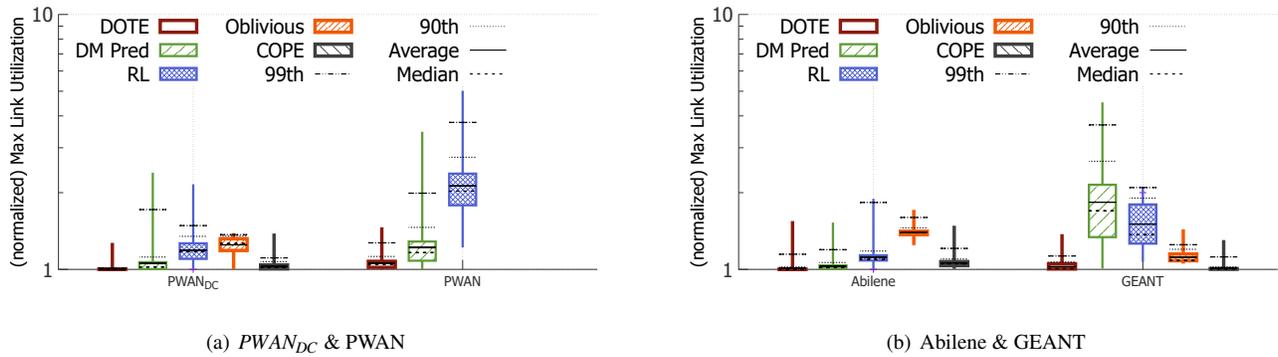

Figure 4: TE quality when aiming to minimize the maximum link utilization with 8 shortest paths per demand. Candlesticks depict results across hundreds of demands; the boxes are from the 25th to the 75th percentile, the whiskers range from min to max value, dashed lines capture other percentiles of interest. *DOTE* achieves much lower MLU compared to the alternatives.

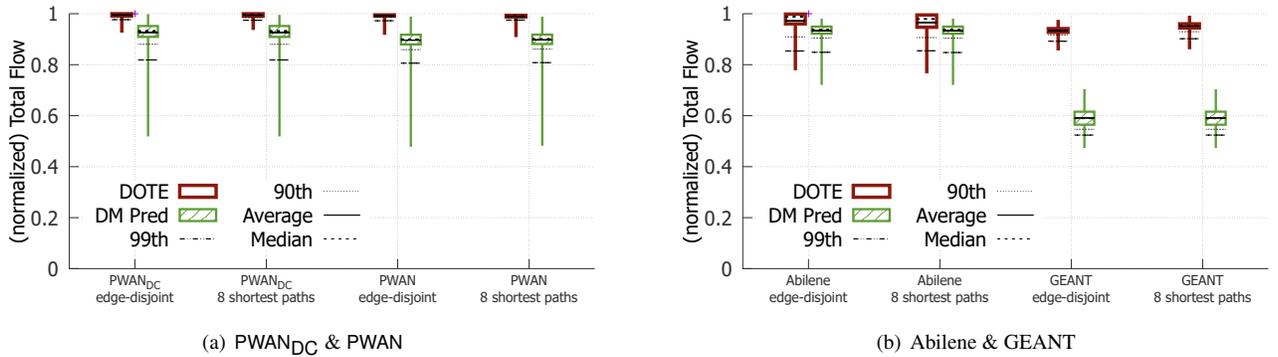

Figure 5: TE quality when aiming to maximize total flow with two different tunnel choices.

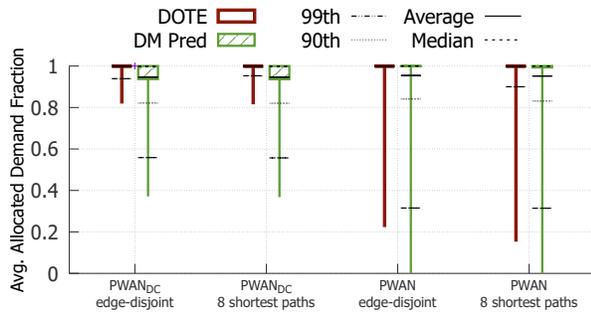

tation on historical demands (training the DNN) and online computation (invoking the DNN). SMORE’s online computation involves solving an LP to optimize over predicted demand matrices and so its latency is roughly as high as the LP’s latency in the table. To compute Racke’s routing trees, SMORE requires several hours on the larger topologies.

The table shows that *DOTE*’s inference time is faster than the latency of using LPs to optimize over one (predicted) DM. The LP’s latency is on par with results in recent studies [4, 40]. *DOTE*’s online computation is short because it is effectively a few matrix multiplications.⁹ LP computation latency increases super-linearly with the network size and prior work notes that solver times can exceed several minutes on networks with thousands of nodes and edges [4, 40]; *DOTE*’s inference latency on large WANs, such as KDL (see Table 4), is still within a few seconds. *DOTE*’s training time is less than 12 hours for PWAN and can be accelerated using standard methods (e.g., by parallelization, SIMD and other model training enhancements).

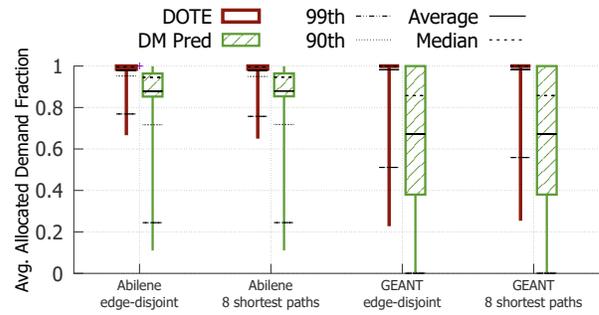

⁹Input is 12 demand matrices and output is splitting ratios or one double per tunnel per demand. On the large PWAN network, both the input and output are a few tens of MBs.

COPE’s precomputation latency is a few orders of magnitude higher than that of the demand-oblivious TE, which is, itself, a couple orders of magnitude higher than that of prediction-based TE. COPE also has much higher memory requirements (over 256GB on PWAN); in fact, on PWAN, COPE did not finish pre-computation even after four days on a 8-core VM with 256GB running Gurobi [19] vers. 9.1, and hence Figure 4 includes no results for COPE on PWAN. To understand COPE’s runtime complexity better, we ran it on WAN topologies from Topology Zoo [31] that are larger than GEANT and PWAN_{DC} but smaller than PWAN. On Janet-Backbone which has 29 nodes and 45 edges, COPE ran for 1.5 hours and on SurfNet (50 nodes, 68 edges), COPE did not finish even in 10 hours. These results suggest that COPE is inapplicable to large WANs.¹⁰

¹⁰Per Table 1 in [55], the previously published results on COPE are on much smaller topologies than considered here.

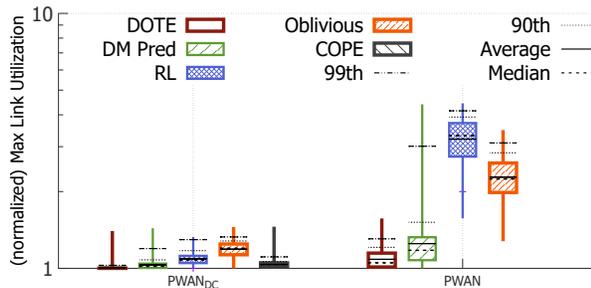

(a) $PWAN_{DC}$ & $PWAN$

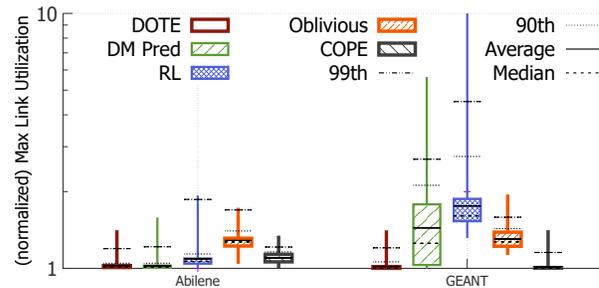

(b) Abilene & GEANT

Figure 6: TE quality when aiming to maximize the concurrent flow for two different tunnel choices. For each demand matrix, we compute the fraction of demand satisfied for each source and destination, and sort these values into a vector. Across many hundreds of demand matrices, the candlesticks plot the average over all such allocation vectors. Note: allocating more flow is better. The box in each candlestick is the 25th and 75th percentile (fractional allocation) and the whiskers go from min to max value.

4.3 Generalizing to Other TE Objectives and Tunnel Choices

Here, we present results for two additional TE objectives – maximizing multi-commodity-flow and maximizing concurrent

flow– as well as two other choices for tunnels.

Note that some of the compared alternatives to *DOTE*, namely, demand-oblivious TE [8] and COPE [55], do not readily apply to these TE objectives (as both build on results from oblivious routing theory that provide provable guarantees for MLU minimization), and it is not clear how to extend them to other objectives. Our evaluation of *DOTE* for these metrics is therefore restricted to benchmarking against the omniscient oracle and prediction-based TE.

Maximizing Total Flow: Figure 5 compares *DOTE* with prediction-based TE on all four WANs for two different tunnel choices when the TE objective is to carry as much total flow as possible while respecting capacity constraints. Observe that *DOTE* carries substantially more flow and closely approximates the TE quality of the omniscient oracle. As before, the gap between *DOTE* and prediction-based TE is larger on WANs where demands are less predictable (i.e., all WANs but Abilene) and at the higher percentiles. Generally, *DOTE* may be able to carry 10% to 20% more flow.

Maximizing Concurrent Flow: Figure 6 compares *DOTE* with the omniscient oracle and prediction-based TE when the TE objective is to maximize the minimum fraction of demand satisfied across all demands. Observe that *DOTE* fully allocates almost all of the demands (the upper candlesticks are at $y = 1$), whereas prediction-based TE allocates a smaller fraction of the demanded volume for many more demands.

Tunnel choice does not qualitatively change our results for TE performance; contrast Figure 7 and Figure 8 with Figure 4. Note that when using Racke’s routing trees (as in SMORE) prediction-based TE coincides with SMORE.

4.4 Coping with Network Failures

Figure 9 shows how *DOTE* performs, in terms of MLU, when different numbers of (randomly chosen) links fail in the PWAN topology. As noted in §3.6, *DOTE* assumes that source nodes (or tunnel heads [44]) identify tunnels that fail and re-balance traffic proportionally among the surviving tunnels. The figure compares *DOTE* with two variants of prediction-based TE: DM Pred. which, similar to *DOTE*, has no a priori knowledge of future traffic demands or the link faults, and FA DM Pred. which is identical to DM Pred. except that it is fault-aware, i.e., knows the links that will fail. Our quality metric is still normalized MLU except that we now normalize based on an omniscient oracle that has perfect knowledge of both future traffic demands and the failures.

Our results show that *DOTE* outperforms both demand-prediction-based TE (DM Pred.) and demand-prediction-based TE with oracle access to future failures (FA DM Pred.) for many concurrent link failures with different tunnel choices. We interpret this result as indicating that the error in demand predictions weights more heavily on attaining a good TE objective than the confusion induced by these link failures. Our results on other topologies (Abilene, GEANT, and PWAN_{DC}) and for the maximum-multicommodity-flow objective show a similar trend (Figure 13 and Figure 14).

4.5 Robustness to Traffic Noise and Drift

Robustness to unexpected traffic changes. To assess *DOTE*’s robustness to noisy traffic, we evaluate *DOTE* on the GEANT, Cogentco, and GtsCe WANs [31], where each demand in the realized DM is independently multiplied by a factor chosen uniformly at random from $[1 - \alpha, 1 + \alpha]$ for $\alpha \in \{0.1, 0.25, 0.35\}$. Our results (see §D) show that under such traffic perturbations, the distance, in terms of MLU, from the omniscient oracle remains low across all evaluated WANs (e.g., 2%, 2.9%, and 3.8% for $\alpha = 0.1, 0.25, 0.35$ for GEANT with edge-disjoint tunnels).

Robustness to natural traffic drift. We investigate to what extent the quality of *DOTE*’s TE configurations deteriorates when *DOTE* is not frequently retrained. We quantify the distance from the omniscient oracle, in terms of both MLU and

maximum-multicommodity-flow, of the average *weekly* value achieved by *DOTE* on the Abilene and GEANT WANs over 4 consecutive weeks (without retraining *DOTE*). See Table 3 and Table 4 in the Appendix. Our results show that while the distance from the optimum increases over time, in general, *DOTE* remains close to the optimum (within a few % on average) even weeks after the model is trained. This suggests that *DOTE* can provide high quality TE even if it was re-trained once every month. *DOTE*’s training time (see Table 2) allows for much more frequent retraining.

5 Limitations and Future Research

We believe that our investigation of direct optimization for WAN TE has but scratched the surface and outline below current limitations of our approach, as well as intriguing directions for future research.

Extending *DOTE* to support latency-sensitive traffic. To accommodate latency-sensitive traffic, the following strategy (similarly to [34]) could be employed: reserve shortest paths (tunnels) for such traffic and always schedule short/latency-sensitive traffic flows to these paths.

More expressive neural network architectures. Our realization of *DOTE* uses a relatively simple neural network that does not leverage knowledge of the WAN topology. Consequently, the neural network has to (implicitly) learn the network topology during training. Directly incorporating the WAN structure into *DOTE* using Graph Convolutional Networks [56] could potentially lead to faster training and/or better quality solutions.

Extending *DOTE* to incorporate data-driven tunnel selection. Our discussion of *DOTE* assumed an underlying tunnel-selection scheme. *DOTE* can be extended to support *data-driven* tunnel-selection by adding DNN output variables specifying a probability distribution over a finite set of candidate tunnels (e.g., shortest-path, edge disjoint, SMORE). At the beginning of each time epoch, the tunnels to be used in that time epoch would be chosen according to this probability distribution. *DOTE*’s optimality results extend to this setting. We defer a more thorough study of data-driven tunnel selection (e.g., not limited to a finite set of predetermined candidate tunnels) to future research.

Learning to contend with link failures. We described (§3.6) an approach for dealing with link failures in the data plane. An alternative is incorporating fault tolerance into the DNN training process by introducing random link failures.

6 Related Work

(WAN) TE. TE has been extensively studied [5, 7, 10, 11, 14, 16, 22, 24, 26–28, 37, 39, 57, 59] in a broad variety of settings, including legacy networks [13, 17], datacenter networks [6],

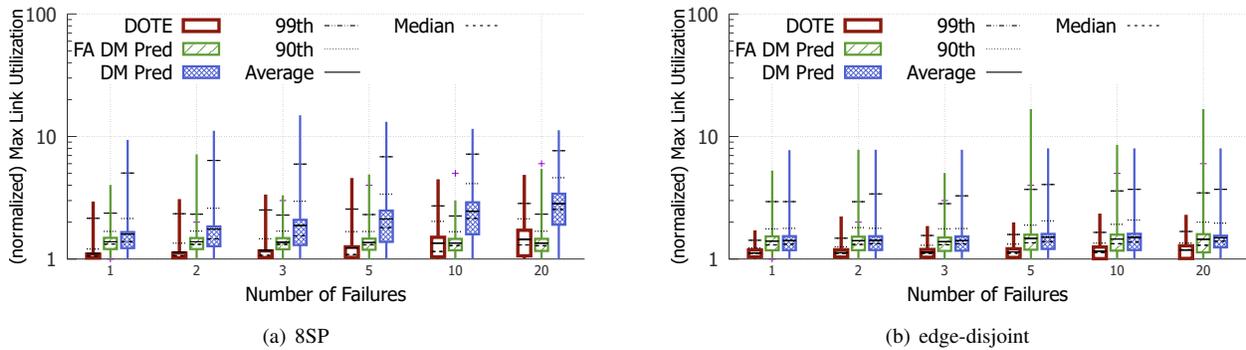

Figure 9: Coping with different numbers of random link failures on PWAN; the candlesticks show the distribution over 1700 different randomly chosen failure cases.

and backbone networks [27]. SDN-controlled WAN TE has also received extensive attention [11, 22, 24, 35, 37–39, 59].

TE via oblivious routing, COPE, and SMORE. Oblivious routing optimizes *worst-case MLU* across *all* possible DMs [8, 9, 42]. Since oblivious routing does not exploit *any* information about past traffic demands, it naturally yields sub-optimal solutions [8, 37]. COPE [55] optimizes *MLU* across a set of DMs spanned by previously observed DMs, while retaining a worst-case performance guarantee. Since COPE both extends oblivious routing *and* optimizes over *ranges* of demand matrices, its optimization phase is extremely time-consuming (§4.2). The key conceptual difference between *DOTE* and such “robust TE” schemes is in the goal of the pre-computation. Instead of emitting a single TE configuration that minimizes some cost function (specifically, *MLU*) over some predetermined set of DMs, *DOTE*’s objective is to identify a mapping from a vector of DMs from the recent past to the next TE configuration. *DOTE* thus achieves higher flexibility by being able to emit different TE configurations on a case-by-case basis, and is also able to pick up on temporal patterns in traffic demands. SMORE [37] employs Racke’s oblivious routing trees [42] to produce static tunnels that are robust to traffic uncertainty, with traffic splitting ratios still optimized with respect to the (inferred/predicted) future traffic demands. Thus, SMORE can be thought of as an instantiation of prediction-based TE.

Online TE [14, 15, 27], wherein traffic configurations (such as splitting ratios) adapt automatically and in short timescales to the observed demands is an enticing design point for TE, but is challenging to achieve. TexCP [27] requires WAN routers to offer novel explicit feedback, while MATE [14] relies on changes in end-to-end latency and hence takes much longer to react and converge and is also less stable [27]. Recently deployed TE schemes [22, 24] (see §2 and Figure 3) are simpler and easier to deploy because they replace such distributed, closed-loop, short-timescale control with centralized, open-loop and periodic adaptation. We view online TE as complementary to *DOTE*; *DOTE* could be used to *periodi-*

cally compute a TE configuration while online TE could be *continuously* used in between *DOTE* updates to tweak this TE configuration in response to changes in network conditions.

Reinforcement-learning-based TE. Demand-prediction-based and RL approaches to TE are contrasted in [54] in terms of *MLU* only on a small network (12 nodes and 32 edges) for *synthetic* traffic patterns and a model of hop-by-hop routing that does not capture routing along tunnels. Our theoretical and empirical results reveal that *DOTE*’s stochastic optimization scheme outperforms both demand-prediction-based and RL-based TE.

Some recent work on TE [4, 40] speeds up the multicommodity flow computations that underpin TE optimization by effectively breaking the large LPs into smaller problems that can be solved in parallel. However, these approaches still rely on predicted demand matrices (unlike *DOTE*). *DOTE* offers an alternate way to speed up TE: replacing the LP solver with invocations of a fairly small DNN. This has the potential to be innately more efficient.

7 Conclusion

We presented a new framework for WAN TE: data-driven end-to-end stochastic optimization using only historical information about traffic demands. Our theoretical and empirical results establish that this approach closely approximates the optimal TE configuration, significantly outperforming previously proposed TE schemes in terms of both solution quality and runtimes.

Appendix

A Predictability of WAN TE Traffic

Figure 10(a) plots the inter-data-center traffic demand between the pair of data centers with the highest average demand over the course of a week. Similarly, Figure 10(b) plots the normalized volume of customer-facing traffic for the pair of nodes with the highest average demand over the course of a week. Demands are shown at 5-minute granularity and are normalized by the peak demand. As shown in Figure 10(a), inter-data-center traffic demands exhibit very distinct diurnal and hourly patterns. Indeed, the figure also presents the predictions of a linear regression model trained on data from the 3 preceding weeks, which takes as input the traffic demands observed in the previous hour (at 5-minute granularity), and outputs the predicted traffic demand for the upcoming 5 minutes. In contrast, the predictions of a linear regressor for customer-facing traffic, as shown in Figure 10(b), are quite often far from the actual traffic demands.

B Analytical Results

B.1 Minimizing Max-Link Utilization

We next prove that, for an infinitely expressive TE function, i.e., when each history of DMs can be *independently* mapped to a TE configuration, and in the limit of infinite empirical data sampled from the underlying Markov process' stationary distribution, *DOTE* attains optimal performance. This establishes that our approach is *fundamentally sound*, and so high performance in practice can be achieved by acquiring sufficient empirical data and employing a sufficiently expressive decision model (e.g., a deep enough neural network).

For the sake of analysis, we make the following simplifying assumptions. We first assume that the set of possible history realizations, which we denote by \mathbf{H} , is finite. Let D_{max} denote an upper bound on the maximum traffic demand between a source-destination pair, c_{min} denote the minimum link capacity, and p_{max} denote the maximum number of tunnels interconnecting a source-destination pair. Note that any valid TE configuration specifies, for each source-destination pair, a point in the p_{max} -dimensional simplex (specifying its splitting ratios across at most p_{max} tunnels); let \mathbf{R} denote the space of valid TE configurations. Let $\pi : \mathbf{H} \rightarrow \mathbf{R}$ denote a mapping from history to TE configuration. π can be represented as a vector with $|\mathbf{H}| \times n^2 \times (p_{max} - 1)$ components.¹¹ Since each element in this vector is itself a vector in the p_{max} -dimensional simplex, we have that $\|\pi\| \leq \sqrt{|\mathbf{H}|n^2(p_{max} - 1)} \doteq B$, where $\|\cdot\|$ is the Euclidean norm. We make the following observation.

¹¹Note that we dropped the subscript θ in π , as in our analysis we consider the space of all possible TE configurations, and not a specific parametrization.

Proposition 1. *The loss function $\mathcal{L}(\pi(D_{t-1}, \dots, D_{t-H}), D_t)$ is convex in π and ρ -Lipschitz, with $\rho = D_{max}/c_{min}$.*

Proof. f_e is, by definition, linear in the traffic splitting ratios and so in π . Since the max is a convex function, we have that \mathcal{L} is convex in π . Similarly, since each component in $\frac{f_e}{c(e)}$ is D_{max}/c_{min} -Lipschitz, the maximum is also D_{max}/c_{min} -Lipschitz. \square

We now consider an idealized stochastic gradient descent (SGD) algorithm where at each iteration k we sample $D_t, D_{t-1}, \dots, D_{t-H}$ from the probability distributions $P(D_{t-1}, \dots, D_{t-H})$ and $P(D_t | D_{t-1}, \dots, D_{t-H})$, and update $\pi_{k+1} = Proj\{\pi_k - \eta v_k\}$, where $v_k \in \partial \mathcal{L}(\pi_k(D_{t-1}, \dots, D_{t-H}), D_t)$ denotes a subgradient of the objective function¹², and $Proj$ denotes a projection onto the simplex for each (s, d) pair. The final output after K iterations is $\bar{\pi} = \frac{1}{K} \sum_{k=1}^K \pi_k$.

The next theorem, based on Theorem 14.12 in [49], bounds the loss of this algorithm. Let $\bar{\mathcal{L}}(\pi) = \mathbb{E}[\mathcal{L}(\pi(D_{t-1}, \dots, D_{t-H}), D_t)]$ denote the expected loss of a TE function, and let $\pi^* \in \arg \min_{\pi} \bar{\mathcal{L}}(\pi)$ denote the optimal TE function.

Theorem 2. *For every $\epsilon > 0$, if SGD is run for $K \geq \frac{B^2 \rho^2}{\epsilon^2}$ iterations with $\eta = \sqrt{\frac{B^2}{\rho^2 K}}$, then the output of SGD satisfies*

$$\mathbb{E}[\bar{\mathcal{L}}(\bar{\pi})] \leq \bar{\mathcal{L}}(\pi^*) + \epsilon,$$

where the expectation is w.r.t. the sampling by the algorithm.

Theorem 2 shows that without function approximation (the TE function space spans *all* possible mappings from history to TE configuration), and with infinite data (the algorithm continuously samples from the true demand distribution), SGD converges to the optimal TE function with arbitrary precision. In practice, we relax both assumptions. In *DOTE* we sample from a large, but *finite*, dataset of historical demands, and use a *parametric* model (specifically, a neural network) to map from an *infinite* set of possible histories to valid TE configurations. Our empirical results show that, with enough data and a deep enough neural network, the approximate TE function *DOTE* learns is still very close to optimal.

B.2 Maximum-Multicommodity-Flow and Maximum-Concurrent-Flow

We begin by stating a general convergence result for quasi-convex functions that satisfy certain assumptions. We then proceed to show that both maximum-multicommodity-flow and maximum-concurrent-flow indeed satisfy these assumptions, implying their convergence.

¹²The objective is not necessarily differentiable everywhere because of the max, but the subgradient exists for every π .

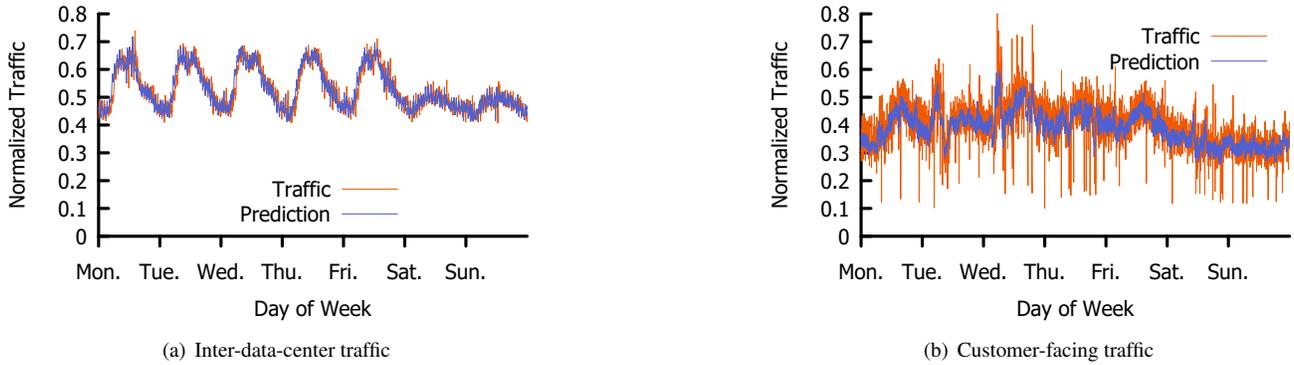

Figure 10: Inter-data-center traffic and customer-facing traffic over the course of a week, along with the predictions of a linear regression model for the time-series.

B.2.1 General results

We begin by providing an analysis of stochastic quasi-convex optimization, under general assumptions. In the next section, we will show that maximum-multicommodity-flow and maximum-concurrent-flow are special cases of this setting.¹³ Our analysis builds on two studies – the analysis of stochastic normalized subgradient of [20], which is for smooth and unconstrained problems, and the study of [33], which considered non-smooth quasi-convex optimization.

A quasi-convex function $f(x)$ satisfies that its level sets, $L(f; \alpha) = \{x | f(x) \leq \alpha\}$, are convex sets for all α .

We first define a normalized subgradient in the context of quasi-convex functions, following [33]. The normal cone to a convex set X at point x is defined by $N(X, x) = \{q \in \mathbb{R}^n | \langle q, y - x \rangle \leq 0 \quad \forall y \in X\}$. The set of subgradients at a point x are given by $N(L(f; x), x)$. The set of normalized subgradients, $Q(f; x)$, at a point x , are given by $Q(f; x) = S(0, 1) \cap N(L(f; x), x)$, where $S(0, 1)$ is the n -dimensional sphere of radius 1. These are directions of ascent – normalized vectors such that taking an infinitely small step in their direction is guaranteed to not decrease the function.

In the following, we consider a general stochastic optimization problem:

$$\min_{x \in X} \mathbb{E}_{D \sim P(D)} [f(x, D)], \quad (1)$$

where f is quasi-convex in x for every D .

We will further assume the following. Let $\mathbb{B}(z, r)$ denote the n -dimensional ball centered on z with radius r .

Assumption 1. *Set X is convex and bounded by $\mathbb{B}(0, \bar{B})$. The function f is bounded by B . It is also G -Lipschitz and quasi-convex in x for every D . Furthermore, $Q(\frac{1}{M} \sum_{i=1}^M f(x, D_i); x) \neq \emptyset$ for any $x \notin$*

¹³While we present results for quasi-convexity, the extension of these results to quasi-concave problems is immediate.

$\arg \min_y \frac{1}{M} \sum_{i=1}^M f(y, D_i)$, and for every D_1, \dots, D_M , we have that $\frac{1}{M} \sum_{i=1}^M f(x, D_i)$ is quasi-convex in x .

Note that the last requirement in Assumption 1 is not immediate, as the sum of quasi-convex functions is not necessarily quasi-convex.

The stochastic normalized subgradient method we consider works as follows [20]. At each iteration k we sample a minibatch $\{D_i\}_{i=1}^b \sim P(D)$ and define $f_k = \frac{1}{b} \sum_{i=1}^b f(x, D_i)$. We then update $x_{k+1} = \text{Proj}\{x_k - \eta v_k\}$, where $v_k \in Q(f_k; x_k)$ denotes a subgradient of the minibatch, and Proj denotes a projection onto the set X . The final output after K iterations is $\bar{x}_K = \arg \min_{x_1, \dots, x_K} f_k(x_k)$.

The analysis in [20] bounds the error of the normalized subgradient method, for smooth and unconstrained functions. We next adapt it to our setting.

The next definition adapts a central definition from [20] to our non-smooth setting.

Definition 1. (SLQC) *Let $x, x^* \in \mathbb{R}^n$, $\kappa, \varepsilon > 0$. We say that f is $(\varepsilon, \kappa, x^*)$ -strictly-locally-quasi-convex (SLQC) in x if at least one of the following applies. (1) $f(x) - f(x^*) \leq \varepsilon$. (2) $Q(f; x) \neq \emptyset$ and for any $\Delta \in Q(f; x)$, and every $y \in \mathbb{B}(x^*, \frac{\varepsilon}{\kappa})$, it holds that $\langle \Delta, y - x \rangle \leq 0$.*

We next show that the Lipschitz and quasi-convex properties in Assumption 1 suffice to establish SLQC.

Lemma 1. *Let f satisfy Assumption 1. Fix D , and let $x^* \in \arg \min_{x \in X} f(x; D)$. Then f is (ε, G, x^*) -SLQC for all $x \in X$.*

Proof. Assume $f(x; D) - f(x^*; D) > \varepsilon$. Let Z denote the $f(x; D)$ -level set of $f(x; D)$. Let ∂Z be the boundary of Z . By definition of the level set, for every $z \in \partial Z$, $f(z) - f(x^*) > \varepsilon$. From the Lipschitz property then, for every $z \in \partial Z$ we must have $\|z - x^*\| \geq \frac{\varepsilon}{G}$. Since Z is convex, we therefore have that $\mathbb{B}(x^*, \frac{\varepsilon}{G}) \subset Z$. From Assumption 1, $Q(f; x) \neq \emptyset$, and from the definition of $Q(f; x)$, we have that for every $y \in \mathbb{B}(x^*, \frac{\varepsilon}{G})$, if $\Delta \in Q(f; x)$ then $\langle \Delta, y - x \rangle \leq 0$. \square

We next show that with high probability, the subgradient of each minibatch is a descent direction for the expected objective in (1).

Lemma 2. *Let Assumption 1 hold, and let $x^* \in \arg \min_{x \in X} \mathbb{E}_{D \sim P(D)} [f(x, D)]$. Assume that the minibatch size satisfies $b = O\left(\frac{8nB^2 \log(G\bar{B}/\delta)}{\varepsilon^2}\right)$. Then, with probability at least $1 - \delta$, we have that the minibatch average $f_k = \frac{1}{b} \sum_{i=1}^b f(x, D_i)$ is $(\varepsilon, 2G, x^*)$ -SLQC in x_k .*

Proof. Let

$$\xi = \frac{1}{b} \sum_{i=1}^b f(x^*, D_i) - \mathbb{E}_{D \sim P(D)} [f(x^*, D)].$$

From Hoeffding's inequality, we have that

$$P(|\xi| \geq t) \leq 2 \exp\left(-\frac{2bt^2}{B^2}\right).$$

Thus, if $b \geq \frac{B^2 \log(2/\delta)}{2t^2}$ we have that with probability $1 - \delta$, $|\xi| < t$.

Let $x_k^* \in \arg \min_{x \in X} \frac{1}{b} \sum_{i=1}^b f(x, D_i)$. Let

$$\xi' = \frac{1}{b} \sum_{i=1}^b f(x_k^*, D_i) - \mathbb{E}_{D \sim P(D)} [f(x_k^*, D)].$$

Then, using a covering number argument [50], we have that for $b \geq \frac{nB^2 \log(G\bar{B}/\delta)}{2t^2}$, with probability $1 - \delta$, $|\xi'| < t$. We have that

$$\frac{1}{b} \sum_{i=1}^b f(x_k^*, D_i) \leq \frac{1}{b} \sum_{i=1}^b f(x^*, D_i) \leq \mathbb{E}_{D \sim P(D)} [f(x^*, D)] + \xi,$$

and

$$\mathbb{E}_{D \sim P(D)} [f(x^*, D)] - \xi' \leq \mathbb{E}_{D \sim P(D)} [f(x_k^*, D)] - \xi' \leq \frac{1}{b} \sum_{i=1}^b f(x_k^*, D_i).$$

Therefore,

$$\frac{1}{b} \sum_{i=1}^b f(x^*, D_i) - \frac{1}{b} \sum_{i=1}^b f(x_k^*, D_i) \leq \xi + \xi'.$$

Now, similarly to the proof of Lemma 1, assume that $\frac{1}{b} \sum_{i=1}^b f(x_k, D_i) - \frac{1}{b} \sum_{i=1}^b f(x_k^*, D_i) > \varepsilon$. We choose $b = O\left(\frac{8nB^2 \log(G\bar{B}/\delta)}{\varepsilon^2}\right)$ such that with probability $1 - \delta$, $\xi + \xi' \leq \varepsilon/2$.

We therefore have:

$$\frac{1}{b} \sum_{i=1}^b f(x_k, D_i) - \frac{1}{b} \sum_{i=1}^b f(x^*, D_i) > \varepsilon - (\xi + \xi') \geq \frac{\varepsilon}{2}.$$

For simplicity, we denote $\bar{f}(x) = \frac{1}{b} \sum_{i=1}^b f(x, D_i)$. Note that \bar{f} is quasi-convex, by Assumption 1. Let Z denote the $\bar{f}(x_k)$ -level set of $\bar{f}(x)$. Let ∂Z be the boundary of Z . By definition

of the level set, for every $z \in \partial Z$, $\bar{f}(z) - \bar{f}(x^*) > \varepsilon/2$. From the Lipschitz property then, for every $z \in \partial Z$ we must have $\|z - x^*\| \geq \frac{\varepsilon}{2G}$. Since Z is convex, we therefore have that $\mathbb{B}(x^*, \frac{\varepsilon}{2G}) \subset Z$. From Assumption 1, $Q(\bar{f}; x) \neq \emptyset$, and from the definition of $Q(\bar{f}; x)$, we have that for every $y \in \mathbb{B}(x^*, \frac{\varepsilon}{2G})$, if $\Delta \in Q(\bar{f}; x)$ then $\langle \Delta, y - x \rangle \leq 0$. \square

We are finally ready to present the converge result.

Theorem 3. *Let Assumption 1 hold. Suppose we run the stochastic normalized subgradient method for $K \geq \frac{4G^2 \|x_1 - x^*\|^2}{\varepsilon^2}$ iterations, $\eta = \varepsilon/2G$, and the minibatch size satisfies $b = O\left(\frac{8nB^2 \log(KG\bar{B}/\delta)}{\varepsilon^2}\right)$. Then with probability $1 - 2\delta$, we have that $f(\bar{x}_K) - f(x^*) \leq 3\varepsilon$.*

Proof. This is a direct application of Theorem 5.1 of [20], where we used Lemma 2 to guarantee that at each iteration the minibatch is SLQC, as required in [20]. We note that by our Definition 1, the proof in [20] holds without change to the non-smooth setting. The projection onto the set X requires a straightforward modification to the proof of [20], where the first equality in their proof of Theorem 4.1 should be a \leq . The rest of the proofs remain unchanged. \square

B.2.2 Results for Maximum-Multicommodity-Flow

We formally define the problem as follows.

for each tunnel T , let x_T denote the flow on that tunnel, and let $x_e = \sum_{T: e \in T} x_T$, for each edge e , denote the total flow on edge e . We define

$$\gamma = \max \left(\max_e \frac{x_e}{C_e}, 1 \right),$$

and normalize the flows by γ , yielding normalized flows on a tunnel,

$$y_T = \frac{x_T}{\gamma},$$

and correspondingly, total normalized flows from source s to target t , $y_{s,t} = \sum_{T \in P_{st}} y_T$. Let $x = \{x_T\}$ denote our decision variables. Given a demand matrix D , the Max-MCF objective is

$$f_{MMCF}(x, D) = \sum_{s,t} \min(D_{s,t}, y_{s,t}).$$

We next show that f_{MMCF} is Lipschitz.

Lemma 3. *For any tunnel T and $x \geq 0$, $\frac{x_T}{\gamma(x)} \leq C_{max}$.*

Proof. Let $e \in T$, then by the definitions of $\gamma(x)$ and x_e , $\gamma(x) \geq \frac{x_e}{C_e} \geq \frac{x_T}{C_{max}}$. \square

Lemma 4. *$f_T(x) = \frac{x_T}{\gamma(x)}$ is Lipschitz on \mathbb{R}_+^n , and its Lipschitz constant is at most $K = 2 \cdot \frac{C_{max}}{C_{min}}$.*

Proof. Assume, without loss of generality, that $f(x) \geq f(y)$.
Case 1: $\gamma(y) = 1$

$$\begin{aligned}
& |f(x) - f(y)| \\
&= f(x) - f(y) \\
&= \frac{x_T}{\gamma(x)} - \frac{y_T}{\gamma(y)} \\
&= \frac{x_T}{\gamma(x)} - y_T \\
&\leq x_T - y_T \\
&\leq |x_T - y_T| \\
&\leq \|x - y\|_1 \\
&\leq 2 \cdot \frac{C_{max}}{C_{min}} \cdot \|x - y\|_1,
\end{aligned}$$

where the first inequality is since $\gamma(x) \geq 1$, and the third inequality is by the definition of $\|x\|_1$.

Case 2: $\gamma(y) = \frac{y_{e_0}}{C_{e_0}} > 1$, for some edge e_0 .

$$\begin{aligned}
& |f(x) - f(y)| \\
&= f(x) - f(y) \\
&= \frac{x_T}{\gamma(x)} - \frac{y_T}{\gamma(y)} \\
&= \frac{x_T}{\gamma(x)} - \frac{y_T}{\gamma(x)} + \frac{y_T}{\gamma(x)} - \frac{y_T}{\gamma(y)} \\
&= \frac{1}{\gamma(x)} \cdot (x_T - y_T) + \frac{y_T}{\gamma(y)} \cdot \frac{1}{\gamma(x)} (\gamma(y) - \gamma(x)) \\
&\leq \frac{1}{\gamma(x)} \cdot (x_T - y_T) + \frac{y_T}{\gamma(y)} \cdot \frac{1}{\gamma(x)} \left(\frac{y_{e_0}}{C_{e_0}} - \frac{x_{e_0}}{C_{e_0}} \right) \\
&\leq \left| \frac{1}{\gamma(x)} \cdot (x_T - y_T) + \frac{y_T}{\gamma(y)} \cdot \frac{1}{\gamma(x)} \left(\frac{y_{e_0}}{C_{e_0}} - \frac{x_{e_0}}{C_{e_0}} \right) \right| \\
&\leq \frac{1}{\gamma(x)} \cdot |x_T - y_T| + \frac{y_T}{\gamma(y)} \cdot \frac{1}{\gamma(x)} \left| \frac{y_{e_0}}{C_{e_0}} - \frac{x_{e_0}}{C_{e_0}} \right| \\
&\leq |x_T - y_T| + \frac{C_{max}}{C_{min}} \cdot |y_{e_0} - x_{e_0}| \\
&\leq 2 \cdot \frac{C_{max}}{C_{min}} \cdot \|x - y\|_1,
\end{aligned}$$

where the first inequality is since $\gamma(y) = \frac{y_{e_0}}{C_{e_0}}$, $\gamma(x) \geq \frac{x_{e_0}}{C_{e_0}}$, $y_T \geq 0$, and $\gamma > 0$, the third inequality is since $|a + b| \leq |a| + |b|$, the fourth inequality is by Lemma 3 and since $\gamma(x) \geq 1$, and the last inequality is by the definitions of $\|x\|_1$, x_e and since $|a + b| \leq |a| + |b|$. \square

Proposition 2. *The function f_{MMCF} is Lipschitz, and its Lipschitz constant is at most $\sum_{s,t} \sum_{p \in P_{st}} 2 \cdot \frac{C_{max}}{C_{min}}$.*

Proof. By Lemma 4 and as a sum and minimum of Lipschitz functions. \square

We next state two lemmas that we will use in our analysis.

Lemma 5. *For any $a, b \geq 0$, $c, d > 0$ and $\lambda \in [0, 1]$, we have that $\min\left(\frac{a}{c}, \frac{b}{d}\right) \leq \frac{\lambda a + (1-\lambda)b}{\lambda c + (1-\lambda)d}$.*

Proof. Let $f(\lambda) = \frac{\lambda a + (1-\lambda)b}{\lambda c + (1-\lambda)d}$. Then,

$$\begin{aligned}
f'(\lambda) &= \frac{(a-b)(\lambda c + (1-\lambda)d) - (c-d)(\lambda a + (1-\lambda)b)}{(\lambda c + (1-\lambda)d)^2} \\
&= \frac{ad - bc}{(\lambda c + (1-\lambda)d)^2}.
\end{aligned}$$

Also, $f(0) = \frac{b}{d}$, $f(1) = \frac{a}{c}$, and $f'(\lambda)$ has a fixed sign for any $\lambda \in [0, 1]$. Therefore, $f(\lambda) \geq \min\left(\frac{a}{c}, \frac{b}{d}\right)$. \square

Lemma 6. *Let $x = \{x_T\}$, $x' = \{x'_T\}$, and $\lambda \in [0, 1]$. Let $x'' = \{\lambda x_T + (1-\lambda)x'_T\}$, and let γ , γ' and γ'' be the respective normalization constants. Then $\gamma'' \leq \lambda\gamma + (1-\lambda)\gamma'$.*

Proof. We have that

$$\begin{aligned}
\gamma'' &= \max\left(\max_e \frac{x''_e}{C_e}, 1\right) \\
&= \max\left(\max_e \frac{\lambda x_e + (1-\lambda)x'_e}{C_e}, 1\right) \\
&\leq \max\left(\max_e \frac{\lambda x_e}{C_e}, \lambda\right) + \max\left(\max_e \frac{(1-\lambda)x'_e}{C_e}, 1-\lambda\right) \\
&= \lambda \max\left(\max_e \frac{x_e}{C_e}, 1\right) + (1-\lambda) \max\left(\max_e \frac{x'_e}{C_e}, 1\right) \\
&= \lambda\gamma + (1-\lambda)\gamma'.
\end{aligned}$$

\square

We next show that Max-MCF satisfies Assumption 1.

Proposition 3. *The function f_{MMCF} is Lipschitz and bounded. Its maximum is obtained inside a convex set X . Furthermore, for every D^1, \dots, D^M , we have that $\frac{1}{M} \sum_{i=1}^M f(x, D^i)$ is quasi-concave in x .*

Proof. By definition, $x_T \geq 0$ for all T . Let $C_{max} = \max_e C_e$, and consider T -dimensional hypercube $X = [0, C_{max}]^T$. By definition, for every $x \geq 0$ that is outside X , there is an $x' \in X$ with an equivalent objective value. To see this, let γ the normalizing constant for x , and set $x' = x/\gamma$. Then,

$$x'_T = \frac{x_T}{\max\left(\max_e \frac{x_e}{C_e}, 1\right)} \leq \frac{x_T}{\max\left(\max_e \frac{x_e}{C_{max}}, 1\right)} \leq \frac{x_T}{C_{max}} = C_{max}.$$

But the normalizing factor for x' is 1, so x and x' have the same objective value.

Clearly, f_{MMCF} is bounded by $\sum_{s,t} \sum_{T:e \in T} C_{max}$.

The function is Lipschitz by proposition 2.

Let $\tilde{f}_{MMCF}(x) = \frac{1}{M} \sum_{i=1}^M f_{MMCF}(x, D^i)$. We shall now show that for any $x, x' \in X$, and $\lambda \in [0, 1]$, $\tilde{f}_{MMCF}(\lambda x + (1-\lambda)x') \geq$

$\min\{\bar{f}_{MMCF}(x), \bar{f}_{MMCF}(x')\}$, proving that \bar{f}_{MMCF} is quasi-concave. We denote by γ' and y' the respective normalization constant and normalized flows corresponding to x' . We also denote $x'' = \lambda x + (1-\lambda)x'$, and let γ'' and y'' denote its corresponding normalization constant and normalized flows, respectively.

$$\begin{aligned}
& \min\left(\sum_{i=1}^M \sum_{s,t} \min(D_{s,t}^i, y_{s,t}), \sum_{i=1}^M \sum_{s,t} \min(D_{s,t}^i, y'_{s,t})\right) \\
&= \min\left(\sum_{i=1}^M \sum_{s,t} \min(D_{s,t}^i, \sum_{T \in P_{st}} \frac{x_T}{\gamma}), \sum_{i=1}^M \sum_{s,t} \min(D_{s,t}^i, \sum_{T \in P_{st}} \frac{x'_T}{\gamma'})\right) \\
&= \min\left(\frac{1}{\gamma} \sum_{i=1}^M \sum_{s,t} \min(\gamma D_{s,t}^i, \sum_{T \in P_{st}} x_T), \frac{1}{\gamma'} \sum_{i=1}^M \sum_{s,t} \min(\gamma' D_{s,t}^i, \sum_{T \in P_{st}} x'_T)\right) \\
&\leq \frac{\lambda \sum_{i=1}^M \sum_{s,t} \min(\gamma D_{s,t}^i, \sum_{T \in P_{st}} x_T) + (1-\lambda) \sum_{i=1}^M \sum_{s,t} \min(\gamma' D_{s,t}^i, \sum_{T \in P_{st}} x'_T)}{\lambda\gamma + (1-\lambda)\gamma'} \\
&= \frac{\sum_{i=1}^M \sum_{s,t} \min(\lambda\gamma D_{s,t}^i, \lambda \sum_{T \in P_{st}} x_T) + \min((1-\lambda)\gamma' D_{s,t}^i, (1-\lambda) \sum_{T \in P_{st}} x'_T)}{\lambda\gamma + (1-\lambda)\gamma'} \\
&\leq \frac{1}{\lambda\gamma + (1-\lambda)\gamma'} \sum_{i=1}^M \sum_{s,t} \min\left(\lambda\gamma D_{s,t}^i + (1-\lambda)\gamma' D_{s,t}^i, \right. \\
&\quad \left. \lambda \sum_{T \in P_{st}} x_T + (1-\lambda) \sum_{T \in P_{st}} x'_T\right) \\
&= \sum_{i=1}^M \sum_{s,t} \min\left(D_{s,t}^i, \frac{1}{\lambda\gamma + (1-\lambda)\gamma'} \sum_{T \in P_{st}} (\lambda x_T + (1-\lambda)x'_T)\right) \\
&\leq \sum_{i=1}^M \sum_{s,t} \min\left(D_{s,t}^i, \sum_{T \in P_{st}} \frac{x''_T}{\gamma''}\right) \\
&= \sum_{i=1}^M \sum_{s,t} \min(D_{s,t}^i, y''_{s,t}),
\end{aligned}$$

where the first inequality is by Lemma 5, the second inequality is since $\min(a, b) + \min(c, d) \leq \min(a + c, b + d)$, and the third inequality is by Lemma 6. \square

Lemma 7. Let $x \notin \arg \max_y f(y)$, $x^* \in \arg \max_y f(y)$, and let γ, γ^* be the respective normalization constants. If $f(x + \lambda(x^* - x)) \geq \frac{\lambda\gamma^* f(x^*) + (1-\lambda)\gamma f(x)}{\lambda\gamma^* + (1-\lambda)\gamma}$ for any $\lambda \in [0, 1]$, then $Q(f; x) \neq \emptyset$.

Proof. The directional derivative of f along $x^* - x$ at x :

$$\begin{aligned}
\nabla_{x^*-x} f(x) &= \lim_{h \rightarrow 0^+} \frac{f(x + h(x^* - x)) - f(x)}{h \|x^* - x\|} \\
&\geq \lim_{h \rightarrow 0^+} \frac{\frac{h\gamma^* f(x^*) + (1-h)\gamma f(x)}{h\gamma^* + (1-h)\gamma} - f(x)}{h \|x^* - x\|} \\
&= \lim_{h \rightarrow 0^+} \frac{\frac{h\gamma^*}{h\gamma^* + (1-h)\gamma} (f(x^*) - f(x))}{h \|x^* - x\|} \\
&\geq \lim_{h \rightarrow 0^+} \frac{\frac{\gamma^*}{\max(\gamma^*, \gamma)} (f(x^*) - f(x))}{\|x^* - x\|} > 0.
\end{aligned}$$

Therefore, since $L(f; f(x))$ is convex, $-\frac{x^* - x}{\|x^* - x\|} \in Q(f; x)$. \square

Lemma 8. Let $x = \{x_T\}$, $x' = \{x'_T\}$, and $\lambda \in [0, 1]$. Let $x'' = \{\lambda x_T + (1-\lambda)x'_T\}$, and let γ, γ' and γ'' be the respective normalization constants. Then, $\bar{f}_{MMCF}(x'') \geq \frac{\lambda\gamma \bar{f}_{MMCF}(x) + (1-\lambda)\gamma' \bar{f}_{MMCF}(x')}{\lambda\gamma + (1-\lambda)\gamma'}$.

Proof.

$$\begin{aligned}
\bar{f}_{MMCF}(x'') &= \sum_{i=1}^M \sum_{s,t} \min(D_{s,t}^i, \sum_{T \in P_{st}} \frac{x''_T}{\gamma''}) \\
&\geq \sum_{i=1}^M \sum_{s,t} \min\left(D_{s,t}^i, \frac{1}{\lambda\gamma + (1-\lambda)\gamma'} \sum_{T \in P_{st}} (\lambda x_T + (1-\lambda)x'_T)\right) \\
&= \frac{\sum_{i=1}^M \sum_{s,t} \min\left(\lambda\gamma D_{s,t}^i + (1-\lambda)\gamma' D_{s,t}^i, \lambda\gamma \sum_{T \in P_{st}} \frac{x_T}{\gamma} + (1-\lambda)\gamma' \sum_{T \in P_{st}} \frac{x'_T}{\gamma'}\right)}{\lambda\gamma + (1-\lambda)\gamma'} \\
&\geq \frac{\sum_{i=1}^M \sum_{s,t} \left(\min(\lambda\gamma D_{s,t}^i, \lambda\gamma \sum_{T \in P_{st}} \frac{x_T}{\gamma}) + \min((1-\lambda)\gamma' D_{s,t}^i, (1-\lambda)\gamma' \sum_{T \in P_{st}} \frac{x'_T}{\gamma'})\right)}{\lambda\gamma + (1-\lambda)\gamma'} \\
&= \frac{\lambda\gamma \bar{f}_{MMCF}(x) + (1-\lambda)\gamma' \bar{f}_{MMCF}(x')}{\lambda\gamma + (1-\lambda)\gamma'},
\end{aligned}$$

where the first inequality is by Lemma 6 and the second inequality is since $\min(a, b) + \min(c, d) \leq \min(a + c, b + d)$. \square

Proposition 4. $Q(\bar{f}_{MMCF}, x) \neq \emptyset$ for any $x \notin \arg \max_y \bar{f}_{MMCF}(y)$

Proof. By Lemma 8 where $x = x^*$, $x' = x$, and by Lemma 7. \square

Since Assumption 1 holds, Theorem 3 guarantees that the stochastic normalized subgradient method will converge to an optimal solution of the Max-MCF objective.

B.2.3 Results for Maximum-Concurrent-Flow

Given a demand matrix D , the Max-Concurrent-Flow objective is

$$f_{MCONC}(x, D) = \min(\{\frac{y_{s,t}}{D_{s,t}}\}_{s,t \in V, D_{s,t} > 0} \cup \{1\}).$$

We assume that when $D_{s,t} \neq 0$, there is a minimal value ε for $D_{s,t}$, corresponding, e.g., to a single packet. We next show that Max-Concurrent-Flow satisfies Assumption 1.

Proposition 5. The function f_{MCONC} is Lipschitz, and its Lipschitz constant is at most $\max_{s,t} \left(\sum_{p \in P_{st}} \frac{2 \cdot C_{\max}}{\varepsilon \cdot C_{\min}}\right)$.

Proof. By Lemma 4 and as a sum, minimum and multiplication by a constant of Lipschitz functions. \square

Proposition 6. *The function f_{MCONC} is Lipschitz and bounded. Its maximum is obtained inside a convex set X . Furthermore, for every D^1, \dots, D^M , we have that $\frac{1}{M} \sum_{i=1}^M f(x, D^i)$ is quasi-concave in x*

Proof. The claims in the beginning of proposition 3 hold for f_{MCONC} , and therefore its maximum is obtained inside a convex set.

Clearly, f_{MCONC} is bounded by 1.

The function is Lipschitz by proposition 5.

Let $\bar{f}_{MCONC}(x) = \frac{1}{M} \sum_{i=1}^M f_{MCONC}(x, D^i)$. We shall now show that for any $x, x' \in X$, and $\lambda \in [0, 1]$, $\bar{f}_{MCONC}(\lambda x + (1 - \lambda)x') \geq \min\{\bar{f}_{MCONC}(x), \bar{f}_{MCONC}(x')\}$, proving that \bar{f}_{MCONC} is quasi-concave. We denote by γ and y the respective normalization constant and normalized flows corresponding to x . We also denote $x'' = \lambda x + (1 - \lambda)x'$, and let γ' and y'' denote its corresponding normalization constant and normalized flows, respectively.

$$\begin{aligned}
& \min \left(\sum_{i=1}^M \min \left(\left\{ \frac{y_{s,t}}{D_{s,t}^i} \right\} \cup \{1\} \right), \sum_{i=1}^M \min \left(\left\{ \frac{y'_{s,t}}{D_{s,t}^i} \right\} \cup \{1\} \right) \right) \\
&= \min \left(\sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} x_T}{D_{s,t}^i} \right\} \cup \{1\} \right), \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} x'_T}{D_{s,t}^i} \right\} \cup \{1\} \right) \right) \\
&= \min \left(\frac{1}{\gamma} \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} x_T}{D_{s,t}^i} \right\} \cup \{\gamma\} \right), \frac{1}{\gamma'} \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} x'_T}{D_{s,t}^i} \right\} \cup \{\gamma'\} \right) \right) \\
&\leq \frac{\lambda \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} x_T}{D_{s,t}^i} \right\} \cup \{\gamma\} \right) + (1 - \lambda) \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} x'_T}{D_{s,t}^i} \right\} \cup \{\gamma'\} \right)}{\lambda\gamma + (1 - \lambda)\gamma'} \\
&= \frac{\sum_{i=1}^M \left(\min \left(\left\{ \frac{\sum_{T \in P_{st}} \lambda x_T}{D_{s,t}^i} \right\} \cup \{\lambda\gamma\} \right) + \min \left(\left\{ \frac{\sum_{T \in P_{st}} (1 - \lambda)x'_T}{D_{s,t}^i} \right\} \cup \{(1 - \lambda)\gamma'\} \right) \right)}{\lambda\gamma + (1 - \lambda)\gamma'} \\
&\leq \frac{\sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} \lambda x_T + \sum_{T \in P_{st}} (1 - \lambda)x'_T}{D_{s,t}^i} \right\} \cup \{\lambda\gamma + (1 - \lambda)\gamma'\} \right)}{\lambda\gamma + (1 - \lambda)\gamma'} \\
&= \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} \frac{\lambda x_T + (1 - \lambda)x'_T}{\lambda\gamma + (1 - \lambda)\gamma'}}{D_{s,t}^i} \right\} \cup \{1\} \right) \\
&\leq \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} \frac{x''_T}{\gamma''}}{D_{s,t}^i} \right\} \cup \{1\} \right) \\
&= \sum_{i=1}^M \min \left(\left\{ \frac{y''_{s,t}}{D_{s,t}^i} \right\} \cup \{1\} \right),
\end{aligned}$$

where the first inequality is by Lemma 5, the second inequality is since $\min(a, b) + \min(c, d) \leq \min(a + c, b + d)$, and the third inequality is by Lemma 6. \square

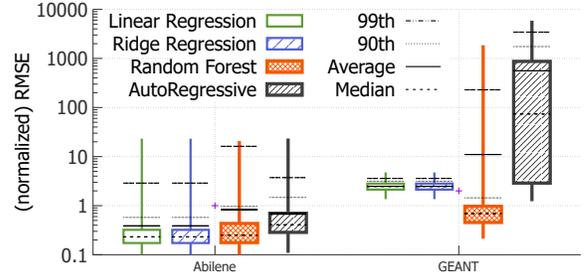

Figure 11: Accuracy of predicting demands; results from different prediction methods.

Lemma 9. *Let $x = \{x_T\}$, $x' = \{x'_T\}$, and $\lambda \in [0, 1]$. Let $x'' = \{\lambda x_T + (1 - \lambda)x'_T\}$, and let γ , γ' and γ'' be the respective normalization constants. Then,*

$$\bar{f}_{MCONC}(x'') \geq \frac{\lambda\gamma\bar{f}_{MCONC}(x) + (1 - \lambda)\gamma'\bar{f}_{MCONC}(x')}{\lambda\gamma + (1 - \lambda)\gamma'}$$

Proof.

$$\begin{aligned}
\bar{f}_{MCONC}(x'') &= \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} \frac{x''_T}{\gamma''}}{D_{s,t}^i} \right\} \cup \{1\} \right) \\
&\geq \sum_{i=1}^M \min \left(\left\{ \frac{\sum_{T \in P_{st}} \frac{\lambda x_T + (1 - \lambda)x'_T}{\lambda\gamma + (1 - \lambda)\gamma'}}{D_{s,t}^i} \right\} \cup \{1\} \right) \\
&= \sum_{i=1}^M \min \left(\left\{ \frac{\lambda\gamma \sum_{T \in P_{st}} \frac{x_T}{\gamma} + (1 - \lambda)\gamma' \sum_{T \in P_{st}} \frac{x'_T}{\gamma'}}{D_{s,t}^i} \right\} \cup \{\lambda\gamma + (1 - \lambda)\gamma'\} \right) \\
&= \frac{\sum_{i=1}^M \left(\min \left(\left\{ \frac{\lambda\gamma \sum_{T \in P_{st}} \frac{x_T}{\gamma}}{D_{s,t}^i} \right\} \cup \{\lambda\gamma\} \right) + \min \left(\left\{ \frac{(1 - \lambda)\gamma' \sum_{T \in P_{st}} \frac{x'_T}{\gamma'}}{D_{s,t}^i} \right\} \cup \{(1 - \lambda)\gamma'\} \right) \right)}{\lambda\gamma + (1 - \lambda)\gamma'} \\
&= \frac{\lambda\gamma\bar{f}_{MCONC}(x) + (1 - \lambda)\gamma'\bar{f}_{MCONC}(x')}{\lambda\gamma + (1 - \lambda)\gamma'},
\end{aligned}$$

where the first inequality is by Lemma 6 and the second inequality is since $\min(a, b) + \min(c, d) \leq \min(a + c, b + d)$. \square

Proposition 7. $Q(\bar{f}_{MCONC}, x) \neq \emptyset$ for any $x \notin \text{argmax}_y \bar{f}_{MCONC}(y)$

Proof. By Lemma 9 where $x = x^*$, $x' = x$, and by Lemma 7. \square

Since Assumption 1 holds, Theorem 3 guarantees that the stochastic normalized subgradient method will converge to an optimal solution of the Max-Concurrent-Flow objective.

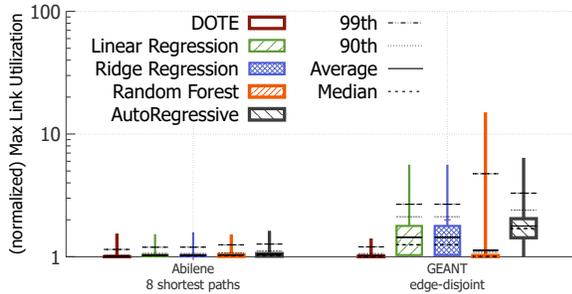

Figure 12: Impact of demand prediction accuracy on max-link-utilization.

C A Closer Look at Demand Prediction

Our results in §4 considered a demand-prediction-based scheme that utilizes linear regression. We next contrast linear regression with other prediction methods on our datasets. Specifically, we consider the following prediction methods: linear regression, ridge regression, random forest, and autoregressive model. With the exception of the autoregressive model, each of these schemes predicts the next traffic demand for each source-destination pair using only that specific pair’s recently observed 12 most traffic demands, *i.e.*, the prediction for each pair is independent from the prediction for other pairs (as in SWAN [22]). The autoregressive model, in contrast, predicts the entire next DM from the 12 most recently observed DMs, to allow for detecting correlations between different pairs that might be conducive for prediction.

Figure 11 plots the accuracy of the different predictors, as quantified by the root-mean-squared-error, for the two publicly available WAN datasets. The accuracy is normalized by the average traffic demand for the dataset and presented in log-scale. Our results for *PWAN* and *PWAN_{DC}* exhibit similar trends. As shown in the figure, linear regression and ridge regression achieve the best results on average on both WANs. We also considered a DNN-based predictor with a single hidden layer with 128 neurons and ReLU activation functions, but its performance was strictly dominated by linear regression on the test data (results omitted). Moreover, treating source-destination pairs individually attains better accuracy than that provided by the autoregressive model. We believe that this is because, on the one hand, the previous traffic demands for a single pair already contain a lot of valuable information and, on the other hand, the much larger input and output of the autoregressive model (entire DMs *vs.* single demands) makes effective learning more difficult.

Figure 12 plots the implications of choosing different predictors for TE performance, as quantified by the max-link-utilization, benchmarked against *DOTE*. Observe that *DOTE* outperforms all considered flavors of demand-based-prediction TE, and also that accuracy in demand prediction does not always translate to better TE performance, exem-

plifying the potential objective mismatch between the two, discussed in the Introduction.

D Robustness to Unexpected Traffic Changes

We consider the GEANT, Cogentco, and GtsCe network topologies with edge-disjoint tunnels. For Cogentco, and GtsCe we use the gravity model to generate demands for both train and test. To evaluate the implications of unexpected traffic changes, we add noise to the test set by multiplying each demand independently by a factor sampled uniformly at random from the range $[1 - \alpha, 1 + \alpha]$ for $\alpha \in \{0.1, 0.25, 0.35\}$.

Recall that for GEANT, *DOTE* generates TE configurations that are extremely close to the optimum (less than 2%). Our results show that even under random traffic perturbations, the distance from the omniscient oracle remains low; 2%, 2.9%, and 3.8% for $\alpha = 0.1, 0.25, 0.35$, respectively. For $\alpha = 0.35$, the distance from the omniscient oracle was 0.01% in the median, 13% in the 90th percentile, and no higher than 28% even in the 99th percentile.

For both Cogentco and GtsCe, *DOTE*’s trained model is roughly 0.5% from the omniscient oracle on the test demands are perturbed. This is because traffic is generated using the gravity model naturally does not reflect the intricate *temporal* patterns and complexity of real-world traffic. Even after perturbing the traffic in our experiments *DOTE* achieved near-optimal performance. Specifically, on Cogentco, the average distance from the omniscient oracle was 0.54%, 0.57%, and 0.6% for $\alpha = 0.1, 0.25, 0.35$, respectively. For $\alpha = 0.35$, the distance from the omniscient oracle was 0.56% in the median, 1% in the 90th percentile, and 1.4% in the 99th percentile. On GtsCe, the average distance from the omniscient oracle was 0.51%, 0.56%, and 0.61% for $\alpha = 0.1, 0.25, 0.35$ respectively. For $\alpha = 0.35$, the distance from the omniscient oracle was 0.57% in the median, 1% in the 90th percentile, and 1.4% in the 99th percentile.

Dashlet: Taming Swipe Uncertainty for Robust Short Video Streaming

Zhuqi Li, Yaxiong Xie, Ravi Netravali, Kyle Jamieson
Princeton University

Abstract

Short video streaming applications have recently gained substantial traction, but the non-linear video presentation they afford swiping users fundamentally changes the problem of maximizing user quality of experience in the face of the vagaries of network throughput and user swipe timing. This paper describes the design and implementation of Dashlet, a system tailored for high quality of experience in short video streaming applications. With the insights we glean from an in-the-wild TikTok performance study and a user study focused on swipe patterns, Dashlet proposes a novel out-of-order video chunk pre-buffering mechanism that leverages a simple, *non* machine learning-based model of users' swipe statistics to determine the pre-buffering order and bitrate. The net result is a system that outperforms TikTok by 28-101%, while also reducing by 30% the number of bytes wasted on downloaded video that is never watched.

1 Introduction

Short video streaming applications like TikTok and YouTube Shorts have rapidly risen in popularity, attracting billions of active users per month [31, 32, 41] and consistently topping popularity lists for mobile apps [33]. Unlike typical video streaming, the median duration of short videos is around 14 seconds [4]. During operation, these apps generate an ordered playlist of short videos (*e.g.*, based on a search or user-specific recommendations), and users watch them serially, with the ability to swipe from one to the next at any time. To provide an immersive experience and keep users engaged, short video streaming applications should minimize the video rebuffering time and maximize the video bitrate, which is modeled by quality-of-experience (QoE) [1, 3, 11, 13].

Although the aforementioned goals are consistent with those in traditional video streaming scenarios, existing ABR algorithms [2, 16, 22, 36, 40] are ill-suited for interactive, short videos. The reason is that predicting user swipes is difficult, and swipe times dictate both which video content will be viewed and when during a session. However, existing algorithms assume that the user will watch content sequentially to completion, and will hence buffer chunks (*i.e.*, multi-second blocks of video) in that order. The deleterious effects, shown in Fig. 1, are twofold: (1) many chunks may be downloaded in the current video but never viewed if the user swipes before their playback, wasting resources and adding delays for the chunks that are required, and (2) users may swipe to the next video and incur significant rebuffering because that video's chunks have not been downloaded yet.

Figure 1: In short video apps, user swipes dictate the playing order of video chunks (and thus, the optimal chunk downloading order).

The fundamental challenge is that there are far too many possible chunk viewing sequences—the user may swipe at any position in each short video, and expects seamless (*i.e.*, no stalls) playback for both the current video, and the next one upon a swipe. The problem thus becomes how to find (at any time during playback) a buffering sequence of chunks in this large search space that maximizes QoE by simultaneously minimizing rebuffering time and wasted bandwidth.

To understand how commercial short streaming platforms attempt to address these challenges, we have conducted a detailed examination of TikTok in the wild (§2). Our key finding is that TikTok does download chunks out of order, but follows a generic algorithm that hedges against immediate rebuffering in the face of fast user swipes (it always pre-buffers the first chunk for the next five videos regardless of network conditions, user patterns, and/or video). This, however, entails substantial QoE penalties and wasted data consumption, as we will show via results from our own study of user swipe patterns across two distinct sets of users on a college campus and Amazon Mechanical Turk (§3). Specifically, we find substantial heterogeneity in the swipe patterns across users, with each warranting a different chunk downloading strategy.

A naïve solution would be to simply predict user swipes— if accurate, this would reduce the problem to a traditional streaming setting since chunk viewing sequences would be known a priori. However, predicting user behavior in interactive applications has consistently proven to be difficult [6, 21, 26]. Instead, we take a more fundamental approach that is rooted in an understanding of where swipe predictions are actually helpful (and actionable).

We present **Dashlet**, a new video streaming algorithm for short video applications (§4). The underlying insight behind Dashlet is that application playback constraints predetermine the relative priorities between many chunks that are candidates for buffering. More specifically, (1) later chunks in a video are only reachable via earlier ones, and (2) later videos are only reachable via swipes from earlier ones. To prioritize among the remaining chunks, *e.g.*, the next chunk in a given video *vs.* the first chunk in the next video, only coarse grained

information about swipe timings in videos is required. We show, via our user study, that although users tend to exhibit multimodal swipe patterns (complicating chunk prioritization) across videos, distributions from aggregating users' swipes *per video* provide a clear enough signal about which mode to expect. This information is readily available to current short video platforms, and our finding is spiritually aligned with past studies that highlight similarities in user engagement for certain video content [35, 43].

Building on this, Dashlet develops functions that characterize the expected rebuffering time for each potential chunk that could be downloaded, as a continuous function over both the expected download and playback times. These functions embed the aforementioned inter-chunk relationships, as well as rough swipe likelihoods at video start and end. Using these functions, Dashlet employs a greedy algorithm to determine the set of ordered chunks that should be downloaded in the current time horizon to minimize expected rebuffering delays for a given network estimate and across potential viewing sequences. This buffer sequence then feeds directly into a traditional ABR algorithm, which determine bitrates for those chunks that maximize overall QoE. Dashlet further improves upon existing short video systems by not prematurely binding bit rate decisions across entire short videos, and not letting the network idle at any point in time.

We have implemented Dashlet in the DASH framework [8], and compare with the TikTok mobile app with both a human subjects study and a trace-drive study¹. Across these conditions, we find that Dashlet outperforms TikTok by 28-101% in QoE values, including 8-39% improvement on video bitrate, 1.6-8.9× reduction on rebuffering penalty, and 30% reduction on data wastage. Dashlet's QoE improvement varies with the network throughput, *i.e.*, 543.7%, 221.4%, and 36.6% over TikTok when the throughput is 2-4, 4-6, and 10-12 Mbps, respectively. The improvement diminishes with throughput approaching to 20 Mbps because both Dashlet and TikTok are getting closer to optimum. Further, Dashlet is tolerant to errors in swipe distributions: QoE degradations are only 10% with distribution errors of 50%. We will open source our datasets and implementation post publication.

2 A TikTok Case Study

We examine how TikTok, a state-of-the-art short video app, operates. We first describe its basic architecture (§2.1), before analyzing its operation and limitations (§2.2).

2.1 Short Video Streaming Primer

Unlike traditional streaming apps that divide video into chunks of equal time duration, TikTok splits each video into size-based chunks. For each supported bitrate, if the video

¹We release the code with the following url: <https://github.com/PrincetonUniversity/Dashlet> under the MIT Open Source License.

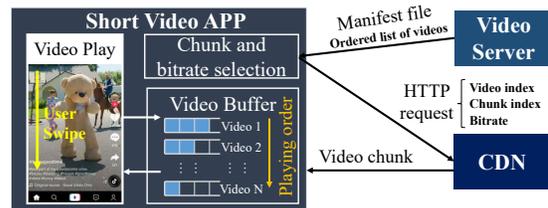

Figure 2: System architecture of TikTok and other short video apps.

file is smaller than 1 MB, TikTok treats the entire video as one chunk; else, the first chunk is the first MB, and the remaining video becomes the second. This chunking strategy enhances reliability, as TikTok pre-buffers first chunks (to cope with swipe uncertainty) so chunking in terms of bytes eliminates first-chunk size variance from variable bitrate encoding.

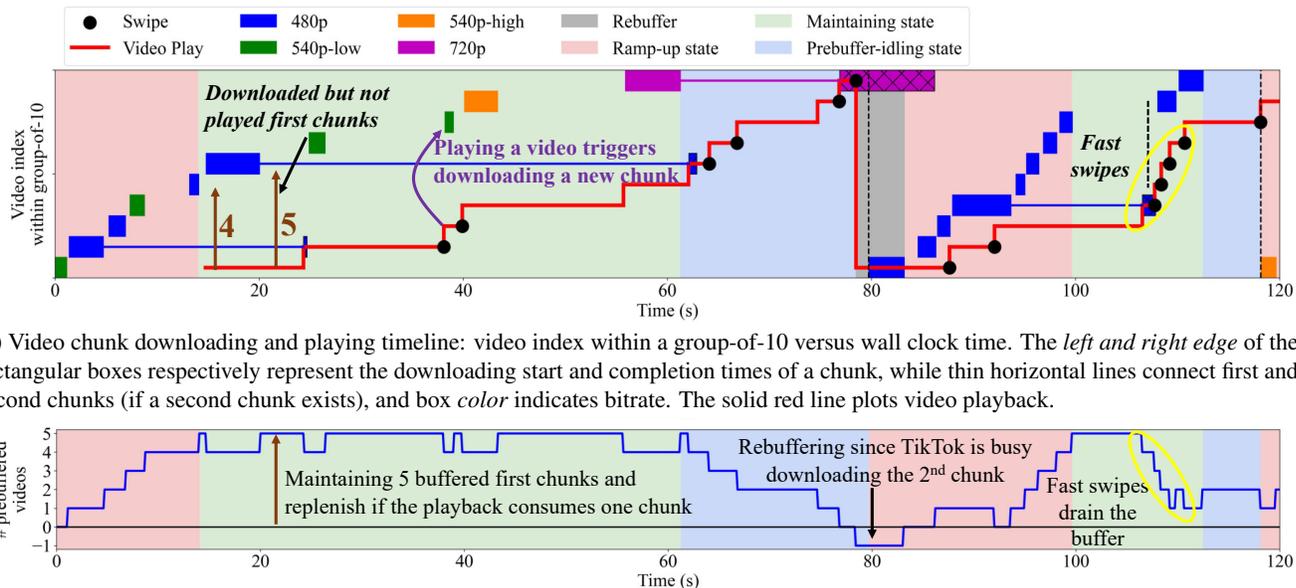

Upon receiving a client session request either via a keyword search or category selection (*e.g.*, recommended videos), the server generates an ordered list of short videos to serve (Fig. 2). The server then ships a *manifest file* to the client which embeds the URL, as well as information about the number of *chunks* (multi-second blocks of video) and available bitrates, per video in the ordered list. The client operates much like a traditional streaming player (*e.g.*, DASH), maintaining a playback buffer for downloaded video and employing an adaptive bitrate (ABR) algorithm to determine what chunk to download next, when, and at what bitrate.

A key difference between traditional and short video streaming is that the client maintains one logical buffer per video in the server-provided manifest file, which contains information for an ordered group of 10 videos. The client requests a new manifest file after it downloads all the first chunks of the videos in the current manifest. Video playback operates sequentially within each logical buffer and across buffers (in the specified order); user swipes and video completion trigger the playback to move to the head of the buffer for the next video. To cope with such semantics, ABR algorithms for short videos have the ability to download chunks for any of the videos in the manifest file at any time.

TikTok provides four bitrate options for each video: 480p, 560p low, 560p high, and 720p, with bitrate adaptation occurring only at video-level (and not chunk-level) granularity. We hypothesize this is because the first 1 MB of a video encoded at different bitrates corresponds to different time durations, precluding seamless bitrate switches for the latter chunk, *i.e.*, content would be missed or repeated. As we will discuss, such constraints significantly limit TikTok from adapting to variations in network capacity during user sessions.

2.2 Analysis of TikTok

To study TikTok in a controlled and systematic manner, we perform our analysis over emulated networks using

(b) Client-side buffer occupancy as a function of time, the gap between playback and highest chunk downloaded in (a).

Figure 3: An illustrative video downloading and video playing trace of TikTok, with associated video bitrate and buffer occupancy statistics.

Mahimahi [23]. We log in to TikTok with a two-year old account and mirror its screen to a Linux desktop with scrapy [28] and use the pyautogui tool [24] to replay aggregated user swipe traces that were collected from our user study (described in §3). During experiments, we use the mitm-proxy [5] to collect and decrypt TikTok’s network traffic. From the deciphered HTTP messages and headers, we are able to extract for each requested chunk, the video that it pertains to, its index in that video, the requested bitrate, and the download start/end time. Finally, we develop a screen analysis tool using pyautogui and opencv [17] to record duration of each rebuffering event (§5.1 further details our setup).

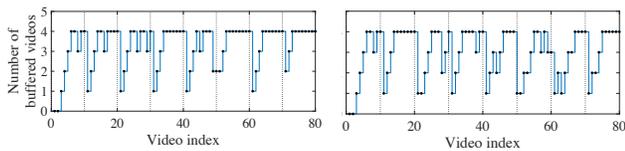

2.2.1 Chunk Download Control

TikTok’s download control algorithm depends both on instantaneous network throughput and the client’s internal buffer status: Fig. 3a illustrates its decisions (*i.e.*, order and timing of chunk downloads across videos, bitrates used each time) during a representative two-minute session. We plot client-side playback buffer occupancy in Fig. 3b, which shows the number of videos with at least one downloaded (but unplayed) chunk. We see that TikTok spends most of its time downloading the first chunk of videos, and downloads the second chunk when and only when the video starts to play, *e.g.*, the download of the second chunk of video two and the play-start of video two start simultaneously at $t = 22$ s.

Our analysis indicates that TikTok proceeds according to three discrete states, cycling among the three in order to handle one *group-of-ten* videos. At startup and the start of every

group-of-ten, the **ramping-up state** continuously downloads first chunks to build up buffers. After accumulating five first chunks at $t = 18$ seconds, TikTok starts to play the buffered video and enters the **maintaining state**, where it aims to maintain a constant five buffered first chunks. Upon playing a new video (due to user swipe or reaching the end of a video), the client fetches one first chunk from the buffer, triggering TikTok to immediately initiate download of the first chunk of the next video in the manifest, as indicated by the additional download events corresponding to either swipes or video changes due to end of video in the green “maintaining state” regions of Fig. 3a. We see in Fig. 3b that as the downloading of each first chunk finishes, buffer levels return to five, the high water mark buffering level TikTok has chosen. The advantage of the maintaining state is resilience to quick user swipes: in the second group-of-ten of Fig. 3 ($t = 110$), the user swipes early in multiple consecutive videos, quickly draining the buffer, but TikTok experiences no rebuffering since its buffer contains the five first chunks.

Finally, after downloading all the first chunks of the 10 videos listed in the current manifest file, TikTok enters the **prebuffer-idling state**, where it stops initiating any new downloads of first chunks. Meanwhile, TikTok continues video playback, consuming video chunks in its buffer, so buffer occupancy decreases monotonically in this state, as shown in Fig. 3b. Our hypothetical explanation of this idle period is that TikTok is waiting to measure the user’s reaction (swiping early means they might not be interested in the content) to the videos TikTok recommends in last round

(a) Net. throughput 10 Mbit/s. (b) Net. throughput 3 Mbit/s.

Figure 4: The number of downloaded videos inside the buffer when TikTok starts to download the first chunk of a new video via networks with capacity of (a) 10 Mbit/s and (b) 3 Mbit/s.

(manifest file), so it can assess its recommendation quality and adjust the subsequent round’s recommendation before sending the next manifest file.

In contrast to the resilience of the maintaining state, TikTok becomes somewhat vulnerable in the prebuffer-idling state, where TikTok drains the buffer by itself. For example, TikTok experiences rebuffering in the middle of two video groups in Fig. 3. At that moment, TikTok has no buffered first chunk and at the same time spends a long time downloading the second chunk of the current video, leaving no time budget for downloading the first chunk of next video. In such a case, one user swipe results in rebuffering.

When the user starts to watch the ninth of the group-of-ten videos listed in a manifest, TikTok exits prebuffer-idle and begins afresh in the ramp-up state to download the videos listed in the next manifest file. The cycle through these three states repeats for each group-of-ten.

2.2.2 Network and Swipe Input Adaptation

We now investigate the effects of swipes, buffer occupancy, and the network on TikTok’s bitrate and buffering choices. To measure the impact of the network on buffering strategy, we control network capacity to 10 and 3 Mbit/s using Mahimahi and plot the number of buffered first chunks at the moment TikTok initiates a download of the first chunks, in Fig. 4. Combining Fig. 4a and 4b, we see that TikTok adopts the same buffering strategy regardless of network capacity.

Next, we analyze the joint impact of network throughput and buffering status on TikTok’s bitrate decisions. We collect instantaneous network throughput and buffer status coupled with TikTok’s bitrate decisions, for 5,300 videos, and plot the results in Fig. 6. In the figure, the x -axis is the network throughput of the one-second period before the downloading of that video, *i.e.*, the time period within which TikTok makes its decisions about the bitrate. The y -axis is the number of downloaded first chunks in the buffer. The color of a tile represents the average bitrate R of the video, which is given by $R = S/L$ where S is the size of the video in bits and L is the length of the video in seconds. Some tiles are not colored because the combination of the throughput and buffer status is not seen during our measurement, *e.g.*, when the throughput is 16 Mbit/s, we always observe four downloaded

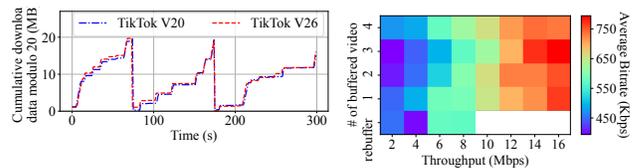

Figure 5: Cumulative downloaded data modulo by 20 MB for TikTok v20.9.1 and TikTok v26.3.3 when throughput and client video playing the same video sequence at the same swipe pace.

first chunks in the buffer. We observe that bitrate decisions correlate positively with network throughput, but observe no evidence for correlation with buffer status.

2.2.3 Buffering logic on different versions of TikTok

Our reverse engineering tool can only decipher complete TikTok telemetry information up to version v20.9.1. To investigate whether there are any updates in the buffering algorithm between v20.9.1 and the newest TikTok version (v26.3.3), we use scripts to watch the same videos on different versions, under the same network throughput and swipe pace. We record the number of bytes downloaded versus time with tcpdump. Fig. 5 shows an example trace for the two versions of TikTok. By correlating the downloading traces at different throughput and swipe speed, we infer that v20.9.1 and v26.3.3 use similar or identical buffering logic. In the rest of the paper, we only present v20.9.1 results.

2.2.4 Limitations of Current Short Video Streaming

Despite pre-buffering the beginnings of short videos, TikTok has a fundamentally static approach to coping with swipe uncertainty, with no evidence for adaptation across different videos or users. This approach is often too cautious or aggressive, manifesting in two particular ways:

Lack of swipe prediction. TikTok prioritizes the downloading of the first chunk, assuming that the user always swipes frequently, and delays the downloading of the second to the beginning of video playback. As we will show next however, there are indeed some users who swipe early when watching a video, but there also a significant number of users who watch most of many videos and swipe at the end or not at all. So, the urgency of downloading the second chunk varies with users and videos: a fixed rule cannot handle all cases.

Premature bitrate binding. TikTok groups the first MB of video data into the first chunk but selects the bitrate for both chunks according to the network conditions present during the first, prematurely binding the system into that bitrate for both. By design, there is often a large time lag between the downloading of the first and second chunks, as discussed above (the median gap between first and second chunk downloads is 25 s., with an interquartile range of 23 s.), resulting in a potential mismatch with network conditions

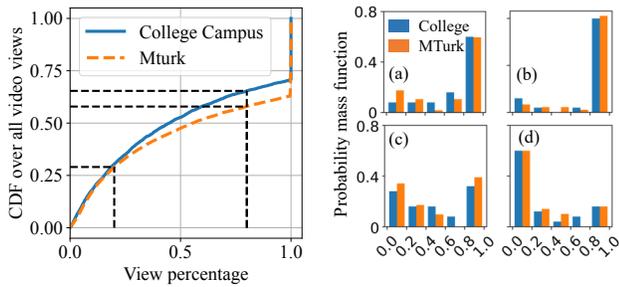

Figure 7: The distribution of average viewing percentage across all short video views.

Figure 8: Distribution (across different users) of video viewing percentage for four sample videos (a)–(d).

that change in the meantime.

Network Idling. As shown in Fig. 3a, TikTok has a prebuffer idling state. In the contrast, the buffer is not full and the bitrate of videos still has room to improve. This also calls for a better ABR algorithm to stream higher bitrate video by utilizing the idle time in a better way.

To understand the mismatch between TikTok’s generic rule and the varying user swipe patterns, in the next section, we characterize the swipe patterns across real users and videos via two user studies.

3 Characterizing User Swipes

To better understand the nature of user interactions (*i.e.*, swipes) with short video applications, we conducted two IRB-approved user studies. In each study, we present users with a web-based short video streaming service that resembles the interface offered by TikTok. We considered 500 popular short videos gathered by crawling the videos displayed on the TikTok landing page over time. The videos were randomly ordered per session, and each user watches 20 minutes of video with the ability to swipe freely (all swipes are recorded). Note that the number of videos watched by a given user depends on the number of swipes they performed.

For generality, we performed two versions of this study:

1. College campus: we recruit 25 student volunteers who collectively swipe 3,069 times during the study.

2. Amazon Mechanical Turk (“MTurk”): we recruit 258 different users. To ensure active user participation, we augment our web application to inject random interactivity tests that ask users to swipe within 10 seconds. Users who fail to swipe in time are entirely excluded from the study; users who do swipe continue the experience, but we exclude the forced swipe(s) from our final dataset. In total, we retain data from 133 workers, which covers 15,344 swipes.

Overall swipe distributions. Fig. 7 shows the distribution of swipe times across all video-user pairs in both studies. Users

are most likely to swipe either soon after video playback begins or at the end of the video (manually or via auto-swiping once the video completes); this is consistent with prior studies on user swipe patterns [44]. For instance, 29% and 42% of swipes from MTurk users are within the first 20% or last 20% of videos, respectively. Swipes between these two endpoints occur, but far less often and with increasingly low likelihood as users watch more videos, *e.g.*, only 6% of swipes in the College Campus dataset are in the 60–80% of videos.

Swipe distributions per video. Fig. 8 shows swipe probabilities for four representative videos, aggregated across users who watched each one in the two studies. Different videos yield significantly different swipe distributions: over 60% of swipes in videos (a) and 80% of swipes in videos (d) come within the last few seconds (indicating low swipe probabilities for these). Video (c) exhibits the opposite pattern—60% of swipes in the first 20% of the video (indicating high swipe probabilities)—while swipes in (b) are more evenly distributed in time. Perhaps more importantly, we observe substantial stability in the swipe distributions per video across different user datasets: KL divergence values between the MTurk and College Campus datasets are 0.2 and 0.8 for the median and 95th percentile videos, respectively.

Conclusions. Despite general similarities in swipe patterns, users follow a few different modes of swiping (*e.g.*, swiping early in the chunk *vs.* not at all), each of which warrants a different buffering strategy to ensure high QoE. Fortunately, cross-user swipe data that is aggregated *per video* provides a relatively stable indicator as to how likely swipes are (and will be) in a given video, and (more coarsely) at what part of the video they will occur. We show in §4 how Dashlet leverages this coarse information – which is readily available at existing short video servers – to make robust buffering decisions that handle cross-user swipe traces.

4 Design

Dashlet leverages swipe distribution stability across videos (§3) to get a *coarse* sense of the likelihood of swipes at different video chunks. Coupling this information with constraints on inter-chunk viewing sequences intrinsic to short video applications, Dashlet models the *expected rebuffering time* for each potential chunk as a continuous function over the expected download and playback times (§4.1), then employs a greedy algorithm atop those functions to find a chunk buffering sequence that minimizes expected rebuffering delay over a time horizon for a given network throughput estimate, and across different user viewing sequences. Lastly, Dashlet feeds that buffering sequence into a bitrate selection algorithm (RobustMPC [40] in our implementation) to control video chunk bitrate and optimize overall QoE (§4.2).

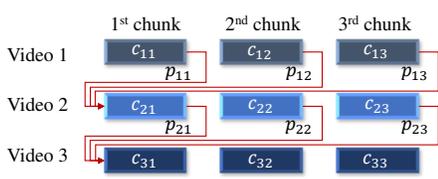

Figure 9: Short video streaming model: the player plays videos sequentially, switching to the first chunk of the next video after a swipe.

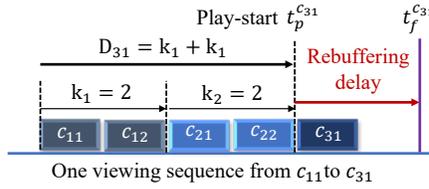

Figure 10: Chunk rebuffering delay depends on the order between the play start time t_p and the download finish time t_f .

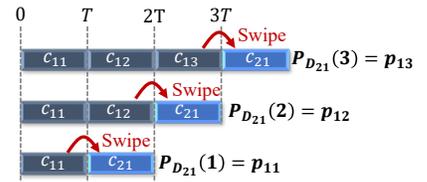

Figure 11: Three possible viewing sequences that start from chunk c_{11} and end at chunk c_{21} .

4.1 Forecasting Rebuffering Delay

Dashlet’s expected rebuffering functions aim to quantify user-perceived delays across different chunk download times and viewing sequences. We begin by explaining the construction of these functions in a discrete setting where users can only swipe at chunk boundaries; we then extend the discussion to incorporate arbitrarily-timed user swipes.

System Model. Short video apps follow the flow shown in Fig. 9. Each video consists of multiple chunks of *chunk time* T . Within the i^{th} video with N_i chunks, if the user does not swipe, the video player plays its chunks c_{ij} sequentially, where $j \in [0, N_i]$ is the chunk index. When playback reaches the end of the video or the user swipes, the player jumps to the first chunk of the next video. Since user swipe distributions vary across videos (§3), we denote the probability that the user swipes after watching chunk c_{ij} as p_{ij} . The list of the chunks the user watches is a *viewing sequence*

$$V_s = [c_{11}, \dots, c_{1k_1}, c_{21}, \dots, c_{K1}, \dots, c_{Kk_L}] \quad (1)$$

where the user views the first k_i chunks of the i^{th} video, assuming that the user watches L videos in total. Then the probability distribution of k_i is $P_{k_i} = \{p_{i1}, p_{i2}, \dots, p_{iN_i}\}$. We define D_{ij} , the number of chunks that a user has watched prior to chunk c_{ij} :

$$D_{ij} = \sum_l^{i-1} k_l + (j - 1). \quad (2)$$

By knowing the number of chunks that a user has watched before c_{ij} , the playback start time of c_{ij} then will be $D_{ij} \cdot T$. As shown in Fig. 10, the expected rebuffering delay for some chunk c depends on the relationship between the chunk’s *play start time* t_p^c and *download finish time* t_f^c . There exists no rebuffering if the chunk downloading finishes before the play start time. Otherwise, rebuffering happens and the time difference between t_p^c and t_f^c tells us c ’s *rebuffering delay*:

$$T_c^{\text{rebuf}}(t_f^c, t_p^c) = \begin{cases} 0, & t_f^c < t_p^c \\ t_f^c - t_p^c, & t_f^c \geq t_p^c \end{cases} \quad (3)$$

The play start time of each chunk is determined by the viewing sequence V_s , as shown in Fig. 10. Since our goal is to

schedule c ’s download to minimize rebuffering, we now formulate a reward function to meet this goal, parameterized on t_f^c and averaging over all possible viewing sequences (which are not under our control). The *expected rebuffering delay* of chunk c given that chunk’s download finish time t_f^c , across all possible viewing sequences, is:

$$\mathbf{E}_c^{\text{rebuf}}(t_f^c) = \sum_{V_s \in \Phi} \Pr(V_s) \cdot T_c^{\text{rebuf}}(t_f^c, t_p^c(V_s)) \quad (4)$$

where probability $\Pr(V_s)$ represents how likely a specific viewing sequence V_s will appear based on user swipe distribution data, $t_p^c(V_s)$ is c ’s play start time in V_s , and Φ is the set of all possible viewing sequences.

To calculate the expected rebuffering delay for a specific chunk, we enumerate all possible viewing sequences that reach this chunk, as Eq. 4 shows. For each sequence, we compute how likely this sequence will appear based on user swipe distributions, and then determine the play start time of that specific chunk. Based on short video chunk playback constraints (§1, p.), we propose separate algorithms for calculating the expected rebuffering delay of a video’s first chunk, and remaining chunks, respectively.

First chunk of a video. The number of possible viewing sequences between chunk one of video one (c_{11}) and chunk one of video i (c_{i1}) increases exponentially with i . On the other hand, the number of sequences from the first chunk of the previous to the first chunk of the current video is bounded by the number of chunks in the former. For example (see Fig. 9), there are three possible viewing sequences from chunk c_{21} to c_{31} . We therefore enumerate the viewing sequences in a recursive manner: deriving the viewing sequences that reach the first chunk of the i^{th} video based on the viewing sequence of the first chunk of the $(i - 1)^{\text{st}}$ video.

We start from the base case, viewing sequences from c_{11} to c_{21} . Fig. 11 lists all three possible viewing sequences that start from c_{11} : we see that random variable $D_{21} = k_1$ (cf. Eq. 2). Similarly, as shown in Fig. 10, $D_{31} = D_{21} + k_2$ (cf. Eq. 1). The distribution of D_{31} is then:

$$P_{D_{31}}[n_0] = \sum_{i=1}^{n_0-1} P_{D_{21}}[i] \cdot P_{k_2}[n_0 - i] \quad (5)$$

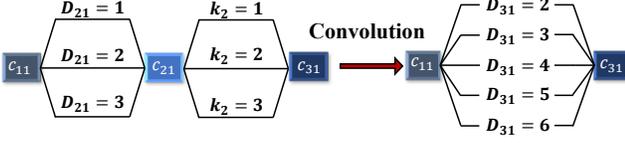

Figure 12: Convolution of the $P_{D_{21}}[\cdot]$ and $P_{k_2}[\cdot]$ provides us the probability distribution $P_{D_{31}}[\cdot]$.

where $P_{D_{31}}[n_0]$ means the probability of there are n_0 chunks before chunk c_{31} is viewed. This formula by definition is the operation of convolution between D_{21} and k_2 , as shown in Fig. 12. Without losing generality, the number of chunks that user watches before chunk c_{i1} , D_{i1} , is $D_{(i-1)1} + k_{i-1}$. Therefore the distribution of D_{i1} is:

$$P_{D_{i1}} = P_{D_{(i-1)1}} * P_{k_{i-1}}. \quad (6)$$

With the knowledge of D_{i1} 's distribution for the first chunk of all the videos, we calculate the expected rebuffering delay of chunk c_{i1} , as the function of download finish time:

$$\mathbf{E}_{c_{i1}}^{\text{rebuf}}(t_f) = \sum P_{D_{ij}}[n] \cdot T_{c_{i1}}^{\text{rebuf}}(t_f, (n+1)T) \quad (7)$$

Remaining chunks in a video. There exists only one viewing sequence from the first to later chunks of the same video: Fig. 13 shows that c_{23} will be played when and only when the user watches the $i = 2^{\text{nd}}$ video continuously without swiping. For non-first chunk c_{ij} , the number of chunks that user watched before it, D_{ij} , is the summation of D_{i1} and $j-1$ since the user has to watch the first $j-1$ chunks in video i before starting to watch it. Then the distribution of D_{ij} is that of D_{i1} , delayed by $j-1$ chunks. In addition, the user might swipe to the next video before watching c_{ij} :

$$P_{D_{ij}}[n_0] = P_{D_{i1}}[n_0 - (j-1)] \times \left(1 - \sum_{m=1}^{j-1} p_{im}\right). \quad (8)$$

With the distribution of D_{ij} , we follow the same procedure to calculate expected rebuffering time for remaining chunks in a video, according to Eq. 7.

Arbitrary user swipes. In reality, swipes do not only happen after a chunk finishes. If the continuously-valued viewing time for video i is κ_i , the PDF of κ_i is $f_{\kappa_i}(t_0)$. The *play start time* of c_{ij} , Δ_{ij} , is a random variable, with PDF $f_{\Delta_{ij}}(t)$. For the first chunk of video i , its playing start time $t_f^{c_{i1}}$ is also the summation of the playing start time of the previous video $t_f^{c_{(i-1)1}}$ and the time the user spends watching the previous video κ_{i-1} . Following a similar principle, we compute $f_{\Delta_{i1}}(t)$ for the first chunk of a video i as

$$f_{\Delta_{i1}}(t) = f_{\Delta_{(i-1)1}}(t) * f_{\kappa_{i-1}}(t). \quad (9)$$

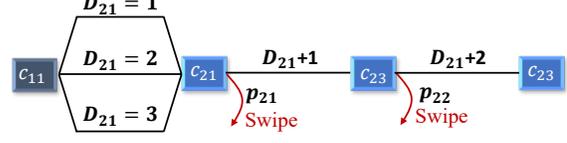

Figure 13: Starting from chunk c_{21} , the user must watch the second video continuously with swiping to reach chunk c_{23} .

For subsequent chunks c_{ij} , we also calculate the playing start distribution based on the first chunk

$$f_{\Delta_{ij}}(t) = f_{\Delta_{(i-1)i}}(t - (j-1) \cdot L) \cdot \left(1 - \int_0^{(j-1) \cdot L} f_{\kappa_i}(x) dx\right) \quad (10)$$

Then the expected rebuffering function can be calculated similarly to Eq. 7:

$$\mathbf{E}_{c_{ij}}^{\text{rebuf}}(x) = \int_{t=0}^x f_{\Delta_{ij}}(t) \times T_{c_{ij}}^{\text{rebuf}}(x, t) dt \quad (11)$$

In the implementation, we approximate the continuous value swipe distribution with a discrete distribution with the time granularity of 0.1 seconds. The integral then can be approximated by the summation in the discrete distribution.

4.2 Determining Buffering Sequences

Given the preceding computation of expected rebuffering delay for each chunk, Dashlet's next task is to determine an order of chunks to download (*i.e.*, a buffering sequence) that minimizes expected rebuffering delay over a lookahead horizon. Prior schemes (*e.g.*, MPC [40]) can then be used to determine the bitrates for those chunks to optimize overall QoE for the horizon. However, unlike prior schemes, the horizon that we use is based on time (not chunks), since different user swipe patterns can translate into different numbers of viewed chunks. Using a horizon sized to a fixed number of chunks could result in optimization over very short viewing times (negating the effects of longer-term planning). Our current implementation uses a lookahead window of 25 seconds based on empirical observations, which is equivalent to the five chunks MPC uses. Chunk ordering relies primarily on whether the user swipes near the beginning of the video or not: *e.g.* if the user is highly likely to not swipe in c_{11} , the algorithm then needs to prioritize c_{12} over c_{21} .

4.2.1 Selecting the candidate chunk set

To determine the set of chunks to consider, we enforce a threshold on the minimum rebuffering penalty that each chunk is expected to incur at the end of the horizon if it is not included in the buffer sequence (Fig. 14(a)). Chunks whose rebuffering penalty falls below the threshold are deemed as unlikely to be viewed during the horizon (c_{32} in Fig. 14(a)), and thus low priority for inclusion in the buffer sequence.

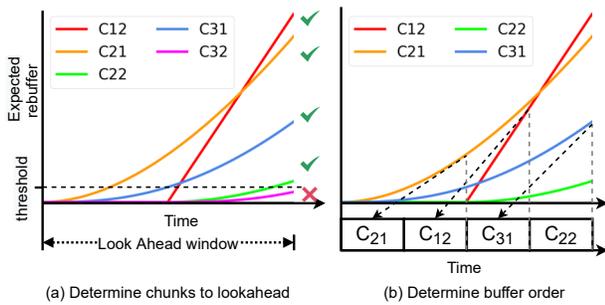

Figure 14: An example to illustrate Dashlet’s algorithm.

Note that buffer sequences are constructed each time a chunk download completes, so an excluded chunk for one horizon may still be downloaded shortly (via inclusion in the next horizon’s buffer sequence). We use an empirically-configured value of $1/\mu$ for threshold, which is the inverse of the rebuffering penalty weight in our target QoE function.

Using the set of chunks to consider, our final task is to order them in a manner that minimizes expected rebuffering penalties. We assign a bitrate to each chunk, and then use estimated network bandwidth to determine when it will complete downloading (assuming some start time). This allows us to compute expected rebuffering time per chunk (§4.1). However, to bound computational complexity (since download decisions must be fast) we temporarily assume an equal bitrate per chunk that is set to the maximum bitrate, which ensures that all chunks in the list will complete downloading before the horizon completes. Although exclusion of per-chunk bitrate decisions here can result in suboptimal orderings, these effects are marginal (evidenced by Dashlet’s closeness to the Optimal scheme in §5.2), as priorities between chunks (and potential per-chunk viewing times) are largely dictated by viewing constraints imposed by the application (§4.1). Thus, minor discrepancies in bitrates across chunks are unlikely to flip the priority order among them.

4.2.2 Priority-ordering the buffer sequence

To sort our list of chunks into a buffer sequence, we follow a greedy algorithm, whereby we partition the horizon into chunk-sized slots. For a given slot i , we select the chunk that will incur the largest additional rebuffering penalty if it were to be scheduled in slot $i + 1$ rather than i . Fig. 14(b) shows this process for a scenario in which chunk c_{11} just completed downloading: c_{21} is assigned to slot 1 as its rebuffering penalty jumps the most between slots 1 and 2; c_{12} is next as it has the highest penalty for not going in slot 2, and so on. Finally, using the generated buffer sequence, Dashlet applies MPC’s algorithm to determine the bitrate for each chunk in the buffer sequence in a way that optimizes the entire QoE (not just minimizing rebuffering) for the horizon according to the forecasted network throughput, *i.e.*, the harmonic mean

over the observed throughputs in the last 5 chunk downloads. We describe the above algorithm with a pseudo code in §A.

4.3 Implementation

Dashlet’s implementation includes one control module and multiple buffer modules. The control module schedules the chunk downloading and the buffer modules reuses the DASH.js playback management implementation to download video chunks. §B provides more implementation details.

5 Evaluation

We evaluate Dashlet across a variety of mobile network conditions, real user swipe traces, and videos. Our key findings:

- Dashlet outperforms TikTok by 28-101% in terms of average QoE, including 8-39% improvement on video bitrate, 1.6-8.9 \times reduction on rebuffering penalty, and 30% reduction on data wastage.
- Dashlet’s QoE improvement varies with the network throughput, *i.e.*, 543.7%, 221.4%, and 36.6% over TikTok when the throughput is 2-4, 4-6, and 10-12 Mbps, respectively. The improvement diminishes with throughput approaching to 20 Mbps because both Dashlet and TikTok are getting closer to optimum.
- Dashlet tolerates errors in swipe distributions: with errors of 50%, Dashlet makes the correct buffering decisions 96.5% of the time, yielding an QoE reductions of only 10%. compared to cases with no distribution errors.

5.1 Methodology

Baselines. We compare Dashlet with the following systems:

- *TikTok*. We compare with TikTok App (version v.20.9.1).
- *Oracle*. We also run an ‘oracle’ baseline that serves as an upper bound for QoE. The oracle is the RobustMPC algorithm [40] running with perfect (a priori) knowledge of both the user swipe traces and network throughput in each experiment. With that information, the algorithm knows the upcoming video viewing sequence at all times, and can thus pick the buffer sequences (and bitrates) that directly optimize QoE for the current network conditions.

Overall setup. All video clients run on a rooted Pixel 2 phone (Android 10). The Oracle algorithm and Dashlet run in the Google Chrome browser (v. 97.0.4692.87), and contact a local desktop which houses the videos accessed in each experiment (described below). In contrast, TikTok runs as an unmodified, native Android app and contacts Akamai CDNs to fetch video content as it normally does. We checked the location of the CDN content server node and verified it was local to our area. All traffic to and from the phone passes over emulated mobile networks (which run atop WiFi connections with average speeds of ≈ 300 Mbps); to compensate for the discrepancy in video servers, we added 6 ms of round trip

delay to traffic for Dashlet and the Oracle algorithm, which reflects the maximum ping time we observed to the CDN used by TikTok.

Evaluation metrics. Short videos share similar goals of traditional video streaming [22, 40]: maximizing video bitrate, minimizing rebuffering delays, and avoiding frequent bitrate fluctuations, so we adopt a widely used QoE metric:

$$QoE = R_{bitrate} - \mu \cdot P_{rebuffer} - \eta \cdot P_{smooth} \quad (12)$$

where $R_{bitrate}$ is the average video bitrate, $P_{rebuffer}$ is the cumulative penalty for rebuffering (i.e., stalled playback), and P_{smooth} is the penalty for frequent bitrate switching across adjacent chunks. We use the same values for μ and η as prior work [40], i.e., $\mu = 3000$ and $\eta = 1$.

Human subjects study for QoE. We conduct a small-scale human study, where we recruit ten participants². We ask them to log in their own accounts to use TikTok under emulated mobile networks (the videos are recommended by TikTok)³. We randomly choose three network traces with average throughput of 4 ± 0.1 , 6 ± 0.1 , 12 ± 0.1 Mbps respectively. We record the content, quality, order of videos TikTok streams to each user, and swipe timestamps. For the evaluation of Dashlet, we first download every video that users have watched in TikTok experiments and collect per-video user swipe distributions with Amazon Mturk. We then stream the same videos in the same order as TikTok using Dashlet, under the same emulated network, during which we replay the user swipes recorded in the TikTok experiment. Take the analogy to machine learning: the “training set” we use for Dashlet is collected by MTurk, and the testing set is real users’ swipe. To quantify performance, we record the quality of every video chunk and the rebuffering event to calculate the QoE for both TikTok and Dashlet.

Human subjects study for users’ satisfaction. We let the same group of participants use TikTok and Dashlet for in total 30 minutes and ask them to rate the video quality and smoothness after they finish. Each participant used both TikTok and Dashlet for three five-minute sessions under three different network traces. Notice that the videos played in TikTok and Dashlet are different in the study since the users would behave differently if shown the same video once more, e.g., users tend to swipe fast when they are already familiar with the content in a video. For Dashlet, the swipe distribution is pre-collected with MTurk before the study.

Trace-driven study. We run a trace-driven study to scale up the evaluation under different user swipe speed and network traces. We use a script to automatically swipe in TikTok

²Among the ten participants, three of them are new users, three of them are occasional users, and four of them are daily users.

³The only action that users perform in the study is to swipe to the next video based on their watching experiences

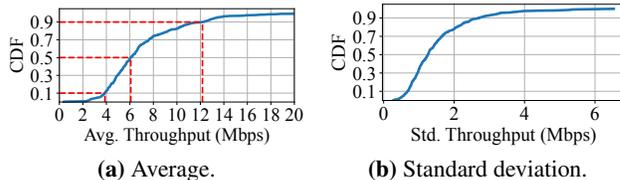

Figure 15: Throughput distribution for our network dataset.

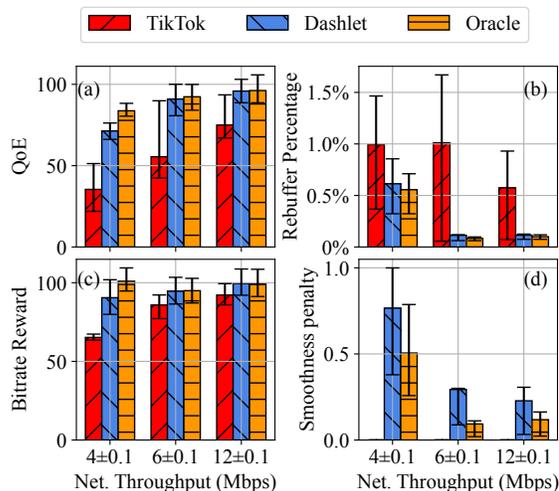

Figure 16: End-to-end result for human subjects study. (a) QoE (b) Rebuffer percentage. (c) Bitrate reward (d) Smoothness penalty

based on the distribution shown in Fig. 7. In order to enforce the same playing sequence (i.e., ordered list) of videos across the considered systems, we exploit the fact that the order in which videos are streamed with TikTok for a given keyword search remains unchanged on the order of many days. We use that same order across all systems and across experiments with different network and swipe traces. Each experiment considers 10 minutes of viewing time to match the average session time for TikTok users [34]. Similar to our human subjects study, we replay the same traces recorded from TikTok experiments to evaluate Dashlet and Oracle. The swipe distribution used for Dashlet in replay is collected from another batch of user study via Amazon Mturk.

Network conditions. We consider the combination of two sets of mobile network traces: (1) the FCC LTE dataset [9] that is widely used in prior work [22, 40], and (2) a WiFi trace dataset that we collected in January 2022 in a shopping mall. Fig. 15 shows the average and standard deviation of throughput traces in the combined dataset.

5.2 End-to-End performance

Human subjects study. Fig. 16 shows the end-to-end result for human subjects study, including QoE, rebuffering

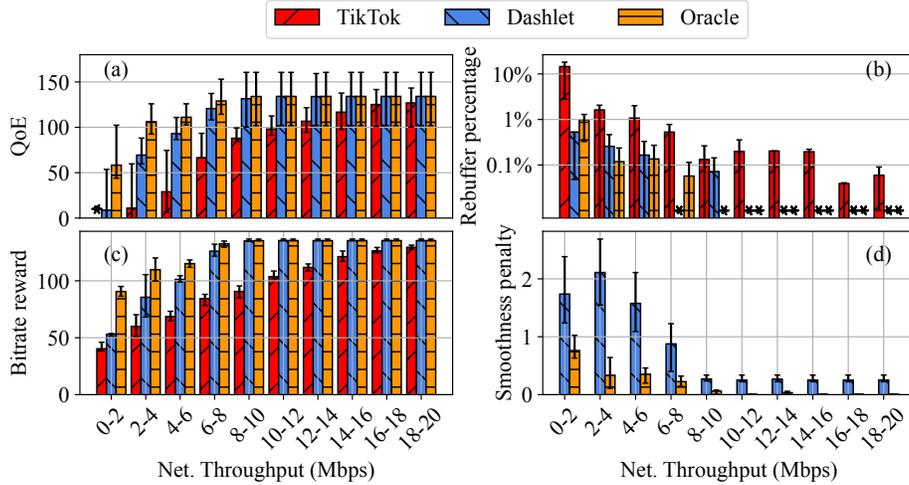

Figure 17: End-to-end result for trace-driven study. (a) QoE. * is the outlier data point with average QoE at -389 due to rebuffer (b) Rebuffer percentage (of total time). Note log ordinate axis; * denotes zero rebuffering. (c) Bitrate reward. (d) Smoothness penalty

Network throughput (Mbps)	4 ± 0.1	6 ± 0.1	12 ± 0.1
TikTok quality	3.1 ± 0.83	3.2 ± 0.87	4.0 ± 0.89
Dashlet quality	3.6 ± 0.80	3.9 ± 0.70	4.1 ± 0.94
TikTok stall	2.8 ± 1.08	3.0 ± 0.77	4.2 ± 0.99
Dashlet stall	3.5 ± 1.02	3.9 ± 0.94	4.3 ± 0.90

Table 1: User survey for TikTok and Dashlet. Each participant is asked to score 1 (worst) to 5 (best) in terms of video quality (resolution) and stall (rebuffer) under three different network throughput. The sample questionnaire is shown in §D. Table summarizes the average and standard deviation of the score.

Network throughput (Mbps)	4 ± 0.1	6 ± 0.1	12 ± 0.1
QoE	-363.2	-287.9	-133.5
Rebuffer percentage	28.0%	24.8%	14.3%
Bitrate reward	77.2	96.6	97.8
Smoothness Penalty	0.38	0.12	0.02

Table 2: End-to-end result for MPC.

percentage, bitrate reward and smoothness penalty. There are two key takeaways from these results. First, Dashlet consistently outperforms TikTok across different network throughput. Dashlet improve the average QoE over TikTok by 101%, 64%, 28% on 4 Mbps, 6 Mbps, 12 Mbps respectively. When break down the QoE into the components, Dashlet reduces the rebuffering by 1.6-8.9x compared with TikTok and improve the QoE by 8% - 39% with the cost of marginal smoothness penalty. Second, Dashlet can reach the close-to-optimal performance starting from 6 Mbps. While TikTok does not achieve that even at 12 Mbps.

We also run experiments on MPC [40], a state of art traditional video streaming algorithm, on the same setup mentioned above. As a traditional video streaming algorithm, MPC only prebuffers chunks for the current video. Table 2

summarizes the end-to-end result. Compared with Dashlet, MPC incurs a much higher rebuffering as it experiences rebuffer delay every time the user swipes to a new video., leading a significant lower QoE compared with Dashlet.

We also perform a experiment to understand the participants’ satisfaction of the service provided by TikTok and Dashlet. We let the participants watch videos using TikTok and Dashlet for five minutes, after which we conduct a user survey by asking the participant to report their satisfaction scores in terms of video quality (resolution) and stall (rebuffer) conditions for both TikTok and Dashlet. Table 1 shows the users’ satisfaction towards the video resolution and rebuffer for both TikTok and Dashlet on the human subjects study. From the figure, we can see that Dashlet improves the users satisfaction on both video resolution and rebuffering.

Trace-driven study. Fig. 17 shows the result for trace-driven study. Key results are: (1) Dashlet’s QoE improvement varies with the network throughput, *i.e.*, 543.7%, 221.4%, and 36.6% over TikTok when the throughput is 2-4, 4-6, and 10-12 Mbps, respectively. The improvement diminishes with throughput approaching to 20 Mbps. (2) Dashlet can reach the optimal QoE at a much lower network throughput than TikTok, *i.e.* Dashlet reaches the optimal at throughput 8-10 Mbps. While TikTok is close to the optimal at the throughput 18-20 Mbps. (3) Dashlet consistently incurs a lower rebuffering compared with TikTok.

5.3 Ablation study

We further perform an ablation study to understand the contribution of five design components (detailed in Table 3). *Idle:* TikTok has a prebuffer idle state as described in §2.2.1 while Dashlet does not. *Chunking:* TikTok splits the video into one or two chunks while Dashlet splits the video into

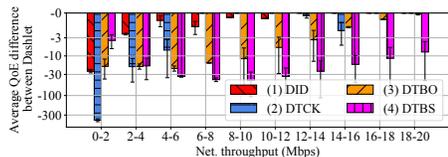

Figure 18: The contribution to End-to-End QoE for different design components. The y-axis in log scale is the QoE difference between the corresponding ablation study systems and Dashlet.

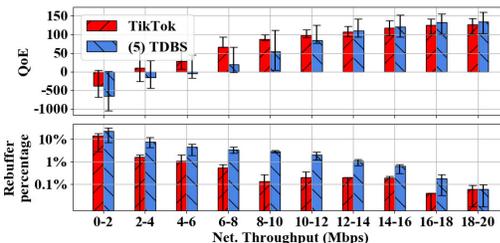

Figure 19: Ablation study for bitrate choice.

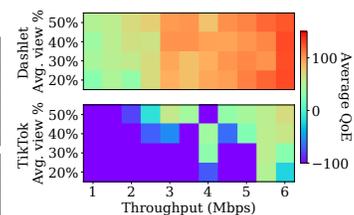

Figure 20: Average QoE of Dashlet and TikTok under different average viewing percentage (based on swipe patterns) and network throughput.

System Name	Idle	Chunking	Fix bitrate	Buffer order	Bitrate selection
(1) Dashlet+Prebuffer idle (DID)	T	D	D	D	D
(2) Dashlet+TikTok Chunking (DTCK)	D	T	T	D	D
(3) Dashlet+TikTok buffer order (DTBO)	D	D	D	T	D
(4) Dashlet+TikTok bitrate (DTBS)	D	D	D	D	T
(5) TikTok+Dashlet bitrate (TDBS)	T	T	T	T	D

Table 3: Setup for ablation study. We summarize the difference in design components between Dashlet and TikTok and evaluate the impact of corresponding design components. “T” and “D” denote TikTok’s and Dashlet’s design components respectively.

various number of equal-length chunks. Notice that Tiktok’s chunking also leads to a *fix bitrate* for chunks in the same video. *Buffer order*: whether the system follows TikTok or Dashlet’s buffer order. *Bitrate selection*. whether the system follows TikTok or Dashlet’s bitrate selection. We implement the TikTok’s logic for the corresponding design components according to our TikTok analysis in §2.2. For the bitrate selection, we use a lookup table to record the TikTok’s bitrate decision under different network throughput and buffer level. Our implementation for TikTok’s bitrate choice will then make the decision according to the look-up table.

We first investigate the performance drop when replacing Dashlet’s design components with the corresponding TikTok’s design component. Fig. 18 shows the QoE difference compared to Dashlet. Dashlet+Prebuffer idle (DID) curve shows that having a prebuffer idle state will have a significant negative impact at low throughput (e.g. 0-2 Mbps). But when the impact diminishes as the network throughput is above 4 Mbps. Similarly, TikTok’s chunking also has a significant negative impact at the low network throughput. The low network throughput forces TikTok to choose a low video bitrate, but consequently increases the first chunk duration, making TikTok more vulnerable to rebuffering when swipe happens. TikTok’s buffering order (DTBO) selection has significant negative impact on QoE until the throughput reaches 14 Mbps. The bitrate selection (DTBS) have the most significant impact on the QoE. Its impact to the QoE dominants as the network throughput reaches 4-6 Mbps. By digging deep in the reason, we find TikTok is very conser-

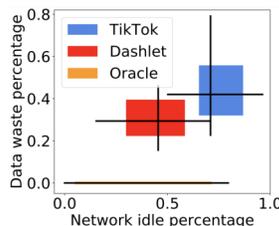

Figure 21: Data wastage and network idle time. Boxes span 25-75th percentiles. Black lines span min/max, and intersect at the median for both properties.

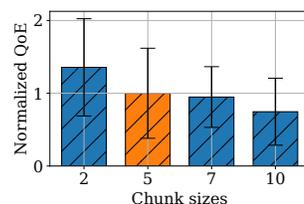

Figure 22: Dashlet’s chunk duration’s impact on QoE (normalized for 5-second chunk). Bars list averages, with error bars for one st. dev. in each direction.

vative in choosing high bitrate. We show the detail in §C. One natural next question arises is that could we just simply increase the request bitrate to improve the QoE. To answer this question, we consider another ablation study case **TDBS**, which includes TikTok’s design for all other components but keeps the high bitrate choices as Dashlet. Fig. 19 shows the comparison between TDBS and TikTok. with the higher bitrate choices, TDBS performs worse than TikTok when the network throughput is less than 12 Mbps. The key reason behind is that TDBS has a higher rebuffer percentage compared with TikTok. The takeaway is that TikTok’s low bitrate is a result of adaptation to avoid rebuffering. Simply increase the downloading bitrate could lead to a worse QoE.

5.4 Micro Benchmarks

Impact of Swipe and Network Speeds on QoE. Patterns in network throughput and user swipes largely influence the performance of short video streaming algorithms. To understand the effect of each, we report Dashlet’s and TikTok’s results for different network throughputs and swipe rates. As shown in Fig. 20, the major factor that affects QoE with Dashlet is the network throughput. Importantly, swipe speed does not have a significant impact on Dashlet’s performance, validating its robustness under different swipe patterns. In contrast, both network throughput and swipe speed have a large impact on TikTok’s QoE.

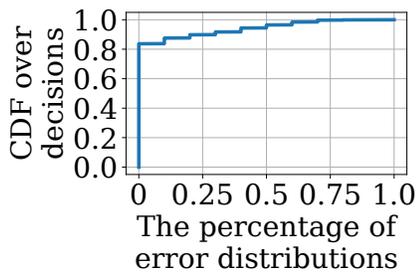

Figure 23: Dashlet’s tolerance to swipe distribution errors.

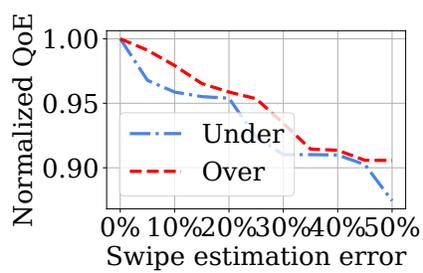

Figure 24: Impact of swipe estimation errors on Dashlet.

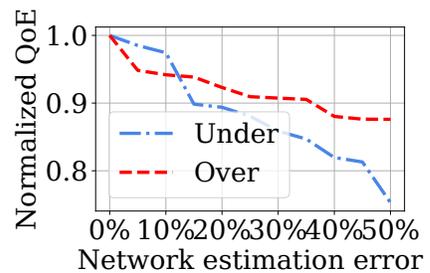

Figure 25: Impact of network estimation errors on Dashlet.

Network Idle and Data Waste. To dig deeper into Dashlet’s performance gain over TikTok, we investigate network idling and data wastage for both systems. Fig. 21 shows our results; note that the Oracle algorithm does not incur any data wastage since it has perfect knowledge of user swipe times. As shown, median data wastage and idle time for Dashlet are 29.4% and 45.5%, respectively, which are 30.0% and 35.9% lower than those with TikTok. These improvements enable Dashlet to stream video at higher bitrates than TikTok while keeping rebuffering delays low.

The impact of chunk size on Dashlet’s QoE. Unlike TikTok which breaks up videos by bytes, Dashlet (by default) breaks up videos into 5-second chunks. We evaluated the impact that chunk sizes have on Dashlet’s performance by considering the following chunk sizes (based on prior work [42]): {2, 5, 7, 10} seconds. Note that we did not modify chunk sizes for TikTok as we could not alter its video servers. As shown in Fig. 22, Dashlet’s performance decreases as chunk sizes grow, *e.g.*, average QoE drops by 35.4% as chunk sizes grow from 5 to 10 seconds. The reason is that data wastage grows with larger chunk sizes: a user swipe at 1 second into a chunk will result in more wasted bytes with a larger chunk size.

Decision Stability with Swipe Prediction Errors Dashlet determines buffer sequences by leveraging (coarse information from) users’ swipe distributions for each video. Thus, a natural question is how robust are Dashlet’s decisions to errors in those distributions, *i.e.*, does it make the right decisions even with different degrees of errors?

Recall that there are three inputs to Dashlet’s algorithm at any time: the swipe distribution for each considered video, the estimated network throughput, and the client-side player’s current buffer state. The algorithm uses this information and returns a buffer sequence of chunks to download, with the first chunk in the ordered list indicating the action to perform immediately, *i.e.*, the chunk to download now. To answer the above question, we profiled the above inputs throughout our experiments, and then compared the actions selected by Dashlet with those that it would select if the input swipe distribution involved errors. In particular, we considered 10 versions of each video’s distribution by (roughly) modeling

its original distribution as an exponential one, and then altering the corresponding λ value to change the average swipe time by $1 \pm \{0-50\}$ (in 10% increments).

Fig. 23 shows our results. As shown, 83.7% of Dashlet’s decisions are unchanged across all of the considered distribution errors. The values remain relatively stable as errors grow – *e.g.*, 96.5% of Dashlet’s decisions are unchanged with errors of 50% – but begin to grow after 82%. These results illustrate that Dashlet only relies on coarse information from swipe distributions (*e.g.*, about whether a user is likely to swipe early or late in the video); it is for this reason that decisions are varied only when errors are very high (and even the coarse information that Dashlet uses has changed).

QoE sensitivity with Swipe and Network Errors Building on the previous results, we now analyze how errors in swipe distribution affect the QoE that Dashlet delivers. We ran Dashlet on all videos and the network traces using same faulty distributions from above. Fig. 24 shows the results, breaking them down in terms of scenarios with over estimation of swipe times (longer average viewing time than the correct distribution, *i.e.*, later swipes) and under estimation (shorter average viewing time). As shown, Dashlet is quite tolerant to such errors, delivering 87% and 91% of its full QoE (with no errors) when the traces are over- and under-estimating swipe times by 50%.

We perform a similar analysis to evaluate Dashlet in the presence of network prediction errors. Specifically, we replace the network predictor in RobustMPC [40] with one that reads in the actual instantaneous throughput from the current Mahimahi trace, and multiplies that value by between $1 \pm \{0-50\}$. Overall, as per Fig. 25, we find that Dashlet’s QoE drops to 88% and 76% of its values without network errors when the network estimate is over- or under-estimating by 50%. These results highlight that Dashlet is more robust to errors in swipe distributions than network forecasts.

6 Related work

Traditional adaptive video streaming Traditional video streaming services deliver video content from the CDN to the user with adaptive bitrate system with the objective of

maximizing the quality of experience for users [20]. Research effort has been made to improve the quality of experience from different perspectives, including streaming algorithm [18, 19, 22, 29, 40], video codec [7, 10], network prediction [30, 36], protocol design [14, 45], and video super resolution [38, 39]. But all these optimization is for the same video streaming model: the video download sequence is the same as the video playing sequence. Dashlet also uses QoE as the optimization goal but tackles a different problem as in the short video streaming the video download sequence is the same as the video playing sequence due to users' swipes. **Streaming new form of video** There are also rising interest on 360 degree video [12, 26] and volumetric video streaming [25]. These systems need to handle the uncertainty from the users' head position or location. Dashlet's design also models the uncertainty from the user swipe patterns. But Dashlet targets on a different problem compared with 360 degree or volumetric video streaming. Some existing works [15, 27] also try to apply reinforcement learning algorithms from traditional video streaming [22] to short video streaming. However, these works do not factor in the impact of user swipes on buffering decisions as Dashlet does.

7 Discussion

TikTok version. Our reverse engineering tool can only decipher the HTTPS messages transmitted by TikTok with version up to v20.9.1. As a result, we cannot conduct our case study (§2) using the up-to-date TikTok v26.3.3, which adopts a different encryption method as V20.9.1. We leave the task of deciphering the HTTPS messages and thus studying the streaming algorithm of the newest version of TikTok as our future work.

Backward swipes, fast-forwarding, and pause. Our current model only allows forward swipes, *i.e.*, swipes to watch next videos. The newest version of TikTok also allows backward swipes where the user swipes to watch the previous video and fast-forwarding, where the user speeds up the playback of the current video: we will study these in future work. In addition, our model does not consider the video pause. The pausing of videos will make it easier for the system since it gives the player more time to download videos. For Dashlet's design, we focus on a harder problem, which assumes no pause in the video.

Diminished gain at higher network speeds. We observe a diminished improvement for Dashlet over TikTok at higher network speeds. At higher network speeds, mistakes made by TikTok are masked by higher network throughput. As network speed increases, TikTok can pick up the highest bitrate but still have enough time to react to users' swipes. In our evaluation, we use the bitrates that TikTok's CDN offers, which are capped at 720P video quality. We expect the gap between Dashlet and TikTok will widen if higher

bitrate videos are used to evaluate both systems, which we expect will happen in the future.

Generalization of Dashlet design. The Dashlet design does not rely on the design of TikTok but only relies on a sequence of videos that are played in chunks. Therefore, it should be able to generalize to other platforms like YouTube Shorts and Instagram Reels.

Energy implication to smartphones. Dashlet could potentially reduce the energy consumption for short video applications. The energy cost includes both the cost to run the algorithm and the cost to download the video content. Dashlet uses a simple non-machine learning algorithm, which causes minimal extra energy overhead. For the cost to download the video content, Dashlet has less energy overhead since its waster download is much less than TikTok.

Evaluation generalizability. We have conducted a small scale human study to compare the performance of Dashlet and TikTok, where ten participants log into their own account to watch TikTok video on a emulated mobile network, repeating the experiments using Dashlet. The personality of the recruited user may lead to biased results, for example, a patient user may tend to not swipe or swipe at the end of the video, leaving larger time window for TikTok to download the second chunk. A larger scale human study that involves more diverse users is needed to eliminate this potential bias.

We conduct our evaluation under emulated mobile networks, but prior work [36, 37] has pointed out that the emulation based evaluation of network applications and congestion control schemes may not always be indicative of real-world performance. For example, although we compensate the average round trip delay to the CDN server in the emulated environment, the variation in the round trip delay might potentially impact the results. While we note that Dashlet does not input network measurements into an ML model, we acknowledge that large-scale evaluation in the wild may be required to verify the full generalizability of our results.

8 Conclusion

In this paper, we design and implement Dashlet with the insight provided by measurement for a commercial short video app and a user study on general user swipe pattern. Dashlet's algorithm strategically determines the buffer order with the input from a coarse-grained swipe distribution. Evaluation result shows Dashlet significantly improves video quality and reduces rebuffering compared with the baseline system.

A Dashlet Pseudocode

Algorithm 1: Dashlet’s ABR algorithm

Input : 1) Buffer status $r_1 \dots r_n$
 2) Video bitrate $B = \{b_{1k} - b_{1k} \dots b_{n1} - b_{nk}\}$
 3) The probability distribution of play start time for each chunk $\hat{G} = \hat{g}_{11}(t) \dots \hat{g}_{nc_n}(t)$
 4) network throughput estimation T
 5) The look-ahead time length F
 6) Chunk length L

Output : The location and bitrate to buffer next

```

1 foreach  $i, j \in \{1 \dots n\}$  do
2   if  $\int_0^F (F-t)\hat{g}_{c_{ij}}(t)dt > 1/\mu$  and  $j > r_i$  then
3      $candidateList.append(c_{ij});$ 
     //Add the chunk to the candidate list if
     there is significant penalty for not
     downloading it
4  $targetBitrate = F \times T / len(candidateList) / L;$ 
5 do
6    $c_{min} = \text{minRebufferCost}(targetBitrate, bufferOrder,$ 
    $candidateList);$ 
7    $bufferOrder.append(c_{min});$ 
8    $candidateList.remove(c_{min});$ 
9 while  $len(candidateList) > 0;$ 
   //use greedy algorithm to put chunks from
    $candidateList$  into  $bufferOrder$ 
10  $bitrateList = \text{getMaxBitrate}(bufferOrder, B, T);$ 
   //Enumerate all the bitrate combination for
   chunks in  $bufferOrder$  to maximize the QoE
11 Return  $bufferOrder[0], bitrateList[0]$ 

```

B Dashlet Implementation Further Detail

Dashlet makes no change to the CDN/server side so our system can be easily deployed client side. Dashlet includes one control module and multiple buffer modules. Each buffer module manages the video playback of one short video, including downloading chunks, tracking playback progress, and reporting buffer status. We reuse the DASH.js playback management for the buffer modules. The control module manages scheduling across short videos, collecting estimated throughput and buffer length from each buffer module. With the collected data, control module runs Dashlet’s algorithm to schedule the video buffering. Based on the algorithm’s output, it assigns the quota to the buffer module that is assigned to download the next video chunk. The quota includes the target video bitrate and the target download finish time. Once the buffer module receives the quota, it sends an HTTP request with target bitrate to the CDN to download the corresponding video chunk. A call back function is set to report the status to control module in case the download time

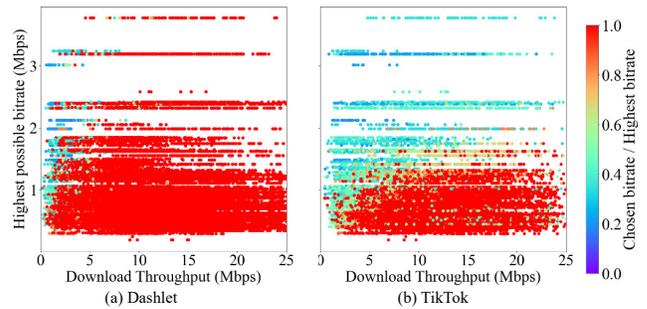

Figure 26: Bitrate choice made by Dashlet and TikTok. The x-axis is the network throughput and the y-axis is the highest available bitrate to choose. The color is the ratio between the chosen bitrate and the highest available bitrate. The red color means the highest available bitrate is chosen.

- How will you rate the quality of the video you watched on **TikTok**
 - Excellent, all the videos are high quality (5)

Figure 27: Questionnaire for user survey.

exceeds the target download finish time. The control module schedules the video buffering when the call back function for target download time is triggered, the chunk download finishes, or the user swipes. Similar to Pensieve [22], we also use an ABR server to run Dashlet’s algorithm on the same machine as the client. The control module communicates with the ABR server using XMLHttpRequests locally.

C TikTok is conservative in video bitrate selection.

We show every bitrate that TikTok and Dashlet has selected in the section with Fig. 26. We can conclude from the figure that TikTok limits its bitrate even if the network throughput is high enough. This then leads to a significant negative impact on the QoE.

D Questionnaire sample.

We show the sample of the questionnaire we used in the user survey in Figure 27.

CellDAM: User-Space, Rootless Detection and Mitigation for 5G Data Plane

Zhaowei Tan, Jinghao Zhao, Boyan Ding, Songwu Lu
University of California, Los Angeles

Abstract

Despite all deployed security fences in 5G, attacks against its data plane are still feasible. A smart attacker can fabricate data packets or intelligently forge/drop/modify data-plane signaling messages between the 5G infrastructure and the device to inflict damage. In this work, we propose CellDAM, a new solution that is used at the device without any infrastructure upgrades or standard changes. CellDAM exploits the key finding that such data-plane attacks by the adversary would trigger unexpected data signaling operations. It thus detects all known and even currently unreported attacks via verifying data signaling correctness with novel state-dependent model checking. CellDAM could work with or without firmware access at the device using inference on low-level 5G signaling and configurations. It mitigates the damage upon detection by inducing frequency band switches at the device via the existing handover procedure. The prototype and empirical evaluation in our testbed confirm the viability of CellDAM.

1 Introduction

The current 5G and its legacy 4G cellular networks provide anywhere, anytime Internet access for billions of users. Security is an important design goal for 5G systems. Multiple security fences are thus deployed or enhanced [7], e.g., device authentication, enforced data encryption and integrity check. They aim to defend against recent attacks against the control plane [23, 41], as well as the data plane [47, 48, 60].

The current security fences are mostly *proactive protection* on data packets. However, this is insufficient for 5G data plane. Certain categories of attacks still cannot be protected. For example, a smart attacker can selectively drop a few data-plane signaling to incur cascading effect. Moreover, proactive protection is sometimes of high cost, such as protecting low-layer, cleartext, data signaling messages. Furthermore, proactive protection could be turned off with certain attacks [43], or unavailable to legacy devices in developing countries [1, 52].

In this paper, we explore a *reactive* solution approach called

CellDAM towards 5G security. Instead of proactively preventing attacks, CellDAM complements the existing efforts by detecting whether a potential attack is underway and mitigating its damage. In addition to identifying the above-mentioned attacks that cannot be handled by proactive solutions, it offers two more benefits. First, the solution needs no standard change or hardware upgrade, thus being immediately deployable. Second, by verifying the correct operations, a reactive solution can find any attacks that do not follow the standard procedure, including both known and unreported ones.

A well-known challenge for data-plane detection is the high data throughput by 5G. It is thus considered impractical to inspect data packets at Gbps on a mobile device without consuming excessive processing or energy resources. CellDAM addresses the issue with a novel approach. We do not check each data packet directly. Instead, we inspect the data-plane signaling messages, which are standardized to facilitate data delivery but incur 1-2 orders of magnitude less overhead compared with monitoring all data packets. Our approach can detect attacks against both signaling messages and data packets. This is because every data delivery must exchange signaling messages for resource grant over the licensed 5G wireless channels. Therefore, *undesired data-plane signaling operations* might be triggered at the device by data-plane attacks.

We “verify what is right” when inspecting data-plane signaling. We thus model signaling operations for 5G data delivery; any operation that deviates from the standardized model is considered as a potential attack. It turns out that, a single-protocol, static checking scheme cannot detect all attacks. We thus devise a novel cross-layer, state-dependent model checking to validate data-plane signaling operations. At each state, we perform context-dependent validation to spot unexpected messages. Our experiments show that we have discovered three unreported attacks in addition to the known ones.

CellDAM is designed to work with various levels of privilege. Note that it requires access to signaling messages for inspection. The messages can be easily obtained with firmware access. However, for a user application, low-level 5G signaling cannot be accessed without root privilege. To overcome

this limitation, CellDAM utilizes SecHub, a separate companion node placed near the device. It uses a new inference technique to capture the signaling messages of interest from/to the protected device, but filter out all others.

Upon detection of an attack, CellDAM mitigates impact by triggering a 5G-standard handover procedure. This switches the device to a new cell. The attacker cannot track the device due to the encrypted handover messages and the dense deployment of 5G cells. Meanwhile, the handover procedure only incurs a disruption that lasts less than 100ms. With firmware access or network assistance, CellDAM could trigger the procedure using standardized commands. If they are unavailable, CellDAM leverages the SecHub to impact the channel measurement results to trigger a handover procedure on the victim device, but does not affect other devices.

We show that, CellDAM offers a practical solution to detecting and mitigating data-plane attacks with high accuracy. We prototype a device-side, user-level solution in C++ and Python based on open-source srsRAN [51]. SecHub implements components to infer the parameters, detect by verifying data-plane signaling, and mitigate with frequency band switching; all components do not require root privilege on the protected device. It achieves the detection accuracy of 0.989~1.0, recall of 0.705~1.0, and the F1 score of 0.823~1.0. It can detect known and new attacks within 28ms on average. For mitigation, the handover can be triggered at 100% success rate with a latency of 1.85s on average. This procedure only incurs an average of 72.3ms disruption on applications. SecHub can successfully find the protected COTS devices with the accuracy of 97.2%~100% under various traffic types.

2 Background

2.1 5G Primer

5G Architecture 5G system has 3 major components (Figure 1): User Equipment (UE), Base stations (gNB), and 5G Core network (5GC). The UE is a 5G user device. The gNB powers up the 5G network and provides wireless access in its coverage area for UE. It also forwards data to and from 5GC. 5GC includes the control plane for authentication and mobility support, and the data plane for data packet delivery.

5G Protocol Stack The 5G protocol stack consists of multiple protocols for both control-plane and data-plane functions. Non-access Stratum (NAS) and Radio Resource Control (RRC) are in charge of control-plane signaling. NAS facilitates control-plane signaling message exchange between the UE and 5GC. RRC carries the control messages and data-plane parameters for setup, power management, and handover behavior between the UE and the gNB. The data-plane enables IP packet delivery. We describe 5 protocols involved in data-plane operations: Service Data Adaptation Protocol (SDAP), Packet Data Convergence (PDCP), Radio Link Control (RLC), Medium Access Control (MAC), and Physical Layer (PHY).

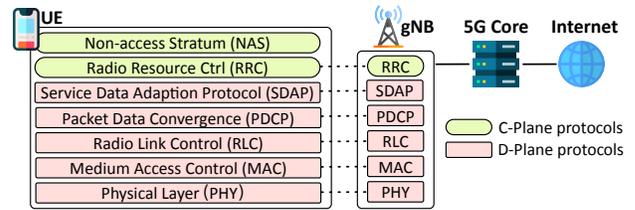

Figure 1: Architecture of 5G and its protocols.

control (RLC), Medium Access Control (MAC), and Physical Layer (PHY). SDAP manages the quality of service for data delivery. PDCP takes charge of encryption and integrity protection for control-plane and data-plane packet. RLC performs data concatenation and reorganization to ensure reliable, in-order data transfer. MAC controls radio access in licensed bands, and PHY performs wireless signal processing.

Data-Plane Signaling In addition to RRC and NAS signaling for the control plane operations, 5G data-plane also has signaling between UE and gNB to facilitate packet delivery. The data-plane signaling exhibits in multiple forms. Various flags at the MAC layer (grant assignment DCI, scheduling request, HARQ acknowledgements, etc.), MAC control elements [3] that convey power control, time alignment or buffer status, and RLC control [5] for reliable transfer are all instances of data-plane signaling.

2.2 Protecting Data-Plane in 5G

Mutual Authentication Mutual authentication is a critical security measure in 5G, inherited from 4G with little change. The UE and network perform a secure Authentication and Key Agreement (AKA) procedure during connection for authentication and session key set-up. The session key is used to generate keystream for every packet with several parameters such as sequence number.

Protection on Data Packets The keystream is generated to encrypt data packets without key reuse for both control-plane and data-plane packets [7]. The sender also updates another keystream to generate an integrity code attached to the message for integrity check at the receiver. While integrity protection for control messages is enforced in 4G, it was optional for data plane due to high overhead. The vulnerability allows attacks that fabricate data packets [48,49]. 5G aims to enforce integrity protection on all data packets. Although its usage is still optional, both 5G UE and gNB should support integrity protection at the full speed starting from release 16 [7]. With the increasing capacity of the hardware, it is expected such integrity protection will be mandatory.

3 A Case for Detection and Mitigation for 5G Data-Plane Attacks

3.1 Threat Model

In this paper, we consider an adversary who seeks to incur various damages on the target victim 5G device on its *data*

plane. The attacker has the following capabilities: 1) Connect to the same cell as the victim device, which is feasible with fingerprinting [32] or social engineering [36]; 2) Eavesdrop on, transmit data, or send noises on physical channels; 3) The adversary may exploit fake base station (FBS) [48, 49] or overshadowing attacks [60]. Although FBS is mitigated in 5G [4], it is still possible to launch certain variants of FBS, such as relay FBS as man-in-the-middle. We do not limit the message that can be forged by the adversary, which could be user packets or signaling messages.

We do *not* consider attacks that threaten control-plane, such as an IMSI catcher. We also do *not* consider an insider attack, where the adversary can steal security keys stored in SIM/networks or even compromise a 5G base station. Protecting such attacks is beyond the scope of this work.

3.2 Proactive Protection is Insufficient

State-of-the-art: Per-message proactive protection The authenticity of 5G user packets is protected by end-to-end (such as TLS [29]) and 5G-specific integrity protection (as introduced in §2.2). However, data-plane attacks are still possible despite the protection.

Issue 1: Not every message could be protected at low cost Unlike end-to-end packets, the small-sized data-plane signaling messages are not protected by proactive solutions [2], due to high overhead or impracticability being in the below-PDCP layer. Fabricating these messages can incur serious damages as shown in recent studies [54]. An attacker only needs to forge a few messages to incur damages consistently. One example attack is shown in Figure 2(a). An attacker forges a Buffer Status Report (BSR) that requests uplink grant from the gNB. The uplink grant in a time period will be assigned in accordance with the request. A malicious BSR could contain a large request, wasting licensed resource and blocking uplink delivery of any UE in the cell for hundreds of milliseconds. The attacker is capable of repeatedly forging such messages, which can continuously drain the resource. We note that, gNB cannot distinguish this attack message from a legitimate one.

Issue 2: Certain attacks cannot be proactively protected The attacker can also intelligently corrupt/drop certain messages to incur serious damages. Such attacks *cannot* be protected by any integrity check. One example attack is shown in Figure 2(b). In this attack, the adversary corrupts an RLC control message NACK, which is used to request retransmission for certain packets. When this NACK is lost, the retransmission is delayed. Due to the RLC mechanism, all subsequent data packets will be blocked. The effect will last until the next RLC message, which could be hundreds of milliseconds based on common RLC configurations. Moreover, the attacker can repeatedly send the message to cause persistent damages. The attacker does not require fake base stations or channel jamming. Instead, a lightweight attacker only needs to send a

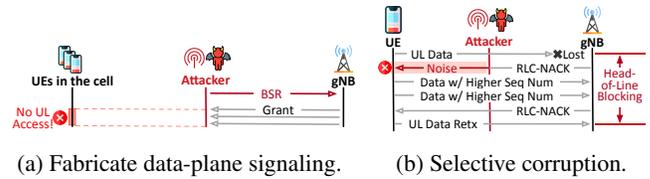

Figure 2: Example data-plane attacks that cannot be protected with current proactive approaches.

single signaling every hundreds of milliseconds.

Issue 3: Proactive protection could be turned off Forging user data packets is still possible despite the data packet integrity check in 5G. The usage of integrity protection is still negotiation-based [7]. Hence, the attacker can disable integrity protection by leveraging certain vulnerabilities, such as those from firmware [43]. Furthermore, legacy 4G devices or 5G devices on earlier versions, which are still a considerable number [42, 52, 56], do not implement mandatory integrity check [1]. For these devices, known attacks can incur serious damage when end-to-end protection is not used. An attacker can manipulate DNS requests to a malicious Web server [48]. The malicious server could then send any forged content to the victim. Beyond Web, the attacker could forge arbitrary encrypted data through a man-in-the-middle [49].

Insight: Reactive detection and mitigation can complement proactive protection Given all the existing threats which cannot be protected by proactive approaches, we shall also develop proper *reactive* solutions to complement the proactive protection. They should include both detection and mitigation. The detection methods will spot any suspicious activities, while the mitigation will help the victim recover from the damages. They can complement existing solutions, while not requiring any 3GPP framework change.

4 Overview of CellDAM

In this section, we present the design goal and challenges of designing a reactive protection.

4.1 Security Goals

Following our insights, we seek to *detect and mitigate* 5G data-plane attacks *without standard changes*. As discussed in §3.2, this solution approach offers an immediate remedy for certain attacks that are not protected by current proactive approaches. We argue that, such detection is essential on the device side. First, it is more scalable compared to network-centric solutions. Second, some attacks are only detectable on the device side. Take the signaling attack (Issue 1) in §3.2 as an example. In this attack, the UE will receive uplink grant that it did not request. However, the network cannot distinguish whether the request is malicious or legitimate. Therefore, device-side detection is required to detect and mitigate the attacks.

Meanwhile, our reactive detection and mitigation scheme should achieve the following goals:

Verify what is right for attack detection We design and implement approaches that verify whether the runtime, data-plane operations follow the correct procedures stipulated by the standards, and treat any undesired behaviors, rather than specific attacks, as suspicious. This ensures the detection of a category of attacks that yield improper data-plane operations. Even if an attack has not been reported yet, it can be detected by our approach as long as it triggers undesired behavior. We admit that certain attacks that adhere to the standardized approach might not be detected by our approach. Our solution prioritizes soundness over completeness.

Detection and mitigation need to be practical We aim to design a reactive method without hardware update or extra privilege. It can thus benefit legacy devices.

•No infrastructure upgrade We will design our solution *on the device side*. Unlike network-centric protection approaches [24, 44, 46, 57], our device-side scheme needs no expensive infrastructure or hardware upgrades. Moreover, as we discussed earlier, certain attacks can only be observed by the device.

•1-2 orders of magnitude lower overhead compared to verifying each data packet It is nontrivial to monitor the 5G data plane. Data throughput in 5G is expected to reach a few Gbps. The traffic volume of data packets is several orders of magnitude higher than the control-plane signaling messages. We aim to design a lightweight security solution that can work under heavy data traffic. The overhead should be 1-2 orders of magnitude smaller compared to monitoring the entire traffic.

Applicable to different defense models The solution should work given different levels of privilege. We consider three defense models in this work: (1) Defense with firmware access; (2) A user-space application that can communicate with the operator; and (3) A user-space application without any privilege. All three models have their own usage scenarios. For (1), a device vendor implements the solution to enhance the security of its 5G devices. For (2), we consider an operator who tries to protect its users with additional security requirements. However, the operator cannot directly access the firmware. For (3), we consider a normal user who tries to protect the device. All three models complement each other under different scenarios to protect 5G data plane.

For the Defense model (1), the solution could be implemented inside the firmware, as it has access to all cellular-specific info and OS-level privilege. For both (2) and (3), mobile OS only provides control-plane basic info [10], such as connection state. The application cannot access device-side cellular-specific info unless extra privilege (e.g., Diag port) is granted for tools like MobileInsight [37] or QXDM [45]. However, such extra privilege (e.g., root access) exposes new vulnerabilities [15, 21, 22, 50] and is unavailable to most devices due to technical or legal concerns [34]. Our solution

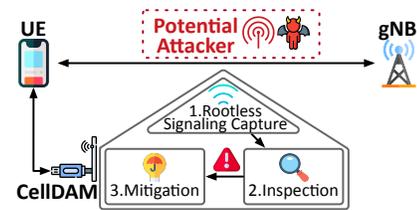

Figure 3: Envisioned procedure of CellDAM.

aims to function despite the limitations.

State-of-the-Art: Existing reactive approaches cannot achieve these goals To the best of our knowledge, all

previous works on 5G/4G attack detection focus on undesired behavior on the control plane [26, 27]. This is insufficient, as recent studies [54, 60] show that an advanced adversary can bypass control plane and directly attack the data plane.

4.2 Solution Overview

We design CellDAM, a 5G data-plane inspection scheme without root privilege, as illustrated in Figure 3. It satisfies all design goals. CellDAM first captures all data-plane signaling messages from/to the protected UE. It could do so in a separated node called SecHub and bypass the requirement of in-device extra privilege. CellDAM then inspects the *lightweight* data-plane signaling messages to spot undesired behavior. Finally, CellDAM uses SecHub and in-device operation to mitigate the attack damage via handover-based cell switching.

Inspecting lightweight signaling messages with state-dependent checking (§5) We first show that, inspecting data-plane signaling offers an effective way to detect data-plane attacks, while it has magnitude lower overhead due to its low volume. We further propose a *cross-layer, state-dependent* model checking for attack detection. If the device spots an incoming signaling message that is undesired in the current state, it detects a potential attack.

Rootless signaling inference (§6) Signaling verification requires access to the messages. For the defense model with firmware access, such privilege is granted. To serve the majority of rootless devices, CellDAM incorporates a separate, companion node named SecHub for the protected device. The goal is to share a consistent view of the physical channels. The node can continuously capture over-the-air signaling messages by inferring the device ID and traffic pattern. It needs no extra privilege on the protected device.

Device-side reaction without infrastructure upgrade (§7) Once a suspicious operation is detected, we activate the mitigation module that switches to other, potentially attack-free 5G channels. This could be done by leveraging the standardized 5G handover procedure and dense cell deployment. Handover incurs small disruptions in the applications, while being resilient to attacks. CellDAM can initiate such a procedure via two approaches. It can directly create a standard-compliant message for handover. It can also leverage SecHub to affect the device to trigger a handover, without affecting other user devices.

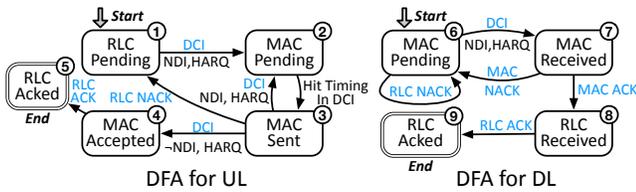

Figure 4: DFA for tracking states with data-plane signaling. See Appendix C for an extended version.

5 Cross-layer, State-dependent Checking on Data Plane Signaling

We now present how `CellDAM` inspects the data-plane signaling messages to detect undesired behavior. We follow our guideline of “verifying what is right” to model the device-side protocols and detect any undesired behavior. To this end, we devise validation schemes using the standardized data-plane delivery procedure to check each incoming/outgoing data-plane signaling message.

The solution has two highlighted components. First, instead of verifying data packets of large throughput, `CellDAM` inspects lightweight, yet critical data-plane signaling messages for attack detection. Second, we present a state-dependent model checking method to find suspicious behaviors.

5.1 Monitor and Inspect Data Plane Signaling

A straightforward solution can verify each data packet. This can be done by applying Deep Packet Inspection (DPI) or detecting anomalies in the wireless signal for each data packet. However, they cannot detect all attacks, such as the attacks that target signaling messages. Meanwhile, this will incur huge overhead, especially given the large 5G throughput.

Why inspect data-plane signaling We show that, monitoring data-plane signaling offers an effective alternative method for detecting data-plane attacks, including attacks on both data-plane signaling and data packets. First, delivering each data has a standardized sequence of signaling messages due to 5G infrastructure-controlled data access. For any type of attack, the attacker needs to tamper with the signaling messages. Therefore, this solution approach will cover a wide range of attacks. Second, the frequency of data-plane signaling is smaller than data packets due to 5G aggregation scheduling.

Data-plane attacks might manipulate data-plane signaling in standardized data delivery For data delivery, each device must follow a standardized approach, as 5G uses gNB to mandate the radio resources. Therefore, we can use the signaling messages to model the state of each packet delivery. To model and track the state, we use Deterministic Finite Automata (DFA), a common technique for state tracking in attack detection [19, 26]. We study 3GPP standards across all 5G-specific data-plane sublayers and manually create DFA based on *mandated, standardized data delivery procedure*. We form cross-layer DFA for each RLC data packet with its

necessary state transition at the MAC layer. We do not include PDCP, as it does not maintain state or buffer packets.

The constructed DFA is shown in Figure 4. For uplink, data transmission follows a scheduling-based feedback loop. The device first sends requests (Buffer Status Reports or BSR) to ask for resource grants until the packet is delivered by MAC. The MAC fast retransmission is notified by a new DCI with the same HARQ ID and NDI. The packet is considered delivered when the RLC ACK is received. For downlink, the data transmission follows the same procedure but without the request-grant loop, as the gNB initiates the transmission. The device sends the MAC feedback of ACK/NACK in PUCCH.

Inspecting data-plane signaling is lightweight Compared with data-plane packets, inspecting data-plane signaling is of much lower overhead. First, the size of each signaling message is much smaller than the actual data packet. The signaling messages (such as DCI, RLC Control) are at most several bytes long. Some PHY messages are merely 1-bit indicators. Second, 5G data delivery will transmit multiple IP data packets in a single data block (aggregated and segmented by the 5G RLC protocol). Therefore, for signaling messages that facilitate data delivery (e.g., DCI), only one such message is needed for the large block.

We validate the hypothesis that control traffic is significantly lower than data traffic by comparing their traffic volume. We show results from operational traces in a commercial network and in our SDR-based testbed. Our testbed runs standard-compliant srsRAN 5G [51] and the details will be shown in §10. Since our testbed does not support features such as MIMO or carrier aggregation for higher throughput, we also collect traces from commercial operators. As the current open-source 5G decoding tools (e.g., MobileInsight 5.0 [37, 38]) have not supported 5G data plane, we collect and analyze 4G data plane as a reference, considering that data-plane signaling design remains largely unchanged in the current 5G NSA [3, 5]¹. As shown in Figure 5, the processing of data-plane signaling is 1~2 orders of magnitude lower than that of data packets.

Therefore, detecting attacks with data-plane signaling is of much smaller overhead than monitoring the entire data-plane packets. Prior work [20] has already shown an SDR-based system is capable of monitoring DCI messages for *all devices in a cell*. It is thus feasible for `CellDAM` to capture all data-plane signaling *for a single device* while performing inspections in real-time (detailed in §9). This is important considering 5G’s high data rate.

5.2 Cross-layer, State-Dependent Checking

Stateless checking cannot detect certain attacks The detector could perform certain checks within each protocol

¹One major difference is that 5G cancels PHICH which is used for uplink data retransmission. Therefore, we do not include it for calculation.

Check	State	Message	Validation Details
c_1	All	Any Message	The data-plane signaling shall be in the accepted list for each state. (Appendix C)
c_2	s_3, s_6	RLC NACK	It shall not be received after RLC timer and MAC retransmission timer expire or after receiving an RLC ACK with higher sequence number.
c_3	s_4, s_8	RLC ACK	An RLC ACK shall not be received before the packet is acknowledged in MAC.
c_4	s_7	MAC ACK/NACK	The ACK/NACK in PUCCH should be delivered at correct timing after DCI; If not, this is an indicator that the previous grant/data is received during DRX OFF.
c_5	s_1	DCI for UL Grant	There should not be large “free” grant when no request is sent or no data in buffer.

Table 1: Validation checks performed by CellDAM based on state and message.

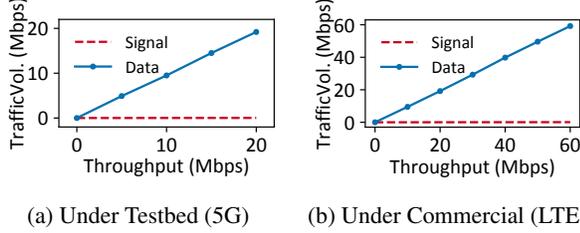

Figure 5: The comparison of traffic volume per second for data packets vs. data-plane signaling messages.

regarding whether the incoming signaling message conforms to the standards. However, this solution will fail to spot certain attacks against 5G data plane.

We showcase a concrete example. When an RLC signaling message ACK is received, it is possible if MAC layer has accepted this message. Otherwise, this message is impossible and a potential attack is detected. Therefore, the checking must rely on the current state across different protocols.

Cross-layer, state-dependent model checking with DFA Therefore, we propose a state-dependent checking for 5G data plane security. Instead of proposing a few checks statically in each protocol, we leverage the cross-layer DFAs we built for data delivery, whose inputs for transition are *data-plane signaling messages* or their derived events. If the next captured signaling message m passes all validation checks, the DFA moves to a new state; Otherwise, a potential attack is detected and we initiate the mitigation procedure.

Formally, we maintain n deterministic finite state machines $M = \{M_1, M_2, \dots, M_n\}$. For each DFA $M_i, i = 1, 2, \dots, n$, we denote it as a 5-tuple $(S_i, S_i^0, S_i^1, \Sigma, T_i)$, where S_i is a finite set of states with $S_i^0 \in S_i$ being the initial state and $S_i^1 \subseteq S_i$ being the accepted states, Σ is a finite set of input messages², $T_i : S_i \times \Sigma \rightarrow S_i$ is a transition function mapping the pairs of a state and a received message to the next state.

We build validation checks $V = \{V_1, V_2, \dots, V_k\}$. Each V_i is associated with a DFA M_j , a state $S \in S_j$, and a message $m \in \Sigma_j$. Every time the DFA M_j with state S inspects a new message m , CellDAM runs the corresponding check(s). They map the signaling message m to 0 (fail) or 1 (succeed) given the current context, which is derived from past records or other DFAs. A potential attack is identified if one of the validation checks fails; Otherwise, M_j accepts message m and updates its state accordingly.

²To make the problem tractable, we only consider the discussed data-plane signaling messages. We prioritize soundness over completeness.

Based on the state, we perform a few validations on each incoming/outgoing signaling message. We show the list of validations in Table 1. First, all states will have a list of accepted messages. CellDAM checks whether the next message is in the list. The detailed list for this check is shown in Appendix C. For c_2 to c_3 , we are checking whether the RLC operations are consistent with the MAC layer for both uplink and downlink. For example, upon receiving RLC NACK, we check whether an early RLC ACK that has already acknowledged a packet is received. For c_4 , we use the indicator of no ACK/NACK to detect a possible forged message received in DRX OFF. For c_5 , CellDAM detects abnormal grants from gNB without any request. Note that a gNB can freely grant the device with small grants. However, they are usually 100-200 Bytes long. Any larger grant incurs a waste of resources. Therefore, it could be the outcome of a forged BSR or grant signal. If all checks pass, the DFAs are switched to the new state.

6 Access Signaling Messages for Detection

With CellDAM’s checking techniques, an end device can inspect signaling messages for attack detection. We now discuss how to access them under three defense models in §4.

With direct firmware access For defense solution that has firmware access, it could directly capture the signaling messages. In fact, these messages are already processed by firmware to realize the functionalities.

No direct firmware access If CellDAM is deployed on the application layer, it cannot directly access the signaling messages. Although messages are available in tools such as MobileInsight [37] or QXDM [45], using these tools and accessing the low-level messages require root, which exposes new vulnerabilities [15, 21, 22, 50] and is unavailable to most users [31]. Even the application is allowed to communicate with the network (i.e., defense model 2), it cannot access the *device-side* signaling for detection.

Idea: Infer signaling messages without root privilege in a separate node To address the concern, we design and deploy a separate gadget (e.g., extended hardware with wireless capability), SecHub. The node is placed close to the protected device within a meter; it passively receives and decodes the data-plane signaling over the air. It can also communicate with the user-space security manager application at the protected device. The device and SecHub connect each other,

either with wire (a gadget that is attached to the device via USB) or wirelessly (i.e., Bluetooth).

However, it is not trivial to infer such info in the user space with SecHub. We address this issue in the next section.

Challenge: Unknown configurations Although 5G data-plane signaling messages are not encrypted, SecHub must identify which ones belong to the protected devices. Several configurations are needed: (1) The carrier frequencies; (2) The physical cell ID (PCI) that indicates the physical-layer identity of the cell; (3) The Cell Radio Network Temporary Identifier (C-RNTI) that distinguishes the target device from other devices connected to the same cell.

Directly infer the parameters will not work Unfortunately, not all these configurations could be acquired from the protected device without root access. Android provides APIs for applications to obtain the current band and PCI [10]. In contrast, C-RNTI can only be extracted from the victim device with root privilege. Without C-RNTI, SecHub cannot recognize which traffic is for the protected device. Therefore, we need a solution that can recognize which configurations are assigned to the protected device over the air.

Idea: Use high-layer traffic pattern that is visible to SecHub Since the user space has no access to lower-layer C-RNTI, we must identify the configurations with higher layer features. We note that, data traffic pattern is *visible to both device and SecHub*. Therefore, it is an ideal “channel” to insert fingerprint and notify the identity to SecHub.

Henceforth, we generate specific traffic patterns on the target device, with SecHub being aware of the pre-agreed pattern in advance. It can thus observe the channel and identify the target device’s C-RNTI by analyzing low-layer signaling. Our approach takes three concrete steps.

Step 1: Traffic Pattern Coordination First, SecHub randomly generates a traffic interval and sends it to the target device through the wired or wireless channel. This interval is used as the fingerprint for the target device. The traffic interval triggers a unique pattern for the data-plane signalings for fast inference. SecHub leverages this shared traffic pattern to recognize the target device in later analysis.

Step 2: Trace Collection Second, the device creates traffic (e.g., small UDP packets) with the acquired interval. The traffic generation is performed by the application and does not require root privilege. gNB will assign grants for the device to deliver data. At the same time, SecHub monitors all the subcarriers in the target cell and tries to decode the C-RNTI from all grants with all possible positions in the band. This is necessary as grants do not always locate on the same subcarrier in the band (for reducing inter-cell interference). SecHub records the decoded C-RNTIs with corresponding time slots for inference.

Step 3: C-RNTI Inference Finally, SecHub aggregates the grants for each C-RNTI decoded from the collected trace.

SecHub first ranks the C-RNTIs by grant numbers and filters the top 10% C-RNTIs as the candidates. The time intervals between consecutive grants are calculated and compared with the negotiated interval for all the candidates. The grants for the fingerprinting traffic will show the same interval. Although there may be background traffic from the target device, the grants triggered by the fingerprinting traffic still show the periodic pattern and could be filtered from the device’s grant traces. By ranking the ratio of matched intervals with the total interval number, the top C-RNTI will be selected as the target’s C-RNTI. To ensure robustness, SecHub performs the procedures twice and checks if the inferred C-RNTI values match. If the candidates do not match, SecHub will perform the inference again until a candidate is selected.

Combining with the frequency and PCI of the device from OS API and the C-RNTI inferred from the collaborated traffic fingerprinting, the SecHub could successfully camp on the cell and capture the downlink/uplink messages. The entire procedure does not require root access at the device.

Tracking configuration change We also note that, the C-RNTI configuration could be updated within an encrypted message in both static and mobility scenarios. CellDAM incorporates a new solution to prevent such change and enable continuous tracking. We detail this solution in Appendix D.

7 Device-Centric Mitigation

Although 5G standard updates could fundamentally defend against forgery attacks, they require months or even years to be deployed in practice. To this end, we design device-centric mitigation to provide a quick remedy for existing devices. We leverage the existing, dense 5G cell deployment to help the victim dodge the attacker.

7.1 “Quick Dodge” with Handover

Band switching to avoid the attacker on a specific cell We observe that, the attacker must camp on the cell that serves the victim device and forge messages in the current band to launch the attack, regardless of the attack methodology (§3.2). Therefore, the victim could quickly escape from attackers by switching to another frequency band (i.e., a different 5G cell).

With the insight, CellDAM thus aims to switch the band (i.e., cell) that serves the victim device to avoid the attacker.

Use handover procedure to trigger band switching In CellDAM, we leverage the 5G handover procedure to realize band switching. In 5G, a UE measures the signal quality by metrics of Reference Signals Received Power (RSRP) and Reference Signal Received Quality (RSRQ). When the experienced signal quality of the serving cell is worse than the thresholds configured by gNB, the UE sends reports to gNB, which makes the handover decision and sends a handover command to the device.

Although rare, it is possible that there are no other cells available. In such cases, `CellDAM` could opt to generate a warning instead of triggering the handover.

Why is band switching via handover effective against attackers?

First, the attacker could not control or know which cell the device is switching to, as the handover command is encrypted. Given that, the attacker needs to enumerate all nearby cells and use fingerprinting on each to find whether the device is in the cell. It takes prolonged time and effort for an attacker. This could take minutes, before which the device might already move to a new cell.

Application is resilient to handover Handover incurs little overhead on applications. UE does not go through the slow cell search or connection setup procedure. Instead, it only has to update its PHY parameters for the new cell. Therefore, the disruption to the applications is minimum.

How to trigger a handover? To initiate a handover procedure, the most straightforward way is by requesting the gNB to send a handover command to the device. This is possible if `CellDAM` can communicate with the operator (Defense model 2). On the other hand, the device can send a 5G measurement report to the base station. It indicates that the measurement result from another cell is better than the current one by an offset configured by gNB (i.e., a measurement event in 5G). This will subsequently trigger a handover procedure. Defense model 1 could take this approach. However, for Defense model 3, neither approach is available. In the next section, we describe how it could still initiate a handover.

7.2 Trigger Handover with `SecHub`

When the handover-related messages cannot be directly created, `CellDAM` takes a different path by affecting the measurement result. If the measured RSRQ on the serving band is bad, a legitimate report will be triggered by the device. Although either bad RSRQ or RSRP can result in handover, we focus on RSRQ, because RSRP is measured based on the reference signal power and is hard to be affected by `SecHub`.

Solution: Precise reference signal downgrade We design adaptive signal degradation to ensure low-overhead band switching. Instead of the entire channel, `SecHub` only copes with the reference signal in 5G. The device measures the reference signal to monitor the signal quality regardless of PHY techniques (e.g., MIMO, carrier aggregation, dual connectivity, etc). The reference signal only exists in specific subcarriers and time slots. `SecHub` calculates the positions of the reference signal based on the current physical band according to the 5G standards [6]. By morphing the reference signals only, `SecHub` downgrades the victim's measurements of the current frequency band without much overhead.

The solution should not affect other devices. `SecHub` adaptively controls its power upon triggering the handover. More details on the power control are shown in Appendix B.

8 Security Analysis

8.1 Attacks Covered by `CellDAM`

In this section, we discuss what attacks can be detected by `CellDAM`. With our design, `CellDAM` can detect multiple attacks that target both data plane packets and signaling message, as shown in Table 2. The details for each attack and how `CellDAM` detects it are elaborated in Appendix A.

Attacks against data packets We consider three attack actions that target data packets: injection, deletion, and manipulation. For injection, the attacker attempts to insert a new data packet. For deletion, the attacker tries to remove a packet from being received by the device or the network. For manipulation, the attacker seeks to change certain bits in a data packet. Any bit in the IP packet (application, transport, or IP headers) could be changed.

We first show that, both injection and manipulation attacks can be detected by `CellDAM`. We note that, neither attack can be directly launched over the air. Flipping data bits over the air will fail the CRC check, while directly injecting a new packet will fail to be decrypted due to mandatory encryption. Therefore, the possible methodology for injection or manipulation is the Man-in-the-Middle (MitM) approach. The adversary intercepts the packet, flips the bits, re-encodes it, and injects the altered packet.

This could be detected by `CellDAM`, as a MitM will incur undesired signaling messages. There are two possible ways to launch MitM. For the scheme using relay FBS (A1 in Table 2), an attacker cannot directly learn the critical data-plane configurations, which are transmitted over the *encrypted* RRC messages [60]. Consequently, the forgery could be sent in an impossible context, e.g., in the time slots when the device is in its Discontinuous Reception (DRX) OFF state (i.e., sleep mode). This behavior will be detected by `CellDAM`. It applies to both uplink and downlink forgery, as the attacker needs to send DCI to the victim device for notification of both uplink and downlink scheduling. For the attack that corrupts the transmission and injects retransmission (A2 in Table 2), it needs to forge DCI and data packets. The next DCI from the attacker could reach the device before the acknowledgment of the forged data, thus incurring an undesired behavior.

Unlike manipulation and injection, deleting data packets cannot be detected by `CellDAM`. The attacker can send noises and corrupt the data packets. `CellDAM` cannot distinguish it from a corruption caused by environmental noises. There is no readily available scheme to defend it without changing the 5G PHY; changing PHY is beyond the scope of this work.

Attacks against data plane signaling We show that, all the detection, manipulation, and deletion of signaling messages can be detected by `CellDAM`. This is relatively straightforward compared with data packet forgery. Since the forged or missing signaling is not anticipated, some messages will be received in wrong or unexpected context. Three examples

#	Attack	Target Message	New?	CellDAM	Undesired Behavior	Check
A1	DL Data Manipulation w/ Relay FBS	Data packet	Adapted from [48, 49]	✓	The forged packet received during DRX OFF.	c_4
A2	DL Data Forgery w/ Retransmission	Data packet	Inspired by [54, 60]	✓	Forged DCI for forged data received in wrong context.	c_1
A3	Packet Delivery Blocking	RLC Control NACK	Adapted from [54]	✓	The RLC Control is not received when the timer expires.	c_1, c_2
A4	Prolonged Packet Delivery	DRX Command	Adapted from [54]	✓	Message received with pending transmission; DCI during DRX OFF.	c_1, c_4
A5	Radio Resource Draining	Buffer Status Report	Adapted from [54]	✓	Grant is received when no data is pending.	c_5
A6	Break Reliable Transfer	RLC Control ACK	Yes	✓	RLC packet is NACKed after being already ACKed.	c_3
A7	Data Collision	DCI UL Grant	Yes	✓	Data sent in unauthorized resource blocks will not be acknowledged.	c_5
A8	Delayed Transfer	MAC ACK	Yes	✓	Sender MAC falsely regards ACK and triggers RLC retransmission.	c_1

Table 2: List of known (A1–A5) and unreported (A6–A8) data-plane attacks and how they trigger undesired messages. See Appendix A for details of each attack.

are listed in Table 2 (A3–A5). They are adapted from those reported in 4G or Cellular IoT and include all three types of attack. Each attack violates a certain context in packet delivery and fails to pass all checks. For A3, the attack corrupts an RLC NACK signaling. This incurs head-of-line blocking, stopping the delivery for more than 100ms. The attack can be detected by the device, as the device observes no RLC NACK after it requests one in the uplink packet. For A4, the attacker injects a DRX command signaling message, which forces the device into DRX OFF even in the presence of new data. The device thus receives a DCI during DRX OFF, detected by its lack of ACK/NACK. For A5, the device manipulates the amount in the BSR request to drain the wireless resource and block access. The device will observe unsolicited grant without pending UL data.

Unreported attacks CellDAM also detects unreported data-plane attacks, since it *verifies what is right* and detects any potential attack that breaks the delivery procedure. For each DFA state, signaling message, and validation, we check if a forged message that fails the validation can be from the adversary to incur damages. Consequently, we illustrate three unreported attacks and how CellDAM can detect them in Table 2 (A6–A8) with details in Appendix A.

8.2 Attacks against CellDAM

We next consider an attacker who is aware of the existence of CellDAM and tries to break it under our threat model. We specifically focus on the security of SecHub. This is because, if the inference or mitigation is implemented within the firmware, it is considered difficult to break it without an insider attacker. This is beyond the scope of our threat model.

Attacker attempts to break CellDAM’s inference We first consider an attacker who tricks SecHub and prevents

CellDAM from recognizing the traffic from the protected device. With CellDAM design, this is not possible. The traffic is generated from the in-device application with the pre-defined pattern. The application is also secure as it needs no root or other privileges. Therefore, the pattern is unknown to the attacker, who cannot insert malicious packet to break the inference. In addition, CellDAM is stable by repeating inference three times to confirm the target, avoiding a malicious attacker to inject noises and break the inference.

Attacker compromises or breaks SecHub The attacker can either gain access to SecHub, or break the communication between SecHub and the device. However, neither is possible. First, SecHub is available to end users without exposing any unnecessary interfaces, such as Internet access or wireless control. A user or an application will be unable to add/change/delete the SecHub software. SecHub is solely used for CellDAM detection and mitigation purposes. A pass-code is set to access its functionalities. Second, SecHub communicates securely with the protected device. The user installs an application in the protected device using the certificate that comes with the SecHub. The device thus mutually authenticates with SecHub and encrypts all traffic between them. Only nonsensitive information is exchanged over this channel.

Attacker leverages SecHub to force handover The attacker could force the device to switch band by deteriorating the signal strength sensed by SecHub. However, such an attack is very limited in its impact. First, the device has immediate data access after moving to a new cell. The handover disruption is short. Meanwhile, the attacker cannot control which new cell the device moves to. For this purpose, the attacker needs to launch a time-consuming identification procedure on all local cells. The attacker cannot control which cell/base station the victim switches to, either. Instead, the band switching in 5G will prioritize the cells from the same (legitimate) base station. Forcing the device to an illegitimate base station is thus unlikely. Therefore, the attacker gains little from forcing

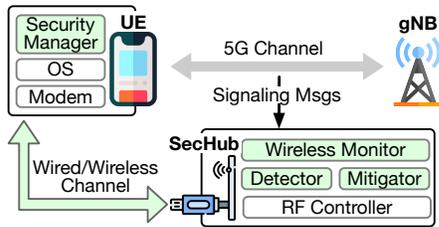

Figure 6: Implementation of CellDAM. Green blocks are CellDAM modules.

a handover with SecHub. Defending against it is out of the scope of CellDAM.

9 Implementation

We implement CellDAM as shown in Figure 6. We implement the defense model with the least privilege (Defence model 3). Based on our discussion, we implement SecHub to perform attack detection and mitigation. A security manager app on UE facilitates SecHub for rootless signaling capture. We next elaborate on each component. It could be adapted to the other two defense models with little change. For detection, our detector module could be directly used by the other two models. For mitigation, they only require to trigger one extra command after detection.

Wireless Monitor A wireless monitor is deployed based on srsRAN [51] to perform the rootless signaling capture through the RF controller with the SDR devices. We implement it with 2,794 lines of C++ code. The monitor collaborates with the UE to camp on the target cell, infer the UE’s C-RNTI, and simultaneously capture real-time messages on both the uplink and downlink channels. After the capture, it decodes the signaling messages accordingly and passes them to the attack detector.

Detector with state-dependent model checking We implement the state-dependent model checking attack detector with 1,252 lines of Python. The real-time traces from the wireless monitor will be fed into the detector for undesired behavior and potential attacks. If any consecutive signaling messages violate the cross-layer model checking, potential attacks will be reported by the detector. The detector will further notify the mitigator module to trigger the mitigation.

Mitigator We deploy the mitigator with 860 lines of Python code. After detecting any attacks, the mitigator triggers the victim handover. With the current signal conditions acquired from the security manager application from the victim, the mitigator calculates the minimum transmit power to trigger the UE handover with the SDR devices. It then notifies the RF controller to initiate signals targeting the victim UE. This will trigger handover to escape from the attacker’s cell.

Security Manager App On the phone side, we deploy a security manager application with 1,264 lines of Java. The application monitors the current band, PCI, and signal conditions (RSRP and RSRQ) with the Android Telephony API [10] to facilitate the rootless signaling capture. It also generates a cor-

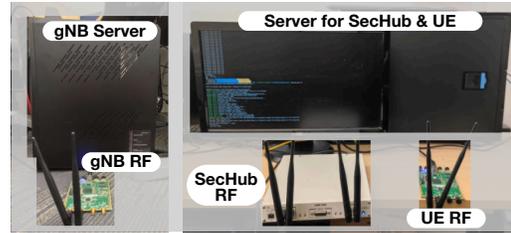

Figure 7: Testbed Setup for CellDAM.

responding UDP traffic after receiving the traffic interval from SecHub for the collaborated traffic fingerprinting. It supports exchanging the data with SecHub through a wired (USB) or wireless (Bluetooth in the current implementation) connection leveraging Android APIs [9]. It supports the X.509 certificate to facilitate the mutual authentication and encryption between the app and SecHub. We also implement an equivalent application for srsUE running on user-space. The same set of information is extracted from the srsUE by hooking the current srsUE functions. Then the information is shared with the SecHub with the socket API.

10 Evaluation

10.1 Evaluation Setup

Testbed Setup We construct a testbed for experimental validation, as shown in Figure 7. The gNB and UE are built upon srsRAN [51] 5G protocols. The physical layer encoding is still kept with 4G due to current hardware limitations. CellDAM does not rely on any 5G-specific PHY feature. The gNB software is run on an i7-9700K PC with Ubuntu 20.04. The UE runs on an Intel Xeon Silver 4214 server running Ubuntu 20.04. Both use USRP B210 as their RF frontend, with the frequency set to an unlicensed 2.4GHz ISM band. SecHub is co-located on the same server as the UE and uses USRP X300 as the RF frontend. The security manager application runs on the same server as a user-space process and shares the information extracted from srsUE with SecHub. The mobile version of security manager application is tested on a Pixel 4a with Snapdragon 730 running Android 12.

Attack Reproduction All attacks listed in Table 2 are recreated within the testbed in order to evaluate CellDAM’s ability of attack detection and mitigation. We realize attacks on both data packets and signaling. We simplify the attacks with partial software emulation on our testbed for controllability and reproducibility. In attacks with relay FBS, we set up both the FBS and the real gNB in the testbed. We emulate the radio link between relay FBS and real gNB in software with ZeroMQ [61] to avoid interference with the link between UE and relay FBS, which uses physical link with USRP.

On the other hand, the attacks without relay FBS rely on manipulation of the underlying data channel. We emulate the attacker using a separate thread within the gNB and UE program, which has access to the transmitting and receiving signal buffer. Eavesdropping is realized with inspection of the receiving buffer, while the forging or corruption attacks are

Attack	A1	A2	A3	A4	A5	A6	A7	A8
Precision	0.989	1	0.999	1	0.996	1	0.996	0.999
Recall	0.705	0.976	1	0.989	1	1	1	1
F1	0.823	0.988	0.999	0.994	0.998	1	0.998	0.999

Table 3: Effectiveness of attack detection with CellDAM.

emulated by injecting encoded attack messages or noise to the transmitting buffer.

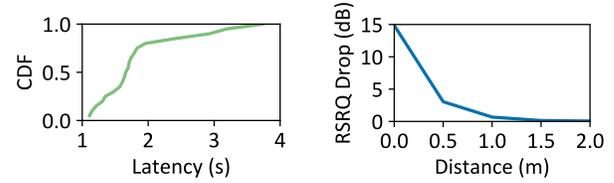

Ethical Considerations This work does not raise any ethical issues. Our testbed is carefully controlled for experiments, operating on an unlicensed 2.4GHz ISM band. The experimentation is conducted within a 5MHz channel centered at 2.49GHz. We ensure no nearby device is using the frequency band. The radio signal emitted by the testbed only reaches a few meters, ensuring that no other device is affected or attempts to communicate with our testbed. Meanwhile, we are working with collaborating mobile operators about the discovered solutions and will open source CellDAM.

10.2 Evaluation Results

Evaluation of CellDAM Attack Detection In this subsection, we answer the question of whether CellDAM can detect all attacks displayed in Table 2. For this purpose, we inject attack messages according to the attacker procedure, and observe if the detector can initiate warnings as expected. We test the attack detection under two different traffic types: A lightweight traffic with ping and a heavy traffic with iPerf3 [30] to saturate the channel. For each attack, we repeat 1,000 times under each scenario. We evaluate the results with three metrics: precision, recall, and F1 score. The ground truth can be easily obtained, as whether there is an ongoing attack is controlled by us.

Table 3 summarizes the precision, recall, and F1 score for the CellDAM detection. As shown in the table, the detection reaches a precision of 98.9%~100% for different attack types. The high precision is achieved by the correctness of the DFA and verification, as the normal operations in legitimate 5G delivery will follow the correct procedure. Meanwhile, the recall is 70.5%~100% for different attack detection. Note that, the relatively low recall for A1 is because a heavy-traffic scenario will extend the ON state for a device. The device can use other FBS detection methods [8, 65] to complement CellDAM. The recall is high for other attacks, as they will incur undesired data-plane signaling. This results in a high F1 score of 0.823~0.999. The detection works well for both light and heavy traffic. This is because CellDAM only requires inspection on lightweight data-plane signaling messages. We also measure the average detection latency for attack detection. The signaling messages could be captured and fed into the detector for real-time detection. The detection achieves an average latency of 28ms. Therefore, CellDAM can quickly spot potential adversaries and take action.

Evaluation of CellDAM Mitigation We evaluate the success rate for mitigation. When SecHub detects any attack, it will trigger the target device handover to escape from the

(a) CDF of the mitigation latency for “quick dodge”. (b) Relationship between the distance and RSRQ drop.

Figure 8: Mitigation Performance.

attack. We enable the handover-related RRC messages and config in gNB and let the UE monitor the handover events. Note that our testbed does not support real handover to a different cell; if UE receives a handover command, we assume a successful handover. We evaluate the ratio of successful handover and the corresponding latency for each mitigation. In all 40 rounds of experiments, SecHub successfully triggers the UE handover. Figure 8a shows the CDF of the latency. The results show that the average mitigation latency is 1.85s. 90% of them could successfully handover within 3 seconds, and all handovers are triggered within 4 seconds.

In our design, signals from SecHub will have minimum impact on other devices. We show this point by measuring the perceived RSRQ drops at the UE at different distances from the SecHub. Figure 8b shows that the RSRQ drop at 1m and 2m are only 0.67dB and 0.06dB, respectively. With the controlled power of SecHub, our mitigation will only trigger handover on the close-by protected device, while not affecting other users or devices.

Impact of CellDAM mitigation on applications We discussed in §7 that handover-based cell switching will incur little overhead on applications. We now evaluate the disruption time on the iPerf3 application during the band switch. We decode the logs and calculate the interval of application packets before and after the handover. The average disruption is 72.3 ms, with a 95th percentile of 83.7ms. We further note that, the packets during 5G handover will be kept and delivered by the new cell afterwards. Therefore, an application would only experience a small delay caused by CellDAM, without triggering any data loss or TCP connection reset.

Evaluation of SecHub Rootless Capture We then present our microbenchmarks for inferring signaling messages. We measure the ratio of correctly captured signaling in both uplink and downlink to show the effectiveness of our rootless signaling capture. We record the traces of PUCCH/PDCCH (SR and DCI) and PDSCH/PUSCH (MAC CE and RLC Control) at the UE as the ground truth. We capture the traces through the SecHub under different traffic scenarios and mobility. We use ping and iPerf3 for the light and heavy traffic scenarios, respectively. The UE and SecHub are kept static or moving at a speed of around 5km/h for mobility. The ratio of correctly decoded signaling is calculated by comparing the traces captured on the SecHub and the ground truth.

Table 4 shows the success ratio for the rootless capture. For

Traffic	Control		Data	
	PUCCH	PDCCH	PUSCH	PDSCH
Light	99.1%	100%	100%	99.7%
Heavy	98.7%	99.9%	98.1%	97.2%
Light-M	98.8%	99.9%	99.1%	98.3%
Heavy-M	98.1%	99.8%	98.0%	97.3%

Table 4: Ratio of success rootless signaling message capture under different traffic scenarios and mobility (-M: Mobile).

the control messages, 99.1% of PUCCH and 100% of PDCCH are successfully captured and decoded from the SecHub with the light traffic. For the heavy traffic, the SecHub still achieves a high success rate with 98.7% for PUCCH and 99.9% for the PDCCH. For data messages, SecHub successfully decodes all the PUSCH messages and 99.7% of PDSCH data under the light traffic scenario. 98.1% of the PUSCH and 97.2% of the PDSCH traffic is successfully captured and decoded for the heavy traffic scenario. We observe similar numbers (97.3-99.9%) in mobility cases (Light-M) and (Heavy-M). The ratio is not impacted by mobility, because the UE and SecHub experience similar channel conditions. Whether one message is decoded on UE or not, SecHub will produce similar results.

The high success rate is possible with accurate C-RNTI inference. We quantify the success rate with the collaborated traffic fingerprinting. Since the inference can be done without actively sending signals over the air, we perform the verification on both the commercial network and our testbed. The ground truth of C-RNTI can be acquired in gNB (by checking logs) and in COTS UE (by using MobileInsight [37]). Every time SecHub collects 5s of traces for the inference after the traffic pattern coordination with the target UE. We perform 120 rounds of experiments with 60 rounds on the testbed and 60 rounds on the commercial network.

On the testbed, SecHub correctly infers the C-RNTI in all 60 rounds, achieving a 100% success rate. On the commercial network, with the increased device number, SecHub successfully infers 98.3% of the C-RNTI. We further measure the overheads caused by the background ping in the continuous tracking. The result shows that CellDAM involves 0.14 KBps traffic overhead, which is marginal on the target device. The results show that CellDAM could continuously perform the monitoring during the mobility, and protect the victim without any root privilege.

11 Related Work

As new attacks on the 5G/4G have drawn increasing attention, detecting potential attacks is a popular research topic in recent years. Due to the high overhead and long cycle for network-side detection [47], current detection methods are mainly on the device side. PHOENIX [19] proposes a solution for control-plane monitoring. [53] studies the device-side attack detection for core network attacks. [16, 18, 25, 38, 63] detect cellular attacks by analyzing on-device application traces. [8,

65] detect the existence of FBS with physical characteristics of FBS such as power or signal signatures. No prior work studies attack detection for data-plane protocols. CellDAM provides the first detection scheme for attacks on data-plane packets/signaling in 5G. Unlike other works that require root access and expose additional risks [62], CellDAM detects the attack without extra privilege.

Existing mitigation for attacks on 4G/5G protocols either needs root access [33] or requires protocol changes [48, 49, 54, 64]. To our knowledge, CellDAM is the first solution that provides rootless mitigation for data-plane attacks without firmware/standard changes. Other mitigation methods for attacks on mobile apps [11, 13, 39] or cellular-based services [35, 40, 55, 58] are orthogonal to our work.

Prior studies have leveraged model checking to verify the cellular standards and discover new vulnerabilities in the protocols. [26, 28] exposed attacks in 4G LTE by adversarial model-based testing. Previous work also formally analyzed the 5G protocol components including the 5G-AKA procedures [12, 17] and NAS/RRC signalings [27]. However, the existing cellular protocol verification runs offline on the control plane and does not have runtime detection. CellDAM performs the runtime verification to discover the potential attacks timely. It targets the relatively more difficult problem of verifying the data plane, whose traffic is heavier.

12 Conclusion

Detection of data-plane attacks at the mobile device has not been viewed favorably to date. This is due to the excessive processing and energy overhead associated with 5G high data rate. In this work, we show how to use data-plane signaling messages to devise a detection solution that yields one or two orders of magnitude lower overhead. We leverage the fact that data-plane attacks would exhibit certain data signaling misbehavior. Our reactive solution may defend against certain attacks that the current proactive schemes cannot. It can work on normal user devices without root privilege or infrastructure upgrade. Once CellDAM detects an attack, it further mitigates attack damages via handover to another available channel.

In a broader scope, we believe data-plane security deserves more attention given that activating all security measures on lightweight control-plane messages is relatively straightforward. In contrast, data plane delivery involves complex interactions across protocols and the adversary has plenty playground to launch various attacks from applications, transport layer, to IP and 5G protocols. While the end-to-end approach and existing 5G data-plane security may secure application data, it fails to secure the 5G infrastructure and mobile device. To this end, this work reports our initial effort to explore a lightweight, reactive solution to 5G data-plane security.

Acknowledgments. We would like to thank the anonymous reviewers and our shepherd, Dr. Aaron Schulman, for their constructive comments and feedback.

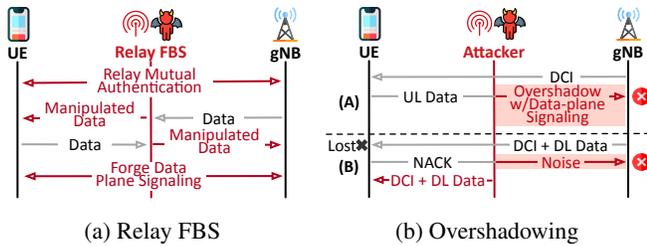

Figure 9: Viable data-plane methodologies for data injection/manipulation.

A Details of Each Attack and Its Detection

In this section, we present the details of each attack shown in Table 2, including the attack procedure that leverages the forgery messages and the attack consequences. We also elaborate on how each attack incurs undesired behavior that can be detected by CellDAM validations.

A.1 Injecting Data with FBS

Attack Procedure The attacker can use a relay fake base station (FBS) to manipulate data packets [48]. The detailed attack procedure is shown in Figure 9a. The attacker sets up a fake base station (FBS). It usually runs on a different band from the real base station, and sends strong broadcast signal to lure the device into connection. The attack also sets up a fake UE that connects to the real base station. It then relays the connection setup messages without any manipulation from/to the real base station. Afterwards, although all data packets are encrypted, the attacker can flip the bits to change the content of the forgery, if data-plane integrity protection is not enforced. This is doable as the encryption is done with simple XOR, as long as the original content is known (e.g., DNS server set up by the operator), the attacker can flip bits and change the contents to target values. For instance, the attacker can manipulate the IP header of a DNS request and compensate the IP header checksum to pass the checks [48].

Undesired Behavior In this attack, we assume the adversary cannot infer the data-plane configurations encrypted in RRC messages. Therefore, when the attacker forwards the data packet, some configurations might be incorrectly set and detected on the device side. One example is DRX configuration. Without the configuration, the forwarded packet might fall in the DRX OFF period, as shown in Figure 10a. As the DRX ON period is usually very short (e.g., 10ms), most messages might be delivered outside of the period, violating check c_4 . Although the FBS can repeat transmitting until the victim device acknowledges to ensure delivery, this behavior will be detected by CellDAM. Note that, 5G DRX includes the mechanism to stay in ON period for an extended period when a new data is received. Therefore, when the traffic is heavy, the device might keep staying in ON state. As we claimed in §10, the attack will be more detectable for light traffic. For this attacker, the PHY layer detection methods mentioned in

§11 can help detect FBS that transmits abnormal signal.

A.2 Data Manipulation with Retransmission

Attack Procedure We also show that, the attacker can serve man-in-the-middle to manipulate data packets without FBS. The detailed attack procedure is shown in Figure 9b. This approach can manipulate data plane packet without FBS. We consider the victim device is directly connected to the authentic base station. Note that, the attacker might not be able to forge data-plane packets directly, as they are encrypted (unlike integrity protection, which is optional). Therefore, to forge data packets, the attacker still needs to take the bit flipping approach as in A1. One viable way is to forge the data as retransmission. The attacker can eavesdrop on the channel and look for data transmission that fails on victim device (i.e., trigger NACK), while it successfully decodes the encrypted data (due to less noisy environment, etc.). The attacker can then forge the DCI and manipulated data as the retransmission.

Undesired Behavior This attack requires sending forged DCI and data to the device. This DCI can be received in an improper context. Each DCI includes a HARQ ID, which indicates the process of the transmission. Each process takes a stop-and-wait procedure. Before the last packet is acknowledged, the process will not move on to transmit the next one. Therefore, the DCI from the authentic gNB can arrive after the DCI forged by attacker and before the forged retransmission has been acknowledged. This causes an undesired behavior that can be observed on the device with c_1 . This is shown in Figure 10b.

We further note two things. First, this attack method can forge *uplink* data packet without obvious undesired behavior on the device side. We do not consider such attack with pure uplink forgery in this work. However, a reasonable forgery attack needs to manipulate both uplink and downlink data. Second, an interested reader might ask whether the attacker can use the legitimate DCI to send the forged data. However, the DL DCI and the corresponding forged data are usually sent in the same time slot in 5G. It is thus hardly possible to infer DCI for data forgery in advance.

A.3 Packet Delivery Blocking

Attack Procedure We have introduced this attack in §3.2 as an example of corrupting data-plane signaling. We now present this attack in more details as shown in Figure 10c. The attacker first eavesdrops on the data channel and learns the packet sequence number that is not delivered over the air. It then selectively corrupts the RLC control that NACKs the packet. Since the packet is not acknowledged, UE will still send uplink data without retransmitting the missing one. These new data packets are blocked in the gNB, which suffers

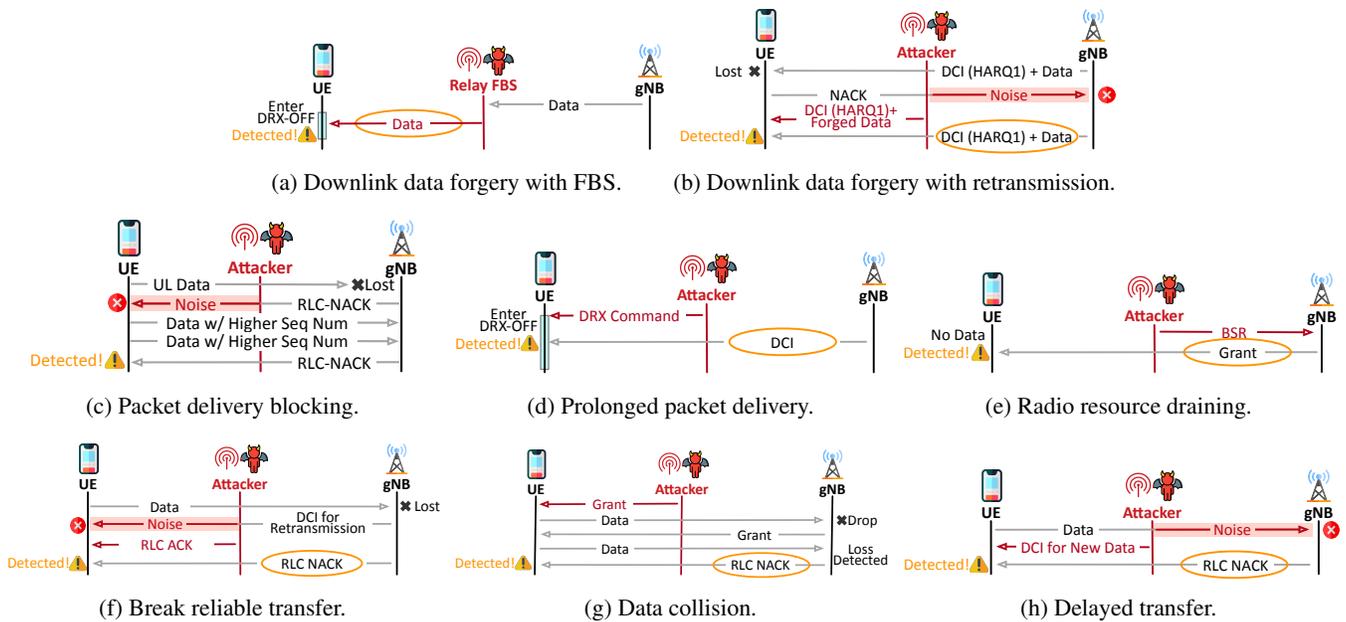

Figure 10: Illustration of undesired behavior caused by attacks.

head-of-line blocking for more than 100ms. No new data will be forwarded during this time period.

Undesired Behavior The attack will cause undesired behavior on RLC. From the perspective of the device, the uplink RLC will receive either ACK or NACK after $T_{reordering}$ when the timer expires. Even if the signaling is corrupted, which is rare given its small size, the MAC layer should retransmit it. Therefore, if the device finds no RLC control after timer expires and MAC retransmissions (which has a configured max count), CellDAM detects a potential corruption attack. We note that all MAC retransmission could fail due to extremely weak channel instead of an attacker. In this case, although no attack is present, switching to a better wireless channel with CellDAM is a reasonable facilitating option.

A.4 Prolonged Packet Delivery

We consider connected mode Discontinuous Reception (CDRX) in this attack. In the RRC connected state, the gNB will only deliver data during DRX ON state. A device will be in DRX ON for a small time period in a fixed periodicity. If any data is received during this period, the DRX ON state is extended for a constant amount of time. gNB will configure the ON period, DRX cycle, and the extended timer amount in encrypted RRC messages.

Attack Procedure The detailed procedure is shown in Figure 10d. In this attack, the adversary forges a DRX command to the device. DRX command terminates the DRX ON state prematurely and the device enters the sleep mode. Therefore, the device will be unable to receive all subsequent transmission in the current DRX cycle with DRX turned to OFF state. The data delivery can be delayed for hundreds of milliseconds

given long DRX cycle. The attack is adapted from [54]. Note that, this attack will not stop uplink data delivery, as a UL data transmission initiated by UE can again switch the DRX state to DRX ON.

Undesired Behavior It is not possible to receive downlink DCI or data during DRX OFF. If such an event happens, the previous DRX command could be forged. As CellDAM does not have root access, it is difficult for SecHub to monitor internal DRX state in real-time or infer the state with encrypted DRX configurations in RRC messages. However, there is another indication for a message during DRX OFF: If the device is in DRX OFF, it will not respond to any downlink data with ACK or NACK in PUCCH. Therefore, SecHub can detect such attack by checking the downlink data without any acknowledgment, after an incoming DRX command. This violates the validation check c_4 . In addition, gNB will not send DRX command when the previous DL transmission has not finished, which means there will be more transmission in the DRX cycle. This violated c_1 .

A.5 Radio Resource Draining

Attack Procedure We have introduced this attack in §3.2 as an example of manipulating data-plane signaling. Here we present more details. 5G/4G adopts scheduling-based data delivery. To transmit uplink data, the device needs to send the buffer status report (BSR) to the gNB for asking grants. An attacker can forge a BSR to the gNB. In the forged BSR, the attacker falsely indicates the victim device has a large amount of data to send. The gNB subsequently assigns excessive resource blocks to the device, wasting wireless resource and

blocking other users' access. The detailed procedure is shown in Figure 10e. The attack is adapted from [54].

Undesired Behavior Although the attacker forges an uplink message, it will incur observable undesired behavior on the device side as well. This is because the DCI (for UL grant) will be triggered by the forged BSR message. If the device receives grant when there is no prior request, the grant can be caused by a forged request by the attacker. We notice that, a gNB can send a device "free" small grants in case the device has something to send. However, these grants are small for the device to sufficiently deliver BSR. Therefore, to reduce false positive, we set a threshold (120 bytes) in the verification check c_5 to find unwanted resources.

A.6 Break Reliable Transfer

Attack Procedure The detailed procedure of the attack is shown in Figure 10f. The attacker can corrupt the data retransmission on MAC layer. It then forges an RLC ACK to UE. Receiving it, the victim device RLC protocol wrongly thinks the packet has been delivered, discarding it in the buffer. Therefore, this packet cannot be reliably delivered in 5G. This might further trigger TCP retransmission, which can cause more serious damage.

Undesired Behavior From the perspective of the base station, it will detect a packet gap in RLC protocol when it receives a later packet from UE. Therefore, it will still attempt to recover it by sending an RLC NACK. The NACK timing is unknown for the attacker, thus cannot be targeted for corruption. The device side will thus receive an RLC NACK first and then an ACK. This behavior is undesired in 5G and can be detected by validation check c_3 .

A.7 Data Collision

Attack Procedure The detailed procedure of the attack is shown in Figure 10g. The attacker forges grant to the victim device. The device will send data using the forged grant. However, any data using these non-authorized grants will not be correctly accepted by the gNB. In addition, the legitimate transmission in the same time and frequency by another user will be corrupted by the victim's false transmission.

Undesired Behavior The attack will trigger undesired behavior on the device side. Since the UL data using false grants will not be accepted, gNB will not ACK or NACK the message delivery and consequently trigger an RLC NACK. CellDAM detects the undesired behavior with RLC control NACK and lack of MAC layer feedback with validation c_5 .

A.8 Delayed Transfer

Attack Procedure The detailed procedure of the attack is shown in Figure 10h. In this attack, the adversary sends

noises and corrupts the uplink data. The attacker can learn the time and frequency of the delivery by eavesdropping on DCI for UL grants. It consequently forges DCI for new data (i.e., indicator for ACK) to stop the UE from retransmitting the corrupted data. Consequently, the UE will start sending new data on MAC. This will later trigger retransmission on the RLC layer, which can take up to hundreds of milliseconds compared to a MAC fast retransmission.

Undesired Behavior The forged DCI from the attacker can be sent in a wrong context, where two consecutive DCIs are received but the data using the first one has not been acked yet. This can also be detected with c_1 .

B Deriving Minimal Power for Targeted Switching

The solution should not affect other devices. SecHub adaptively controls its power upon triggering the handover. Previous 5G measurements show that -20dB RSRQ is enough to trigger the handover in more than 98% cases [59]. SecHub adaptively derives the minimal power so that RSRQ drops to -20dB, thus triggering handover. The current RSRQ is derived by:

$$RSRQ = \frac{N \times RSRP}{RSSI}$$

To reduce the RSRQ to -20dB, the minimal power (P_m) needed by SecHub follows:

$$\frac{N \times RSRP}{RSSI + P_m} = -20dB = \frac{1}{100}$$

Thus, the P_m could be derived by:

$$P_m = N \times RSRP \times \left(100 - \frac{1}{RSRQ}\right)$$

All needed information can be acquired from the victim by the OS API (e.g., Android [10]) without root privilege. Furthermore, the power density is inversely proportional to the square of the distance from the antenna [14]. Assume SecHub is located close to the device (<0.1m). The RSRQ drop at the 1m distance is smaller than 1dB, which could be neglected by other devices. Only the victim device perceives a notable RSRQ drop and triggers its handover.

We admit that, even theoretically not affecting any other device, sending weak signals might require licensing from the operational networks or government. We envision SecHub can acquire such permission from mobile operators, or even manufactured by the operators themselves. If this privilege is not available, CellDAM could fallback to using airplane switching. Even if the cell is not changed after toggling, the device will be reassigned a physical ID C-RNTI, which makes it more difficult for the attacker to track the victim.

C List of Accepted Messages

We elaborate on c_1 by enumerating each state and the list of accepted message for each one. The results are shown in Table 5. If a message is in the list, we show the next state if all other validations are passed. Otherwise, we mark an \times in the table which means an undesired behavior that fails c_1 . As we mentioned, our method prioritizes soundness. Therefore, for messages that are not explicitly considered, CellDAM will ignore them and stay in the current state.

D Continuous Inference

We describe how SecHub could keep tracking the C-RNTI used by the victim device.

Challenge: Dynamic configurations Upon user mobility, the configurations could be updated within an encrypted message after the device connects to a new gNB. It is also possible that gNB updates the C-RNTI for the device upon RRC state changes without user mobility. Tracking the up-to-date configurations for the target device is critical.

Can we track the config change? One solution idea is to track the configuration change once it happens and launch the inference again. This is possible when a handover happens. CellDAM develops an application on the target device to track the possible configuration changes due to mobility. The application leverages the existing API to detect the PCI/band change due to handover. It requires no root access. The application could track the updates with OS-level API and notify the SecHub to start a new round of C-RNTI inference.

However, the same method cannot be used to infer the config change within the same cell. SecHub or OS APIs cannot report the change of configurations from the base station.

Idea: Prevent config change in a cell Since change detection is hard, we approach it differently by keeping the configuration constant. Indeed, this is possible. CellDAM leverages the operational C-RNTI update logic in the cellular deployment to retain the same C-RNTI when the device stays on the same gNB. Our study on commercial devices and operators shows that, the current gNB updates C-RNTI when the device transits from the RRC-Idle state to the RRC-Connected state. The gNB recycles the C-RNTI from the idle devices and reuses them for other devices. Therefore, we aim to keep the device in RRC-Connected to avoid configuration change.

Preventing configuration change for continuous inference We trigger a lightweight ping in the background inside the application. Our experiments show that the ping traffic with 2s interval could keep the C-RNTI unchanged. We validate it on 216 cells from three major US carriers. In all tests, the C-RNTI remains unchanged for at least 30 minutes with our light background traffic. To tolerate unexpected updates, SecHub also triggers the C-RNTI inference (in §6) every 10 minutes to validate that the current configuration is up-to-date.

Marginal energy consumption The ping messages incur low traffic volume to keep the device in RRC-Connected. We further note that, this has small impact on 5G energy saving. This is because, the device could still go to sleep mode for energy reservation in logical RRC-Connected state. A 5G device saves power by entering Discontinuous Reception or DRX OFF mode. However, given the device will quickly re-enter DRX OFF (within 100ms) after a data transmission, the infrequent messages (every 2s) would only incur small energy overhead. Besides, regular user traffic will also wake up the device, during which the extra ping does not further reduce sleep period. In addition, the impact on the energy from the sleep mode has a smaller impact as compared to other factors, such as the screen brightness. We run the application for 30 minutes while normally using the device (with mixed heavy and infrequent messages). The additional energy only incurs 0.5% extra energy on average.

E ACRONYMS

Abstract

Cellular operators today know both the identity and location of their mobile subscribers and hence can easily profile users based on this information. Given this status quo, we aim to design a cellular architecture that protects the location privacy of users from their cellular providers. The fundamental challenge in this is reconciling privacy with an operator's need to provide services based on a user's identity (e.g., post-pay, QoS and service classes, lawful intercept, emergency services, forensics).

We present LOCA, a novel cellular design that, for the first time, provides location privacy to users without compromising on identity-based services. LOCA is applicable to emerging MVNO-based cellular architectures in which a virtual operator acts as a broker between users and infrastructure operators. Using a combination of formal analysis, simulation, prototype implementation, and wide-area experiments, we show that LOCA provides provable privacy guarantees and scales to realistic deployment figures.

1 Introduction

Providing users with *location* privacy is an important part of the larger challenge of online privacy. Unfortunately, today's cellular architecture offers little location privacy: network operators know the identity of a user and the geographic location of the access point to which that user connects and hence can trivially track a user's location in time. There is mounting concern over this situation as cellular providers are reported to routinely share their users' location profiles [28, 29, 62, 66, 105]. Moreover, 5G is likely to require smaller cell sizes [19] thus exposing much finer-grained location information and exacerbating the privacy problem.

Hiding a user's location from their network operator is challenging because connecting to an access point fundamentally reveals the user's location. One approach to improving privacy is to hide the user's *identity* from the network operator using so-called "blindly signed tokens" [23, 78, 86]. However, as discussed in §3, this approach comes at the cost of preventing network operators from providing *identity-based services*. These are services whose correct execution depends on the user's identity, such as post-pay [22], QoS prioritization [1] and lawful interception [3]. Such services are an essential part of today's networks and hence it is unlikely that operators can/will abandon them in exchange for improved user privacy. Thus, our question is whether we can enable location privacy

Figure 1: LOCA's overall architecture.

(i.e., ensuring that network operators cannot easily track or infer a user's location) *without* compromising on identity-based services.

Privacy and identity-based services might seem to be fundamentally at odds. However, we see a way forward via mobile *virtual* network operators (MVNOs) such as Google Fi and Cricket [30, 49]. MVNOs are service providers that do not own radio infrastructure but instead provide user-facing services (sales, billing, *etc.*) while relying on business agreements with some number of traditional mobile network operators (MNOs) to provide the radio infrastructure. In this scenario, users pay MVNOs for service and MVNOs settle with MNOs on behalf of users. In other words, with MVNOs in the picture we can decouple infrastructure operation from user management and the MVNO acts as a broker between the user and the infrastructure operator.¹

As shown in Fig. 1, our insight is that the existence of a broker between the user and operator enables us to reconcile privacy with identity-based services by strategically hiding different pieces of information from each party: the broker (i.e., MVNO) knows the user's identity but not her location, while the operator (i.e., MNO) knows the user's location but not her identity. With this arrangement, the broker can still tell the operator what identity-based services are to be applied to the user without revealing the user's identity, and the operator can implement the required services without knowing the identity of the user on whose behalf they are implemented.

However, hiding information in this manner is challenging for four reasons. First, in order to hide the user's identity from the operator, we must hide not just her identity but also her *trajectory* across multiple cell towers. This is because the operator could still infer the user's identity based on the sequence of towers she has visited, a form of privacy loss we refer to as *trajectory leakage* (§3.3).

Second, in order to hide the user's location from the broker, we must also hide the *identity of its operator* from the broker. This is because the locations of an operator's cell

¹In this paper, we use the terms MVNO and broker interchangeably; we do the same with the terms MNO and operator.

tower deployments are public knowledge and hence can reveal a user's location [81]. The emergence of operators with small footprints, such as private and enterprise 5G networks, underscores the importance of this [13, 38, 52, 97].

The last two challenges arise because of this need to hide the identity of the operator from the broker. Brokers will always want to ensure that only authorized operators service their users. Since our approach hides the operator's identity from the broker, we now need a solution that allows the broker to verify the legitimacy of an operator *without revealing the operator's identity*. Lastly, when it comes time to settle payments, the operator should be able to claim payment from the broker *without* revealing what users it has served (since doing so would otherwise reveal user locations).

We design a privacy-preserving protocol that addresses the challenges above. Our contribution lies in developing new techniques (*e.g.*, aggregate claims) and synthesizing them with existing ones (*e.g.*, blind signatures, zero-knowledge proofs) into an end-to-end **Location-Oblivious Cellular Architecture (LOCA)**. To our knowledge, LOCA is the first system to enable location privacy for users while also supporting a provider's operational goals such as usage-based billing, QoS and service levels, lawful intercept, and so forth.

We evaluate the privacy and scalability of our protocol through formal analysis, simulation, prototype implementation, and wide-area experiments. We recognize that LOCA does introduce certain complexity and system overheads. However, our evaluation shows that these overheads are modest and within reach of what can be practically supported today. An important part of our contribution is thus in exposing the architectural complexity and performance tradeoffs that might be necessary to achieve our privacy goals.

Our work is based on certain assumptions about user and operator incentives. We assume that privacy concerns will influence some users in their selection of providers which will incentivize some operators to adopt the proposed techniques.² In addition, a growing number of jurisdictions have enacted policies that require providers to protect user privacy and, as discussed in §3, our architecture makes it easier for a provider to ensure compliance with these legal requirements. We do not assume that this motivation will apply to all users or operators: since our architecture can co-exist with the existing cellular infrastructure, we envision it will be applied to (by) the subset of users (providers) that are motivated by location privacy.

Finally, we recognize that there are many ways in which a user's location may be revealed through their online activities (*e.g.*, posting timestamped photos). We do not claim to prevent all forms of location leakage. Our focus is only on preventing the leakage of location information that today occurs every time a user connects to the cellular network.

In summary, the contributions of this paper are: (1) a new approach to preserve user location privacy while providing

²Such market dynamics are already emerging in other contexts such as the smartphone market [10, 57, 85].

identity-based services; (2) the detailed design and implementation of a protocol (LOCA) based on this approach, and an evaluation of its performance and scalability; and (3) a formal analysis of the privacy provided by LOCA. Looking forward, we view LOCA as a first step towards privacy-preserving cellular infrastructure with room for improvement along multiple dimensions. We discuss these limitations extensively in the paper to motivate efforts on addressing these issues.

2 Background

The cellular ecosystem: MNOs and MVNOs Traditionally, the two main participants in a cellular network are the user with her device (called User Equipment, or UE) and the Mobile Network Operator (MNO). The MNO owns and operates cellular infrastructure and also provides user support services such as sales, billing and customer care. The user typically enters into a contractual agreement with one MNO which serves as her "home" provider. The user then consumes cellular services from her home provider or visited MNOs that her home provider has roaming agreements with.

In recent years, we've seen the rise of Mobile *Virtual* Network Operators (MVNOs). MVNOs are service providers that do not own radio infrastructure, but instead provide user-facing services (sales, billing, *etc.*), often focusing on serving specific underserved market segments [72, 91], while relying on business agreements with some number of MNOs to provide use of their radio infrastructure. In other words, the MVNO acts as a *broker* between the user and the infrastructure operator. In this scenario, the user contracts with an MVNO, and the MVNO in turn contracts with MNOs. Two well-known MVNOs in the US are Google Fi [49] and Cricket [30]. MVNOs can be involved in cellular operations to varying degrees, ranging from fully offloading to MNOs to operating their own core networks.

Identity-based services: These are services whose correct execution depends on the user's identity. An example of such services is lawful interception, a function that allows law enforcement agencies to selectively wiretap individual users [3, 4, 39]. In most countries, operators are legally required to support lawful interception. Additional examples of identity-based services include: (i) post-pay, which relies on identity-based accounting to charge a user based on her service consumption; (ii) QoS prioritization, where the network's treatment of a user's traffic depends on details of the user's subscription plan and past usage; (iii) deep packet inspection (DPI), where traffic is filtered based on the user's identity for purposes such as parental controls.

Location privacy in cellular networks: Location privacy, as defined in [17], is "the ability to prevent other parties from learning one's current or past locations". In the cellular context, this means that neither MVNOs nor MNOs should be able to learn a particular user's current or past locations. The exception is when location information must be revealed for legal purposes like emergency services and forensics.

3 Approach and Design Rationale

In this section, we briefly discuss the goals and assumptions that motivate LOCA’s approach.

3.1 System Assumptions and Threat Model

System model: LOCA assumes a broker-centric architecture like today’s MVNOs. This architecture involves three entities: (i) users, (ii) brokers, and (iii) operators. Operators own and operate cellular infrastructure. Brokers act as intermediaries between users and operators: a user subscribes to services from her broker, and the broker represents the user to operators, including handling settlements with each. LOCA requires brokers to authenticate their users.³ The user need not be aware of the specific operator her device is attached to.

Threat model: We adopt a common threat model among privacy preserving systems that seek to prevent inadvertent information leakage between participants [25, 34, 54, 61, 79]. We assume brokers and operators are *semi-honest* (i.e., honest-but-curious) and *non-colluding*: they follow the protocol but will attempt to extract user location information from the protocol execution, and that brokers and operators do not collude. We also assume that operators may attempt to *overbill* brokers by lying about session usages or what users they serve⁴. Attacks based on out-of-protocol information or collusion are out of scope but discussed in §5.

Incentives: One might ask why brokers and operators would implement the changes we propose. We believe that adopting our system is beneficial to them for both financial and legal reasons: as users are becoming more privacy-conscious [50, 74, 104], brokers that offer an opt-in location-oblivious service will be more attractive to customers. Second, doing so may soon become mandatory: regulations like GDPR recommend the privacy-by-design approach, which continues to place increasingly strong requirements on manipulating PII [16, 98, 107, 108]. By implementing a design such as ours, brokers and operators reduce their risk of inadvertently infringing privacy regulations. We explicitly assume that these benefits will outweigh the benefits of selling location data or implementing ad-hoc approaches to enforcing regulations, and thus we focus on the technical feasibility of a location-oblivious cellular architecture that also supports operational goals like usage-based billing and customized service levels.

3.2 Goals

Consider a user U, operator O, and broker B. We say that U’s location privacy is violated when O and/or B know both U’s

³For MVNOs who by default offload all cellular operations, they can still support LOCA users by deploying their own authentication servers.

⁴One might ask whether we need to protect against over-billing if the operator is semi-honest. The reason we do so is because, as we’ll see, *once we have privacy*, it becomes much easier for an operator to overbill since the broker cannot tell which users were serviced by the operator and hence cannot check the operator’s billing claims. Hence, an operator can follow the protocol and yet overbill with impunity. To avoid this, we assume operators may overbill and design our protocol to prevent this.

Arch	Operator (O)	Broker (B)	ID-based SVC
Today	UID, Location, Trajectory	UID, OID	Full
PGPP	Location, Trajectory	OID	Partial
LOCA	Location	UID	Full

Table 1: Comparison of today’s MVNO architecture, PGPP and LOCA in terms of information revealed to participants and support for identity-based services (ID-based SVC); U/OID: U/O’s identity.

identity and location. Today’s cellular protocol trivially reveals both U’s identity and her location. By protocol we mean the messages – their syntax and semantics – exchanged between U, B, and O as defined by the standard. Today, protocol messages carry U’s identity, and the identity of the tower that U attaches to reveals U’s location. Hence simply implementing the protocol allows an operator to track U’s location with no special effort. In contrast, we are interested in modifying the existing cellular protocol standard to protect user privacy.

3.3 Approach

In research, the state of the art is the recently proposed PGPP protocol [86] which tries to provide location privacy by *hiding* U’s identity from O and B. In PGPP, users are identified by a “blindly signed token” [23, 78] which they obtain during a registration phase prior to consuming service.⁵ I.e., a user prepays for a certain quota of service (e.g., some number of minutes of connectivity at a specified data rate) and in return obtains a blindly-signed token. When connecting to the network, the user presents this token via which the broker can authenticate the user without learning her identity.

To our knowledge, PGPP is the first system that tries to provide location privacy for cellular users. However, as we detail in §8, PGPP faces two drawbacks. First, PGPP does not easily allow operators to support identity-based services, which are widely deployed in today’s networks. Second, a user’s *trajectory* across towers is still visible to operators and hence the protocol is vulnerable to “trajectory-based location leakage” in which the operator can learn the user’s identity by correlating her trajectory with other out-of-band information.⁶ In designing LOCA, we wished to avoid these limitations which, as we will see, leads to an altogether different approach.

In summary, our goal in LOCA is to design a cellular protocol that protects the location privacy of users by achieving the following properties: no party in the protocol (broker, or operator) should simultaneously know both the identity and the location of a user; the protocol should also not reveal the user’s trajectory to either broker or operator. Finally, the protocol should support identity-based services including post-pay and lawful intercept. In this work, we propose LOCA, a new cellular protocol that achieves these stronger privacy guarantees while supporting identity-based services.

We briefly comment on the scope and limitations of LOCA

⁵Such a token is *blindly* signed by the broker who can later verify the signature without being able to link it back to the original signing request.

⁶For example, consider a user that regularly travels between their home and office location: the operator could narrow down the identity of the user by correlating this trajectory with residential information in billing records.

as presented in this paper. Our goal is to safeguard users' location privacy at the *protocol* layer. This raises the bar relative to today's protocols but isn't sufficient to safeguard against violations that might occur outside the protocol, at other layers. For example: at the application layer, a user's identity might be revealed by inspecting their packets [14, 88], or physical-layer characteristics (*e.g.*, signal patterns) might be exploited to track a specific device [33, 47]. Such attacks are possible but (to our knowledge) not exploited today. However, if cellular protocols evolve to protect privacy, such app/physical layer leakages could become a more important issue. Fortunately, the research literature provides solutions to such attacks [43, 56, 60, 103, 110, 114] that we believe can coexist with protocol-layer solutions like LOCA. We elaborate on this in §5.2 but leave an in-depth exploration to future work.

There is an obvious tension between guaranteeing location privacy and offering identity-based services: connecting to a cellular tower fundamentally reveals a user's location, while customizing service to a user requires knowing the user's identity. Our insight is that we can extend broker-centric architectures to create a situation in which the broker knows the user's identity but not their location, while the operator knows the user's location but not their identity; neither broker nor operator knows the user's trajectory.

How do we achieve this? First, to hide U's location from B, we hide the identity and location of the *operator* O from B. Recall that U attaches to the network (and hence to B) via O's infrastructure and hence, if B cannot tell where O is located, then it cannot tell where U is located either. Hiding O's location is not sufficient: we must also hide O's identity from B, as knowing O's identity might be sufficient to narrow down O's location (and hence U's location). An operator's tower locations are public knowledge and, moreover, we're seeing an increasing deployment of small-scale cellular networks due to the emergence of private and enterprise 5G networks, as well as various forms of community networks [13, 38, 52, 97].

As we will describe in §4, we hide O's identity from B by having O obtain an unlinkable token from B during an offline registration process.⁷ O later uses this token (denoted \hat{O}) as its identifier when interacting with B. By the properties of blind signatures, B can verify that \hat{O} is a pre-authorized operator but cannot link \hat{O} to O. In addition, O hides its IP address from B by using anonymous communication solutions.

The above suffices to hide U's location from B. The other half of our arrangement is to hide U's identity from O. This is easily achieved since O does not need to know U's identity to service U; since B knows U's identity, B can tell O what services are required (rate limits, filtering rules, *etc.*) thus enabling identity-based services without revealing U's identity. Thus, U simply uses a temporary pseudonym (denoted \hat{U}) in her interactions with O. Finally, by periodically changing U's

⁷The use of such a token is similar to PGPP but used by O instead of U which we will see leads to a very different set of considerations.

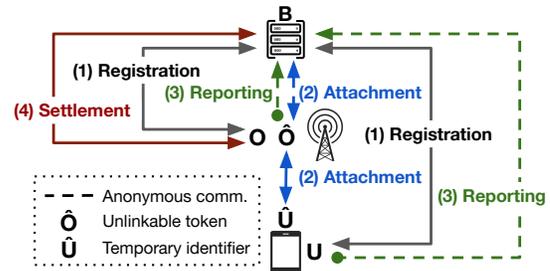

Figure 2: An overview of LOCA's protocols.

temporary pseudonym and randomizing attachment timing, we limit O's ability to track a particular user's trajectory.

As summarized in Table 1, the above approach offers U location privacy while still supporting identity-based services. However it gives rise to a new challenge: how does O receive payment for its services to U? In today's architecture, B directly settles with O based on the service that U received. We wish to preserve this direct billing system between O and B. Yet, our protocol intentionally hides O's identity from B. To address this issue, we devise a solution that allows O to reveal its true identity *only* when claiming payment from B. Our solution leverages zk-proof techniques to design a novel *aggregate claiming* procedure via which (i) O claims payment for an aggregate of the user sessions it has serviced, and (ii) B can verify the correctness of O's claim without revealing the identity of the users that O serviced.

4 Design

At a high level, the process of obtaining cellular services can be broken down into four phases or steps: (i) *registration*, during which the various parties (U, B, O) enter into pairwise contractual relationships: U signs up with B for service, and B with O as an operator for its users; (ii) *attachment* involves the protocol by which U discovers and connects to a tower in O's infrastructure, (iii) *mobility* involves the handover protocols via which U is migrated from one tower to another as needed, and (iv) *settlement* refers to the norms and processes via which B pays O for the service that O has provided B's users.

Of the above, *attachment* and *mobility* are defined by today's 3GPP standard while *registration* and *settlement* are out-of-band processes. Our goal is to implement LOCA with minimal disruptions to today's protocols, and without involving any new entities in the registration or settlements process.

Next, we describe LOCA's operation in these phases, an overview of which is given in Fig. 2. We briefly summarize how each phase is typically implemented in today's networks and then present the changes that LOCA introduces. Finally, we elaborate on how identity-based services work in LOCA.

4.1 Registration

Today: In today's networks, when U signs up with a broker B, they exchange shared secret keys (*SSKs*) that will be used for mutual authentication during the attachment process. In 5G, B also shares its public key (PK_B) with U so that U can encrypt her identity in later attachment requests.

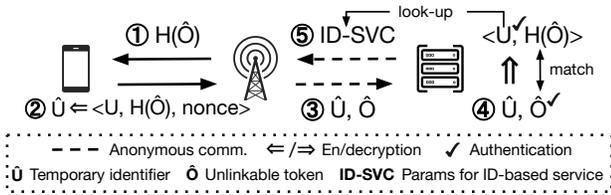

Figure 3: LOCA's attachment procedure.

LOCA: With LOCA, B and U continue to exchange PK_B and SSK . Like today, these keys will be used for mutual authentication between U and B (§4.2) and to hide U's identity from O. The main change LOCA introduces is in the registration process between B and O. When B and O sign up with each other, LOCA requires that they participate in a blind signature protocol [23, 78] as a result of which O obtains unlinkable tokens (denoted as \hat{O}) that are blind-signed by B. When \hat{O} is later presented to B, the blinding process ensures that B can verify the signature but cannot link \hat{O} to O. Thus blind tokens allow B to authenticate O without learning O's identity. LOCA uses a standard blind-signing protocol [23] (summarized in Appendix A). In addition to blind tokens, B and O also exchange a shared hash function H that will be used in our attachment and settlement processes as described later.

4.2 Attachment

Today: Attachment today involves three main steps. First, O broadcasts its identity on the radio control channel that U listens on to discover O. Next, after discovering O, U sends an *attachment request* to O who forwards the request to B for authentication. In 5G, U uses an encrypted identifier (termed SUCI [2]) in this attachment request. Finally, once U has been authenticated, B responds to O authorizing service. B's response includes U's permanent identifier (termed SUPI [5]).

Thus today's attachment process reveals O's identity to U in the first step. In the second step, B learns O's identity (and hence U's location) from both the contents of the attachment request and the act of receiving it from O (which reveals O's IP address). Finally, O learns U's identity via the authorization response it receives from B.⁸ Thus today's attachment reveals U's identity and location to both B and O.

LOCA: We describe LOCA's attachment process with an emphasis on how we prevent (i) B from learning O's identity and (ii) O from learning U's identity. As mentioned in §3.3, we achieve the former by having O interact with B as \hat{O} (O's unlinkable tokens) via anonymous communication channels. LOCA achieves (ii) by encrypting U's identity (with PK_B) and never exposing it outside of B. As shown in Fig. 3, LOCA's attachment process consists of the following five steps.

- (i) *Operator discovery.* Instead of its actual identity, O broadcasts the hash of its token (*i.e.*, $H(\hat{O})$) on the control channel.
- (ii) *User preparation.* U sends an attachment request to O (formatted as a NAS message [7]). This request includes B's

⁸Prior to 5G, U's permanent identifier (IMSI) was included in the initial attachment request, allowing O to directly discover U's identity. Since 5G, U's attachment request uses an encrypted temporary identifier over the air to defend against IMSI catchers [93]. Nonetheless, O still learns U's permanent (SUPI) identifier from B's authorization response (step 3).

identity, U's identity (IMSI) plus a nonce, and $H(\hat{O})$. The last two – (IMSI+nonce) and $H(\hat{O})$ – are encrypted by B's public key and serve as a temporary identifier for U which we denote as \hat{U} . We assume that B has a large user group so that its identity leaks little information on U's identity. The nonce ensures that \hat{U} is different every time U attaches to the same O which helps prevent O from tracking U's trajectory (§4.3).

(iii) *Operator preparation.* On receiving U's attachment request, O forwards the request to B over an anonymous communication channel and uses its unlinkable token \hat{O} to identify itself. Typical solutions for anonymous communication are Tor [99] and VPN [80] with different performance/security trade-offs, which we will discuss in §6.3. This anonymous channel can be set up offline, prior to attachment, whenever O changes token \hat{O} . Thus B does not see O's true identity nor the IP address from which \hat{O} sends the request. The latter is necessary as several studies have shown that IP addresses can often be geo-located with high accuracy [26].

(iv) *Broker authorization.* On receiving the attachment request, B first verifies the \hat{O} token thus ensuring that the request comes from an operator that B has previously authorized during the registration phase. Next B decrypts the request, and authenticates U via today's challenge-response protocol based on the shared secret key SSK [6]. In addition, B verifies that \hat{O} is indeed the operator to which U wants to attach; B can verify this by validating $H(\hat{O})$ (using the shared hash function established when O registered with B) and thus prevents replay or hijacking attacks. Once B has authenticated and verified the request, it looks up the parameters associated with U's service plan (as today): *e.g.*, rate limits, QoS parameters, whether to intercept U's traffic, and so forth. B then crafts a response authorizing the attachment (including the proper service parameters, security parameters that allow U to authenticate the network, etc), signs it, and returns it to \hat{O} .

(v) *Access attachment.* B's response authorizes \hat{O} to service U as per the parameters from B. Beyond this point, \hat{O} (*i.e.*, O) serves U as in today's networks. We elaborate on how O provides identity-based services to U in §4.4. Note that O can still perform functions like establishing radio bearers that require binding U's identifier to temporary identifiers like GUTI and RNTI; O simply uses \hat{U} instead of U.

4.3 Mobility

Today: In current networks, mobility is implemented via a handover process, where O initiates U's migrations by directing U to switch from a tower T1 to another T2. This approach ensures a seamless mobility experience for U because U's IP address remains unchanged after the migration. However, as O initiates U's migrations, O trivially observes U's trajectory across handovers, jeopardizing U's location privacy.

LOCA: Trajectory leakages are inevitable if O fully controls U's mobility like today: although LOCA already hides U's identity from O during attachments, O can still track \hat{U} 's trajectory and use that to infer U's identity, making LOCA vulnerable to trajectory analysis. To mitigate this fundamental

issue, we leverage a user-driven mobility approach proposed in [77]. In this approach, U initiates migrations across towers by simply detaching from T1 and then attaching to T2. U then relies on modern transport protocols like MPTCP [82] and QUIC [71] to maintain connections despite changing IP addresses. Prior work has shown that this user-driven approach does not degrade service even when reattaching on a *per-tower* basis [77]. LOCA adopts and extends this approach to minimize trajectory leakages with two techniques: (i) periodic reattachment and (ii) randomized attachment timings.

First, U will detach and reattach periodically (not at every tower) with a new temporary identifier. Thus, O cannot trivially track U across new sessions based on U's identifiers. The reattachment frequency is a configurable parameter that bounds the length of U's trajectory that is visible to O where length might be measured in time (*e.g.*, valuable for a mostly stationary user), in towers, or some combination thereof.

Even with periodic reattachment, O may still attempt to infer U's trajectory by doing a timing analysis over her detach and attach events. In particular, such analysis would be effective in a naive implementation that uses a fixed interval between when U detaches from T1 and subsequently attaches to T2. To address this issue, we have U wait for a randomized but bounded duration of time before issuing her attachment. When possible, we can also leverage make-before-break attachments⁹ in which U may attach to T2 *before* detaching from T1 thus increasing the time window over which U can randomize their attach/detach events which makes inference harder. Together with periodic reattachment, this randomization of U's attachment times limits O's ability to correctly infer U's trajectory, because U's (re)attachments are obfuscated by the periodic (re)attachments from other nearby users.

We recognize that user-driven mobility introduces some complexity as well as dependencies on newer transport stacks, however this tradeoff is fundamentally necessary if we are to prevent trajectory leakages, and supporting these techniques incurs a minimal impact on the user's performance (§6.3). As we will detail in §5.1.3, the obfuscation effect of our approach depends on the specific configurations, *i.e.*, reattachment frequency and attachment time window; as well as the deployment scenarios, *i.e.*, the number of nearby users and the length of U's trajectory. Overall, under realistic deployment scenarios and configurations, the probability that O can correctly infer U's trajectory is negligible.

4.4 Identity-based Services

LOCA ensures that operators and brokers can continue to provide critical identity-based services, including allowing law enforcement agencies to locate specific users when required.

The key reason LOCA can support identity-based services is that brokers continue to know the identity of their users. This enables B and O to collaborate on identity-based services.

⁹The support for make-before-break, so-called dual active protocol stack (DAPS) handovers has been introduced in 5G 3GPP specifications [8, 45, 95].

For instance, during attachment, B can select the service level associated with U's plan and indicate that to O in its authorization response – *e.g.*, via the QoS Class Identifier (QCI) parameter [109]. O then simply enforces the QCI for the duration of its session with \hat{U} without knowing U's true identity.

To realize services such as lawful interception, law enforcement agencies work with B and O. As today, O runs a lawful interception (LI) system — *e.g.*, installing an interception gateway [96]. A law enforcement agency notifies B of the user whose communication it wants to intercept. B passes on this notification to O during the attachment process, and then O's LI systems report the required information to the agency.

Emergency services (*e.g.*, 911 calls) work in a similar manner. A law enforcement agency knows U's identity and needs to learn U's location. The agency reaches out to B; B looks up U's current temporary identifier \hat{U} , and asks \hat{O} (via their anonymous communication channel) to reveal \hat{U} 's location to law enforcement. Thus, the agency can collect U's current location without violating LOCA's privacy guarantees (*i.e.*, O does not know U's identity while B does not know O's identity or location). The same approach can be used to recover U's past locations based on the records logged at B and O.

4.5 Settlements

Today: In today's MVNO networks, B pays O based on U's service parameters and the resources consumed, as reported by O to B. While differing in the details, existing settlement processes all require that B knows which users/sessions were serviced by O, thus potentially violating user location privacy.

LOCA: To settle O's payments while preserving U's location privacy, LOCA's settlement process contains two phases: a *reporting* phase, where U and O report session usage to B; and a *claiming* phase, where O claims settlement from B.

Reporting phase: In LOCA, we define a *session* as the user-operator association that starts when U completes the attachment process with \hat{O} and ends when U detaches from the same. At some point after a session ends, U and \hat{O} independently send traffic reports to B. Note that O continues to hide its identity and location when sending its report to B. U reveals its identity to B but also sends its reports over an anonymous channel because its IP address can reveal its whereabouts. The traffic report from U lists the sessions in which U participated; \hat{O} does the same for its sessions. Each entry in the list contains a session identifier (SID), usage metrics (*e.g.*, bytes, duration), and QoS metrics (*e.g.*, packet loss rate). In addition, O appends a nonce to each session in its report. These nonces are generated from the shared hash function H known to both O and B, and taking secret inputs that are only known to O. We call these inputs “embedded secrets”, and as we will see, O later uses these secrets to claim its settlement from B.

B then compares the reports from U and \hat{O} , generates bills for U and publishes a *session table* to start the claiming phase. The table includes the usage calculated based on the reports from \hat{O} and U, for all sessions during the last billing cycle.

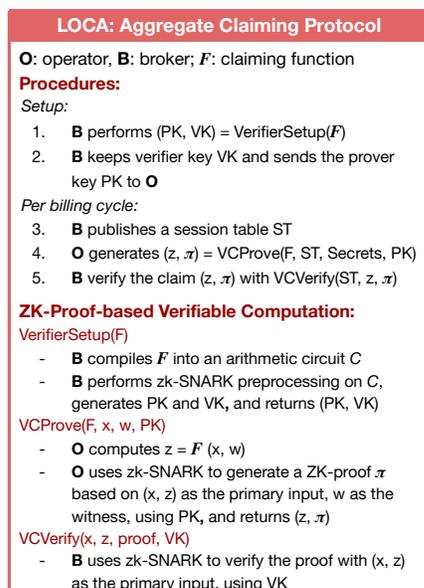

Figure 4: A summary of the aggregate claiming protocol.

When generating statistics in the session table, **B** can consider factors other than reported usages such as QoS metrics.

Claiming phase: Every billing cycle, **O** reveals its identity and claims settlement from **B** but does so without revealing which sessions **O** has serviced. To achieve this, we must solve three problems: (i) *No over-claims*. How does **B** verify that **O** is claiming only the sessions **O** actually serviced? (ii) *No mis-claims*. How do we ensure that **O** can claim the sessions but no one else? (iii) *Session oblivious*. How does **O** claim settlement without revealing to **B** which sessions it is claiming? We combine zero-knowledge proofs with the above mentioned “embedded secrets” to address (i) and (ii); and “aggregate” claims to address (iii).

Embedded secrets serve as the basis for **O** proving its session ownership to **B**. However, naively having **O** reveal its secrets fails the session oblivious requirement because **B** now knows what users **O** has serviced. This leads to our aggregate claiming protocol that fulfills all three requirements:

Aggregate claiming with ZK-proof: First, we observe that in order to generate **O**’s payments, **B** does not need to know *individual* session ownership; instead, it only needs to know the session ownership in *aggregation*, *i.e.*, the aggregate usages for payments for a specific **O**. Based on this insight, our *aggregate claiming* mechanism works as follows: the claiming begins with **B** publishing a session table readable to all **O**s. **O** then reveals its identity and claims its payment from **B**:

Intuitively, **O**’s claim takes the form: “I have sessions that add up to X bytes.” Because the number of different sessions that could add up to X is large, it is difficult for **B** to infer whether an individual session is part of **O**’s claim or not, thus obfuscating the session ownership. In §5.1.2, we show that the expected number of session combinations that add up to the same X grows *exponentially* w.r.t. the total number of sessions in the table via both theoretical and empirical analysis.

Note that this naive aggregate claiming suffices if we as-

sume **O** will not overbill **B**. However, it is important to realize that without additional mechanisms (like the zk-proof that follows), **O** can more easily overbill **B** without being detected in LOCA than in today’s (non-privacy preserving) architecture simply because **B** does not know what users **O** serves.

Hence, since naive aggregate claiming allows **O** to overbill, we extend our solution such that **O** can *prove* its claim by showing that **O** knows the embedded secrets corresponding to its claim. For this, we leverage *proof-based verifiable computation* [102], a cryptographic tool that uses zero-knowledge proof to enable one party to prove to another that it has run a computation $z = f(x, w)$, where f is the function, x is the public input, w is the prover’s private input and z is the output, without revealing any information about w . Proof-based verifiable computation systems have two components: (i) a zk-SNARK backend [84] that proves and verifies satisfiability of *arithmetic circuits*, and (ii) a compiler frontend that translates program executions to arithmetic circuits. Such an arithmetic circuit is also referred to as “a set of *constraints*”.

Fig. 4 describes LOCA’s aggregate claiming protocol. First, **B** performs *VerifierSetup*, where **B** compiles a claiming function F into an arithmetic circuit, and uses zk-SNARK to preprocess the circuit and generate prover key PK and verifier key VK . This verifier setup step needs to be performed only once, after which **B** keeps VK and sends PK to each participating **O**. The claiming function F takes two inputs: a session table with at most N sessions as the public input, and a set of (at most K) secrets as the private inputs. F computes the hashes of the provided secrets, iterates all the sessions in the session table, adds a session’s usage to the aggregate usage if one of the precomputed hashes matches the nonce of that session, and finally returns the aggregate usage.

Next, once per billing cycle, each **O** performs *VCProve*, which involves two steps: (i) **O** executes the claiming function F with the session table and its embedded secrets, which returns the aggregate usage z for **O**’s sessions. (ii) **O** passes to zk-SNARK the session table, its secrets, the computed aggregate z and the prover key PK , to generate a zero-knowledge proof π , which allows **O** to prove to **B** that it has secrets for sessions that add up to z , without leaking any information about individual session ownership. **O** then sends a *claim* including the aggregate usage z and proof π to **B**.

For each **O**’s claim, **B** performs *VCVerify*, where **B** uses zk-SNARK to verify the proof π with the session table, the claimed aggregate z and the verifier key VK . If the verification passes, given the soundness property of the zk-SNARK proof system [84], **B** can confidently approve **O**’s claim and generate **O**’s payment according to the claimed aggregate usage and other factors such as **O**’s reputation. The duration of a billing cycle is configurable: longer cycles lead to larger session tables, which in turn indicates stronger privacy protections (§5.1.2) at the cost of more expensive operations (§6.2).

Session group: The design presented above assumes a single session per token, which may not scale to large deployments:

O generates a proof every billing cycle, and proving with zk-SNARK is expensive [111]. In our setup, as we will show in §6.2, the time complexity to prove a circuit for the claiming function F is $O(K*N)$, where K is the maximum number of sessions O can claim and N the total number of sessions in the session table. Such proving time would be prohibitively long when there are a large number of sessions to claim.

To address this scalability challenge, we introduce the notion of a *session group*, which includes all the sessions that are associated with the same unlinkable token. By grouping multiple sessions into a single session group, we can reduce the number of entries in the session table. To support session groups, we made the following extensions to our protocol:

- **Attachment:** We allow O to use a single token and the corresponding anonymous communication channel for multiple sessions as the same session group.
- **Reporting:** We allow O to send a traffic report containing all the sessions of the session group.
- **Claiming:** We allow B to publish a session group table with one session group for each row. O claims session groups the same way as it claims sessions before.

The size of the session group is tunable in LOCA and determines how many sessions each token is used for. Tuning the group size allows LOCA to explicitly trade off between privacy and scalability: (i) a smaller session group is better for privacy, because it minimizes indirect location leakages (detailed in §5.3), which occur when a user of a session within a session group has her locations leaked, in which case users of other sessions within the group also suffer a privacy loss; (ii) larger session groups are desirable in terms of scalability of zk-SNARK, as it takes longer to actually generate a session group (with users' attachment), while proving cost remains the same, as N is the same, so zk-SNARK proving becomes relatively faster. Fortunately, modern zk-SNARK is fast enough that a balance between privacy and scalability can be achieved: as we will show in our evaluation (§6.2), LOCA can scale to large deployments with sufficiently small session groups and thus introduces only minimal privacy loss.

5 Privacy Analysis

Safeguarding location privacy requires fulfilling three properties: (i) O does not know U's identity, (ii) B does not know U's location, and (iii) neither B nor O knows U's trajectories. To our knowledge, LOCA is the first protocol to meet these requirements. In this section, we analyze the conditions and assumptions under which LOCA meets these requirements. We show that LOCA achieves all three properties under the assumptions of our threat model which are that participants are semi-honest and do not collude (§5.1). We then briefly consider attacks beyond our threat model and show that LOCA offers substantial protection even when participants use out-of-protocol information (§5.2) or collude (§5.3).

5.1 Semi-honest and Non-colluding

We first analyze LOCA's privacy properties under our threat model of semi-honest and non-colluding participants (§3.1).

5.1.1 Hiding U's identity from O

LOCA hides U's identity from O. Specifically, U's identity is encrypted using B's public key. B is thus the only party that can decrypt and observe U's identity in plaintext. B also never exposes U's identity to O, even after U successfully attaches.

5.1.2 Hiding U's location from B

LOCA hides U's location by (i) hiding O's identity and location when O interacts with B on behalf of U and (ii) hiding which users were serviced by O when O reveals its identity to claim its settlement. Next, we show how LOCA achieves (i) via the security properties of existing cryptographic constructs (*i.e.*, anonymous communication and blind signature) and achieves (ii) via aggregate claiming; we establish the latter property via formal analysis and empirical simulations.

For (i), LOCA leverages anonymous communication such that two parties can communicate without revealing their identities to one another. Similarly, LOCA builds on a blind signature scheme that allows a participant to authenticate another without learning its identity. Taken together, these existing cryptographic constructs allow operators to register and report sessions to brokers without revealing their identities.

Discussing the security of aggregate claiming requires more care. We break this process down into two halves (i) the security of the claiming mechanism itself, (ii) the information leaked by revealing the aggregate value to B. The former follows directly from the security of our zero-knowledge proof construction. We do not discuss this further. Instead, we focus on the impact of B learning the aggregate value of the claimed sessions. Specifically, we show that B has an exponentially small likelihood to correctly infer what sessions/users O has serviced based on the aggregate value.¹⁰ Our core intuition is simple. Let us assume that for N session groups with a uniform distribution of session group usage from 1 to m , operators will claim the aggregate usage of K session groups, which sum to aggregate value S . The total number of possible session group combinations grows exponentially as a function of N . In contrast, the number of possible claimed values only grows linearly ($m*N$). In expectation, there will consequently be exponentially many possible session group combinations that could have summed to S . We formally prove that this result holds as long as the ratio between K (the number of session groups belonging to an operator) and the total number of session groups N falls within a specific range. We identify this range formally below, and show through simulation that these bounds can be further improved and are wide enough to support realistic deployment scenarios.

Theoretical proof: We formulate the aforementioned problem as follows. Consider arrays X and Y , one of size $N - K$,

¹⁰The general reasoning extends to when B analyzes multiple claims from different operators but we don't get into the details in this paper.

and one of size K , where each cell contains a value from 1 to m drawn from the discrete uniform distribution. Let S be the sum of all elements in Y . We derive a bound on the expected number of possible subsets of elements in X that sum to S .

Theorem 5.1. *Considering two independent arrays X and Y , consisting of $N - K$ and K iid random variables from $U\{1, m\}$, there exists $L(m), U(m)$ such that the expected number of subsets in X , whose sums are equal to the sum of Y , is exponential w.r.t N , if $L(m) \leq \frac{K}{N} \leq U(m)$. Note that $L(m), U(m)$ depend on m , and $0 < L(m) \leq U(m) < 1, \forall m \in \mathbb{Z}_{>0}$*

The proof, at a high level, works by (i) deriving the closed-form distributions of the sum and the subset sum of an array of discrete uniform variables similar to prior theoretical work [20], (ii) expressing the expected number of matched subsets with these two closed-form distributions, and finally (iii) reducing to an exponential lower bound for the expression. More details of the proof can be found in the appendix.

The reductions in step (iii) are highly conservative. Hence the proven feasible range of ratio $[L(m), U(m)]$ is narrow, and the exponential bound is small. We confirm through simulation that this bound holds analytically for a significantly wider range and encompasses many real-world scenarios:

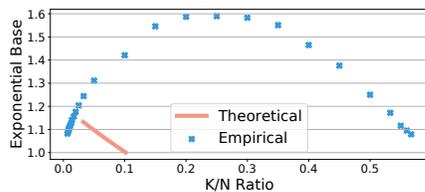

Figure 5: Exponential bounds for different K/N ratios with $m = 5$.

Empirical simulations: In these experiments, our goal is to understand within what range of ratio, the number of matched subsets grows exponentially w.r.t N . For each ratio K/N , we scale N while increasing K proportionally according to the ratio and estimate the expected number of matched subsets for the (K, N) . More details about our simulation setup are in Appendix B. Now that we have estimates for multiple (K, N) 's of the ratio K/N , we fit the results with an exponential curve of N by performing linear fittings on the logs of the estimates:

$$R = a * b^N \rightarrow \log(R) = \log(b) * N + \log(a)$$

The slope of the fitted linear curve is thus the log of the exponential base. Our fitted linear curves closely match the logs of estimates with an adjusted R-squared value of over 0.99, which suggests a significant exponential relation between our estimates and N . Fig.5 shows the exponential bounds of different K/N ratios for uniform distribution with $m=5$. Compared with the theoretical results, the empirical results suggest much larger exponential bounds over a wide range of ratios: exponential base over 1.1 for ratios from 1/150 to over 1/2. We observe similar behavior with other values of m and with other non-uniform session group usage distributions.

5.1.3 Hiding U's trajectory

LOCA hides U's trajectory from O via (i) periodic reattachment and (ii) randomized attachment timing. The former pre-

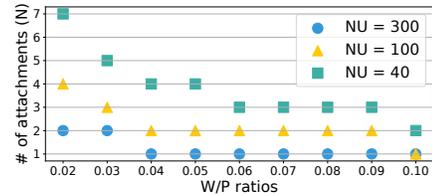

Figure 6: The longest trajectories beyond which the likelihood of correct inference is less than 1% for different NU s and W/P s.

vents O from directly observing U's trajectory, and the latter makes accurate timing-based trajectory inference infeasible:

With periodic reattachments, O is unaware of which attachments belong to U and hence O can only *infer* U's trajectory by correlating between detachment and subsequent attachment. By randomizing attachment timing, any detachment that arises within a time window before and after (with make-before-break handovers) an attachment is equally likely to correlate with that attachment. We call this set of detachments "candidate detachments", and since all users periodically reattach, there is a *lower bound* on the number of candidate detachments. Lastly, to recover U's trajectory, O has to select the correct detachments for all of U's attachments along the trajectory, which becomes *exponentially* harder for longer trajectories. Modelling all these factors, we can analyze the difficulty of trajectory inference in LOCA: denoting time window as W , the reattachment period as P , the number of nearby users as NU , the number of candidate detachments as ND , the number of attachments in U's trajectory as N , we can derive the likelihood of O correctly inferring the trajectory *Prob*:

$$ND \geq 1 + NU * \frac{W}{P}, \quad Prob \approx \left(\frac{1}{ND}\right)^N$$

This formulation tells us why accurate trajectory inference is infeasible: (i) since *Prob* decays exponentially w.r.t N , even with a ND of 2 (only one alternative candidate detachment), O has a less than 1% likelihood of inferring a trajectory with more than 6 attachments; (ii) The ratio between the time window and re-attachment period (*i.e.*, $\frac{W}{P}$) is configurable, and a larger ratio increases ND and thus the inference difficulty. Fig.6 shows the longest trajectories that O can infer with a likelihood larger than 1% for different NU s and $\frac{W}{P}$ s. For $\frac{W}{P}$ larger than 0.03, O is unable to infer long trajectories ($N > 4$), even if the number of nearby users is small ($NU = 40$).

We've shown that LOCA safeguards user location privacy at the protocol layer and under the assumptions of our threat model. We believe this raises the bar relative to the status quo however, as discussed earlier, LOCA would still be vulnerable to attacks that exploit either: (i) out-of-protocol information or (ii) information from other participants via collusion. We will next discuss such attacks, their impact, and potential mitigation strategies, but leave an in-depth study to future work.

5.2 With out-of-protocol information

Next, we show that (i) as a protocol-layer solution, LOCA does not prevent attacks based on out-of-protocol information, (ii) the impact of these attacks on LOCA is minimal and, (iii) mitigation strategies for these attacks can coexist with LOCA.

Attacks: B and O can compromise U’s location privacy by exploiting out-of-protocol information. Here we enumerate some attacks that violate each of the three privacy properties: (i) If O has access to a resident directory near its cell towers, it can nail U down to a smaller user group. O might also learn U’s identity by inspecting U’s data traffic. (ii) If B is capable of network monitoring, it might learn O’s identity by conducting a traffic analysis, where it observes traffic at each operator and correlates that with incoming traffic it receives. (iii) O might track U’s trajectory by profiling U’s physical-layer characteristics, such as its signal patterns and strengths.

Impact: LOCA’s design limits the impacts of out-of-protocol attacks on user’s location privacy: (i) Attacks that allow O to uncover \hat{U} ’s identity only incur *per-hop* leakages: U’s identity remains unknown to O when she reattaches with a different \hat{U} . (ii) Attacks that allow B to uncover \hat{O} ’s identity only incur *per-token* leakages: O’s identity remains unknown to B when O switches tokens. This means that locations of users who are served by O with a different token from the revealed one remain unknown to B. (iii) Lastly, inter-operator attachments can minimize impacts of attacks that allow O to track U’s trajectory. Firstly, instead of having her entire trajectories leaked, U suffers only *per-operator* leakages. Secondly, as U moves in and out of O, it is challenging for O to link all of U’s trajectories within its footprint, because O is unaware of U’s locations when U connects to other operators.

Mitigation: LOCA can coexist with countermeasures designed for different out-of-protocol information. For instance, for attacks based on traffic characteristics, end-to-end encryptions of U’s traffic can help counter packet inspections by O; and communication systems that are robust to traffic analysis like Vuvuzela [101] could be adopted for communications between O and B. For attacks based on physical-layer signals, one could use defense mechanisms such as randomizing transmission coefficients [89] and injecting artificial noises [56].

5.3 With collusion

In the following, we show that (i) there are forms of collusion that lead to violations of user location privacy, and (ii) except for direct collusion between brokers and operators that serve the user, other forms of collusion only incur minimal leakages.

Attacks: Collusion between B and O reveals both U’s identity and location. Note that this is the case for any MVNO-based architecture where B knows U’s identity (for offering identity-based services) and O knows U’s location (as it provides connectivity). Therefore, we focus on showing what other forms of collusion also impair user location privacy. For O, colluding with participants other than B does not provide it with extra information on U’s identity or trajectories. For B, however, it can gain additional knowledge regarding U’s location by colluding with (i) other users or (ii) other operators. The former is due to the use of session groups. Specifically, B knows that sessions in a session group belong to the same O, hence that users of these sessions have visited the same location at a similar time. Therefore, if some users who share

session groups with U reveal their locations to B, then B knows U’s location via such collusion. We call these “indirect location leakages”. The latter is due to operators sharing the session table in the claiming phase. Specifically, B now effectively has a “smaller” session table consisting of only sessions from non-colluding operators, which is detrimental to the privacy guarantee provided by aggregate claiming.

Impact & Mitigation: While brokers gain extra user location information via collusion with other users or operators, the actual impacts are minimal and can be further reduced with different mitigation strategies. First, the impact of indirect location leakages is bounded by the size of session groups, which in turn depends on how fast the zk-SNARK backend is. Fortunately, even with a single-core backend, aggregate claiming can scale to large deployments with a session group that lasts as little as 20 s (§6.2). One could adopt faster backends like distributed zk-SNARK [111] to further reduce the size of session groups and hence leakages. Secondly, since the obfuscation effect of aggregate claiming is *exponential* w.r.t. the size of the session table (§5.1.2), a smaller table still grants sufficient protections. One could use a longer billing period to ensure a large enough session table even with collusion.

6 Implementation and Evaluation

In this section, we present the implementation of our LOCA prototype (§6.1) and investigate the two key questions regarding the feasibility of LOCA: (i) can LOCA scale to realistic deployment sizes? and (ii) how much overhead does LOCA introduce compared to existing cellular protocols? We answer the first question by performing a scalability analysis of the privacy building blocks (§6.2); and the second by conducting a performance analysis with wide-area experiments (§6.3).

6.1 Implementation

We prototyped LOCA as an extension to the CellBricks system [21] which is itself built from open source cellular platforms (Magma [41] and srsLTE [92]). We extended the operator and broker modules with the following: (i) the token generation and verification procedures implemented with rsabind [32]; (ii) the anonymous communication channel between the operator and broker implemented with Torsocks [51, 99] and NordVPN [80] and (iii) the claiming procedure implemented with Pequin [83, 102] that has a single-core libsnark [69] as the zk-SNARK backend. In total, our extension includes 478 LoC in C (for claiming), 144 LoC in Go (for unlinkable token), and 16 LoC shell scripts (for anonymous communication and various setup). We prototyped LOCA with these languages as they were used in the original implementations that we extended. We built a testbed with two x86 machines: one as the user’s device and the other as the operator’s cell and core. We connect each machine to an SDR device (USRP B205-mini [40]) for radio connectivity. Lastly, the broker’s service is deployed on AWS instances [15].

As an opt-in service, LOCA can be incrementally deployed and adopted starting with a small number of LOCA-

compatible users, brokers, and operators: users can have partial privacy by signing up with brokers that support LOCA and by using LOCA-based operators when available and falling back to legacy ones otherwise. We leave an evaluation of the privacy benefits under incremental adoption to future work.

6.2 Scaling analysis

LOCA must be able to scale to a large number of operators serving many users. Therefore, we evaluate whether the three privacy building blocks that we adopt can scale to large deployments, on the order of today’s large MVNOs.

6.2.1 Blind signature

Blind signatures are used for generating and verifying unlinkable tokens. We measure a blind signature generation throughput of 522/sec and a verification throughput of 17202/sec on a 2.6GHz Intel I7-8850H CPU. These single-core throughputs are significant: generating 50 tokens for 10 operators per second. Moreover, brokers can easily achieve higher throughput with more cores or machines, hence we conclude that scaling blind signature operations will not be a problem.

6.2.2 Anonymous communication

For anonymous communication schemes in LOCA, an operator must have sufficient network capacity to send attachment requests to brokers. We measure the average network throughput of a Tor circuit to be 4.2 Mbps uplink and 6.1 Mbps downlink (consistent with Tor’s reports [73]). Such throughput can support ≈ 400 attachment requests per second. Operators can easily scale up the throughput by establishing multiple Tor circuits with the same token. Alternatively, operators can use other anonymous communication schemes that have higher network throughput, such as VPNs (§6.3).

6.2.3 Aggregate Claiming with zk-SNARK

zk-SNARK has a long setup and proving time [111]. Given our aggregate claiming protocol is based on zk-SNARK, we evaluate whether the protocol can scale to large deployments. Since the generated keys are reused across billing cycles, zk-SNARK setup is performed offline only once, which excludes the setup time from the performance critical path. Hence we focus on the zk-SNARK proving time, which is invoked by each operator at every billing cycle to claim its session groups.

As noted in §4.5, LOCA allows claiming sessions in groups with a configurable size: smaller session groups offer stronger privacy guarantees as they minimize indirect location leakages. However, due to the slow zk-SNARK proving, operators may need to use large session groups so that they can *claim session groups faster than the rate of session group creation* and not develop a backlog of unclaimed sessions, at the cost of some privacy loss. To evaluate the amount of such privacy loss, we answer the following question: how small can session groups be while allowing operators to claim them fast enough? Specifically, we would like to obtain a *lower bound* for the average duration of a session group T^{11} . As we will

¹¹One can calculate the average number of sessions in a group as $T * r$, where r is the deployment-dependent rate of attachments for an operator.

show next, even a single-core zk-SNARK implementation is fast enough to support session groups of small T , hence aggregate claiming will not be a scalability bottleneck.

As noted, we let K represent the maximum number of session groups an operator can claim and N represent the maximum number of session groups in the broker’s session group table. If we denote $P(K, N)$ as the time it takes for zk-SNARK to prove the circuit of the claiming function parameterized by K and N , we have the following lower bound for T :

$$T \geq \frac{P(K, N)}{K}$$

To obtain the lower bound, we evaluate the proving time of our implementation for the claiming procedure $P(K, N)$. As mentioned in §4.5, proof-based verifiable computation has a compiler frontend and a zk-SNARK backend. Therefore, to evaluate $P(K, N)$, we need to answer two questions: (i) for a given K and N , how many constraints will the claiming function be compiled into? and (ii) how long will zk-SNARK take to prove these circuits of different sizes?

To answer the first question, we compile claiming functions with different K s and N s, and find the following formula that closely matches the numbers of constraints:

$$\# \text{ of constraints} = K * (128 * N + 35394)$$

Terms in this formula are tied to the logic of the claiming function. As mentioned in §4.5, the claiming function contains two steps: (i) calculating hashes of the K provided secrets, and (ii) iterating through the N rows in the session table, checking whether the hash matches with one of the K precomputed hashes and adding it to the aggregate if so. Therefore, step (i) generates $35394 * K$ constraints, where 35394 is the number of constraints for computing a single SHA256 hash, consistent with prior work [65]; step (ii) contains an outer loop of N and an inner loop of K , which gets unrolled by the compiler into $128 * K * N$ constraints. Therefore, for a large enough N , the number of constraints scale almost linearly with $K * N$.

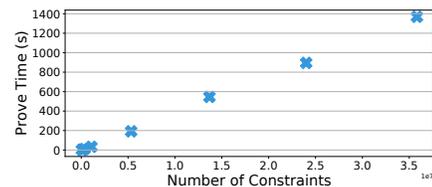

Figure 7: Proving time under varied number of constraints.

To answer the second question, we evaluate the proving time of compiled circuits with different numbers of constraints with a single-core libsnark backend on a 2.5GHz Intel 8259CL CPU. As shown in Fig 7, consistent with prior work [84, 111], the proving time increases linearly with the number of constraints: about 38 seconds per 1 million constraints.

Since we have shown that (i) the number of constraints of the claiming circuit increases linearly w.r.t $K * N$, and (ii) the proving time is linear w.r.t the number of constraints, we know that the *zk-SNARK proving time increases linearly w.r.t $K * N$* , i.e., $P(K, N) = O(K * N)$. The constant factor c depends on the specific compiler frontends and zk-SNARK backends. For

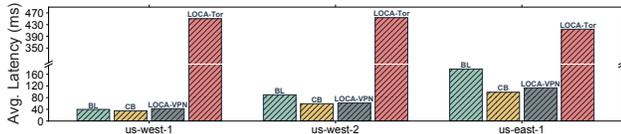

Figure 8: Average attachment latency of Magma baseline (BL), CellBricks (CB), LOCA-VPN and LOCA-Tor.

our implementations, $c \approx 128 * 38 \text{ us} = 4.894 \text{ ms}$. Therefore,

$$T \geq \frac{P(K, N)}{K} \approx \frac{c * K * N}{K} = c * N$$

This means that the lower bound on the duration of the session group grows *linearly w.r.t.* N . As stated earlier, we are mostly interested in cases of large N s (*i.e.*, larger numbers of smaller session groups) as these lead to stronger privacy guarantees (§5.1.2). Fortunately, even with only the single-core libsnark backend, the lower bound of T for large N is reasonably small. As an example, the largest circuit that we evaluated ($K=64$, $N=4096$) has proving time $P(64, 4096)=1369 \text{ s}$; this translates to a lower bound of $T=P(64, 4096)/64=21.4 \text{ s}$. The asymptotic expression of $T = c * N = 4.864 \text{ ms} * 4096 \approx 20 \text{ s}$ matches with the measurement. The gap is due to ignoring the $35394 * K$ term, which will reduce as N goes even bigger.

Therefore, with $N = 4096$, the smallest session group that a single-core zk-SNARK can support has a duration of 20 s. This means that users who attach more than 20 s apart cannot reveal any information about each other’s location, even if one user’s location were leaked to the broker. We do not evaluate circuits with more than 35M constraints due to the scaling limit of the libsnark implementation. Recent work [111] on distributed zk-SNARK allows faster proving of much larger circuits, the evaluation of which is left to future work.

6.3 Performance analysis

Lastly, we would like to understand the performance that users receive with LOCA. Procedures like token generation and aggregate claiming happen off the critical path of users receiving services, thus do not affect user experience. Instead, we focus on the attachment procedure, since LOCA’s attachment is both more complex and more frequent than today’s protocols. We thus measure the additional latency overhead that LOCA adds to the attachment procedure.

We replicate the wide-area test setup from CellBricks [77]: the user equipment and the operator’s cell and cellular core are always located in our local testbed, and we run experiments with the subscriber database (in the case of Magma) and the broker hosted on AWS EC2 [9]. This matches deployment practice where certain core network components are run in the carrier’s datacenter. For each setup, we repeat the same attachment request using different cellular implementations 100 times and report the average performance.

Fig.8 shows the attachment latency after removing the time spent in lower radio layers (*i.e.*, RRC layer and below) for different placements of the subscriber database and broker. We compare four schemes: (i) unmodified Magma (baseline, denoted BL, that captures today’s cellular architecture), (ii) CellBricks (denoted CB), LOCA’s attachment protocol with

(iii) VPN (denoted LOCA-VPN) and (iv) Tor (denoted LOCA-Tor) as the anonymous communication channel.

We make two observations from these results. First, the choice of anonymous communication scheme introduces a tradeoff between trust assumptions and attachment latency: LOCA-VPN requires trusting the VPN provider but achieves faster attachments than LOCA-Tor. In fact, LOCA-VPN is only 5 to 15 ms slower than CellBricks and still faster than today’s attachment (*i.e.*, Magma). The reason we outperform Magma’s attachment latency is because today’s attachment procedure requires two round trips to the cloud, while CellBricks optimized this process to a single round-trip; since we build on CellBricks, we inherit this performance gain.

Our second observation is that even the slower LOCA-Tor is sufficiently fast for periodic reattachments: prior work [77] shows that attachment latencies of up to 500 ms have a minimal impact on application performance, even when users reattach on a per-tower basis. Hence LOCA-Tor, with a constant 400 ms latency due to the overhead of Tor [73], can support frequent reattachments with minimal disruptions.

7 Discussion

Viewing LOCA as a first step towards privacy-preserving cellular infrastructure, we next discuss two notable areas for improvement and potential directions to achieving them: (i) supporting beyond semi-honest and non-colluding participants, and (ii) improving non-privacy-related aspects of LOCA.

7.1 Beyond semi-honest and non-colluding

As stated in §3.1, there are both financial and legal reasons for brokers and operators to be semi-honest and not collude. However, relaxing these assumptions can certainly facilitate adoption. We next discuss directions towards such relaxation. **Semi-honest:** LOCA suffers from privacy leakages in the face of various active attacks, *e.g.*, those based on out-of-protocol information (§5.2), which restricts it to semi-honest participants. We see two orthogonal directions towards supporting more aggressive participants. First, one could adopt specific defense mechanisms for different attacks (*e.g.*, traffic analysis, device fingerprinting) that have been proposed in prior work [43, 56, 60, 103, 110, 114]. LOCA, as a protocol-layer solution, can coexist with these mechanisms. Second, instead of averting attacks, one can detect these attacks and punish the misbehaving participants. The detection mechanism can involve multiple parties. For instance, operator over-reporting usage can be detected by brokers cross comparing the operator’s reports with the ones from users. For the punishment mechanism, a promising approach is to build up a reputation system [77], where misbehaviors are factored into participant’s reputation scores. Participants with poor reputation then receive degraded treatments: *e.g.*, a broker can decline to authorize an operator in the registration phase (§4.1). Such an approach is appealing in the cellular context, where brokers and operators need to remain operational for long enough to see a profit, allowing their track records to be built up.

Non-colluding: As elaborated in §5.3, except for direct collusion between brokers and operators that serve the user, other forms of collusion only incur minimal leakages in LOCA. An interesting question is then whether we could relax this requirement of no broker-operator collusion. Intuitively, preserving location privacy with *arbitrary* collusion seems unattainable: if a broker colludes with all the operators, it easily knows both the user’s identity and all of her locations. Instead, we believe it is both feasible and interesting to investigate whether one could provide *partial* privacy guarantee if only a *subset* of operators collude with brokers. Under such a scenario, the coverage of non-colluding operators forms a region where little location information is revealed. Such a region is referred to as a *mix zone* and widely studied for location privacy in non-cellular contexts [17, 18, 53], and future work could leverage the insights of these work for cellular privacy.

7.2 Beyond privacy

Another area for improvement is the design and evaluation on non-privacy-related aspects of LOCA, such as performance and operational support. For performance, in §6.3, we measure LOCA’s attachment latency to be less than 500 ms even with slower anonymous communication channel (*i.e.*, Tor), which was evaluated in [77] to have minimal performance impacts to applications like voice calls, video streaming and web browsing. It would be interesting to evaluate on more challenging applications such as video conferencing. Moreover, besides reducing trajectory leakages (§5.1.3), make-before-break handovers are expected to have better performance as well, the evaluation of which in LOCA is left to future work.

For operational support, LOCA supports tasks like identity-based services by having brokers offload these tasks to authorized but identity unknown operators (§4.4). However, there might be tasks that require knowledge of the operator’s identity, such as recording misbehaving operators (for the aforementioned reputation system) and performing on-site inspections. To support these tasks, one potential approach is to involve a trusted third party when generating unlinkable tokens (§4.1). The goal is that upon legitimate requests, this third party can later assist in revealing the operator’s identity for a token. One promising direction towards achieving this goal is to extend the registration phase with cryptographic constructs like secure multi-party computation (MPC) [35, 48, 113].

8 Related Work

Cellular: There has been extensive prior work on mitigating privacy violations by third parties other than network operators [11, 46, 58, 63, 68, 87, 93, 94, 100]. Our work instead focuses on protecting a user’s location privacy from the network operator itself. To our knowledge, PGPP [86] is the only prior work that systematically studies this issue. As discussed earlier, PGPP adopts a different approach based on hiding users’ identities from the network operator, which however compromises the network’s ability to provide identity-based services and does not address the issue of trajectory-related

leakages. One advantage of PGPP is higher tolerance for collusions, as it hides user’s identity from both operators and brokers. However, it also assumes semi-honest participants who will not actively thwart its privacy mechanisms.

CellBricks [77] is a new cellular architecture that aims to democratize cellular access by enabling users to easily leverage small-scale operators. LOCA borrows the idea of user-driven mobility, although we use it for privacy reasons while CellBricks requires it to give users the ability to dynamically select an operator of their choice. CellBricks does not address the issue of location privacy and hence is similar to 3GPP protocols in this regard. In fact, we note that the importance of hiding O’s identity from B is greater under the CellBricks vision of larger numbers of smaller-scale operators.

General location privacy: There is extensive prior work on location privacy in non-cellular contexts [17, 36, 67, 76, 90, 106, 112]. These reveal four general methods for protecting location privacy: (i) regulatory strategies – government rules to regulate the use of personal information; (ii) privacy policies – trust-based agreements between individuals and whoever is receiving their location data; (iii) anonymity – use a pseudonym and create ambiguity by grouping with other people. (iv) obfuscation – temporal or spatial degradation of the location data. Regulatory strategies and privacy policies are orthogonal to computational countermeasures like techniques adopted in LOCA. In the cellular context, neither obfuscation nor anonymity is desirable: obfuscation is not feasible, because a user’s location data is generated by the infrastructure, the temporal or spatial resolution of which is not determined by the user; anonymity is the approach adopted by PGPP [86] which, as discussed earlier, compromises on identity-based services. LOCA exploits the unique role of brokers and adopts a novel approach to preserving location privacy while supporting identity-based services. LOCA’s approach of strategically hiding different pieces of information from each party has been investigated for preserving privacy in other contexts as well, such as Apple’s private relay [31].

Applications of LOCA’s privacy building blocks: Blind signatures have been applied for e-voting [59, 64, 75]. Anonymous communication has been used in social networking and web browsing [44, 55, 99]. Proof-based verifiable computation has been used in outsourced computing [24, 27, 70]. LOCA synthesizes these building blocks to support cellular procedures like attachment and aggregate claiming.

9 Conclusion

We presented LOCA, a novel cellular architecture that provides location privacy while supporting identity-based services such as usage-based billing, QoS, and lawful intercept.

We view our work as a first step towards enabling privacy-preserving communication infrastructure and hope that future work will extend our design to address additional threat models and reduced overheads, as well as explore the applicability of LOCA’s design to other access technologies.

Appendix

A Unlinkable token

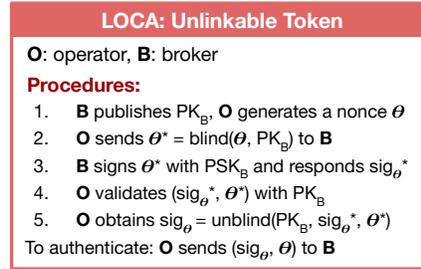

Figure 9: A summary of how to generate and use unlinkable tokens.

Fig.9 summarizes how O obtains tokens. The protocol starts with B publishing its public key PK_B and O generating a nonce θ (i.e., the token). To get B *blindly-sign* the θ , O first *blinds* θ using PK_B and sends the blinded token θ^* to B, requesting B to sign the token. O reveals its identity to B who can decide whether to accept this request. Next, B signs θ^* using its private key PSK_B and returns the blind signature sig_{θ^*} to O which O can validate using PK_B .

Next, O obtains the *unblinded signature* of the token using PK_B , sig_{θ^*} , and θ^* . To authenticate itself to B, O sends θ and the unblinded signature sig_{θ} to B. B can then verify the token's authenticity with sig_{θ} as a normal digital signature. Note that B *cannot* link θ to O since θ was blindly-signed and never seen by B (only the blinded θ^* was).

B Aggregate Claiming

Simulation setup: For each ratio K/N , we scale N while increasing K proportionally according to the ratio and estimate the expected number of matched subsets for the (K, N) . For example, for the ratio $K/N=1/10$, we run experiments for $(K, N)=(1, 10), (2, 20), \dots, (5, 50)$. For each (K, N) , we again make the simplification to not consider subsets that contain any of the K session groups. By doing so, we can independently sample arrays X s of length $(N - K)$ and Y s of length K , count the number of subsets in X that have the same sum as Y for each pair of (X, Y) , and report the average of all the pairs as the estimate for (K, N) , denoted as R . To ensure that the estimate is accurate, we use a large number of samples for each (K, N) , up to 2^{25} so that the simulation can finish within a reasonable time frame.

Theoretical proof: For this proof, we make use of *polynomial coefficients*, also named as extended binomial coefficients, which are natural extensions of the well-known binomial coefficient. For $n, m \in \mathbb{Z}_{>0}$ Polynomial coefficients $\binom{n}{k}_m$ is the coefficient of x^k in the following expansion:

$$(1 + x + \dots + x^m)^n = \sum_{k=0}^{k=mn} \binom{n}{k}_m x^k$$

Note that $\binom{n}{k}_m = 0$ for $k \notin \{0, \dots, mn\}$. Binomial coefficient is the special case where $m = 1$. An equivalent definition of $\binom{n}{k}_m$ is:

$$\binom{n}{k}_m = \sum_{\substack{k_0 \geq 0, \dots, k_m \geq 0 \\ k_0 + \dots + k_m = n \\ 0 \cdot k_0 + \dots + m \cdot k_m = k}} \binom{n}{k_0, \dots, k_m} \quad (1)$$

It is known that polynomial coefficients are symmetric: $\binom{n}{k}_m = \binom{n}{mn-k}_m$, and $\binom{n}{k}_m$ is a non-decreasing function of k for $0 \leq k \leq \lfloor \frac{mn}{2} \rfloor$ and a non-increasing function for $\lceil \frac{mn}{2} \rceil \leq k \leq mn$ [42].

Prior work has shown that the sum of N iid random variables from the discrete uniform distribution of $\{0, \dots, m\}$ ($U\{0, m\}$), denoted as S_N , has the following closed-form distribution expressed with polynomial coefficients [20]:

$$\begin{aligned} P(S_N = y) &= \sum_{\substack{a_0 \geq 0, \dots, a_m \geq 0 \\ a_0 + \dots + a_m = N \\ 0 \cdot a_0 + \dots + m \cdot a_m = y}} P(a_0, \dots, a_m) && (a_i \text{ stands for the number of elements equal to } i) \\ &= \sum_{\substack{a_0 \geq 0, \dots, a_m \geq 0 \\ a_0 + \dots + a_m = N \\ 0 \cdot a_0 + \dots + m \cdot a_m = y}} \left(\frac{1}{m+1}\right)^N \binom{N}{a_0, \dots, a_m} && (\text{each element can be putted into bucket } i \text{ with a likelihood of } \frac{1}{m+1}) \\ &= \left(\frac{1}{m+1}\right)^N \binom{N}{y}_m && (\text{according to definition (1)}) \end{aligned}$$

Lemma B.1. The distribution of sums of N iid random variables from $U\{1, m\}$ has the following closed-form expression:

$$P_N(y) = \left(\frac{1}{m}\right)^N \binom{N}{y-N}_{m-1}$$

Proof. The proof is similar to the proof above for sums of N iid random variables from $U\{0, m\}$, with some minor adjustment:

$$\begin{aligned} P_N(y) &= \sum_{\substack{a_1 \geq 0, \dots, a_m \geq 0 \\ a_1 + \dots + a_m = N \\ 1 \cdot a_1 + \dots + m \cdot a_m = y}} \left(\frac{1}{m}\right)^N \binom{N}{a_1, \dots, a_m} \\ &= \sum_{\substack{a_1 \geq 0, \dots, a_m \geq 0 \\ a_1 + \dots + a_m = N \\ 0 \cdot a_1 + \dots + (m-1) \cdot a_m = y-N}} \left(\frac{1}{m}\right)^N \binom{N}{a_1, \dots, a_m} && \text{(align with the format of (1))} \\ &= \left(\frac{1}{m}\right)^N \binom{N}{y-N}_{m-1} && \text{(according to definition (1))} \quad \square \end{aligned}$$

Lemma B.2. The distribution of subset sums of N iid random variables from $U\{1, m\}$ has the following closed-form expression:

$$Q_N(y) = \left(\frac{1}{2m}\right)^N \sum_{k=0}^N \binom{N}{k} m^k \binom{N-k}{y-(N-k)}_{m-1}$$

Proof. Subset sums of $U\{1, m\}$ can be equivalently treated as sums of elements X_i that has the following distribution:

$$P(X_i) = \begin{cases} \frac{1}{2}, & \text{if } X_i = 0 \\ \frac{1}{2m}, & \text{if } X_i \in \{1, \dots, m\} \\ 0, & \text{otherwise} \end{cases}$$

Therefore, we can calculate the probability of a subset sum by multiplying the probability of having different numbers of zeros with the probability of adding up to the sum with the remaining non-zero elements:

$$\begin{aligned} Q_N(y) &= \sum_{k=0}^N \binom{N}{k} \left(\frac{1}{2}\right)^k \sum_{\substack{a_1 \geq 0, \dots, a_m \geq 0 \\ a_1 + \dots + a_m = N-k \\ 1 \cdot a_1 + \dots + m \cdot a_m = y}} \left(\frac{1}{2m}\right)^{N-k} \binom{N-k}{a_1, \dots, a_m} \\ &= \sum_{k=0}^N \binom{N}{k} \left(\frac{1}{2}\right)^k \sum_{\substack{a_1 \geq 0, \dots, a_m \geq 0 \\ a_1 + \dots + a_m = N-k \\ 0 \cdot a_1 + \dots + (m-1) \cdot a_m = y-(N-k)}} \left(\frac{1}{2m}\right)^{N-k} \binom{N-k}{a_1, \dots, a_m} && \text{(similar to Lemma B.1)} \\ &= \sum_{k=0}^N \binom{N}{k} \left(\frac{1}{2}\right)^k \left(\frac{1}{2m}\right)^{N-k} \binom{N-k}{y-(N-k)}_{m-1} && \text{(according to definition (1))} \\ &= \left(\frac{1}{2m}\right)^N \sum_{k=0}^N \binom{N}{k} m^k \binom{N-k}{y-(N-k)}_{m-1} \quad \square \end{aligned}$$

Lemma B.3. Here we define a "head" function $H(hN; N, p)$ ($0 \leq h \leq 1$) and a "tail" function $T(tN; N, p)$ ($0 \leq t \leq 1$), where:

$$H(hN; N, p) = \sum_{k=0}^{hN} \binom{N}{k} p^k; \quad T(tN; N, p) = \sum_{k=tN}^N \binom{N}{k} p^k$$

Then we can prove the following: if $h < \frac{p}{1+p}$, $H(hN; N, p) \leq (b_H)^N$, with $b_H < (1+p)$. Similarly, if $t > \frac{p}{1+p}$, $T(tN; N, p) \leq (b_T)^N$, with $b_T < (1+p)$.

Proof. Here we show the proof for the head function, the proof for the tail function is very similar. The idea is to rewrite the head function to follow the format of a binomial distribution, so that we could use tail bounds for binomial distributions to

provide a lower bound. Specifically:

$$\begin{aligned}
H(hN; N, p) &= \sum_{k=0}^{hN} \binom{N}{k} p^k \\
&= (1+p)^N \sum_{k=0}^{hN} \binom{N}{k} \left(\frac{p}{1+p}\right)^k \left(\frac{1}{1+p}\right)^{N-k} \\
&= (1+p)^N \sum_{k=0}^{hN} \binom{N}{k} (p')^k (1-p')^{N-k} && \text{(with } p' = \frac{p}{1+p}\text{)} \\
&= (1+p)^N F(hN; N, p')
\end{aligned}$$

where $F(hN; N, p')$ refers to the probability of having at most hN successes in a Binomial trial $B(N, p')$. For $F(hN; N, p')$, it's known that if $\frac{hN}{N} = h \leq p'$, we have the following tail bounds [12]:

$$F(hN; N, p') \leq \exp[-Nf(h, p')] \quad \text{with } f(h, p') = \begin{cases} 2(h-p')^2, & \text{with Hoeffding's inequality} \\ D(h||p'), & \text{with Chernoff bound} \end{cases}$$

where $D(a||p)$ is the relative entropy between a *Bernoulli*(a) (a -coin) and a *Bernoulli*(p) (p -coin):

$D(a||p) = (a \log \frac{a}{p} + (1-a) \log \frac{1-a}{1-p})$. For either of this, $f(h, p') > 0$ for $h < p'$. Therefore, for $H(hN; N, p)$, if $h < p' = \frac{p}{1+p}$, we have:

$$\begin{aligned}
H(hN; N, p) &= (1+p)^N F(hN; N, p') \\
&\leq (1+p)^N \exp[-Nf(h, p')] \\
&= \{(1+p) \exp[-f(h, p')]\}^N \\
&= (b_H)^N && \text{(with } b_H = (1+p) \exp[-f(h, p')] < (1+p)\text{)} \quad \square
\end{aligned}$$

Lemma B.4.

$$\frac{1}{m^2 + m + 1} < 1 - \frac{\ln(m)}{\ln(m+1)}, \quad \forall m \in \mathbb{Z}_{>0}$$

Proof. This is equivalent as showing

$$h(m) = (m^2 + m + 1)\ln(m) - (m^2 + m)\ln(m+1) < 0, \quad \forall m \in \mathbb{Z}_{>0}$$

Taking derivative, we have

$$\begin{aligned}
h'(m) &= (2m+1) \ln\left(\frac{m}{m+1}\right) + 1 + \frac{1}{m} \\
&\leq (2m+1) \left(\frac{m}{m+1} - 1\right) + 1 + \frac{1}{m} && \text{(with } \ln(x) \leq x - 1\text{)} \\
&= \frac{-m^2 + m + 1}{m(m+1)} < 0 && \text{(for } m \geq 2 > \frac{1+\sqrt{5}}{2}\text{)}
\end{aligned}$$

Therefore, because (i) $h(m)$ monotonically decreases for $m \geq 2$, and (ii) $h(1), h(2) < 0$, we have $h(m) < 0, \forall m \in \mathbb{Z}_{>0}$ □

$f[n]$ is said to be exponential w.r.t n iff:

$$\exists M \in \mathbb{R}_{>0}, c \in \mathbb{R}_{>1}, \quad \lim_{n \rightarrow \infty} \frac{f[n]}{c^n} = M$$

Therefore, a sufficient condition for $f[n]$ to be exponential is that

$$\exists M \in \mathbb{R}_{>0}, c \in \mathbb{R}_{>1}, N_0 \in \mathbb{Z}, \quad f[n] \geq M \cdot c^n, \quad \forall n \geq N_0$$

With this we could prove the following lemma:

Lemma B.5. For any integer $K \geq 1$, $h_K[n] = a^n - \sum_{i=1}^K b_i^n$ is exponential w.r.t n , if $a > 1$ and $a > \max_{i:i \in \{1, \dots, K\}} b_i$

Proof. $h_K[n]$ can be rewritten as $h_K[n] = \sum_{i=1}^K \frac{1}{K} a^n - b_i^n$. We can prove that $\frac{1}{K} a^n - b_i^n$ are exponential for all b_i 's. Specifically, we can show that.

$$\forall c \in \{x \in \mathbb{R} \mid \max(b_i, 1) < x < a\}, M \in \mathbb{R}_{>0}, \exists N(a, c, M) \in \mathbb{Z}, \quad \frac{1}{K} a^n - b_i^n > M c^n, \quad \forall n \geq N(a, c, M)$$

This because $\frac{1}{K} a^n - b_i^n > M c^n \Leftrightarrow \frac{1}{K} \left(\frac{a}{c}\right)^n > M + \left(\frac{b_i}{c}\right)^n$. By having $n \geq N(a, c, M) = \lceil \log_{\frac{a}{c}} [k(M+1)] \rceil$, we have $\frac{1}{K} \left(\frac{a}{c}\right)^n > M+1 > M + \left(\frac{b_i}{c}\right)^n$. Therefore, $h_K[n] = \sum_{i=0}^K \frac{1}{K} a^n - b_i^n$ is obviously exponential:

$$\forall c \in \{x \in \mathbb{R} \mid \max(\max_{i:i \in \{1, \dots, K\}} b_i, 1) < x < a\}, M \in \mathbb{R}_{>0}, \exists N(a, c, M) \in \mathbb{Z}, \quad h_K[n] > K M c^n, \quad \forall n \geq N(a, c, M) \quad \square$$

We are now ready to prove the main theorem, which, in the context of LOCA, states that with the usage of each session as a uniform distribution of $\{1, \dots, m\}$, a bTelco's number of sessions as N_B and the total number of sessions a broker receives from all bTelcos as N_A , if $\frac{N_B}{N_A}$ meets certain requirements (depending on m), the expected number of session subsets that have the same aggregate usage as the bTelco's N_B sessions grows exponentially w.r.t the total number of sessions, N_A .

Next, we prove that a lower bound of this expected number, considering subsets consisting of only the remaining $N_A - N_B$ sessions, is already exponential w.r.t N_A :

Theorem B.6. Considering two independent arrays X and Y , consisting of $N_A - N_B$ and N_B iid random variables from $U\{1, m\}$, there exists $L(m), U(m)$ such that the expected number of subsets X , whose sums are equal to the sum of Y , is exponential w.r.t N_A , if $L(m) \leq \frac{N_B}{N_A} \leq U(m)$. Note that $L(m), U(m)$ depend on m , and $0 < L(m) \leq U(m) < 1, \forall m \in \mathbb{Z}_{>0}$

Proof. We prove this theorem by showing a valid $L(m), U(m)$ pair. We denote this expected number as $E(m, N_A, N_B)$, and derive its closed-form expression by using the distributions of sums and subset sums, which were computed in Lemma B.1 and Lemma B.2. Specifically, for a random array B , the probability that its sum equals to y is $P_{N_B}(y)$, and the expected number of subsets in A that add to y is $2^{N_A - N_B} Q_{N_A - N_B}(y)$:

$$\begin{aligned} E(m, N_A, N_B) &= 2^{N_A - N_B} \sum_{y=N_B}^{mN_B} P_{N_B}(y) Q_{N_A - N_B}(y) \\ &= 2^{N_A - N_B} \sum_{y=N_B}^{mN_B} \left(\frac{1}{m}\right)^{N_B} \binom{N_B}{y - N_B}_{m-1} \left(\frac{1}{2m}\right)^{N_A - N_B} \sum_{k=0}^{N_A - N_B} \binom{N_A - N_B}{k} m^k \binom{N_A - N_B - k}{y - (N_A - N_B - k)}_{m-1} \quad (\text{B.1, B.2}) \\ &= \left(\frac{1}{m}\right)^{N_A} \sum_{y=N_B}^{mN_B} \binom{N_B}{y - N_B}_{m-1} \sum_{k=0}^{N_A - N_B} \binom{N_A - N_B}{k} m^k \binom{N_A - N_B - k}{y - (N_A - N_B - k)}_{m-1} \\ &= \left(\frac{1}{m}\right)^{N_A} \sum_{k=0}^{N_A - N_B} \binom{N_A - N_B}{k} m^k \sum_{y=N_B}^{mN_B} \binom{N_B}{y - N_B}_{m-1} \binom{N_A - N_B - k}{y - (N_A - N_B - k)}_{m-1} \end{aligned}$$

By using identities of polynomial coefficients [42], we can transform the last term as:

$$\begin{aligned} \sum_{y=N_B}^{mN_B} \binom{N_B}{y - N_B}_{m-1} \binom{N_A - N_B - k}{y - (N_A - N_B - k)}_{m-1} &= \sum_{y=N_B}^{mN_B} \binom{N_B}{(m-1)N_B - (y - N_B)}_{m-1} \binom{N_A - N_B - k}{y - (N_A - N_B - k)}_{m-1} \quad (\text{symmetry}) \\ &= \binom{[N_B] + [N_A - N_B - k]}{[(m-1)N_B - (y - N_B)] + [y - (N_A - N_B - k)]}_{m-1} \quad (\text{Vandermonde}) \\ &= \binom{N_A - k}{(m+1)N_B - N_A + k}_{m-1} \end{aligned}$$

Therefore, we have a closed-form expression for $E(m, N_A, N_B)$:

$$E(m, N_A, N_B) = \left(\frac{1}{m}\right)^{N_A} \sum_{k=0}^{N_A - N_B} \binom{N_A - N_B}{k} m^k \binom{N_A - k}{(m+1)N_B - N_A + k}_{m-1}$$

According to the definition of polynomial coefficients:

$$\binom{N_A - k}{(m+1)N_B - N_A + k}_{m-1} \geq 1 \text{ if } 0 \leq (m+1)N_B - N_A + k \leq (m-1)(N_A - k) \Leftrightarrow N_A - (m+1)N_B \leq k \leq N_A - (1 + \frac{1}{m})N_B \quad (2)$$

Therefore, we could obtain a lower bound for E :

$$\begin{aligned} E(m, N_A, N_B) &\geq \left(\frac{1}{m}\right)^{N_A} \left\{ \sum_{k=0}^{N_A - N_B} \binom{N_A - N_B}{k} m^k - \sum_{k=0}^{N_A - (m+1)N_B - 1} \binom{N_A - N_B}{k} m^k - \sum_{k=N_A - (1 + \frac{1}{m})N_B + 1}^{N_A - N_B} \binom{N_A - N_B}{k} m^k \right\} \\ &= \left(\frac{1}{m}\right)^{N_A} \left\{ (1+m)^{N_A - N_B} - H(N_A - (m+1)N_B - 1; N_A - N_B, m) - T(N_A - (1 + \frac{1}{m})N_B + 1; N_A - N_B, m) \right\} \end{aligned}$$

According to Lemma B.3, we know that with

$$\frac{N_A - (m+1)N_B}{N_A - N_B} \leq \frac{m}{1+m} \implies \frac{N_B}{N_A} \geq \frac{1}{m^2 + m + 1} \quad (3)$$

$$\frac{N_A - (1 + \frac{1}{m})N_B}{N_A - N_B} \geq \frac{m}{1+m} \implies \frac{N_B}{N_A} \leq \frac{m}{2m+1} \quad (4)$$

We have:

$$\begin{aligned} E(m, N_A, N_B) &\geq \left(\frac{1}{m}\right)^{N_A} \left\{ (1+m)^{N_A - N_B} - H(N_A - (m+1)N_B - 1; N_A - N_B, m) - T(N_A - (1 + \frac{1}{m})N_B + 1; N_A - N_B, m) \right\} \\ &\geq \left(\frac{1}{m}\right)^{N_A} \left\{ (1+m)^{N_A - N_B} - (b_H)^{N_A - N_B} - (b_T)^{N_A - N_B} \right\} \quad \text{with } b_H < (1+m), b_T < (1+m) \end{aligned}$$

Therefore, according to Lemma B.5, we can ignore the head and tail, and E has an exponential lower bound w.r.t N_A as long as the base of $\left(\frac{1}{m}\right)^{N_A} (1+m)^{N_A - N_B}$ is larger than 1. Since:

$$\left(\frac{1}{m}\right)^{N_A} (1+m)^{N_A - N_B} = \left[\frac{(1+m)^{1 - \frac{N_B}{N_A}}}{m} \right]^{N_A}$$

to ensure base larger than 1, we need

$$\frac{(1+m)^{1 - \frac{N_B}{N_A}}}{m} > 1 \implies \frac{N_B}{N_A} < 1 - \frac{\ln(m)}{\ln(m+1)} \quad (5)$$

Combining constraints (3), (4) and (5), we show an exponential lower bound for $E(m, N_A, N_B)$ with the following $\frac{N_B}{N_A}$:

$$\frac{1}{m^2 + m + 1} \leq \frac{N_B}{N_A} < 1 - \frac{\ln(m)}{\ln(m+1)}$$

As proved in Lemma B.4, such a range is always valid for any $m \in Z_{>0}$. Therefore, we show that for

$$L(m) = \frac{1}{m^2 + m + 1}, U(m) = 1 - \frac{\ln(m)}{\ln(m+1)}, E(m, N_A, N_B) \text{ has an exponential lower bound of } \left[\frac{(1+m)^{1 - \frac{N_B}{N_A}}}{m} \right]^{N_A}.$$

We believe one could achieve a much large exponential bounds and/or a wider range for feasible $\frac{N_B}{N_A}$ by carefully reexamining the two reductions that we made:

- Only the remaining $N_A - N_B$ elements are considered for subsets that have the same sum. This is to simplify the problem so that we can treat it as a problem involving two independent arrays of length $N_A - N_B$ and N_B . This, however, significantly underestimates the number of matched subsets, especially when $\frac{N_B}{N_A}$ is high.
- The reduction we made in (2): $\binom{N_A - k}{(m-1)N_B - N_A + k}_{m-1} \geq 1$ is obviously coarse grained. □

Lastly, we can prove the other side of the story: if $\frac{N_B}{N_A}$ is too large or too small, the expected number of subsets out of $N_A - N_B$ elements that have the same sum as the N_B elements *does not* grow exponentially w.r.t to N_A :

Theorem B.7. *Considering two independent arrays X and Y , consisting of $N_A - N_B$ and N_B iid random variables from $U\{1, m\}$, there exists $LL(m), UU(m)$ such that the expected number of subsets in X , whose sums are equal to the sum of Y , can not be exponential w.r.t N_A , if $\frac{N_B}{N_A} \leq LL(m)$ or $\frac{N_B}{N_A} \geq UU(m)$. Note that $0 < LL(m) \leq UU(m) < 1, \forall m \in \mathbb{Z}_{>0}$*

Proof. Firstly, we show that such a $UU(m)$ exists. We start with the closed-form expression of $E(m, N_A, N_B)$ that is derived in the proof above.

$$\begin{aligned} E(m, N_A, N_B) &= \left(\frac{1}{m}\right)^{N_A} \sum_{k=N_A-(m+1)N_B}^{N_A-(1+\frac{1}{m})N_B} \binom{N_A - N_B}{k} m^k \binom{N_A - k}{(m+1)N_B - N_A + k}_{m-1} \\ &\leq \left(\frac{1}{m}\right)^{N_A} \sum_{k=0}^{N_A-(1+\frac{1}{m})N_B} \binom{N_A - N_B}{k} m^k \binom{N_A - k}{(m+1)N_B - N_A + k}_{m-1} \\ &\leq \left(\frac{1}{m}\right)^{N_A} \sum_{k=0}^{N_A-(1+\frac{1}{m})N_B} \binom{N_A - N_B}{k} m^k \binom{N_A}{(m+1)N_B - N_A + k}_{m-1} \quad \left(\binom{n}{k}_m \geq \binom{n-\Delta}{k}_m \quad \forall \Delta \in \mathbb{Z}_{\geq 0}\right) \end{aligned}$$

As noted above $\binom{n}{k}_m$ is a non-increasing function of k for $\lceil \frac{mn}{2} \rceil \leq k \leq mn$ [42], therefore, if we have

$$(m+1)N_B - N_A \geq \lceil \frac{(m-1)N_A}{2} \rceil \implies \frac{N_B}{N_A} > \frac{1}{2}$$

$\binom{N_A}{(m+1)N_B - N_A + k}_{m-1}$ decreases as k increases from 0 to $N_A - (1 + \frac{1}{m})N_B$, thus:

$$\begin{aligned} \binom{N_A}{(m+1)N_B - N_A + k}_{m-1} &\leq \binom{N_A}{(m+1)N_B - N_A}_{m-1} \quad (\text{for } k \in \{0, \dots, N_A - (1 + \frac{1}{m})N_B\}) \\ &= d^{N_A}(m, N_A, \frac{N_B}{N_A}) \quad (\text{with } d(m, N_A, \frac{N_B}{N_A}) = \left[\binom{N_A}{(m+1)N_B - N_A}_{m-1} \right]^{\frac{1}{N_A}}) \end{aligned} \quad (6)$$

where:

$$d(m, N_A, \frac{N_B}{N_A}) = \left[\binom{N_A}{(m+1)N_B - N_A}_{m-1} \right]^{\frac{1}{N_A}} = \left[\binom{N_A}{\lfloor (m+1)\frac{N_B}{N_A} - 1 \rfloor N_A}_{m-1} \right]^{\frac{1}{N_A}}$$

We denote

$$f(m, \frac{N_B}{N_A}) = \lim_{N_A \rightarrow \infty} d(m, N_A, \frac{N_B}{N_A})$$

There are two properties of $g(m, \frac{N_B}{N_A})$ that we leverage here: (i) $1 \leq f(m, \frac{N_B}{N_A}) \leq m$, this is because $\binom{N_A}{\lfloor (m+1)\frac{N_B}{N_A} - 1 \rfloor N_A}_{m-1} < m^{N_A}$ and $\binom{N_A}{\lfloor (m+1)\frac{N_B}{N_A} - 1 \rfloor N_A}_{m-1}$ is a non-decreasing function w.r.t N_A ; (ii) $f(m, \frac{N_B}{N_A})$ is a non-increasing function w.r.t $\frac{N_B}{N_A}$ for $\frac{1}{2} < \frac{N_B}{N_A} < \frac{m}{m+1}$, this is because $d(m, N_A, \frac{N_B}{N_A})$ is a decreasing function w.r.t $\frac{N_B}{N_A}$. Moreover, $f(m, \frac{m}{m+1}) = 1$ and $f(m, \frac{1}{2}) = m$. The later is because, as shown in [37], $\binom{n}{\frac{n}{2}}_m \sim \frac{(m+1)^n}{\sqrt{2\pi n \frac{m(m+2)}{12}}}$ as $n \rightarrow \infty$, which indicates that $\lim_{n \rightarrow \infty} \left[\binom{n}{\frac{n}{2}}_m \right]^{\frac{1}{n}} = m + 1$. Therefore, $f(m, \frac{1}{2}) = \lim_{N_A \rightarrow \infty} \left[\binom{N_A}{\lfloor \frac{m-1}{2} N_A \rfloor}_{m-1} \right]^{\frac{1}{N_A}} = m$. With (6), we now have the following upper bound for $E(m, N_A, N_B)$ (to simply notation, we use d for $d(m, N_A, \frac{N_B}{N_A})$):

$$E(m, N_A, N_B) \leq \left(\frac{d}{m}\right)^{N_A} \sum_{k=0}^{N_A-(1+\frac{1}{m})N_B} \binom{N_A - N_B}{k} m^k$$

Similar to Lemma B.3, we can then bound the term $\sum_{k=0}^{N_A - (1 + \frac{1}{m})N_B} \binom{N_A - N_B}{k} m^k$ by using tail bounds of binomial distribution. Specifically, as mentioned in the proof of Lemma B.3:

$$\sum_{k=0}^{N_A - (1 + \frac{1}{m})N_B} \binom{N_A - N_B}{k} m^k \leq \left\{ (1+m) \exp\left[-D\left(\frac{N_A - (1 + \frac{1}{m})N_B}{N_A - N_B} \parallel \frac{m}{1+m}\right)\right] \right\}^{N_A - N_B}$$

$$\text{if } \frac{N_A - (1 + \frac{1}{m})N_B}{N_A - N_B} \leq \frac{m}{1+m} \Rightarrow \frac{N_B}{N_A} \geq \frac{m}{2m+1} \quad (7)$$

where $D(a||p)$ is the relative entropy between a *Bernoulli*(a) (a -coin) and a *Bernoulli*(p) (p -coin): $D(a||p) = (a) \log \frac{a}{p} + (1-a) \log \frac{1-a}{1-p}$. Here we denote

$$g\left(m, \frac{N_B}{N_A}\right) = (1+m) \exp\left[-D\left(\frac{N_A - (1 + \frac{1}{m})N_B}{N_A - N_B} \parallel \frac{m}{1+m}\right)\right]$$

$$= (1+m) \exp\left[-D\left(\frac{1 - (1 + \frac{1}{m})\frac{N_B}{N_A}}{1 - \frac{N_B}{N_A}} \parallel \frac{m}{1+m}\right)\right]$$

Note that $g\left(m, \frac{N_B}{N_A}\right)$ is a decreasing function of $\frac{N_B}{N_A}$ for $\frac{N_B}{N_A} \geq \frac{m}{2m+1}$. Moreover, $\lim_{\frac{N_B}{N_A} \rightarrow \frac{m}{m+1}} g\left(m, \frac{N_B}{N_A}\right) \rightarrow 0$, and $g\left(m, \frac{1}{2}\right) > 1$ for $m \geq 2$. The later is because $g\left(m, \frac{1}{2}\right) = (1+m) \exp\left[-D\left(\frac{m-1}{m} \parallel \frac{m}{1+m}\right)\right]$ is an increasing function with m , thus $g\left(m, \frac{1}{2}\right) \geq g\left(2, \frac{1}{2}\right) = 3 \exp\left[-D\left(\frac{1}{2} \parallel \frac{2}{3}\right)\right] > 1$.
With (7), we now have:

$$E(m, N_A, N_B) \leq \left(\frac{d}{m}\right)^{N_A} \left[g\left(m, \frac{N_B}{N_A}\right)\right]^{N_A - N_B}$$

$$= \left\{ \left(\frac{d}{m}\right) \left[g\left(m, \frac{N_B}{N_A}\right)\right]^{1 - \frac{N_B}{N_A}} \right\}^{N_A}$$

Considering the limit of the base:

$$\lim_{N_A \rightarrow \infty} \left[\frac{d(m, N_A, \frac{N_B}{N_A})}{m} \right] \left[g\left(m, \frac{N_B}{N_A}\right)\right]^{1 - \frac{N_B}{N_A}}$$

$$= \left[g\left(m, \frac{N_B}{N_A}\right)\right]^{1 - \frac{N_B}{N_A}} \lim_{N_A \rightarrow \infty} \left[\frac{d(m, N_A, \frac{N_B}{N_A})}{m} \right]$$

$$= \left[g\left(m, \frac{N_B}{N_A}\right)\right]^{1 - \frac{N_B}{N_A}} \left[\frac{f(m, \frac{N_B}{N_A})}{m} \right]$$

With the properties of $f\left(m, \frac{N_B}{N_A}\right)$ and $g\left(m, \frac{N_B}{N_A}\right)$ that we mentioned, one could prove that there exists a ratio $R(m)$ such that:

$$h\left(m, \frac{N_B}{N_A}\right) = \left[g\left(m, \frac{N_B}{N_A}\right)\right]^{1 - \frac{N_B}{N_A}} \left[\frac{f\left(m, \frac{N_B}{N_A}\right)}{m} \right] \leq 1 \quad \forall \quad \frac{N_B}{N_A} \geq R(m)$$

where $h(m, R(m)) = 1$

This means that $E(m, N_A, N_B)$ is not exponential w.r.t N_A for $\frac{N_A}{N_B} \geq R(m)$

We could prove that there is a unique $R(m)$ with $h(m, R(m)) = 1$, and $\frac{m}{2m+1} < R(m) < \frac{m}{m+1}$, with the following properties of $f\left(m, \frac{N_B}{N_A}\right)$ and $g\left(m, \frac{N_B}{N_A}\right)$: (i) both of them are decreasing functions w.r.t $\frac{N_B}{N_A}$; (ii) $1 \leq f\left(m, \frac{N_B}{N_A}\right) \leq m$, $f\left(m, \frac{m}{m+1}\right) = 1$ and $f\left(m, \frac{1}{2}\right) = m$; (iii) $g\left(m, \frac{1}{2}\right) > 1$, and $\lim_{\frac{N_B}{N_A} \rightarrow \frac{m}{m+1}} g\left(m, \frac{N_B}{N_A}\right) \rightarrow 0$.

Firstly, because $\frac{f\left(m, \frac{N_B}{N_A}\right)}{m} \leq 1$, for $\frac{N_B}{N_A}$ such that $g\left(m, \frac{N_B}{N_A}\right) < 1 \Rightarrow \left[g\left(m, \frac{N_B}{N_A}\right)\right]^{1 - \frac{N_B}{N_A}} < 1$, we have

$h\left(m, \frac{N_B}{N_A}\right) = \left[g\left(m, \frac{N_B}{N_A}\right)\right]^{1 - \frac{N_B}{N_A}} \left[\frac{f\left(m, \frac{N_B}{N_A}\right)}{m} \right] < 1$. Moreover, since $\lim_{\frac{N_B}{N_A} \rightarrow \frac{m}{m+1}} g\left(m, \frac{N_B}{N_A}\right) \rightarrow 0$, we know that $R(m) < \frac{m}{m+1}$

Secondly, for $\frac{N_B}{N_A}$ such that $g(m, \frac{N_B}{N_A}) > 1$, we have $h(m, \frac{N_B}{N_A})$ as a decreasing function w.r.t $\frac{N_B}{N_A}$. Moreover, since $g(m, \frac{1}{2}) > 1$, $f(m, \frac{1}{2}) = m$, we have $h(m, \frac{1}{2}) = [g(m, \frac{1}{2})]^{1-\frac{1}{2}} [\frac{f(m, \frac{1}{2})}{m}] > 1$. Therefore, we know that $R(m) > \frac{1}{2}$.

Therefore, we have proved a valid $UU(m)$: $\frac{1}{2} < UU(m) = R(m) < \frac{m}{m+1}$, where $R(m)$ is defined as:

$$R(m) = \arg_{\frac{1}{2} < \frac{N_B}{N_A} < \frac{m}{m+1}} h(m, \frac{N_B}{N_A}) = 1$$

$$\text{where } h(m, \frac{N_B}{N_A}) = [g(m, \frac{N_B}{N_A})]^{1-\frac{N_B}{N_A}} [\frac{f(m, \frac{N_B}{N_A})}{m}]$$

$$f(m, \frac{N_B}{N_A}) = \lim_{N_A \rightarrow \infty} \left[\binom{N_A}{[(m+1)\frac{N_B}{N_A} - 1]N_A} \right]^{\frac{1}{N_A}}$$

$$g(m, \frac{N_B}{N_A}) = (1+m) \exp[-D(\frac{1 - (1+\frac{1}{m})\frac{N_B}{N_A}}{1 - \frac{N_B}{N_A}} || \frac{m}{1+m})]$$

and $E(m, N_A, N_B)$ is not exponential if $\frac{N_B}{N_A} \geq UU(m)$.

Next, we show a valid $LL(m)$ by using a similar approach. We use E to represent $E(m, N_A, N_B)$ in the follows.

$$E \leq (\frac{1}{m})^{N_A} \sum_{k=N_A-(1+m)N_B}^{N_A-N_B} \binom{N_A-N_B}{k} m^k \binom{N_A-k}{(m+1)N_B-N_A+k}_{m-1}$$

$$\leq (\frac{1}{m})^{N_A} \sum_{k=N_A-(1+m)N_B}^{N_A-N_B} \binom{N_A-N_B}{k} m^k \binom{(m+1)N_B}{(m+1)N_B-N_A+k}_{m-1} \quad \left(\binom{n}{k}_m \geq \binom{n-\Delta}{k}_m \quad \forall \Delta \in \mathbb{Z}_{\geq 0} \right)$$

$$< (\frac{1}{m})^{N_A} m^{(m+1)N_B} \sum_{k=N_A-(1+m)N_B}^{N_A-N_B} \binom{N_A-N_B}{k} m^k \quad \left(\binom{(m+1)N_B}{(m+1)N_B-N_A+k}_{m-1} < m^{(m+1)N_B} \right)$$

$$\leq (\frac{1}{m})^{N_A} m^{(m+1)N_B} \left\{ (1+m) \exp[-D(\frac{N_A - (1+m)N_B}{N_A - N_B} || \frac{m}{1+m})] \right\}^{N_A-N_B} \quad \left(\frac{N_A - (m+1)N_B}{N_A - N_B} \geq \frac{m}{1+m} \Rightarrow \frac{N_B}{N_A} \leq \frac{1}{m^2+m+1} \right)$$

$$= \left\{ m^{(m+1)\frac{N_B}{N_A}-1} \left\{ (1+m) \exp[-D(\frac{1 - (1+\frac{1}{m})\frac{N_B}{N_A}}{1 - \frac{N_B}{N_A}} || \frac{m}{1+m})] \right\}^{1-\frac{N_B}{N_A}} \right\}^{N_A}$$

We could prove that for $l(m, \frac{N_B}{N_A}) = m^{(m+1)\frac{N_B}{N_A}-1} \left\{ (1+m) \exp[-D(\frac{1 - (1+\frac{1}{m})\frac{N_B}{N_A}}{1 - \frac{N_B}{N_A}} || \frac{m}{1+m})] \right\}^{1-\frac{N_B}{N_A}}$, there exists a $0 < S(m) < \frac{1}{m^2+m+1}$,

which is the $LL(m)$ that we try to prove, that $l(m, \frac{N_B}{N_A}) \leq 1$ for any $\frac{N_B}{N_A} \leq S(m)$. This is because (i) $l(m, \frac{N_B}{N_A})$ is an increasing function of $\frac{N_B}{N_A}$, and (ii) $l(m, \frac{1}{m^2+m+1}) = m^{-\frac{m^2}{m^2+m+1}} (1+m)^{\frac{m^2+m}{m^2+m+1}} > (1+m)^{\frac{m}{m^2+m+1}} > 1$ and $\lim_{\frac{N_B}{N_A} \rightarrow 0} l(m, \frac{N_B}{N_A}) = 0 < 1$.

Therefore, we have proved a valid $LL(m)$: $0 < LL(m) = S(m) < \frac{1}{m^2+m+1}$, where $S(m)$ is defined as:

$$S(m) = \arg_{0 < \frac{N_B}{N_A} < \frac{1}{m^2+m+1}} l(m, \frac{N_B}{N_A}) = 1$$

$$\text{where } l(m, \frac{N_B}{N_A}) = m^{(m+1)\frac{N_B}{N_A}-1} \left\{ (1+m) \exp[-D(\frac{1 - (1+\frac{1}{m})\frac{N_B}{N_A}}{1 - \frac{N_B}{N_A}} || \frac{m}{1+m})] \right\}^{1-\frac{N_B}{N_A}}$$

and $E(m, N_A, N_B)$ is not exponential if $\frac{N_B}{N_A} \leq LL(m)$. □

mmWall: A Steerable, Transflective Metamaterial Surface for NextG mmWave Networks

Princeton Univ.¹, Univ. of Massachusetts Amherst², UCLA³

Abstract

Mobile operators are poised to leverage millimeter wave technology as 5G evolves, but despite efforts to bolster their reliability indoors and outdoors, mmWave links remain vulnerable to blockage by walls, people, and obstacles. Further, there is significant interest in bringing outdoor mmWave coverage indoors, which for similar reasons remains challenging today. This paper presents the design, hardware implementation, and experimental evaluation of *mmWall*, the first electronically almost-360° steerable metamaterial surface that operates above 24 GHz and both refracts or reflects incoming mmWave transmissions. Our metamaterial design consists of arrays of varactor-split ring resonator unit cells, miniaturized for mmWave. Custom control circuitry drives each resonator, overcoming coupling challenges that arise at scale. Leveraging beam steering algorithms, we integrate mmWall into the link layer discovery protocols of common mmWave networks. We have fabricated a 10 cm by 20 cm mmWall prototype consisting of a 28 by 76 unit cell array and evaluated it in indoor, outdoor-to-indoor, and multi-beam scenarios. Indoors, mmWall guarantees 91% of locations outage-free under 128-QAM mmWave data rates and boosts SNR by up to 15 dB. Outdoors, mmWall reduces the probability of complete link failure by a ratio of up to 40% under 0–80% path blockage and boosts SNR by up to 30 dB.

1 Introduction

Millimeter-wave (mmWave) spectrum has emerged in the 5G/6G era as a key next generation wireless network enabler, fulfilling user demands for high spectral efficiency and low latency wireless networks. Higher carrier frequencies offer greater network capacity: for instance, the maximum carrier frequency of the 4G LTE band at 2.4 GHz provides an available spectrum bandwidth of only 100 MHz, while mmWave (above 24 GHz) can easily hold spectral bandwidths five to ten times greater, enabling multi-Gbit/sec data rates. Hence, mmWave spectrum enables a plethora of mobile applications

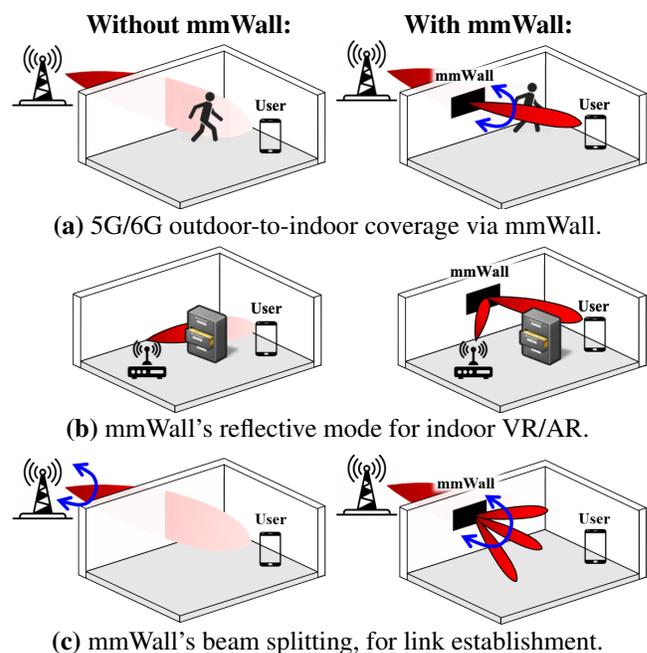

Figure 1: mmWall re-focuses outdoor coverage indoors towards the user and potentially around obstacles, provides path diversity indoors by reflection, and splits an incoming beam for fast link establishment.

that are currently infeasible due to their requirements of very high data rates, such as virtual and augmented reality (VR/AR), camera-based purchase tracking in smart stores, and robotic automation in smart warehouses.

mmWave technology faces significant headwinds, however, in at least three key scenarios:

1. 5G outdoor coverage is difficult to bring indoors, as exterior building walls block mmWave signal, as do outdoor windows' tinted glass (Fig. 1(a)). Attenuation at 28 GHz is *ca.* 40 dB versus 4 dB through indoor glass [44], as outdoor metalized glass coatings attenuate by 25–50 dB per layer [35]. Currently, operators are forced to offload

mmWave traffic onto lower frequencies or off their networks entirely (Wi-Fi) when users move indoors, incurring handover delay and application disruptions.

2. Indoors, people, furniture, doors, and other clutter block mmWave (Fig. 1(b)), forcing data to flow over a much less reliable reflection path. Indeed, in an extensive indoor measurement campaign at 28 GHz, MacCartney *et al.* observe a close-in best non-line of sight path loss exponent *ca.* 3, with a normally-distributed additional loss with an 11 dB variance [22]. While the resulting temporary outages are common, highly demanding applications like VR/AR streaming cannot tolerate these glitches.
3. Third, NextG cellular providers face challenges in adopting mmWave frequencies outdoors for primary service as well as wireless backhaul because mmWave signals are readily absorbed by foliage, and reflection off buildings is largely specular, constraining the angle of reflection to be equal to the angle of incidence. Measurements in New York City highlight this issue: 28 GHz data shows most links greater than 200 meters in outage [3].

This paper describes the design and implementation of *mmWall*, an electronically reconfigurable surface that addresses all three foregoing use cases, also shown in Figure 1. Like much prior work (§2), mmWall leverages *metamaterials*, artificial composite materials engineered at a sub-wavelength scale to exhibit unique electromagnetic properties that do not exist in naturally occurring materials [17]. But mmWall is the first practical work to our knowledge to use a specific class of metamaterials capable of refracting incoming radiation with (theoretically) no loss: *Huygens* metamaterials [9, 25]. mmWall is a reconfigurable intelligent surface that uses a novel Huygens metasurface (HMS) metamaterial to reflect/refract and precisely steer incoming mmWave beams towards desired directions, thus enhancing path diversity for mmWave networks. Work has shown that surfaces that can steer incoming mmWave transmissions in this way have the potential to dramatically improve spatial multiplexing [41] and spectral efficiency [39] of networks as a whole. Hence when obstacles like a human body or outdoor foliage blocks the line of sight (LoS) or non line of sight (NLoS) paths, mmWall can often provide an alternative path that is not a simple reflection or a straight-line transmission, and hence would not otherwise exist. In the first scenario, mmWall can refract mmWave signals from outdoors to steer them directly towards an indoor receiver, making outdoor to indoor communication possible. In the second scenario above, mmWall reflects mmWave beams at non-specular angles (those for which the angle of reflection is not equal to the angle of incidence). And in the third scenario, mmWall can reflect outdoor transmissions at non-specular angles, ameliorating outdoor blockages.

mmWall is electronically reconfigurable to either reflect or refract incoming energy, allowing it to time-multiplex the

different roles of each of the three above use cases without human intervention, while installed in a fixed location. Also, its multi-beam functionality (Fig. 1(c)) enables fast beam search, and support for multiple users at the same time. mmWall has no RF chain, and its electric components draw only a couple-of-hundred microwatts order of power. Consequently, it consumes much lower power compared to a conventional AP that necessitates multiple RF chains for multi-beam operations. To our knowledge, mmWall is the first surface able to achieve near-360° angular coverage (§5).

This work addresses several hardware and software design challenges that arise in the realization of such a design. Since mmWave transmissions are “pencil-beam” in nature, they work only when the transmitter’s beam is perfectly aligned with the receiver’s beam. To correctly steer the beam towards the receiver, we design a metamaterials-based surface that can precisely control the phases of the incoming signal, focusing signal power in a narrow beam. Secondly, since the size of meta-atom scales with its operating frequency, mmWall’s meta-atoms are much smaller than the conventional antennas and therefore extremely sensitive to coupling. Hence, we not only scale the surface to mmWave frequency but also deliberately design the control lines to avoid undesirable coupling. Lastly, existing systems use their own beam searching protocol to find the best alignment. To make mmWall compatible with different mmWave applications, we design an effective beam alignment protocol that leaves the existing systems unchanged [16].

Contributions and Results. mmWall is the first design that can arbitrarily reflect, refract, and split the mmWave beam in a nearly lossless manner. We analyze our meta-atom designs and compare them with simulation results, allowing our designs to scale to different frequencies for potential applications like Terahertz communication. To the best of our knowledge, this is the first study that theoretically analyzes and builds a working prototype of a reconfigurable Huygens metasurface at mmWave frequency. We have designed and implemented mmWall hardware with a novel control network in custom PCB, and in §5, evaluate its performance through experiments in environments matching the scenarios, we outline above. Our empirical results show that when both the AP and the client are in the same room, we can provide an SNR of 25 dB or more for all locations in a $10 \times 8m$ room, using a single mmWall surface. This SNR is sufficient to support 128-QAM in 91% of locations. Moreover, the SNR improves to 30 and 35 dB when we place two surfaces, respectively, on different walls. Finally, we show the effectiveness of mmWall in bringing outdoor mmWave networks indoors. When the AP is 6 meters away from the building, mmWall improves the SNR by up to 30 dB, providing an SNR of 20 dB or more in all locations in a room using a single surface placed on a window.

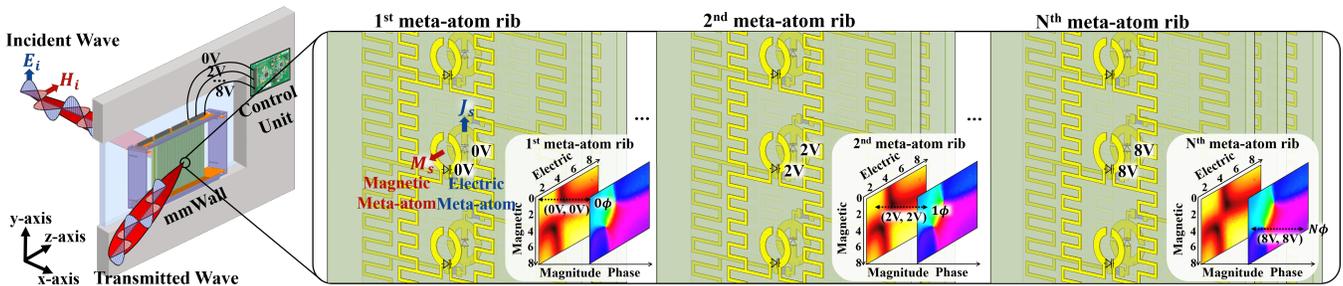

Figure 2: mmWall’s design converts an incident mmWave beam to a refracted (or reflected, not shown) beam via field discontinuities created by current in its resonators. *Inset:* magnetic meta-atoms are shown in front of the electric meta-atoms.

2 Related Work

HMSs comprise a layer of co-located *magnetic* and *electric* meta-atom, etched onto the two respective sides of a dielectric substrate (Fig. 2, *inset*). The magnetic meta-atom is an enclosed metallic ring with one split, while the electric meta-atom has two splits and a metal strip in the center (Fig. 4(b)). As the incident wave passes through the magnetic meta-atom, the wave’s magnetic field H_i induces a rotating current (green arrows in Fig. 4(b), *upper*) on the magnetic meta-atom that, in turn, creates a magnetic response (\vec{M}_s along the z-axis in Fig. 2). Likewise, the electric meta-atom is excited by the wave’s electric field \vec{E}_i , resulting in two symmetric, oscillating current loops (green arrows in Fig. 4(b), *lower*) that create an electric response (\vec{J}_s along the y-axis in Fig. 2). These responses interact with the wave’s fields, causing an abrupt phase shift. By varying the applied voltage to a tunable component loaded on each meta-atom, the surface precisely controls the responses, thereby allowing any phase shift from 0° to 360° with near-unity transmission and/or reflection.

Prior work in passive HMSs [8,9,29,40] has demonstrated a “lensing” effect and negative refraction index [29] and the engineering of complex beam patterns [8]. However, they lack the capability to reconfigure and both refract and reflect the beam. Prior work in actively-controlled HMSs [4,7,21,38,43] uses varactors or PIN diodes to tune each element in a continuous or binary (*i.e.*, on-off) manner, respectively. Such devices can shift signals’ frequency [21] and polarization [5,38]. While these designs have shown great promise in theoretical prediction models [23] and/or at low frequencies [36], they do not scale to higher mmWave frequencies in a straightforward way, due to a mismatch between the required meta-atom size and a varactor’s size, and the attenuation that commonly available substrate would induce on an incident mmWave signal. Scaling these designs also requires narrower trace widths that are hard to fabricate and prone to breaking during diode soldering. More importantly, they focus on steering one beam in a one-sided direction, rather than steering one or more beams in a reflective and/or transmissive direction. mmWall is the first mmWave work to do so. Evaluation efforts in this group of prior work stop short of realistic end-to-end experiments.

Work in actively-controlled mmWave Reconfigurable Intelligent Surfaces (RISs) includes a solely reflective, PIN-diode based surface at 2.3 and 28 GHz [7], whose evaluation at 28 GHz states a gain of 19 dBi, but which stops short of further experimental evaluation of steerability or any further end-to-end evaluation at 28 GHz. Tang *et al.* describe similar PIN-diode, reflective surfaces at 27 and 33 GHz, model path losses in such scenarios, and experimentally evaluate [33]. Tan *et al.* consider a similar design at 60 GHz [31], but neither consider HMS-based designs such as mmWall’s, which can shift between reflective (on both sides of the surface) and transmissive modes instantly via electronic control. Existing reflective RISs only reflect on one side, while mmWall performs both indoor *and* outdoor non-specular reflections from a fixed location. In press releases ([a], [b], [c]) NTT DoCoMo describe reflective, outdoor-to-indoor surfaces operating at 28 GHz. They state top line experimental results, but do not disclose design details or details of their experimental evaluation. Other work uses split ring resonators as antennas for a Massive MIMO base station [28], a related but distinct application to mmWall. This paper is an extension of the authors’ previous workshop publication [6] that describes a new control line design, documents real hardware implementation, and presents significant new evaluation results in realistic, diverse scenarios.

Recent work in passive non-HMS based mmWave RISs includes proposals that reflect signals at angles of reflection different than incidence [11,26], but cannot be tuned to target a receiver’s location, hence wasting incident energy and resulting in at most 10 dB of gain, significantly below mmWall’s achieved gain. Also, these approaches do not refract as mmWall can, yielding reduced applicability. Recent amplify-and-forward proposals for Wi-Fi [42] use a mesh topology, but do not scale to mmWave frequencies, and at mmWave [1] are limited to indoor reflection. Recent complementary approaches leverage multi-beam transmission [18,19], sensing and leveraging ambient reflectors [37], and use Wi-Fi as a control plane to discover mmWave links [20,30]. While they align with mmWall’s goals, such approaches cannot create paths whose reflection angles diverge from their incident angles, or refract through a surface.

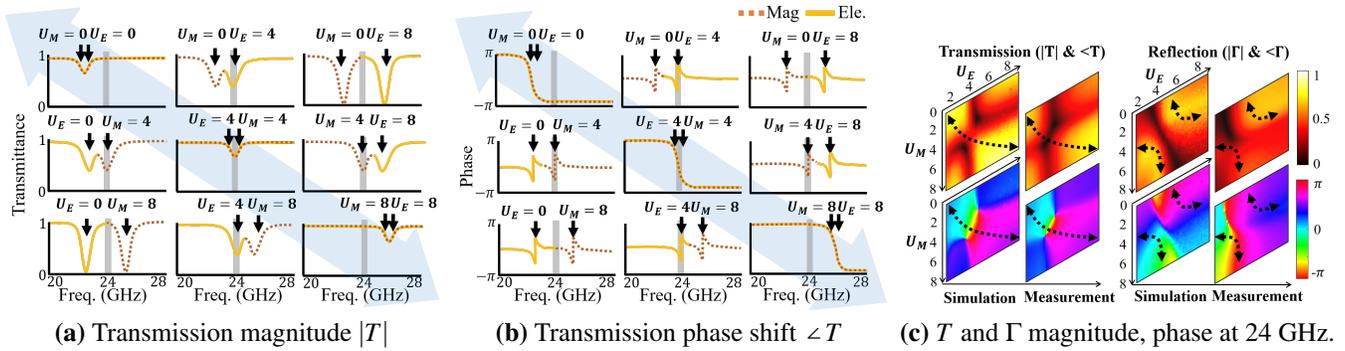

Figure 3: Unit cell response *v.* electric- and magnetic-side control voltages U_E and U_M —(a): magnitude and (b): phase. (c): HFSS simulation (*left*) and near-field, real world VNA measurement (*right*)— arrows indicate control voltage pairs that yield a 360° phase shift of the incoming signal, with high transmission or reflection magnitude.

3 Design

We describe in turn mmWall’s hardware (§3.1), their control mechanism (§3.2), and their link layer integration (§3.3).

3.1 Surface Hardware

mmWall’s unit cells (also known as *meta-atoms*) are stacked vertically with a $\lambda/3$ separation, on each Rogers substrate board (also known as a *meta-atom rib*), as shown in Fig. 2 (see §3.2.1 for a discussion of vertical and horizontal unit cell spacing considerations for beamforming). A control unit connected to mmWall provides a set of voltages to the ribs. In Fig. 2, 0V is applied to both magnetic and electric meta-atoms on the first rib, causing the meta-atoms to shift the phase by 0ϕ with minimal loss. For the second rib, 2V is applied to shift the phase by 1ϕ . Ultimately, the beam is steered by all N ribs collectively forming an array factor.

3.1.1 Design Goals

The two primary design goals of the unit cell are to simultaneously **1)** achieve transmission T or reflection Γ loss levels as close to zero as possible, and **2)** effect any phase shift in $[0, 2\pi]$ on the incoming signal, both at mmWave frequencies.

The unit cell consists of two meta-atoms, *magnetic* and *electric*. The magnetic (electric) meta-atom induces a magnetic (electric) field response to the incoming signal that can resonate at different, tunable frequencies by varying the applied voltage to the varactor of the magnetic- (electric-) meta-atom.

Without loss of generality, we now describe how transmission works (reflection is fully complementary to transmission, and we refer the reader to Appendix A for a rigorous mathematical exposition of both). In Fig. 3(a), we observe that increasing the voltage applied to the magnetic meta-atom U_M from 0 to 8 V (down the three leftmost subplots) shifts its resonance frequency (lowest transmission magnitude point

of the red dotted line¹) to the right (we will analyze how this frequency shifting works in §3.1.2). Similarly, the electric meta-atom induces an electric response and its resonant frequency can be shifted by its own varactor (reading similarly across the three topmost subplots). Together their effects are superposed and we manipulate the collective magneto-electric response that interferes with the incident plane wave.

The key characteristic that allows near-perfect amplitude with full phase coverage appears when the two responses overlap at the same frequency. Otherwise, the phase response undergoes a sharp change of only π and its magnitude dips to nearly zero at its resonant frequency, as we see in Fig. 3(a) and Fig. 3(b) when the voltages applied to the magnetic and electric meta-atom differ by 8 V. However, as the two resonances start to overlap, transmission loss decreases and the phase shift becomes 2π (on-diagonal sub-figures, Fig. 3(a) and Fig. 3(b)). As a result, we achieve 2π phase coverage with near-unity magnitude by increasing the voltage applied to both the magnetic and electric meta-atoms together (Fig. 3(c), at control voltages indicated by the black curves).

While the overlapped resonances can reach a perfect unitary transmission magnitude in theory, the Huygens pattern from our measurement shows a lower transmission magnitude on the area where abrupt phase shifts occur due to various reasons, including the sensitivity at mmWave frequency, fabrication loss, and measurement errors.

3.1.2 Design Process

We now describe challenges we overcame in scaling the resonance of the mmWall unit cell to mmWave frequencies. By definition, the meta-atom behaves as an LC circuit with resonant frequency $1/(2\pi\sqrt{LC})$, determined by the capacitance or inductance of the meta-atoms. Hence, we must markedly *decrease* the inductance and capacitance of prior microwave designs (§2), if we can hope to achieve a mmWave reso-

¹In operation we largely avoid the lowest transmission nulls.

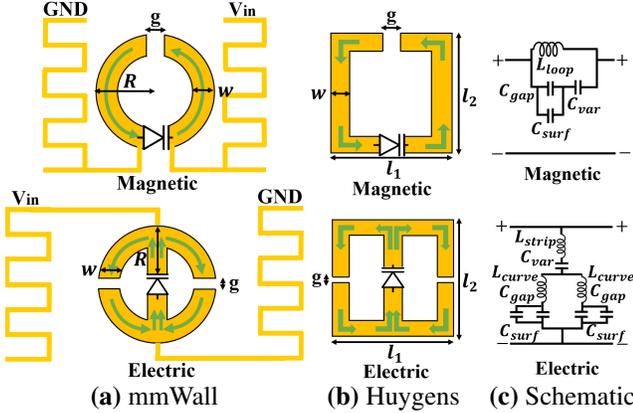

Figure 4: mmWall, prior Huygens unit cell designs (*top*: magnetic; *bottom*: electric side), and equivalent circuits. Green arrows indicate the oscillating current loops, and V_{in} indicates where the input voltages connect.

nant frequency. As we will see next, the smaller the ring is, the higher the resonant frequency becomes. However, the state-of-the-art approach to scale the frequency of a Huygens resonator (Fig. 4(b)) requires a loop width l_1 and loop height l_2 of $\lambda/10$. At mmWave, however, the varactor packaging itself would significantly distort the tailored electromagnetic surface properties when a meta-atom is sized $\lambda/10$, and so the straightforward approach fails. Moreover, the varactor is soldered with heat, causing tighter designs to become more fragile. Changing the rectangular cell shape to a circular one with equal diameter reduces size while preserving varactor placement on the diameter.

We thus instead adopt the design shown in Fig. 4(a), but this is only tenable with a careful tradeoff of meta-atom design parameters *radius* R , *trace width* w , and *trace gap width* g (cf. Fig. 4) as we next describe.

Magnetic meta-atom. Fig. 4(a) (*upper*) shows the design parameters that determine inductance L_m and capacitance C_m . L_m ($= L_{loop}$, the inductance of the physical conductor loop), is largely proportional to R (also $L_{loop} \propto t^{-1}$, w^{-1} , and g^{-1}). C_m consists of three capacitance values, C_{gap} , C_{surf} , and C_{var} :

$$C_m = \left(\frac{1}{C_{gap} + C_{surf}} + \frac{1}{C_{var}} \right)^{-1} \quad (1)$$

Here, C_{gap} is the parallel-plate capacitance induced by the gap in the ring ($\propto g^{-1}$), C_{surf} is a capacitance induced by the metallic surface ($\propto R$ [34]), and C_{var} is the capacitance of the varactor, a voltage-dependent capacitor. While L_{loop} , C_{gap} , and C_{surf} are fixed after fabrication, C_{var} varies with control voltage. Increasing U_M decreases C_{var} (see Fig. 17 in Appendix A for the precise relationship), and thus C_m (Eq. (1)), which in turn increases the resonance frequency, as depicted in Fig. 3.

When tuning the physical loop design parameters, we fix

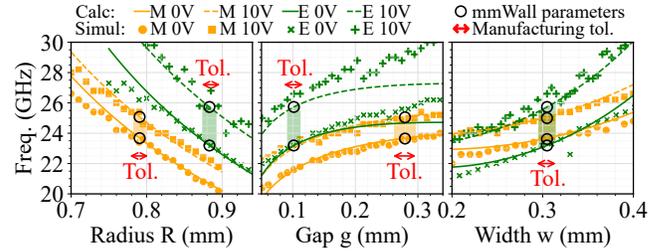

Figure 5: mmWall design parameter sensitivity analysis.

$C_{var} = 4$ V for both the magnetic and electric meta-atoms since at that voltage, the resonant frequency is at our desired mmWave frequency and an abrupt phase change occurs. Fig. 5 shows our chosen design parameters (denoted with black circles) and its corresponding magnetic side resonant frequency when $U_M = 0, 10$ V. Calculated (curves) and simulated (markers) data in our sensitivity analysis show that among all feature dimensions, decreasing R , followed by increasing g has the greatest effect on increasing resonant frequency for the magnetic meta-atom. We note that after fixing our meta-atom geometry as shown in the figure, 24 GHz lies in the middle of the resulting resonant frequency range. Also, we observe that PCB manufacturing tolerance ($\pm 5\%$) does not greatly shift the resonant frequency (we refer Appendix C for meta-atom sensitivity analysis against fabrication tolerance).

Electric meta-atom. Fig. 4(a) (*lower*) shows the electric meta-atom, in which current oscillates in two different directions, while the current of the magnetic meta-atom oscillates in one direction only (cf. green arrows in Figs. 4(a) and 4(b)). Hence, we analyze its inductance L_e as the combination of the inductances of the half-circular loop on the left half (L_{curve}), the inductance of the other half on the right half (L_{curve} , by symmetry), and the inductance from the metallic strip shared by two loops (L_{strip}). Since the two half-loops are arranged in parallel, with the metallic strip arranged in series, $L_e = (L_{curve}/2) + L_{strip}$ [11]. Since inductance generally depends on the surface area of the copper trace, $L_{curve} \propto R$, and $L_{strip} \propto w^{-1}$, L_e largely depends on both R and w , but not g . We see the impact of w on the resonant frequency in Fig. 5: compared to magnetic meta-atom, the resonant frequency of the electric meta-atom increases steeply as w increases due to L_{strip} . To minimize the difference in resonant frequencies between the electric and magnetic sides as desired, Fig. 5 guides us to design an electric meta-atom with equal w as the magnetic meta-atom, greater R and lesser g . The electric meta-atom has two gaps and two surface capacitances, with respective associated capacitances C_{gap} and C_{surf} , all in parallel, and that combination in series with C_{var} :

$$C_e = \left(\frac{1}{2(C_{gap} + C_{surf})} + \frac{1}{C_{var}} \right)^{-1} \quad (2)$$

Because there are many capacitances in parallel, changes in

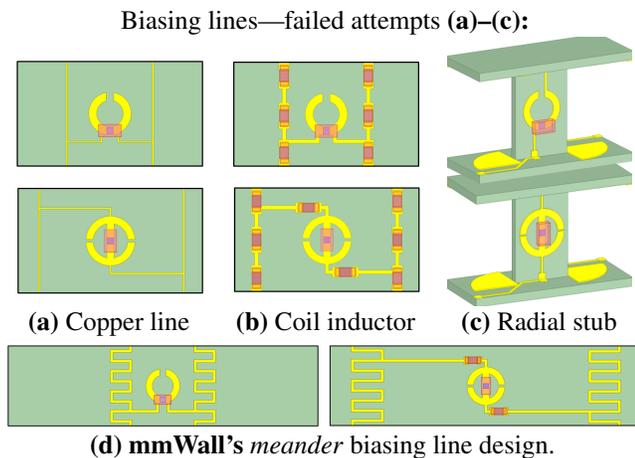

Figure 6: Biasing line designs: notable failed attempts include (a) straight microstrip, (b) coil inductor, and (c) radial stub. (d) mmWall uses an inner meander line for magnetic, and an outer meander line for electric meta-atoms.

C_{var} lead to a wider frequency shift than analogous varactor tuning of the magnetic side. Using more precise equation-based analysis (available in Appendix A) that matches our qualitative analysis, we cross-check and finalize design parameters R , g , and w for the magnetic and electric meta-atoms. We refer Appendix A.3 for the values of the design parameters and voltage distributions for different steering angles.

In Fig. 5, we observe that the difference in resonant frequencies between 0 and 10 V for the electric meta-atom are larger than the magnetic meta-atom. Hence, since the effect of C_{var} differs, overlapping of resonance will not always occur when $U_M = U_E$. Rather than of simply finding the area where $U_M = U_E$ as suggested above, we instead need to search for the voltage pair for every desired phase that also maximizes the reflection or transmission magnitude. We do this by running one-time optimization that searches for the voltage pair that maximizes $|T|$ (or $|\Gamma|$) for each phase and generates a static lookup table that will later be used for beam steering.

3.2 Surface Control

To control the meta-atoms, we connect an off-surface control unit via ribbon cables with on-surface *biasing lines*, which altogether comprise the entire *control network* (Fig. 2 on p. 3).

3.2.1 Biasing lines

This design process concerns the problem of designing the on-surface control network to interact with mmWave-frequency meta-atoms. Directly connecting a line to the meta-atoms changes the performance of the meta-atom, which causes mmWave signal loss and invalidates the design process described previously (§3.1). To mitigate such adverse effects,

we seek to design biasing lines that incorporate radio frequency (RF) chokes, low pass filters that block RF signals within a certain frequency band from propagating on direct current (DC) signal paths. Our primary design goals are to design a biasing network that **1)** minimizes the use of extra components, **2)** avoids a large amount of copper on the panel where the meta-atom is placed, and **3)** is straightforward to fabricate. This is challenging because mmWave meta-atoms are sensitive to the shape and placement of the choke.

Failed attempts. Fig. 6 shows various biasing line structures we have considered. First, we try a straight copper line design (a). We use a narrow width resembling a very high impedance transmission line, to try to attenuate the RF signal while the DC biasing voltage is applied. However, to achieve the desired impedance, a very narrow width transmission line (0.07 mm) is required which is not possible to fabricate by common PCB manufacturing techniques.

Second, we try the use of inductors to create a high-impedance line (b). The impedance of an inductor is determined by the RF frequency and is proportional to its inductance. However, inductance of mmWave inductor components are limited. Hence, we would need to apply at least four inductors in series to achieve the desired isolation, introducing significant surface complexity and also internal resistance that adversely affects unit cell efficiency.

Third, a radial stub which is an open ended transmission line is employed. The length of the stub determines the input impedance of the line, and so thus acts as an RF “choke” that blocks mmWave signals, while a DC biasing voltage is applied to the cell from the control network. The required length of the stub is one-quarter wavelength, which is comparable to the cell size. But if the stub is designed on the same panel, the stub itself would reflect most of the wave, stealing energy to illuminate the cell itself. To avoid this problem, one can put the stubs on a perpendicular panel, as shown in Fig. 6(c). This could potentially solve the wave reflection issue, but would complicate implementation, since there would be one perpendicular panel for each unit cell.

Proposed meander structure. To achieve our design goals, we have formulated a meander structure (Fig. 6(d)) that acts as an RF choke, but at the same time connects the vertically adjacent meta-atoms. Longer and thinner traces provide more inductance, so by bending the straight wire vertically and horizontally, we enable the control network itself to be an inductor that outperforms the multiple off-the-shelf inductors. But this increases capacitance between the two meander lines on opposing sides of the unit cell, which also invalidates our meta-atom design process. So mmWall places the meander line of the magnetic meta-atom in a non-overlapping configuration relative to the meander line of the electric meta-atom. To compensate the loss from the microstrip that connects the electric meta-atom and the meander lines, we add two off-the-shelf inductors next to the electric meta-atom.

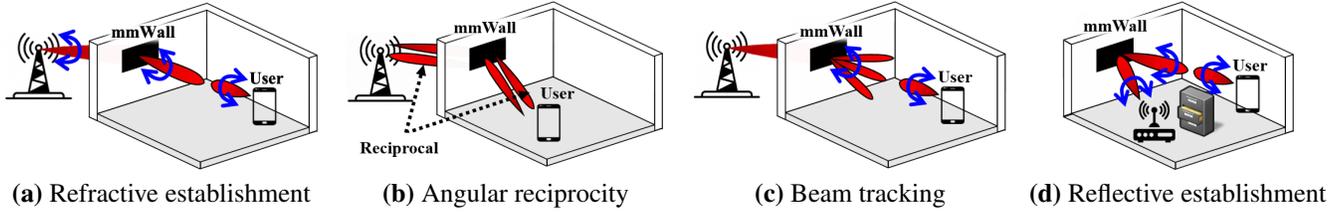

Figure 7: mmWall’s refractive link establishment, angular reciprocity property, tracking, and reflective link establishment.

3.2.2 Beam steering and splitting

A conventional phased array transmitter has a net radiation pattern multiplying the radiation pattern of a single element by the *array factor* (AF), the pattern induced by the array. Unlike prior mmWave receive-transmit relay systems which require two phased antenna arrays (one to receive and another to transmit a new phase-shifted signal), mmWall uses only a single array of meta-atoms to directly shift the phase of an existing mmWave signal. For L omni antennas with d separation, each with transmit amplitude A , $AF = A \sum_{n=0}^{L-1} e^{2\pi jnd(\cos\theta)/\lambda}$ with radio wavelength λ and steering angle θ .

mmWall applies different phase shifts to each meta-atom rib for beam steering. Specifically, by searching over the space of control voltages to maximize reflection or transmission amplitude subject to achieving the desired phase (Fig. 3(c)), we construct a look-up table that maps steering phase φ to the chosen unit cell voltage pair (and without loss of generality) transmission coefficient: $\Phi(\varphi) \rightarrow \langle U_M, U_E, \Gamma \rangle$. The difference with conventional beamforming is that element amplitudes vary, so mmWall’s net radiation pattern becomes $\sum_{n=0}^{L-1} \Phi_\Gamma(\varphi) e^{j\varphi}$ where $\varphi = 2\pi nd \cos\theta$.

To transform a single beam into multi-armed beams, we modify the above AF to account for angles θ_1 and θ_2 :

$$\sum_{n=0}^{N-1} (\alpha \Phi_\Gamma(\varphi_1) e^{j\varphi_1} + \beta \Phi_\Gamma(\varphi_2) e^{j\varphi_2}) \quad (3)$$

where $\varphi_k = 2\pi nd \cos\theta_k$, and α and β are weighting terms that that determine the power of each beam.

3.3 Link Layer Design

Recall that mmWall operates in two different modes, a lens mode and a mirror mode.² **1)** In lens mode, a mmWave signal refracts through mmWall allowing, *e.g.*, a user inside the building to communicate with the base station (ENodeB) in a cellular network. This requires two beam alignments: one between the ENodeB and mmWall, and another between mmWall and the user. **2)** In mirror mode, mmWall reflects mmWave signals. For example, in wireless LAN settings, it reflects the beam between the AP and user, which requires

²Reflective mode and mirror mode are equivalent.

beam alignment between the AP and mmWall, and again between mmWall and the user.

mmWall electronically switches between the two modes because different users may be located outdoors and indoors. Hence, mmWall sweeps the beam in both lens and mirror mode to align to the user during a beam search.

Our development here follows the outline of the existing 5G New Radio (NR) beam management protocol, but adapts it to mmWall’s unique capabilities. The current 5G NR beam search proceeds in three steps: **1)** the ENodeB sweeps its beam, the user equipment (UE) selects a best direction, and reports it to the ENodeB; **2)** the ENodeB refines its beam (*i.e.*, sweeping a narrower beam over a narrower range), the user detects the best direction and reports it to the ENodeB; **3)** the ENodeB fixes a beam and the UE refines its receiver beam.

To establish a link from a cold start, the ENodeB sweeps different directions such that the user can detect the best beam for an initial link establishment (Fig. 7(a)). If the UE cannot detect the beam or the beam strength is low, it turns mmWall to a lens mode and signal it to simultaneously sweep the beam received from the ENodeB, via sub-6 GHz control. At the same time, the UE scans its receiving beam to various directions. After the search, the UE knows the combination of the ENodeB’s transmit beam angle, mmWall’s beam refraction angle, and its receive beam angle that maximizes the SNR of downlink signals. Given an initial link, ENodeB and mmWall refine the beam by simultaneously sweeping narrower beams over narrower ranges, and lastly, the user refines its receiving beam.³ ENodeB-mmWall alignment takes $O(n)$ steps (for n directions), and mmWall-UE alignment takes $O(n^2)$ steps, so cold-start beam alignment as described above takes $O(n^3)$ steps, but only once *ever* when mmWall is installed, because both ENodeB and mmWall are stationary. As long as mmWall remains in the same location, the one-time initial beam alignment is kept constant. Hence, the common case of cold-start beam establishment between mmWall and user in fact requires $O(n^2)$ steps (*cf.* Fig. 7(c)). Also, the above notably does not require modifications to the existing 5G NR protocols.

As illustrated in Fig. 7(b) and demonstrated experimentally in §5.4, mmWall refracts beams in one direction at the same angle as they arrive at the surface from the other side of the

³We note that some full-duplex relays [1] require the relay node’s receive direction aligned to the ENodeB, which is not necessary with mmWall.

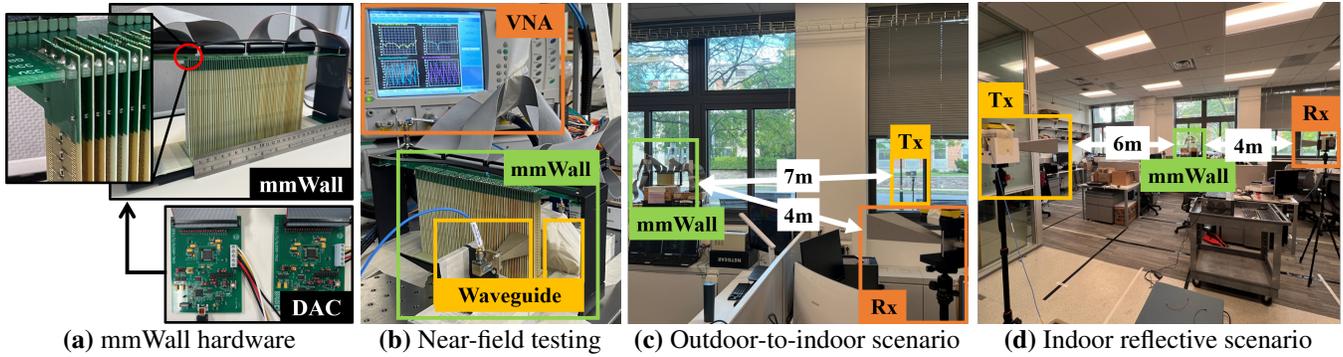

Figure 8: mmWall’s hardware implementation, transmissive (‘lens’) and indoor reflective (‘mirror’) evaluation scenarios. We placed mmWall at the same location for both scenarios.

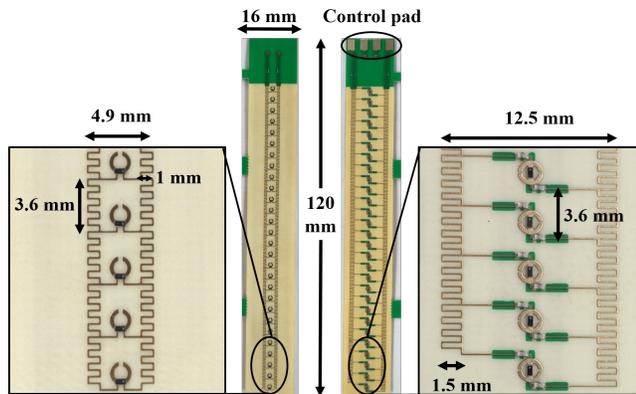

Figure 9: mmWall’s ribs, comprised of our proposed meta-atom design fabricated on a Rogers printed circuit board.

surface (angular reciprocity), which obviates the need for separate downlink and uplink link establishment. If the downlink has already been established, mmWall does not reconfigure for the uplink. Instead, ENodeB simply switches the direction of its receiving beam to match its transmit beam, and the user transmits in the direction of its receiving beam. This facilitates a quick transition between downlink and uplink.

Since the UE controls mmWall, the user can alternate between the ‘lens’ mode for outdoor-to-indoor communication and the ‘mirror’ mode for indoor communication. For example, when the user switches from an outdoor to an indoor ENodeB, it signals mmWall to re-establish the beam estimation process for indoor usage.

Multi-beam search. mmWall can create irregular beam shapes such as multi-arm beams (§5.3), which allows it to leverage state-of-the-art beam searching algorithms that exploit the sparsity of the mmWave channel to accelerate beam search [2, 27] by orders of magnitude improvement (essential for agile and mobile applications such as VR), now for the first time at a surface.

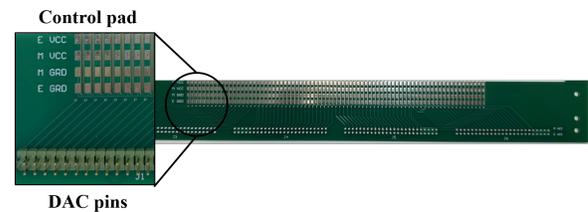

Figure 10: mmWall’s FR4 holder/control board.

4 Implementation

We have fabricated and assembled a complete hardware prototype of mmWall, summarized in Fig. 8. mmWall’s meta-atoms are fabricated on a 16 by 120 mm rib made of Rogers 4003C printed circuit board (PCB) substrate, as shown in Fig. 9. We assemble the PCB and constituent Macom MAVR-000120-1411 varactor diodes⁴ and 026011C-1N7 inductors.

In total, we have fabricated 76 ribs, each consisting of 28 vertical meta-atoms. These ribs are mechanically hold together with two perpendicular FR4 panels; one in top and the other in bottom of the structure. The top FR4 also provides control lines as it is shown in Fig. 10. Each rib’s control pads are then soldered to the upper holder board, which connects the ribs to a DAC through its microstrip traces and pin headers. The lower holder boards are installed to position and the ribs fixed into these boards. For holding the ribs and FR4 panels steady, a 3D printed enclosure is fabricated that provides a standing support, as shown in Fig. 8(a). The spacing between the adjacent ribs are 2.6 mm, making the dimension of our mmWall prototype 120 × 197.6 mm. We note that scaling up our prototype with identical ribs and expanded FR4 holder boards is straightforward.

Four 40-channel AD5370 16-bit DACs from Analog Devices allow independent control of both electric and magnetic cells of every mmWall rib. Each DAC supplies a variable

⁴We have modeled this varactor based on its *Simulation Program with Integrated Circuit Emphasis* (SPICE) model (see Appendix, Fig. 17).

0 to 10 V control voltage for each of 40 channels (*i.e.*, one DAC per 20 boards with one channel for U_E and U_M apiece). A laptop is connected to four DACs and listens for control signals from the UE. Once a signal is received, it sends a command to the DACs, which then apply the voltage levels, corresponding to a particular steering angle. Different voltage levels are found from a pre-stored voltage-to-phase look-up table. This control program is written in Microsoft Visual C++, and it can be executed from EnodeB, instead of UE. mmWall hardware, including the DACs, takes 20 μ s to reconfigure the beam. The speed of DACs is the key determinant of the total latency, and deploying faster DAC hardware will lower the latency.

5 Evaluation

We begin with field studies that quantify mmWall’s SNR gain compared to the best NLoS environment path for both indoor-to-indoor and outdoor-to-indoor links (§5.2). Moreover, we explore the SNR gain and link failure rate under dynamic link conditions. We then evaluate multi-armed beams created by mmWall at various receiver locations (§5.3). We conclude with microbenchmarks to characterize mmWall’s steering performance, its support for wide steering angle, angular reciprocity, operation across wide bandwidths, and the impact of the surface size (§5.4).

5.1 Methodology

We conduct evaluations of various indoor and outdoor scenarios. For indoor-to-indoor settings, we place both the receiver (circles in Fig. 11) and transmitter (triangles in Fig. 11) in an office measuring 10 \times 8 m, which includes interior walls, windows, and a server room. Between the three windows, there are two brick walls (black rectangles in Fig. 11). For the outdoor-to-indoor testbed, we locate the transmitter outside the office, approximately 6–7 m away from the window, while the receiver is inside the office. During the experiments, we place mmWall in front of the window inside the room, and the loss of window is approximately –4 to –5 dB. For each outdoor-to-indoor and indoor-to-indoor experiment, we conduct two sets of experiments, each with a fixed transmitter location and 23 receiver locations. In the first set, the transmitter is perpendicularly facing mmWall and is 6.3 m away (upper subfigures of Fig. 11(a) and left two subfigures of Fig. 11(b)). The second set has the transmitter 6.8 m away from mmWall, and its beam hits the surface at approximately 30° to 40° angle (lower subfigures of Fig. 11(a) and right subfigures of Fig. 11(b)). During the beam search, mmWall steers the angle by the step of 0.5°. For end-to-end performance, we report SNR with a noise floor of 80 dBm.

Near-field experiments. Given that the measured Huygens pattern is likely to deviate from simulated results due to

manufacturing tolerances, it is crucial to conduct accurate measurement through near-field experiments and compile a voltage-to-phase look-up table. Specifically, we collect near-field reflection and transmission coefficients of mmWall using two-port Anritsu MS4647B VNA, operating from 70 kHz to 70 GHz, as shown in Fig. 8(b). The Huygens pattern measured from the VNA is shown in Appendix C. To minimize measurement error, we perform a two port calibration before acquiring the data. For data collection, we program the VNA using LabVIEW, which communicates with four DACs through the socket. During the measurement, mmWall is placed in between two waveguide horn antennas that are connected to the VNA. We place two horn antennas closely to mmWall to resemble the near-field simulation. Since the area of mmWall is larger than the aperture of waveguide horns, we collect the pattern on multiple locations of mmWall. In Appendix C, we present a measured Huygens pattern at different locations of mmWall and demonstrate the robustness of mmWall against fabrication variations.

Far-field experiments. A standard mmWave base station is equipped with highly directional phased array antennas and supports an average EIRP range of 55-60 dBm [12, 13] or more. With a 25 dBi transmit horn antenna, the maximum EIRP we achieved is 31 dBm, which is in accordance with FCC rules [14]. We use the same antenna at the receiver but apply a –10 dB correction to reflect typical UE antenna gain. Specifically, to generate mmWave signals, we use off-the-shelf phase-locked loop (PLL) frequency synthesizers ADF4371 with integrated VCO and frequency quadrupler, which quadruples 6.125 GHz VCO signals to 24.5 GHz. At the transmitter, the PLL output power is < –13 dBm, and we use the PLL in conjunction with a variable gain amplifier (VGA) HMC997LC4, which amplifies signals by 18 dBm.

5.2 In-situ Performance

In this section, we evaluate the end-to-end performance of mmWall for indoor and outdoor scenarios.

SNR improvement over the best environment path. To evaluate the effectiveness of mmWall in improving SNR in scenarios with blocked LoS paths, we conduct SNR measurements at multiple transmitter and receiver locations (two locations for the transmitter and 23 locations for the receiver). For each link, the transmitter and receiver (and mmWall if deployed) search for an NLoS path that maximizes the SNR.

Fig. 11 illustrates the measurements taken prior to and following the deployment of mmWall. Specifically, Fig. 11(a) presents the SNRs obtained when the transmitter was positioned towards the window at 0° (upper subfigure) and 30° (lower subfigure) in an indoor testbed. The results of both subfigures show that our indoor testbed has a rich scattering environment, with some receiver locations achieving SNR levels exceeding 25 dB in the absence of mmWall. However,

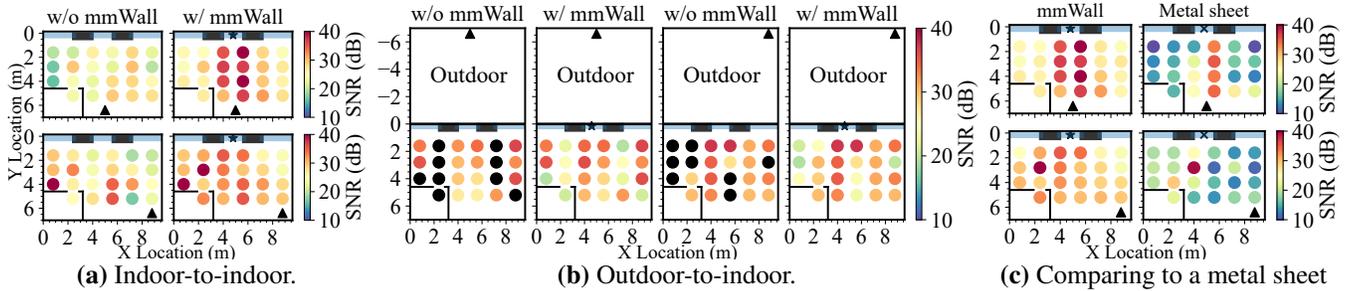

Figure 11: mmWall’s SNR improvement over the best NLoS environment path in two scenarios: (a) when both transmitter and receiver are located indoors (*upper*: transmitter facing mmWall perpendicularly; *lower*: transmitter facing 30° away from mmWall) and (b) when the transmitter is located outdoors (*left*: transmitting perpendicularly; *right*: transmitting at a 30° off-angle). We use the following notations: mmWall ★, transmitter ▲, receiver ○. ● indicates no signal.

receivers located at either end of the room experience SNR levels below 20 dB. With mmWall, all receivers, including the ones in the corner, achieve SNRs of at least 24 dB. Also, the nodes located within mmWall’s steering angle of -45° to 45° has SNRs greater than 30 dB. This improvement in SNR is particularly evident in Fig. 12. In Fig. 12 (*left*), we plot a CDF of the best environment SNRs (black curves) alongside the SNRs of mmWall links at the corresponding receiver location (rectangles). Fig. 12 (*center*) shows the CDFs of maximum SNRs between the environment and mmWall links, while Fig. 12 (*right*) shows the CDFs of the SNR gains over the environment path per receiver location. As shown in Fig. 12 (*upper*), mmWall ensures outage-free communication for 91% of receiver locations at 128 QAM [24] mmWave data rates, while only 40-50% of receivers achieve the same rate in the absence of mmWall. Moreover, among 80% of receivers that experience the gain from mmWall, some receive more than a 15 dB SNR boost.

In Fig. 11(b), we present the SNR improvement in outdoor-to-indoor scenarios. Without mmWall, receivers unable to establish a NLoS link through the window experience complete link failure. With mmWall, on the other hand, all receivers achieve SNRs of at least 19 – 20 dB. Fig. 12 (*lower*) shows the CDFs of outdoor-to-indoor SNR improvement. A single mmWall guarantees 64-QAM for almost all receiver locations and a 30 dB SNR boost for 40% of the links. Our results demonstrate that mmWall is highly beneficial for improving mmWave signals quality in the cases of wall blockage.

Deploying multiple mmWalls. To evaluate more than one mmWall, we place another mmWall (downward triangles in Fig. 12) in front of the window on the right side of the room. Fig. 12 (*upper*) demonstrates the SNR gain from deploying two mmWalls for indoor-to-indoor links. Compared to the gain from a single mmWall, an additional mmWall provides ≤ 5 dB SNR gain for some links. As shown in Fig. 12 (*lower*), there is almost no gain from adding an extra mmWall for outdoor-to-indoor links. The results indicate that a single mmWall is sufficient to provide good coverage (at least 128-

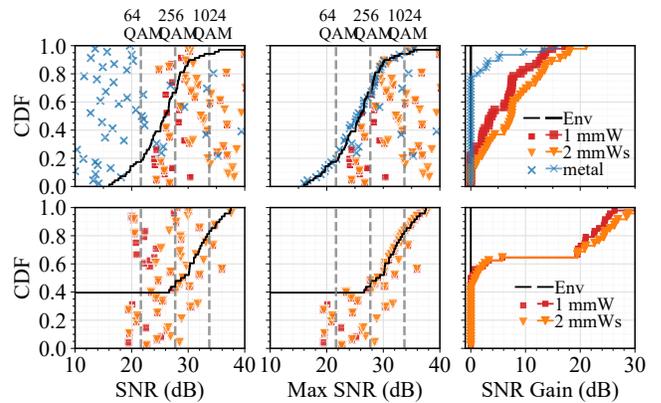

Figure 12: The SNR improvement from the use of one or more mmWalls at various receiver locations in indoor-to-indoor (*upper*) and outdoor-to-indoor (*lower*) scenarios. SNRs collected from a given receiver location are plotted on the same y-axis value (*left*: CDFs of the best environment SNRs in black curves alongside the SNRs of mmWall links at the corresponding receiver location in rectangles. The maximum SNRs between two mmWalls placed in different locations are denoted with downward triangles; *center*: the best available SNRs with or without one or more mmWalls; *right*: the SNR gains attained with one or more mmWalls compared to the best environment path in various Rx locations).

QAM for reflective and 64-QAM for transmissive links) in a 10×8 m office room. In a static environment another mmWall will not help if a mmWall path is already available.

Improving reliability for dynamic links. While a single mmWall delivers good SNRs throughout all receiver locations, it is still possible for blockages to occur on mmWall links. Likewise, even if there is a robust NLoS path present, it can still be blocked. At mmWave frequencies, the indoor environment typically provides three to four strong paths, including the LoS path [23]. Due to the limited number of available paths, an increase in blockages can easily result

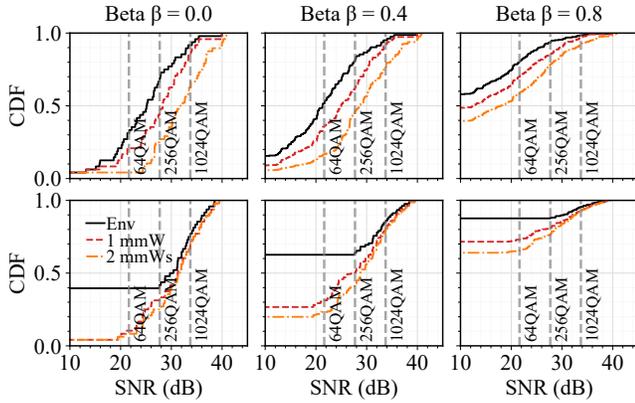

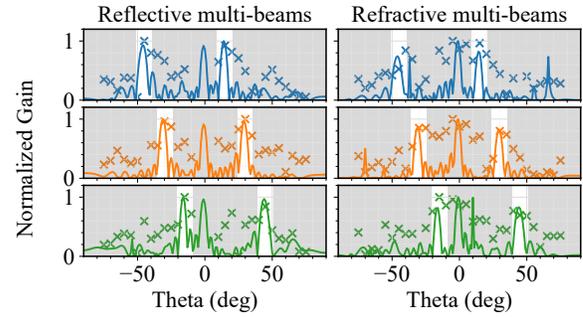

Figure 13: The SNR improvement (multiple mmWalls) for dynamic links (*upper*: indoor-to-indoor; *lower*: outdoor-to-indoor scenarios). β is a blockage probability.

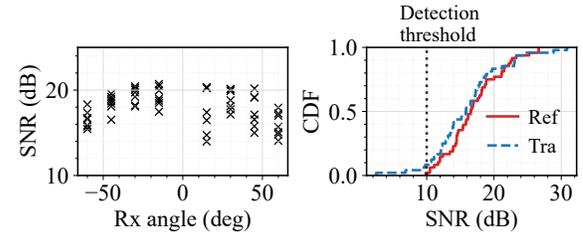

in link failure, which exacerbates when these obstructions are in motion. One of the primary benefits of using one or multiple mmWalls is the enhancement of link reliability. By providing a diverse, strong alternative path, mmWall reduces the probability of link scarcity. In Fig. 13, we demonstrate the SNR gain across various Rx locations as a function of the *blockage probability* β^5 for both environment and mmWall links. In indoor-to-indoor scenarios, a single mmWall and two mmWalls reduce the probability of link failure by a ratio of up to 10% and 20% under 80% path blockage, respectively. For the outdoor testbed, the probability of link failure decreases by 40% for a single mmWall and 45% for two mmWalls under 40% blockage probability. Hence, we conclude that multiple mmWalls are beneficial when channel environments are highly dynamic.

One may argue that deploying a simple reflective metal sheet could help, but mmWall’s ability to steer the beam has a significant impact on the extent of coverage. We evaluate the SNRs of links reflected by a 60×60 cm metal sheet, along with the SNRs of links steered by a 10×20 cm mmWall. As shown in Fig. 11(c) (*right*), only 10% of the receivers achieves SNRs above 30 dB, and the remaining 90% have SNRs below 15 dB. It is also worth noting that for a metal sheet, the SNRs depend largely on the location of the receiver and transmitter. In Fig. 11(c) (*right*), only the receivers that are placed and perfectly aligned with the angle of specular reflection achieve a high SNR. In Fig. 12, only 8% of the receivers achieve more than 5 dB SNR gain from the metal sheet. On the other hand, mmWall guarantees at least 25 dB SNRs across all areas. We conclude that, compared to fixed-angle reflection, mmWall links are less sensitive to the location of the transmitter, receiver, and surface, making them much more robust.

⁵A blockage probability is equivalent to a probability of complete link failure for each path. Under various available paths, the blockage probability of one path is independent from the other.

(a) mmWall’s multi-armed beam pattern (*upper*: $-45/15^\circ$ degree beam split; *middle*: $-30/30^\circ$ split; *lower*: $-15/45^\circ$ split). Empirical points are denoted \times , with simulation curves.

(b) The SNRs of aligned multi-beams (*left*: a fixed distance between the transmitter and mmWall and between the receiver and mmWall; *right*: various Tx and Rx locations in the office setting.)

Figure 14: Evaluation of mmWall’s multi-armed beams.

5.3 Multi-armed Beams

We next evaluate mmWall’s capability to generate multi-armed beams. Fig. 14(a) presents our measurements on the multi-armed beams, along with simulation results from HFSS. Here, mmWall splits an incident beam into two beams at $-45^\circ/15^\circ$ and steers these multi-beams to $-30^\circ/30^\circ$ and $-15^\circ/45^\circ$. To measure the beam pattern, we position the transmitter and receiver three meters away from mmWall and record the gain of mmWall as we move the receiver from a -90° to 90° angle with respect to mmWall. Since we did not measure the beam pattern in an anechoic chamber, the received beam interfered with signals reflected off the indoor environment. Despite the interference, we observe that the gain peaks at the angles where mmWall splits the beam. Furthermore, as mmWall steers its multi-armed beams, the measured peaks change accordingly. Our results show a peak at 0° due to leakage that was directly fed from the transmitter to the receiver. Reducing the distance between the transmitter and receiver and/or increasing the size of mmWall will reduce the peak at 0° .

We then measure SNRs as mmWall generates and steers various multi-beams, the beams that are 15° to 120° apart from each other. The distance between the transmitter and mmWall and between the receiver and mmWall are fixed to 2 m. Fig. 14(b) (*left*) reveals that as the beam is split into a wider angle, SNR drops.

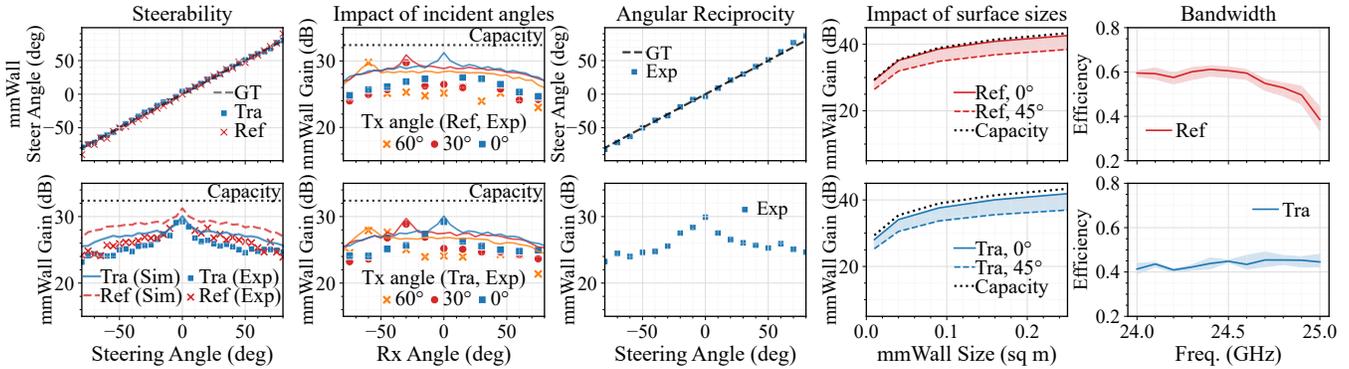

Figure 15: Microbenchmarks evaluating (left to right:) surface steerability, performance sensitivity of the incident wave angle, angular reciprocity, surface size, and frequency bandwidth. Empirical points are denoted with markers, with simulation curves.

To demonstrate the feasibility of a beam search using multi-armed beams, mmWall again splits the beam into two beams that are 15° to 120° apart from each other. Then it aligns the beam with the receivers at 23 different locations in the room. Fig. 14(b) (right) reports the SNRs of mmWall’s multi-beam links aligned with various receivers. The results show that more than 90% of multi-beam links achieve SNRs above 10 dB. Considering that no signal is detected in many locations under outdoor-to-indoor settings, 10 dB SNR is enough for the receiver to detect the beam and start the alignment. We conclude that mmWall can generate multi-armed beams that are sufficiently strong to accelerate beam search.

5.4 Microbenchmarks

We now evaluate mmWall’s steering performance, its support for wide steering angle, angular reciprocity, operation across wide bandwidths, and the impact of the surface size. The microbenchmark testbed consists of the receiver and transmitter modules that are three meters away from mmWall. Fig. 15 presents both the actual experimental measurements (markers) and simulated results (curves) acquired from HFSS.

Since mmWall does not have an amplifier, the effective aperture A_e is the primary factor that determines its gain. A well-defined relation for the effective aperture in terms of the aperture gain G is $A_e 4\pi/\lambda^2$. We define the aperture gain as our capacity and compare it against our measured mmWall gains in our microbenchmarks. A rigorous analysis on mmWall gain is available in Appendix B.

mmWall controllability. Fig. 15 (upper first) presents mmWall’s beam alignment accuracy. We place the receiver at 37 locations in our testbed and find the angle that provides the maximum SNR as mmWall sweeps the beam from -80° to 80° angle. During the experiment, the transmitter is facing mmWall at 0° angle. For both reflection and transmission, mmWall accurately steers the beam with at most 3° difference from the groundtruth (GT). Second, we evaluate the effect of a steering angle on the mmWall gain in Fig. 15 (lower first).

As mmWall increases the steering angle, the gain slowly decreases. Furthermore, reflection provides a slightly higher gain than transmission.

Support for wide steering angle. In this microbenchmark, we evaluate the effect of incident beam angles on the mmWall gain jointly with the steering angle. Here, we move the transmitter to three different locations and the receiver to 37 locations. Fig. 15 (upper second) and Fig. 15 (lower second) show the impact of incident angles for reflection and transmission, respectively. For both scenarios, increasing the incident beam angle does not greatly reduce the mmWall gain. An important observation is that even with 135° steering angle (e.g., Tx angle at 60° and Rx angle at -75°), mmWall achieves more than 22 dB gain, indicating that mmWall is capable of refracting the beam in a very wide angle.

Angular reciprocity. Once mmWall achieves alignment for the downlink channel, the uplink channel also becomes aligned due to its angular reciprocity. To demonstrate this property, we evaluate the accuracy of uplink beam alignment and the corresponding mmWall gain when downlink alignment is already established. In Fig. 15 (upper third), uplink alignment using reciprocity is very accurate and is within an error of 3° . Also, Fig. 15 (lower third) shows that all corresponding mmWall gains are above 23 dB using reciprocity.

Operation across wide bandwidths. To demonstrate mmWall’s phase coverage across a wide bandwidth, we present our VNA measurements from 20 to 30 GHz. In Fig. 16, each curve indicates the phase response of voltage levels in our lookup table that we compiled at our center frequency, 24.5 GHz. Here, we emphasize three points. First, mmWall provides a full phase coverage from $-\pi$ to π over the 200 MHz 5G mmWave link bandwidth. Second, within 200 MHz bands (highlighted in gray), the phase distributions are mostly constant, allowing improvements over the entirety of these bandwidths. Third, mmWall can operate in the entire 23.5 to 25.5 GHz band, as it provides a wide range of phases there. Hence, mmWall operates over the mmWave 5G band-

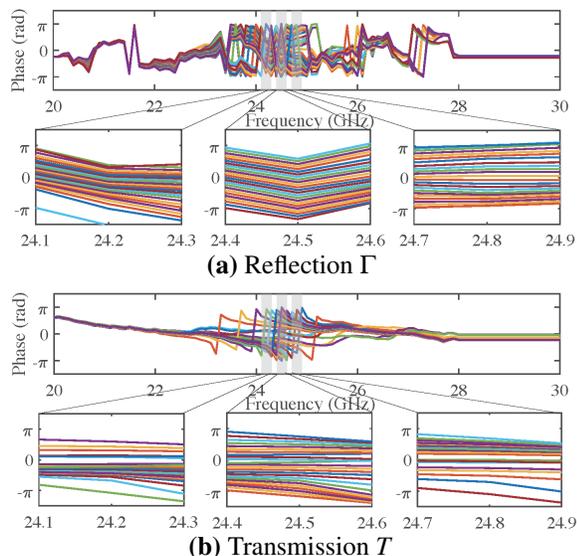

Figure 16: mmWall’s phase coverage and consistency (VNA measurement) across different frequencies. The curves indicate the voltage pairs (U_M, U_E) that provide -180° to 180° phase shift with the step of 15° at 24.5 GHz. The phases are unwrapped across the mmWall’s operating bandwidth.

width. More importantly, our meta-atom design goal is to reduce transmission or reflection *loss level* with a full phase coverage. To quantify both magnitude and phase coverage at the same time, we define *efficiency* as $\sum_{\phi=-180}^{180} (T e^{-j\phi}) / 360$ where T is a set of points obtained from the near-field transmissive (reflective) Huygens pattern that provides the maximum magnitude for -180° to 180° phases. Fig. 15 (*rightmost*) demonstrates that for both reflection and transmission, the efficiency is consistent and declines after 24.9 GHz. Since targeted operational bandwidth for 5G mmWave is 200 MHz, we conclude that mmWall operates within the 5G bandwidth.

Increasing mmWall size. Fig. 15 (*fourth*) shows an increase of simulated gains as mmWall size increases from 10×10 cm to 50×50 cm with 0° (for reflection, it is a specular reflection) and 45° steering angle. Also, we compare our simulated results against the effective aperture-based capacity. mmWall gains at both 0° and 45° steering angle increase with increasing surface size, following the capacity trend.

6 Discussion

In this section, we discuss several limitations of mmWall and our potential solutions.

3D beamforming. 3D beamforming technique is beneficial in massive MIMO communications as it sophisticatedly controls the beam in different directions in spatial domain. With mmWall, meta-atoms on the same rib share the voltage level, and therefore it is structured as a 2D linear array. To achieve

3D beamforming, we can simply separate mmWall control lines in the vertical direction. In the future, we will vertically partition mmWall and separately control them.

Tinted window. While mmWave waves propagate through a glass wall with virtually no loss, the penetration loss increases when the glass is metal-coated. Our window has approximately -4 to -5 dB loss with a light tint. If our window is tinted more, SNRs will drop, and this decrease will be equivalent to the increase of penetration loss from a different level of a tint. There is an existing work [45] that measures reflection coefficients and penetration loss for common building materials at mmWave. According to the paper, the penetration loss may increase by more than 20 dB when the window is heavily tinted. With such windows, we can remove the tint of the small area of the window (approx. 0.02 sq m) for mmWall.

Indoor AP as a 5G mmWave relay. An indoor mmWave AP can serve as a relay when the outdoor cell coverage fails to reach indoors. To accomplish this, cellular operators require indoor infrastructure to install an AP capable of receiving 5G signals. This AP then communicates with an internal modem through an Ethernet cable, and the modem wirelessly transmits the signal to the user through Wi-Fi. This deployment is not only costly and time-consuming but also hard to implement. On the other hand, a single mmWall at a fixed location can achieve all three use cases, including 5G outdoor-to-indoor and outdoor-to-outdoor coverage, and indoor WiFi.

7 Conclusion

This paper presents mmWall, the first Huygens metasurface that can reconfigures itself to relay an incoming mmWave beam as either a non-specular “lens” or “mirror.” Our prototype steers single- or multi-armed beams at non-specular directions, arbitrarily in real-time. We conduct an extensive evaluation in various indoor and outdoor settings, demonstrating significant SNR improvement, and describe how scaling to even larger sizes is eminently possible.

A Unit Cell Electromagnetic Analysis

We now present a full mathematical analysis of mmWall's unit cells. Since electromagnetic fields are naturally continuous and will not change the propagation characteristics by itself, we artificially introduce electric and magnetic surface currents (\vec{J}_s, \vec{M}_s) from the electric and magnetic meta-atoms, enforcing a field discontinuity:

$$\vec{J}_s = \hat{n} \times [H_t - H_i], \quad \vec{M}_s = -\hat{n} \times [E_t - E_i] \quad (4)$$

where \hat{n} is a unit normal. The average tangential field applied on the meta-atom pair induces (\vec{J}_s, \vec{M}_s). To induce suitable surface currents, we need a proper surface impedance for each meta-atom:

$$\begin{aligned} \hat{n} \times [E_{avg}] &= Z_e \vec{J}_s = Z_e \hat{n} \times [H_2 - H_1] \\ \hat{n} \times [H_{avg}] &= Y_m \vec{M}_s = -Y_m \hat{n} \times [E_2 - E_1] \end{aligned} \quad (5)$$

where Z_e is the electric surface impedance and Y_m is the magnetic surface admittance equivalent to $1/Z_m$. In fact, the electric and magnetic meta-atoms are each described by a surface impedance of LC oscillating circuit containing inductance L and capacitance C . Mathematically, we can formulate the surface impedance of the electric and magnetic meta-atom as

$$Z_e = \left(\frac{2\pi f C_e - 1}{(2\pi f)^2 L_e C_e} \right) j, \quad Y_m = \left(\frac{1 - (2\pi f)^2 L_m C_m}{2\pi f C_m} \right) j \quad (6)$$

where f indicates the resonant frequency. Each meta-atom behaves as an LC circuit when its resonant frequency f matches the frequency of the incident wave. Mathematically, the resonant frequency is equivalent to $f = (2\pi\sqrt{LC})^{-1}$.

Given Z_e and Y_m , we can formulate the transmission coefficient T and reflection coefficient Γ of a meta-atom pair:

$$T = \frac{4 - Y_m \cdot Z_e}{(2 + Y_m \cdot \eta)(2 + Z_e/\eta)}, \quad \Gamma = \frac{2(Z_e/\eta - Y_m \cdot \eta)}{(2 + Y_m \cdot \eta)(2 + Z_e/\eta)} \quad (7)$$

where η is the wave impedance in free space. Hence, by changing the surface impedance (Z_e, Y_m), we precisely control the phase of the coefficients, creating an arbitrary phase shift on the incident wave [10].

The excitation of the electric and magnetic surface currents, or, equivalently, the values of Z_e and Y_m is tuned by changing the capacitive or inductive loading of the meta-atoms as shown in Eq. (6). Hence, to make HMS reconfigurable, we load a voltage-controlled capacitor, varactor diode, on each meta-atom. By applying voltage across each varactor, we can arbitrary change the surface impedance, or equivalently, the phase of the transmission or reflective coefficient.

Since the electric and magnetic meta-atoms are superimposed on the surface, we dissect the equivalent circuit model for the electric and magnetic meta-atom individually.

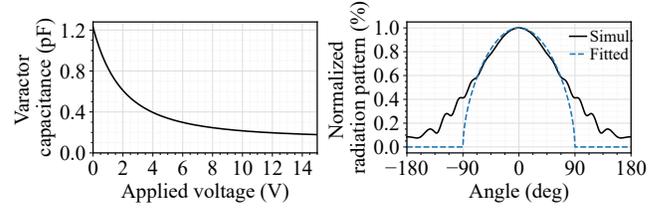

Figure 17: *Left:* C_{var} as the voltage applied to varactor changes, modeled with SPICE simulation; *Right:* mmWall element normalized beam pattern $F(\theta)$ simulated with HFSS and fitted function.

A.1 Magnetic Meta-atom

In this section, we provide the formulas for the magnetic meta-atom's capacitance and inductance discussed in §3.1.2. First, we define the inductance of a circular metallic loop L_{loop} as

$$L_{loop} = \mu_0 R \left(\log \left(\frac{8R_m}{t+w} - \frac{1}{2} \right) \right), \quad (8)$$

where R is a mean radius, and μ_0 is free-space permeability. Since there is a gap on the top of a metallic loop, the inductance of our magnetic meta-atom can be calculated as

$$L_m = p_m L_{loop} = \left(1 - \frac{g}{2\pi R} \right) L_{loop}, \quad (9)$$

where g is a length of the gap. Now, we present the calculation of C_m . First, the gap in the metallic loop creates a parallel-plate capacitance as follow:

$$C_{gap} = \epsilon \frac{wt}{g} + \epsilon(t+w+g), \quad (10)$$

where w is the width of the loop, and t is the thickness of the copper. Here, $\epsilon = \epsilon_0 \epsilon_{eff}$ where ϵ_0 is free-space permittivity, and ϵ_{eff} is effective permittivity, which can be calculated as

$$\epsilon_{eff} = \frac{\epsilon_r + 1}{2} + \left(\frac{\epsilon_r - 1}{2} \right) \left(\frac{1}{\sqrt{(1 + 12t/e)}} \right) \quad (11)$$

where ϵ_r is the permittivity of the substrate. Second, there is a capacitance induced by the metallic ring itself:

$$C_{surf} = \frac{2\epsilon(t+w)}{\pi} \ln \left(\frac{4R}{g} \right) \quad (12)$$

Lastly, the varactor diode adds the capacitance as discussed in §3.1.2. We have modeled our varactor, of Macom MAVR-000120-1411, based on its *Simulation Program with Integrated Circuit Emphasis* (SPICE) model and demonstrate our simulated C_{var} values in the left subfigure of Fig. 17. Then, we formulate C_m according to Eq. (1). Finally, we model the circuit diagram as a series impedance where the series impedance itself corresponds to the surface impedance $Z_m = 1/Y_m$.

	Radius R (mm)	Gap g (mm)	Width w (mm)
<i>Ele.</i>	0.8831	0.1016	0.3048
<i>Mag.</i>	0.7907	0.2794	0.3048

Table 1: mmWall design parameters.

A.2 Electric Meta-atom

Now, we provide the capacitance and inductance calculation for the electric meta-atom. First, we formulate the inductance of a half-circle ring L_{curve} as follow:

$$L_{curve} = (peL_{circle})/2 = \frac{1}{2} \left(\left(1 - \frac{g}{2\pi R_m} \right) L_{circle} \right). \quad (13)$$

Based on [11], we compute the the inductance of the strip as

$$L_{strip} = \mu_0 l / 4\pi \left[2 \sinh^{-1} \left(\frac{l}{w} \right) + 2 \left(\frac{l}{w} \right) \sinh^{-1} \left(\frac{w}{l} \right) - \frac{2(w^2 + l^2)^{1.5}}{3lw^2} + \frac{2}{3} \left(\frac{l}{w} \right)^2 + \frac{2}{3} \left(\frac{w}{l} \right) \right] \quad (14)$$

where l is the length of strip, which is equivalent to $2R_m$, and w is the width of the trace. We then combine all inductance values into L_e as

$$L_e = (L_{curve}/2) + L_{strip} \quad (15)$$

The formulas for the gap capacitance and surface capacitance for the electric meta-atom are the same as the magnetic meta-atom, and we define C_e according to Eq. (2). Finally, the surface impedance of the electric meta-atom corresponds to a shunt impedance.

A.3 Design Parameters

We present the exact values for our design parameters, including radius R , gap g , and width w of the magnetic and electric meta-atom, in Table. 1. Also, the voltage levels applied to the magnetic and electric meta-atoms for different phase shifts are shown in Fig. 18. The y-axis indicates the voltage level, and the x-axis is different ribs. Specifically, Fig. 18(a) demonstrates a set of U_M and U_E required for -30° , -15° , 0° , 15° , and 30° transmissive steering. Similarly, Fig. 18(b) shows the voltages values required for reflective steering.

B Path Loss Model

This section presents a standard path loss model calculation largely following the development in prior similar efforts targeting lower frequencies [32], useful for our purposes to establish the basic feasibility of our design prior to hardware fabrication and full-scale evaluation.

First let us assume that a transmitter directly communicates with a receiver. According to the Friis formula [15], the power

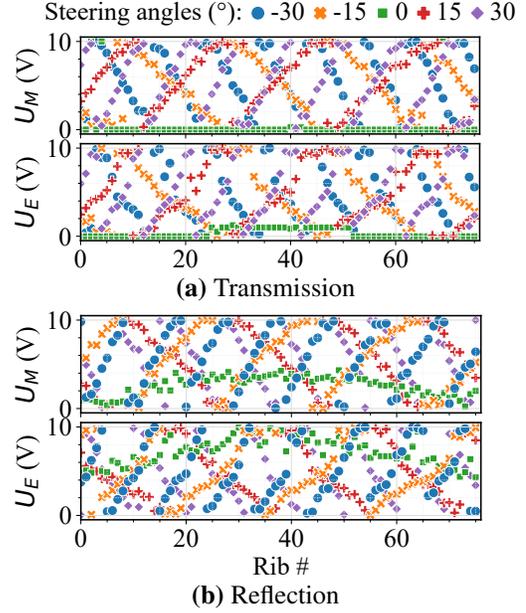

Figure 18: Upper: a set of voltage levels applied to the magnetic and electric meta-atoms U_M and U_E for transmissive steering; Lower: voltage levels applied for reflective steering.

intercepted by the receiving antenna with effective aperture A_{eR} and distance between transmitter and receiver d is:

$$P_i = S_R A_{eR} = \left(\frac{P_T}{4\pi d^2} G_T \right) A_{eR} \quad (16)$$

where S_R is the received power density, and G_T is the peak gain of the transmitting antenna. Since the effective aperture $A_{eR} = \frac{\lambda^2}{4\pi} G_R$ where G_R denotes the gain of the receiving antenna, we rewrite Eq. (16) as

$$P_i = \left(\frac{P_T}{4\pi d^2} G_T \right) \left(\frac{\lambda^2}{4\pi} G_R \right) = P_T G_T G_R \left(\frac{\lambda}{4\pi d} \right)^2. \quad (17)$$

Now we consider a transmitter communicating with the receiver via mmWall. Given Eq. (17), we formulate the power the nm^{th} meta-atom captures from the transmitter as

$$P_{nm}^i = P_T G_T G_w \left(\frac{\lambda}{4\pi d_{i,nm}} \right)^2, \quad (18)$$

where G_w denotes the gain of the meta-atom in the direction of the transmitter, and $d_{i,nm}$ is the distance between the transmitter and nm^{th} meta-atom. Similarly, we can calculate the power received by the receiving antenna from the nm^{th} meta-atom as:

$$P_{R,nm} = P_{nm}^s G_R G_w \left(\frac{\lambda}{4\pi d_{s,nm}} \right)^2, \quad (19)$$

where G_w is the meta-atom gain scattered in the direction of the receiver, $d_{s,nm}$ is the distance between nm^{th} meta-atom

to the receiver, P_{nm}^s is the power applied by each meta-atom, and $P_{nm}^s = P_{nm}^i \epsilon$. Here, ϵ accounts for the limited efficiency of meta-atom and insertion losses associated with components. To simplify the formula, we assume $\epsilon = 1$. To calculate the power from the transmitter to the receiver, we then combine Eqs. (18) and (19):

$$P_{R, nm} = P_T G_T G_R \frac{G_w G_w}{d_{i, nm}^2 d_{s, nm}^2} \left(\frac{\lambda}{4\pi} \right)^4 \quad (20)$$

Here, we emphasize that in the link budget, we must calculate the gain of mmWall twice, one for receiving and another for transmitting. Hence, Eq. (20) has two G_w . Since mmWall consists of a large array of meta-atoms, we can formulate the total received power as a sum of the received powers from all meta-atoms as

$$P_R = \left| \sum_{n=1}^N \sum_{m=1}^M C_{nm} \sqrt{P_{R, nm}} e^{j\phi_{nm}} \right|^2, \quad (21)$$

where $C_{n, m}$ denotes the transmission or reflection coefficient of the nm^{th} meta-atom, and the phase $\phi_{nm} = 2\pi(d_{i, nm} + d_{s, nm})/\lambda$. In a lens mode $C_{n, m} = T_{n, m}$, and in a mirror mode $C_{n, m} = \Gamma_{n, m}$. We already defined $T_{n, m}$ and $\Gamma_{n, m}$ in eq. Eq. (7). Finally, we write the total received power as:

$$P_R = P_T G_T G_R \left(\frac{\lambda}{4\pi} \right)^4 \left| \sum_{n=1}^N \sum_{m=1}^M C_{nm} \frac{\sqrt{G_w G_w}}{d_{i, nm} d_{s, nm}} e^{j\phi_{nm}} \right|^2. \quad (22)$$

However, the meta-atom gain G_w is unknown. Thus, we re-define G_w as a power radiation pattern from each meta-atom, which is equivalent to $GF(\theta_{nm})$. G is a gain that depends on the physical area (*i.e.* the effective aperture) of the meta-atom, and $F(\theta_{nm})$ is the normalized power radiation pattern. Based on the effective aperture formula, $G = (4\pi/\lambda^2) A e_{nm} = (4\pi/\lambda^2)(xy)$ where x and y are vertical and horizontal meta-atom spacing, respectively. Unlike traditional antennas with $x = y = \lambda/2$, our meta-atom has $x = \lambda/4.8$ and $y = \lambda/3.4$. Moreover, $F(\theta_{nm})$ defines the variation of the power radiated or received by a meta-atom:

$$F(\theta) = \begin{cases} \cos^q(\theta) & \theta \in [0, \pi/2] \\ 0 & \theta \in [\pi/2, \pi] \end{cases} \quad (23)$$

where θ are the angle from the meta-atom to a certain transmitting or receiving direction. In the right subfigure of Fig. 17, we present a simulated mmWall element beam pattern $F(\theta_{nm})$ as well as the curve fitted with Eq. (23). Based on our curve fit, $q = 0.5611$.

Far-field beamforming. In the far-field, we can approximate $d_{s, nm} = d_s$ and $d_{i, nm} = d_i$ since d_i and d_s are much greater than the distance between different meta-atoms. However, we do not approximate $d_{s, nm} = d_s$ and $d_{i, nm} = d_i$ for the phase ϕ_{nm} .

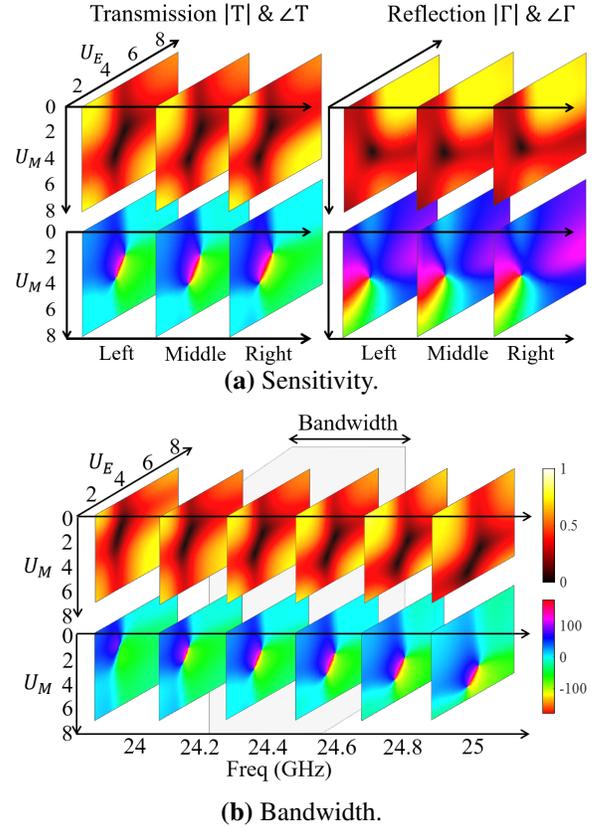

Figure 19: Meta-atom microbenchmark

Then, we can simplify Eq. (22) as:

$$P_R = P_T G_T G_R \left(\frac{A e_{nm}}{4\pi d_i d_s} \right)^2 F(\theta_i) F(\theta_s) \left| \sum_{n=1}^N \sum_{m=1}^M C_{nm} e^{j\phi_{nm}} \right|^2 \quad (24)$$

This indicates that we can maximize the received power by configuring each meta-atom's $\angle C_{nm}$ to $-\phi_{nm}$. Finally, the path loss of a correctly reconfigured mmWall as:

$$L_{mmWall}^{-1} = \left(\frac{xy}{4\pi d_i d_s} \right)^2 F(\theta_i) F(\theta_s) \left| \sum_{n=1}^N \sum_{m=1}^M |C_{nm}| \right|^2 \quad (25)$$

Since $0 < |C_{nm}| < 1$ for both transmissive and reflective mode, increasing the number of meta-atoms N and/or M reduces the path loss. Assuming $|C_{nm}|$ is close to 1, the path loss of mmWall is proportional to $1/(NM)^2$. While increasing the element spacing x and y seems to reduce the loss, it is not always true because $|C_{nm}|$ decreases when x and y increase due to increasing coupling between adjacent meta-atoms.

C Meta-atom controllability and sensitivity

We present the Huygens pattern measured from the VNA in Fig. 19(a). We measure the near-field Huygens pattern

in three different areas of mmWall to evaluate its sensitivity against fabrication variation. For all three areas, we observe a 360-degree phase variation with high magnitude for both transmission and reflection. Moreover, the patterns do not vary across the different areas of the surface, signifying that manufacturing tolerance do not greatly affect mmWall's near-field performance. We also demonstrate the Huygens pattern across mmWall's operating bandwidth in Fig. 19(b). Within the 200 MHz bandwidth, the pattern is consistent.

Building Flexible, Low-Cost Wireless Access Networks With Magma

Abstract

Billions of people remain without Internet access due to availability or affordability of service. In this paper, we present Magma, an open and flexible system for building low-cost wireless access networks. Magma aims to connect users where operator economics are difficult due to issues such as low population density or income levels, while preserving features expected in cellular networks such as authentication and billing policies. To achieve this, and in contrast to traditional cellular networks, Magma adopts an approach that extensively leverages Internet design patterns, terminating access network-specific protocols at the edge and abstracting the access network from the core architecture. This decision allows Magma to refactor the wireless core using SDN (software-defined networking) principles and leverage other techniques from modern distributed systems. In doing so, Magma lowers cost and operational complexity for network operators while achieving resilience, scalability, and rich policy support.

1 Introduction

Good Internet connectivity has become a basic necessity for people and enterprises all over the world. Yet, more than one-third of the global population does not have access to the Internet [54], and many other users do not have the high-speed connectivity needed for many important applications. The problem is primarily a matter of economics: commercial network operators claim that today’s Internet has reached the user footprint that seems commercially viable to serve [29]. To reach the next billion users, we must reduce the *cost* of providing Internet access or enable actors beyond traditional, large-scale commercial operators to build sustainable, scalable network infrastructure. We need effective ways to reduce both capital and operational costs, through less expensive equipment and software, less reliance on highly skilled network administrators, and increased utilization of existing local capabilities. At the same time, providers need ways to manage their limited network resources effectively to enable sustainable network operation. Cellular networks typically achieve

these goals with per-user policies, which may include per-user data caps, rate limits, or usage-based charging.

Unfortunately, conventional wireless solutions are not well suited to many scenarios affecting under-served users. WiFi access points operating on unlicensed spectrum cannot generally provide efficient coverage to large geographic regions (e.g., sparsely populated rural areas) due to the propagation characteristics of the radios. Plus, WiFi networks typically do not offer fine-grained policies to manage resources. In contrast, cellular base stations offer wider coverage, support more users, and connect to core networks that support more flexible policies. However, today’s cellular access networks rely on expensive equipment, complex protocols, and a highly skilled workforce, limiting their ability to cost-effectively connect the next billion. While cellular networks scale *up* to large user populations, they do not scale *down* well. That is, a small cellular deployment is typically quite expensive. Magma aims to bridge the gap between these two classes of solution: cellular networks with rich policies, large user populations, and long distances, and the simpler but less scalable WiFi networks.

More fundamentally, we observe that choosing to use a cellular radio access network (RAN) today *forces* a network operator to make a series of decisions that deeply impact their network operations that are not inherently related to their choice of access network technology. This choice binds a network operator to: (i) a specific network architecture—namely the 3GPP-defined arrangement of interfaces for network management and on-path devices for policy enforcement, (ii) an ecosystem of vendors that has largely evolved to meet the needs of massive-scale telecom operators, and (iii) a particular set of radio frequencies and associated regulatory requirements. The Magma project aims to change all this, by creating an open-source, carrier-grade wireless networking platform that supports a wide range of deployment scenarios. Magma deployments can leverage whatever radio access technology is readily available and most appropriate for their density of subscribers or deployment scenario. Magma achieves this goal through *access gateways* that terminate the radio-specific protocols as close to the radios as possible. As a result, Magma

allows carriers to augment an existing cellular deployment with WiFi hotspots in popular locations (e.g., athletic venues), or use LTE base stations to serve homes in rural areas, using a single core network and management platform.

Ideally, new deployments could start small and grow over time. Magma achieves a “scale as you go” design through horizontal scaling of software components that run on commodity hardware, as is common in cloud-computing environments. Magma also leverages open-source software components (e.g., Open vSwitch, gRPC, Kubernetes, Prometheus) commonly used in cloud settings. Magma simplifies network management by adopting software-defined networking concepts, so that a central point of control can be used to set network policies, manage subscribers, etc. Magma adopts a hierarchical control plane to improve scalability. Magma supports only the essential features for efficient Internet access (e.g., authentication, accounting, and per-user policies), and forgoes some complex features. For example, while Magma supports both mobility (within the area served by an access gateway) and roaming, it does not yet support seamless user mobility *between* access gateways; this is because mobility has not been a requirement for the use cases that commercial deployments of Magma support (e.g., home broadband or backhaul to WiFi hotspots). As other work has observed [38], modern end-host protocols and applications can perform well without in-network mobility support.

In this experiences paper, we present the lessons learned in designing and deploying Magma. We discuss how the goals of supporting heterogeneous radio and backhaul technologies and flexible policies, all at low cost, lead to a novel software architecture. Magma is used in real-world deployments that vary significantly in geographic scope, number of users, technology choices, and the business models that make them financially sustainable. In Section 2 we motivate Magma’s central tenet that the radio access technology should not dictate the network architecture. Then, Section 3 discusses how the design of the access gateways enables Magma to support diverse technologies, a scalable control plane, fault tolerance, and more. Next, Section 4 presents an experimental evaluation that demonstrates that Magma design and implementation achieves good performance and scalability along with a discussion of two production access networks. We have seen cost savings in one deployment of 43% compared to traditional approaches due to lower operational, hardware, and software costs. Our deployment experience also illustrates how Magma scales both up and down, with one deployment supporting more than 800 eNodeBs (base stations) in 45 US states at the time of writing. Section 5 presents related work. The paper concludes in Section 6 with a discussion of ongoing work on Magma and future challenges.

Ethics. This paper raises no ethical concerns. For the deployments discussed in Section 4, we only consider operational data and did not have access to any user data or traffic.

2 The Radio Access Technology Should Not Drive the Network Architecture

Traditionally, the choice of radio access technology dictates a raft of other decisions about the network architecture. In contrast, Magma starts with the premise that each radio access technology has a role to play in reaching diverse user communities and that network operators should be able to use the radio and backhaul technologies most suited for a deployment scenario. In short, wireless network architectures should, like the Internet itself, abstract away the link layer.

2.1 WiFi vs. Cellular Access Networks

The two main classes of radio access technologies emerged as extensions to existing wireline networks with different design philosophies. WiFi extended IP networks, whereas modern cellular data networks began as extensions to voice telephony networks. Many of the differences between these two classes of access networks follow directly from this early distinction.

WiFi: WiFi allows inexperienced users to run simple low-cost local-area networks on their own. These networks use unlicensed radio spectrum (typically at 2.4 GHz and 5 GHz) that do not require WiFi network operators to get advance regulatory approval. At the same time, anyone can access the same spectrum, subject to limits on transmission power. As a result, WiFi networks share their bands with devices including baby monitors, cordless phones, and smart power meters, so the WiFi MAC layer must assume that a WiFi access point (AP) operates in the presence of physical-layer interference. Combined with power restrictions that limit transmit distance, WiFi is most suitable for dense coverage in small areas. WiFi service is best-effort, consistent with the Internet design philosophy—and realistic given the likelihood of interference. Enterprise WiFi deployments, such as those on college campuses and in corporate office buildings, perform more centralized management of interference across multiple overlapping access points. Still, the risk of interference means that the service remains best-effort.

Cellular: Cellular access networks allow telecommunication providers to offer wireless service to their subscribers, typically using licensed spectrum that is owned or leased by the carrier for long periods of time at high cost. Since the radio has exclusive access to spectrum over a geographic region, cellular waveforms are designed for wide-area coverage and high spectral efficiency, with deployments by well-resourced actors that can acquire land, build and connect towers, and hire skilled staff.

Regardless of access technology, any network of significant scale requires substantial investment in equipment, staffing, and, in the case of cellular networks, regulatory licenses. Thus, beyond very small networks, operators implement policies to manage limited spectrum, ranging from access control; charging for service based on time, usage, or more sophisticated

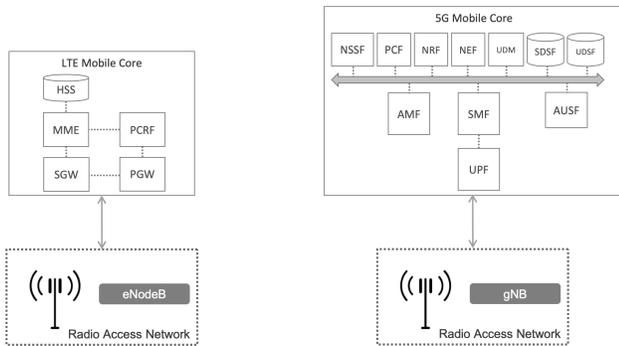

Figure 1: Differences between the LTE and 5G architectures. See Appendix for explanation of acronyms.

techniques that incorporate community values [36]; usage caps; and throttling. The policy specification for LTE, for example, runs to almost 300 pages [14]. A simple example policy would be: “rate limit customer C to X Mbps until they have sent Y GB in interval t_1 , then limit to Z Mbps for interval t_2 .” Supporting flexible policies can help carriers reach under-served users in a financially sustainable manner: even networks operating for social reasons still incur costs and must efficiently manage limited resources.

These capabilities are implemented by a sophisticated packet core network that connects multiple base stations to the Internet. In contrast to how the Internet architecture changes incrementally, each generation of cellular network has been an opportunity to rethink everything from authentication to the modularity of the control and data planes.

As such, different generations of the 3GPP standards [15] have different packet core architectures. UTMS (“3G”) differs from LTE (“4G”), which differs from 5G, and all of the generations differ from enterprise WiFi. The differences between LTE and 5G are illustrated in Figure 1, adapted from [46]. The different radio technologies require differences in the base stations (eNodeB versus gNB) but note also the change in modularity of the mobile core. WiFi would be different again, and less standardized, with functions such as Authorization, Authentication, and Accounting (AAA) corresponding roughly to Mobility Management Entity (MME) and Home Subscriber Server (HSS) components in LTE.

Today, the boundaries between cellular and WiFi are increasingly blurry, with operators deploying each technology in scenarios more classically served by the other. In recent years, large WiFi deployments have adopted more sophisticated methods for user authentication, power control, seamless mobility, and more [23, 24, 60], with efforts like Eduroam [58] and OpenRoaming [57] bringing cellular-like wide area roaming to users of WiFi access networks. Similarly, some cellular access networks now use “lightly licensed” spectrum, such as Citizen’s Band Radio Service (CBRS) [17] that supports dynamic allocation of radio spectrum to give radios exclusive

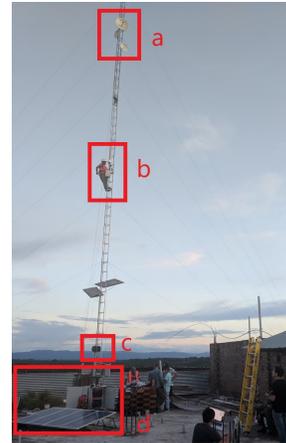

Figure 2: An early Magma deployment with a small rural ISP in Peru (their first cellular site). Components (top to bottom) include (a) point-to-point wireless backhaul, (b) LTE radio and antenna, (c) ruggedized embedded PC serving as Magma AGW, and (d) solar power and battery backup for site.

access to some portion of the spectrum (on the timescales of tens of minutes). Enterprises are deploying *private* cellular access networks for a range of use cases—such as industrial automation, medical applications, and Internet access at hotels and sporting events—that need better radio efficiency, authentication, and performance than WiFi traditionally offers.

2.2 Lowering the Barriers

Magma aims to lower the barrier to connecting under-served populations via wireless networks. We argue that operators should be able to choose the appropriate access technology for any deployment without then being locked into a core architecture that is compatible only with that access type. A single design that supports heterogeneous technologies amortizes the substantial engineering effort for creating software and the costs of training and supporting those who operate the networks. Plus, the design enables a single carrier to use multiple radio technologies (e.g., WiFi in shopping malls and cellular elsewhere) on a single core.

Cellular access has high barriers to *entry*. Network operators deploying cellular access technologies must make large capital investments (CapEx) in infrastructure: whereas a WiFi access point can cost under US\$100, even a low-cost cellular deployment would cost at least 1-2 orders of magnitude more. Traditionally, cellular core network equipment is designed for large deployments with hundreds of base stations and does not “scale down” to small initial deployments at reasonable cost; these networks also have high operational costs (OpEx), relying on highly skilled staff to manage the equipment. In addition, remote communities may not have affordable access to the high-quality, low-latency backhaul (e.g., fiber) links cellular networks typically rely upon. Instead, these networks may use satellite or wireless backhaul links with lower reliability and performance.

In contrast, WiFi deployments can start small, but present high barriers to *scale*. WiFi networks do not typically require skilled staff to deploy. Because WiFi is an inherently best-

effort access technology, these networks can leverage any available backhaul, even ad-hoc mesh backhaul using the same physical WiFi radios. Yet WiFi networks do not typically offer scalable ways to implement network policy or (beyond proprietary and vendor-specific solutions) to manage large networks. Thus, it is difficult for a WiFi-oriented operator to offer financially sustainable service over a wide area along the lines of large (usually cellular) operators.

Despite the differences between WiFi and cellular, these barriers are *not* fundamental. The building blocks of network policies are common in each; what is missing is architectural support. Software-defined networking can help address these gaps by enabling network-wide control over a distributed infrastructure, and adopting “scale out” techniques based on commodity components can reduce cost. In short, adopting and extending successful Internet and cloud approaches to scalability and management can make it possible to create a wireless access network that is both flexible and affordable.

3 Magma Architecture

Magma cannot overcome the shortcomings of existing solutions simply by reimplementing a standard, 3GPP-compliant mobile core. Instead, Magma terminates the radio-specific protocols as early as possible, in *access gateways* (AGWs) connected directly to the radio access network, as shown in Figure 3. These access gateways are instrumental in handling a variety of radio technologies in a single design. The Magma architecture goes beyond the traditional RAN/core split of 3GPP to place additional functionality in the access gateway, with a goal of making the packet core more scalable, including scaling down. Notably, Magma adopts the architecture of software-defined networking (SDN) systems, using a hierarchical control-plane design where a local controller in each access gateway interacts with a centralized *orchestrator*. The orchestrator is the central point of control for the system and maintains authoritative state related to system-wide configuration (*config* state). Runtime state, which relates to the activity of user equipment (UEs), is localized to the AGW that serves the appropriate base station for a given UE.

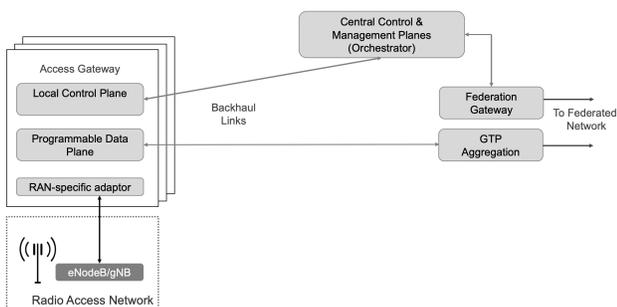

Figure 3: Simplified Magma architecture

Each AGW is a small fault domain, ensuring that the failure or upgrade of any one component affects relatively few users. In this way, Magma’s architecture is similar to modern cloud systems designed to run on low-cost hardware that is prone to failure [26]. Magma adopts other ideas from cloud architectures, including the use of gRPC for communication among components, a “desired state” model for state synchronization, and software-based, programmable data plane. While common in cloud computing deployments, these decisions deviate significantly from the way typical 3GPP networks are designed and managed.

3.1 Abstracting the Radio Access Technology

As Figure 1 illustrates, the details of the radio access technology traditionally “leak” into the core network. To counter this, Magma identifies a core set of functions that the AGW must implement for any radio technology (e.g., finding the appropriate policy for a given subscriber) and provides them in an access-technology-independent way. These functions form the heart of an AGW, as illustrated on the right side of Figure 4. Control protocols, which are specific to a given radio technology, are terminated *early* in technology-specific modules close to the radio. These modules, on the left of the figure, communicate with the generic functions (e.g., subscriber management, access control and management) on the right using messages that are RAN-agnostic.

Consider the example of “attaching” a newly active UE. The UE communicates with a nearby base station over a temporary (unauthenticated) radio link. In traditional 4G implementations, the base station forwards the request to the Mobility Management Entity (MME), which initiates an authentication protocol with the UE. The MME consults a subscriber database, authenticates the UE, creates an entry in a session table, and informs the other components of the parameters needed to serve the UE including: (a) assigning an IP address to the UE and setting the appropriate QoS parameters in the data plane; (b) instructing the base station to establish an encrypted channel to the UE; and (c) giving the UE the symmetric key for the encrypted channel. At the end of this sequence of events, the UE has an active *session* established with the mobile core and is able to send and receive data.

These functions are performed in the Magma AGW in a way that abstracts the details of the radio technology, as illustrated on the right-hand side of Figure 4. For example, Magma’s subscriber database has the union of all capabilities across the radio access types, even if some fields in a given database row are valid only for some technologies. QoS policies, for example, are less rich in WiFi than in 4G networks, while 4G policies are in turn less rich than those of 5G. Similarly, UE authentication and session establishment are done in a common way by generic functions that cover 4G, 5G, and WiFi procedures. The data plane, which is implemented in different devices across 4G, 5G, and WiFi, is implemented in

Magma	LTE	5G	WiFi
Access Control/Management	MME	AMF	RADIUS AAA
Subscriber Management	HSS	UDM/AUSF	RADIUS AAA
Session/Policy Management	MME/PCRF	SMF/PCF	RADIUS AAA
Data Plane Configuration	SGW/PGW	SMF	WiFi data plane
Data Plane	SGW/PGW	UPF	WiFi data plane
Device Management		per-box configuration	
Telemetry and logging		no equivalent defined	

Table 1: Magma abstractions vs. RAN-specific versions

a common, programmable data plane for Magma.

Table 1 shows how the various components of 4G, 5G, and WiFi are all mapped onto a common set of Magma abstractions. The key observation here is that there are a certain set of functions that need to be performed to authenticate users, establish session state, control the data plane, and so on. Magma does all of these in a generic way that is agnostic to the radio technology in use, thus providing an implementation in which the radio-specific details are abstracted from the core and limited to protocol termination close to the radio itself.

Additionally, Magma adds some generic functions that are not part of the 3GPP standards: device management and telemetry. Coupled with the SDN architecture, this simplifies the management of a large number of devices spread over a wide geographical area. Rather than logging into a specific device to configure it or check its statistics, Magma provides central management and monitoring from the orchestrator, where it can be leveraged by other systems that consume the northbound API. We have found that considering device management and telemetry as first-class responsibilities of Magma significantly reduces the operational complexity and cost of operating access networks (Section 4.3.1).

We do not claim that Magma’s decomposition of functionality (Figure 4) is fundamental, but our operational experience shows that it is useful both from an engineering perspective and for a wide range of use cases (as discussed further in Section 4). The modularity between components allows Magma’s internal interfaces to evolve independently of the RAN, aligning with an iterative development approach and in stark contrast to rigid 3GPP interface definitions. This has enabled the team to perform major changes to AGW functionality, such as adding new features (e.g., 5G support) or refactoring internal services without exposing these changes southbound toward the RAN or northbound toward the orchestrator API.

All communication between the RAN-specific modules on the left of Figure 4 and the generic functions on the right use gRPC [5], an open-source Remote Procedure Call (RPC) framework, as does all long-distance communication (e.g., from the AGW to the orchestrator). Although this is a typical approach for building modern distributed systems, it differs substantially from the protocols defined for communication among 3GPP components, which leak endpoint (e.g., UE and MME) consistency requirements into a network-level protocol. By running over HTTP, gRPC inherits the resilience to loss and delay of TCP/IP, which is absent from some 3GPP

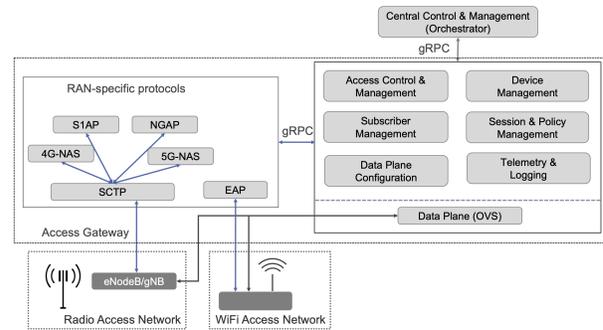

Figure 4: Common functions and RAN-specific protocols in the Magma architecture.

protocols designed for more benign, controlled environments (e.g., leased lines). A concrete example is GTP (GPRS Tunneling Protocol), which is sensitive to loss and latency to the point that it struggles to operate over lower quality or congested backhaul links, such as satellite or shared microwave links. Thus, adopting gRPC allows Magma more latitude to implement alternative consistency models without breaking UE state machines in a wider range of backhaul network conditions. In practice, this tolerance helps mitigate poor error handling on devices: while UEs should reconnect after experiencing a 3GPP protocol-level failure, we find that UEs with low-end baseband processors do not do so reliably. When a UE fails to reconnect, the failure manifests as a confusing lack of coverage to people using these devices, and the failure typically only resolves after power cycling the UE. Since Magma terminates GTP locally in the AGW without traversing the backhaul link, a UE never sees a dropped GTP connection and does not have to handle the error.

While agnostic to the radio technology, Magma necessarily makes practical choices about the order of feature development. Many early Magma deployments used LTE, so we have prioritized support for LTE features, with 5G support coming later. A good example is the support of QoS policies. Simple policies to impose rate limits and usage caps, as outlined in Section 2.2, are supported today for both LTE and 5G. More complex policies could be expressed, particularly in 5G, but full support for richer policies is currently under development.

3.2 Hierarchical SDN Control Plane

Magma adopts software-defined networking (SDN) to reduce operational complexity and minimize reliance on skilled staff. Rather than configuring a distributed collection of devices, providers specify network-wide policies at the orchestrator. The orchestrator provides a central point of control and exposes a northbound API for integration with other systems (e.g., for metrics, alerting, and monitoring). However, running the entire control plane in a central controller would impose limits on the scalability of the system. Hence, practical SDN

systems like Network Virtualization Platform (NVP) [37] and Open Virtual Network (OVN) [42] adopted a hierarchical control plane, and this is the model used by Magma.

In a hierarchical control-plane design, we identify those elements of the control plane that have network-wide scope; these are candidates for the central controller. For example, to add a new subscriber to the network, the long-lived information about the subscriber is network-wide information that is created and maintained by the central controller. Conversely, much of the runtime state associated with a UE can be localized to a single AGW. For example, upon becoming active, a UE is associated with a single AGW. The UE's session state can be created and managed by the local control plane of that AGW. Thus, much of the control plane is able to scale out with increasing numbers of base stations and subscribers, rather than increasing the processing in the central controller.

This division between central and local control planes roughly corresponds to the timescale of changes to the control-plane state. The addition of a new subscriber happens on configuration timescales, and that state is managed centrally. The creation of session state—when a UE becomes active and attaches to an AGW—happens more frequently. This runtime state is handled by the local controller on an AGW.

As with any SDN architecture, we must consider “headless” operation, i.e., the situation where a data plane node is disconnected from the central control plane. In a traditional SDN approach, the goal is to ensure that the data plane continues to operate without the control plane, even as updates to the data plane may be impossible while the control plane is disconnected. With a hierarchical control plane, many local operations are still possible even while the central controller is unreachable. For example, an AGW can still establish a session for a UE that attaches to a base station, because the local control plane has enough information (e.g., cached subscriber profiles) to process the session establishment. Conversely, network-wide actions like the addition of users or changes to user policies must wait until the central control plane becomes available again. Magma makes trade-offs for availability versus consistency as the CAP theorem [22, 28] implies. It is generally possible for state stored in an AGW to be stale during times of disconnection, which might, for example, allow a UE to temporarily consume resources beyond its quota.

This design helps to achieve the scaling goals of Magma, in allowing both a small minimum footprint (scaling down) as well as scaling up. A minimal Magma deployment would be a single AGW and an orchestrator. The orchestrator is typically three virtual machine instances in a cloud, while the AGW itself is a small (4-core) x86 commodity server. This is dramatically less hardware than a conventional cellular packet core. Scaling up is essentially a matter of adding more AGWs, which increases the number of base stations and UEs, without much increase in the load on the orchestrator. We discuss our experiences in scaling up in Section 4.3.

The decision to place local control-plane functions on the

AGWs, while beneficial for scalability, does introduce trade-offs. In particular, it complicates the picture for some features that require coordination among AGWs. Notably, while Magma supports mobility across radios served by a common AGW, seamless mobility *between* AGWs would require communicating some control-plane state from one AGW to another during hand-offs. While many use cases can be supported without this feature, we expect to add it in the future.

3.3 Fault Tolerance Via Small Fault Domains

The desire to build a low-cost solution for Magma has a significant effect on how the architecture approaches fault tolerance. Low-cost hardware is prone to failure, and so Magma adopts the view common to most modern cloud systems: it is expected that individual components will fail. A failure of a component must affect as few users as possible (i.e., fault domains must be small) and must not affect other components. This approach also has a positive impact on operations such as software upgrades, as it is possible to upgrade small components independently without taking down the whole system. This is in stark contrast to traditional 3GPP implementations.

The SDN-like architecture of Magma localizes state more fully than a typical 3GPP implementation. In a standard implementation, the runtime state of a UE is spread among several large components (e.g., the PGW, SGW, and MME in the LTE case). In contrast, Magma localizes the runtime state of a UE to a single AGW. This simplifies failure handling. The runtime state stored in an AGW is checkpointed regularly and may be copied to a backup instance of the AGW running as a cloud service. When an AGW fails, the backup cloud instance is brought into service, and can manage connections for the affected set of UEs until the primary AGW is restarted. As noted above, an AGW may continue to establish sessions to UEs even when disconnected from the orchestrator. The state synchronization approach described in Section 3.4 mitigates the long-term effects of such failures.

While it is common for a traditional cellular packet core to serve millions of subscribers, Magma distributes much of the functionality to a large number of Access Gateways. Each AGW is thus a fault domain that holds state for a relatively small number of UEs served by a small number (typically less than ten) of base stations. The failure of a single AGW would impact the set of UEs currently served by the attached base stations, but has no impact on the rest of the network or its customers. This contrasts with the much larger fault domains typical of a standard mobile core implementation.

3.4 State Synchronization

State in a mobile core needs to be communicated among components. Generally, one component is the authoritative owner of some piece of state, and it needs to synchronize state

with another component. In Magma, state can take one of three forms, for which Magma makes different guarantees.

The first is *runtime state* associated with a UE and its network activity. Backwards compatibility with existing user devices and RAN equipment requires Magma to implement standards-defined state machines to support operations like connecting to the network; modifications to runtime state can occur due to events in the UE itself, the RAN equipment, or Magma’s “core” network elements. Importantly, runtime state within Magma is encapsulated within the AGW, which as discussed in Section 3.3 is the failure domain for Magma, and we assume a crash-recovery failure model for AGWs.¹ Further, most runtime state is both ephemeral and recoverable in the event of failure: a UE can simply reconnect.

The second is the *configuration state*, associated with the configuration of a Magma network element, such as an AGW. This is only ever written by the orchestrator and pushed asynchronously to the AGW. Examples include classes of network policy to be applied to classes of user or radio configuration to be applied by an AGW to connected RAN equipment. AGWs recover configuration state after a crash, and the source of truth for configuration state is stored durably in the orchestrator (Postgres); we only permit modification to configuration state through the orchestrator. Configuration state generally changes on human timescales (i.e., minutes or hours).

Finally, Magma also manages *metrics state*, telemetry from Magma elements. This operational data, while useful, is captured on a best-effort basis.

Like many cloud-native systems, Magma adopts a “desired state” model for runtime and configuration state. By this we mean that to communicate a required state change (e.g., the addition of a new session in the data plane), the desired end state is set via an API. This contrasts with a “CRUD (Create, Read, Update, Delete)” interface, which is common in 3GPP specifications. Magma replaces the CRUD model with the desired state model to simplify reasoning about changes across elements of the system in the case of partial failures. This is a common case in challenged environments, where portions of the end-to-end system (e.g., backhaul) are far less reliable than others (e.g., the link between the UE and the RAN). This is best explained via a simple example.

Consider the case of establishing data-plane state in an AGW for a set of active sessions. Suppose there are two active sessions, X and Y. Then a third UE becomes active and a session Z needs to be established. In the CRUD model, the control plane would instruct the data plane “add session Z”. The desired state model, by contrast, communicates the entire new state: “the set of sessions is now X, Y, Z”. The CRUD model is brittle in the face of failures. If a message is lost, or a component is temporarily unable to receive updates, the receiver falls out of sync with the sender. So it is possible that the control plane believes that sessions X, Y and Z have

¹We generally assume the same for individual AGW software components; per-process state is held externally for most critical services.

been established, while the data plane only has state for X and Y. By sending the entire desired state, we ensure that the receiver comes back into sync with the sender once it is able to receive messages again.

This approach is hardly a novel idea in the cloud-native world, but it differs from typical 3GPP systems. It allows Magma to tolerate occasional communication failures (caused by poor quality backhaul, for example) or component outages due to software restarts, hardware failures, etc. Limiting the scope of 3GPP protocols to the very edge of the network gave us the flexibility to rethink state synchronization to improve fault tolerance (in addition to other benefits noted above).

We close by considering how Magma manages state for one particularly salient policy: billing users based on data volume, and the possibility of double-spending. Volume-based billing policies are typically implemented using a third-party online charging system (OCS) that integrates with both the network operator’s existing business support systems (BSS) as well as Magma. In this arrangement, *billing and charging* are handled by the OCS, while Magma handles *metering and accounting*. The OCS tracks a user’s account balance (e.g., in US\$) and then authorizes small quotas of data (e.g., 1MB) to the user via Magma; when the user nears completion of their quota, Magma requests another quota on the user’s behalf from the OCS, which makes the decision on whether to grant or deny the request. Whether or not a user has been allocated a quota is *configuration state* from Magma’s perspective, while the amount remaining in a user’s current quota is *runtime state*. Thus, while it is possible for a malicious user to double-spend by moving between AGWs strategically, the maximum amount of double-spend permitted is capped as a business decision by the quota size. Operators for whom this is a particular concern could also adopt techniques for volume-based accounting in a distributed context [31].

3.5 Software Data-Plane Implementation

The data plane is responsible for (i) recognizing the flows for active sessions (traffic to and from active UEs); (ii) collecting statistics for those flows; (iii) adding and removing tunnel headers; and (iv) enforcing policies such as rate limits per subscriber. Magma’s data plane is implemented using Open vSwitch (OVS) [47]. OVS provides a programmable data plane that is controlled by OpenFlow [39]. While OpenFlow and OVS are convenient implementation choices, they are not fundamental to the architecture. Other options may be used in the future. The important points are that the data plane is highly programmable and implemented entirely in software.

The software implementation of the data plane enables Magma to operate on commodity hardware. While throughput, latency, and jitter of the data plane are important for cellular networks, we have found OVS to offer entirely adequate performance. OVS performance has been well studied and optimized for many years [47]. In Section 4 we evaluate

the performance of OVS in the Magma context. It is worth noting that other aspects of the system such as backhaul and RAN capacity are likely to have a larger performance impact overall than the data plane within the access gateway.

The “data plane configuration” box in Figure 4 generates the commands necessary to program the data plane with a set of rules to handle the flows of current sessions. Currently, those commands are OpenFlow commands. If OVS were replaced with a different forwarding engine, only the “data plane configuration” component would be affected.

3.6 Federation With Other Networks

To this point we have described standalone deployment of Magma, but it can be deployed in one of three modes:

- *Standalone*: Magma supports an independent network, with all 3GPP control and user plane traffic terminated in the AGW.
- *Local breakout roaming*: Magma *federates* with an existing cellular network, with control-plane traffic terminated externally but user-plane traffic still handled by the AGW and routed directly to or from the Internet.
- *Home roaming*: Magma federates with an existing cellular network, with both control and user-plane traffic terminated in an external network.

Much as the AGW terminates access-specific protocols from the radio network, Magma introduces additional elements to terminate access-specific protocols with an external core network, using a component referred to as a *Federation Gateway* (FeG). The FeG implements 3GPP-defined interfaces to support “home roaming” as well as “local breakout roaming”. The latter is made possible in Magma by the fact that rich policy enforcement is provided in the AGW. As an example, an AGW can obtain the policy to apply to a UE by querying the subscriber data base in the federated network, then enforce that policy in the AGW. Signalling traffic between UEs and the MNO core is handled by the FeG service in the orchestrator². User data-plane traffic is tunneled to an analogous component, the GTP Aggregator (GTP-A) which in turn connects to the MNO’s existing P-GW.

Unlike the AGW, the FeG and GTP-A are centralized, on-path devices. This serves a practical purpose: traditional MNOs prefer a single point of interconnection between their sensitive core network and “extension” networks [31]. This has scaling implications as discussed in Section 4.3.2.

4 Evaluation

Magma makes a number of fundamental design choices that differ from traditional core network software to improve flexibility and scalability, while supporting rich network policies.

²This is necessary to coordinate low-level network state between the UE and the MNO’s traditional core, such as GTP bearer identifiers.

The aim is to support *practical* cellular access deployments. To evaluate Magma, we first consider system performance in an emulated environment, and then discuss a large-scale commercial Magma deployment.

4.1 Supporting Typical Deployments

Emulation Testbed Although evaluating Magma’s performance in a real deployment is possible at small scale, evaluating scenarios with hundreds of UEs and RAN elements is impractical. Further, extracting data from commercial deployments is challenging due to privacy and commercial considerations. Thus, we instead evaluate Magma using a commercial emulation system, Spirent Landslide [53], which allows us to emulate arbitrary configurations of virtual UEs and RAN elements in a replicable fashion.

For our evaluation, we deployed the most recent stable release of Magma, v1.6.1. We deployed the orchestrator on a cluster of AWS EC2 instances and two AGWs in our lab. The first AGW was a bare-metal AGW on an Intel J3160 quad-core 1.6GHz CPU with 8GB of RAM and four Intel I210 1Gbps NICs. The second was a virtual AGW running with Intel Xeon 6126 2.60GHz, 8GB of RAM, and 2x10G Mellanox ConnectX-3 NICs; we assigned a variable number of vCPUs to the virtual AGW as defined in our experiments below. Both the bare-metal and virtual AGWs were connected directly to the Landslide emulator as well as to the Internet via 1Gbps and 10Gbps links, respectively. We also verified that memory was not a bottleneck for the AGW during our experiments and that all machines in the orchestrator deployment were running well under capacity. Finally, the emulated SIM cards for the emulated UEs were pre-provisioned into the orchestrator and AGW in advance of all experiments, as is typical for network operator deployments of Magma.

Unlike traditional core networks, Magma’s AGW is co-located with RAN equipment (for example, at a tower site), and the unit of scaling for Magma is the AGW itself: as operators grow their network, they add both additional RAN capacity (i.e., radio equipment) but also additional “core” capacity (i.e., AGW instances). Since the AGW is an on-path device for all traffic associated with the cell site, the AGW should be provisioned such that site is limited by the capacity of the RAN as the site, rather than the AGW. This is a notable observation that, in part, motivates Magma’s design: when co-locating core network functionality with RAN elements, the *RAN is the bottleneck* for performance on a per-site basis.

The recommended (and typical) deployment scenario has roughly one AGW per “cell site”, which in practice consists of 1-3 eNodeBs in the case of an LTE network. A typical eNodeB (such as those described in Table 2 or depicted in Figure 2) can support at most 96 simultaneously active users³ and radio channels of at most 20MHz; this channel capacity, in turn, corresponds to a peak aggregate throughput of

³More users may be attached but not actively transmitting data.

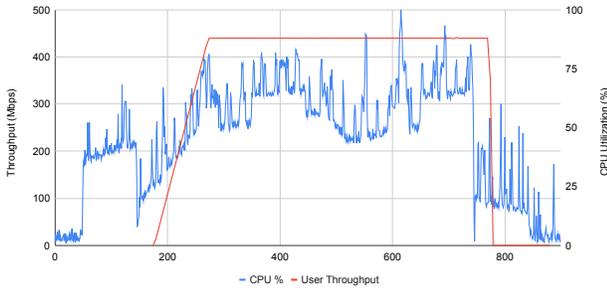

Figure 5: AGW CPU utilization under maximum “typical” workload for a cell site. Aggregate throughput is limited by radio capacity, not the AGW.

Item	Unit Cost	Qty	Total	Notes
LTE eNodeB	US\$4,000	3	US\$12,000	Baicells Nova 223: 1W, 3.5GHz, 96 user, 2x2 MIMO.
AGW	US\$450	1	US\$450	Same as used in experiments.
Accessories	US\$450	3	US\$1,350	18dBi sector antenna, RF cables, connectors, grounding.
RAN CapEx (per site)			US\$18,760	

Table 2: Cost breakdown of active RAN equipment for a typical Magma deployment. Excludes site-specific passive infrastructure and backhaul costs.

126Mbps [16] under ideal conditions, for a typical cell site maximum capacity of 378Mbps. We note that the additional cost of an AGW is modest in comparison to the cost of a cell site, similar to the site cost breakdown observed in related work [31]. Although LTE site costs can vary widely and are, in our experience, dominated by non-networking costs such as land, power, and tower (also known as “passive infrastructure”), a representative deployment could consist of the hardware in Table 2; AGW cost represents less than 3% of the cost of active equipment for the site. Power costs can be especially significant in “off-grid” locations, but these are largely driven by the power needs of the radio equipment and hence not greatly influenced by the mobile core implementation. Note the use of solar and battery power in Figure 2.

Magma must be able to support this type of workload. We evaluate this by emulating the peak load of a the cell site described above: a total of 288 UEs connect (or “attach”) to the network for the first time at a rate of 3UE/sec, and each then performs a short HTTP download at a rate of 1.5Mbps, for an aggregate total offered load of 432Mbps. Figure 5 demonstrates our results, focusing on the total CPU utilization as well as achieved throughput of the AGW. At a high level, the AGW accepts attach requests from all new users over the course of approximately 1.5 minutes, after which the AGW enters a steady state for the duration that UEs are making HTTP requests. In this experiment, average sustained UE throughput reaches the expected throughput of 432Mbps throughout the duration of the experiment, indicating performance is limited by the RAN, rather than Magma’s AGW, as expected.

We acknowledge that other RAN configurations can exist (including vRAN/cRAN arrangements) where many RAN ele-

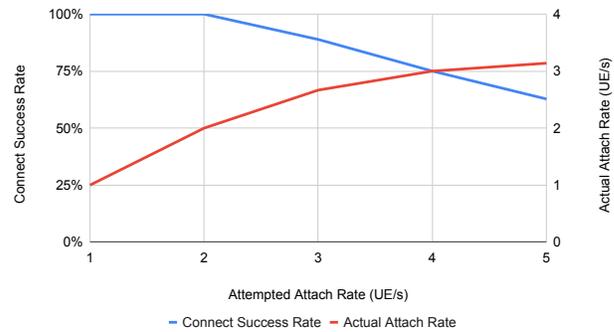

Figure 6: Maximum supported attach rates are limited by the AGW (specifically, the MME component). Results depict a physical AGW.

ments are effectively “co-located” to a single point within the operator’s network. Magma can be used effectively in these deployments, with one (or more) AGWs allocated to support this range of RAN equipment. However, no deployments at scale of Magma to date have used that configuration (to our knowledge), and Magma can be deployed on any general-purpose compute (e.g., VM or container) alongside this RAN infrastructure to support it. Similarly, a radio vendor could integrate an AGW into the same physical enclosure as a traditional eNodeB for a combined RAN and AGW element.

4.2 Control and User Plane Separation

Different usage patterns of a network stress user plane or control plane elements of the network core: a common example of the former would be human users accessing video content while the latter would be an IoT workload consisting of large numbers of devices that only exchange occasional small messages. This presents a major dimensioning challenge in traditional cellular core networks and motivates efforts to separate control and data plane elements so operators can scale them independently (statically or dynamically); this is known as “control/user plane separation” (CUPS) in LTE and 5G.

Magma’s distributed design naturally facilitates a CUPS architecture. By default, every AGW implements a data plane at the network edge, and all control plane functions are implemented as user-space processes at the AGW, with configuration state managed by the orchestrator.

From Figure 5, we observe that the AGW operates in two distinct and characteristic domains. At the start of our experiment, while UEs are attaching to the network, the AGW’s CPU workload is dominated by the *control plane* workload associated with handling attach requests, including performing cryptographic operations necessary to authenticate users as well as setting up per-user, per-session state in the data plane and control plane to implement the desired policy for each UE; in our experience, this is the most computationally-intensive control plane procedure. After UEs attach, the CPU workload is dominated by *user plane* workload associated with forwarding UE traffic.

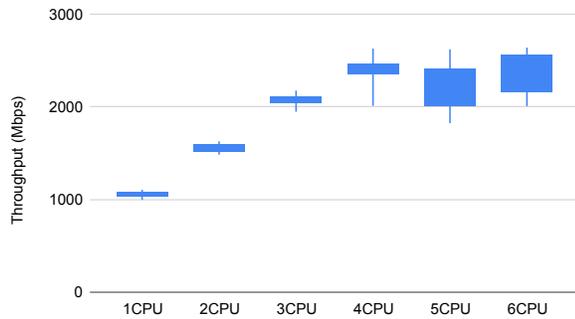

Figure 7: Steady state throughput vs. CPUs allocated to user plane. Note our traffic generator was unable to saturate the virtual AGW’s user plane in the 5CPU case and above.

Figure 6 illustrates how our bare-metal AGW copes with a “worst case” control plane workload, a surge of new UEs attaching then saturating the data plane. We define the *connection success rate* (CSR) to be the number of connection attempts that succeed over the total number of connection attempts made, for each five second bin during the experiment. We observe that above 2UE/s, the bare-metal AGW is unable to service all connection attempts, with the connection success rate (CSR) falling linearly beyond this point. On a per-AGW basis, Magma’s control-plane performance is relatively limited; improving this is an active area of engineering effort. Attach rate is a function of hardware as well: a 4 vCPU instance of our virtual AGW supports 16 attaches per second, which would saturate the RAN capacity of the “typical” site described above in 18 seconds.

Lastly, we consider per-AGW allocation of resources to the control and user plane. To do this, we statically limit the number of cores available to the user plane and evaluate steady-state throughput and median connection success rate. These results are shown in Figures 7 and 8; note that these experiments use the VM AGW, and as such the absolute throughput numbers are not comparable with earlier experiments. We observe that increasing the cores available to the user plane improves steady-state throughput at the cost of decreased connection success rate (i.e., control-plane performance), but allowing the kernel scheduler to allocate resources flexibly between user plane and control plane tasks provides both high throughput and good connection success rates. We note that we expect raw user-plane performance to increase beyond what is shown here; the commercial test equipment we used was unable to generate more than 2.5Gbps aggregate load.

Taken together, these emulation results demonstrate that Magma can handle typical workloads using low-cost commodity hardware. For more intensive workloads, Magma’s control and user plane capacity scales with additional hardware. We finally note that these results provide an upper-bound on the performance of a *single* Magma AGW; the *network* capacity of a Magma network scales linearly with AGWs.

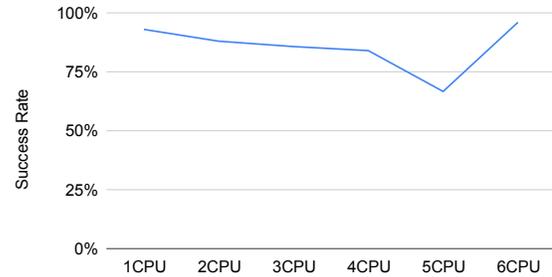

Figure 8: Median connection success rate vs CPUs allocated to user plane.

4.3 Deployment

We now turn to large commercial deployments of Magma. We first note that Magma is an open-source project governed by the Linux Foundation, and as such the core development team (including the authors of this paper) do not directly operate any production deployments; as such, we draw our examples from partners within the project’s ecosystem.

Magma adoption. To understand how Magma is used in practice, we interviewed two people working in product management and marketing for the Magma open-source project; in their roles, they speak regularly with operators as well as other commercial entities within the Magma ecosystem. Based on our discussion, as of February 2022, twenty commercial networks were operating using Magma across eight countries in Africa, Asia, North America, and South America. These networks support a range of access modalities and policies. For example, Magma has been used in networks providing backhaul for WiFi hotspots, fixed wireless broadband to homes and businesses, “carrier” WiFi to extend a traditional mobile operator’s service to indoor WiFi, and traditional mobile broadband service. Today, Magma has approximately 100 active committers to its codebase.

Magma deployments. To demonstrate how Magma is used, we worked with one of the largest commercial entities, FreedomFi, that provides support to operators deploying Magma. FreedomFi provided data to characterize two significant deployments they help operate. This data was provided to the authors in de-identified form, and only operational data (not user data) was used in our analysis.

4.3.1 Fixed Wireless Hotspots

One of FreedomFi’s first commercial deployments was AccessParks [1], a US-based operator that provides public WiFi hotspot networks in large outdoor areas; their deployment locations require multiple WiFi access points (APs) to provide consistent service. With the availability of CBRS spectrum, AccessParks sought to use LTE to provide backhaul to their WiFi hotspots in some of their larger deployments. End users connect to AccessParks’s WiFi access points via traditional WiFi mechanisms and an existing captive portal system, and

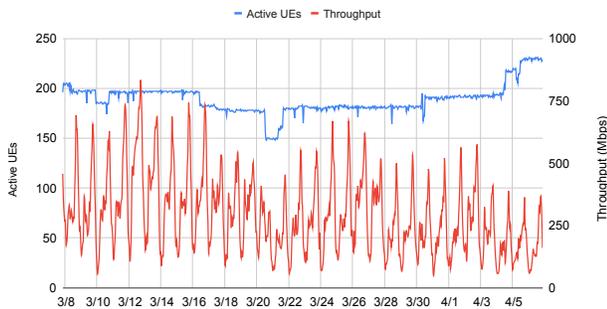

Figure 9: Per-hour AccessParks usage during Mar-Apr 2022.

the UEs in the Magma network are fixed wireless modems that connect the WiFi APs to the Internet via Magma. The setup is illustrated in Figure 10.

AccessParks’s deployment began in December 2020 with a ten site pilot to evaluate Magma. Today, the network consists of fourteen sites providing backhaul to over 200 access points, with plans to continue expanding. Figure 9 depicts active subscribers and hourly throughput of the network.

Network policies for the AccessParks networks are very simple: because the LTE network simply serves as backhaul, all UEs simply have unrestricted access. Per-user policies are implemented by AccessParks’s pre-existing captive portal and pre-paid billing software, which is implemented using standard techniques (i.e., RADIUS for AAA at the WiFi AP).

Operational complexity. AccessParks’s original Magma pilot was motivated in part by their poor experiences with the operational complexity of other commercial and open-source cellular core software in their previous two years of deployment. Although operational complexity is subjective, one quantifiable way in which it manifests is in an operator’s labor costs: simpler systems should require less staff time and support to manage. Table 3 shows the results of this comparison for AccessParks. For identical access network infrastructure, AccessParks achieved a 43% reduction in per-site deployment costs using Magma compared to traditional architectures, largely driven by a reduction in support costs and engineering time for site configuration and planning.⁴

4.3.2 Franchised MNO Extension

A second (and, to our knowledge, the largest) deployment of Magma is an early-stage deployment to provide a franchised, neutral host network.⁵ This network is unique in that the physical deployment of network infrastructure is not man-

⁴Unfortunately, we do not have data on ongoing maintenance costs from AccessParks; however, AccessParks’ decision to use Magma for future deployments suggests it compared favorably.

⁵A neutral host network describes a business model in which a mobile network is operated by an entity for the sole purpose of providing wholesale capacity to third-party retail MNOs and MVNOs; the neutral host network operator does not have its own users, but instead enables users of its customers to use the neutral host network on a shared basis.

Item	Traditional	Magma	Difference (%)	Notes
RAN	\$7,950	\$7,950	-	Identical RAN and backup power.
Core HW	\$1,200	\$300	-\$900 (-75%)	
Core SW	\$2,000	\$600	-\$1,400 (-70%)	Licenses/support.
Field Eng.	\$200	\$200	-	Installation.
LTE Eng.	\$5,000	\$330	-\$4,670 (-93%)	Planning, core config.
Cost/Site	\$16,350	\$9,380	-\$6,970 (-43%)	

Table 3: Comparison of per-site installed costs for AccessParks’s traditional cellular system compared to Magma. Total cost per site decreased by 43%, driven primarily by Magma’s reduction in operational complexity for deployment.

aged by any single network operator. Instead, “micro network operators” (which include individuals, small ISPs, and enterprises) deploy LTE and 5G RAN equipment alongside Magma AGWs that have been customized by FreedomFi to support their proprietary traffic accounting and settlement system.

Services and Policy. The neutral host network is operated by FreedomFi and allows customers of incumbent MNOs to use this network for service. The core “policy” supported by this network is tunnelling all user traffic back to the appropriate MNO; a user’s MNO, in turn, applies their standard network policies for billing, charging, and throttling within their existing core network. The FreedomFi network provides access on a best-effort basis, with each micro network operator leveraging shared CBRS [17] spectrum in the 3.5GHz band (as done in the previous deployment). This service requires integrating the thousands of distributed AGWs with a partner MNO’s centralized core network, leveraging the federation capabilities described in Section 3.6.

Scale. As of this writing, this network is still in early testing, so does not have significant user traffic. However, it still provides a useful example of how the Magma *control plane* scales with network size: even without users, Magma still manages device configuration, network monitoring, and supports interconnection with partner MNO core networks.

The FreedomFi network began initial deployments in November 2021, and as of April 2022 consists of 5370 AGWs and 880 eNodeBs (FreedomFi reports the discrepancy between AGWs and eNodeBs is due to supply-chain issues: while AGWs are commodity x86 PCs, cellular radios are specialized equipment with fewer vendors and the ones used in this network only began shipping in January 2022). The network is currently adding on average 150 new AGWs and 90 new eNodeBs per week, all of which are deployed on an ad-hoc basis by micro-network operators; these AGWs are deployed in 45 states across the United States.⁶

Supporting this network is a dedicated orchestrator running on six AWS virtual machines managed by Kubernetes (EKS) [18]. Three instances are dedicated towards “heavy” tasks: operation of the FeG, device configuration, and metrics reporting; these systems are each equipped with 16 vCPUs and 32GB RAM. Remaining orchestrator services run on a

⁶The network only operates in the United States for regulatory reasons.

collection of smaller VMs (4 vCPU/16GB RAM). The GTP-A runs on a single bare metal server with a 3.4GHz 8-core Xeon E2278G CPU, 32GB RAM, and 2x10G NICs, and is physically co-located near the facilities of a partner MNO’s core network. In total, this costs FreedomFi approximately \$4,000 per month to operate.

We view the rapid deployment of this network as cautious evidence for Magma’s ability to support large-scale networks with unique business models. We hope to further investigate the operational dynamics of this network in future work.

5 Related Work

Open-source LTE/5G core networks: Several projects share our goal of creating an open-source LTE/5G cellular core network [4, 9, 10, 13]; these were preceded by similar efforts to build open 2G and 3G networks [11, 12]. With the exception of OpenBTS [11] (a GSM-to-VOIP bridge), each of these focuses on implementing traditional, 3GPP-compliant, core networks.⁷ Aether [2, 43] is an open-source 5G-connected edge platform, which brings together 5G connectivity and edge-cloud servers. Like Magma, Aether adopts cloud design principles. However, Aether does not refactor the network design to break the coupling of the radio access technology with the core, and Aether does not focus on low-cost equipment to reach under-served users.

Expanding connectivity access: Many efforts have proposed or described novel solutions for expanding Internet access to under-served people [25, 30, 44, 45, 48, 55, 56]. Similarly, small(er)-scale network operators have a rich history providing service to especially rural communities [27], such as community networks [3, 6, 7, 21] and small ISPs [32]. Of this extensive literature, Magma is most closely related to work on community cellular networks [19, 33, 51].

NextG cellular core architecture. The networking research community is actively rethinking the design of next generation networks. PEPC [50] refactors the packet core by consolidating user state into one location, similar in spirit to Magma’s AGW. ECHO [40] refactors an EPC to run on less-reliable public cloud infrastructure. SCALE [20] explores an elastically scalable cellular control plane, and KLEIN [49] describes a similarly elastic control and data plane. Although these works all focus on (logically) centralized core networks, the techniques described are complementary to Magma.

Other work takes a more “clean slate” approach to reimagining the cellular core. CellBricks [38] contemplates a highly federated cellular network and moves support for mobility, authentication, and billing into end hosts; it is implemented as an extension to Magma. dLTE [35] makes 4G networks more like WiFi through a decentralized design, including a global registry for peer discovery. SoftCell [34] uses SDN

⁷We note that the Magma AGW’s LTE-specific portion was originally based upon OpenAirInterface [9], as it was the most mature open-source core available at the inception of Magma’s development.

principles to improve the scalability and flexibility of the packet core network. Magma draws on this body of work for inspiration while maintaining a backwards-compatible, standards-compliant edge to facilitate production deployment.

Magma directly builds on recent work exploring core architectures for under-served communities. CCM [31] presents a distributed cellular 2G core that enables semi-disconnected operation over unreliable rural backhaul connections; this work served as an early inspiration for Magma, which extends these concepts to modern wireless access technologies. Similarly, CoLTE [52] provides a lightweight core which—like an AGW—is co-located with RAN elements, but unlike Magma focuses on small, independent community networks.

Open radio access networks: Several recent initiatives focus on opening up the radio access network (RAN). For example, the OpenRAN project [59] and the O-RAN alliance [8, 41] develops standards that disaggregate 3GPP RANs, with open interfaces between the layers. These efforts are complementary to Magma, as they focus on the cellular interface—the part of the network *before* reaching Magma’s access gateway.

6 Conclusion

We have presented our experiences in designing and deploying Magma, an open-source platform for building access networks. The most important design decision was to terminate the RAN-specific protocols in access gateways close to the radio. This simple design decision brings many benefits: supporting diverse radio technologies, tolerating disruptions in backhaul links, using a low-cost software data plane, and scaling naturally with a hierarchical SDN control plane. Magma also adopts modern cloud-computing design patterns (e.g., desired-state synchronization, tolerance to failure of individual components) and open-source software components (e.g., gRPC, Open vSwitch, Kubernetes, Prometheus). In line with Magma’s goal to enable practical networks, we demonstrated that Magma can support typical deployment scenarios and discussed two large-scale commercial networks that use Magma. Importantly, Magma also scales *down*, with a small minimum footprint that supports incremental deployment, thus filling a gap between traditional WiFi and cellular. All software artifacts for Magma are available on GitHub⁸.

Magma was designed with the primary goal of reaching under-served communities, by supporting heterogeneous radio and backhaul technologies and reducing capital and operational cost. We believe that Magma is a good fit for other deployment scenarios, including enterprise 5G networks. Future work on Magma can expand the set of supported features, including seamless mobility between access gateways as well as network virtualization. We look forward to extending the Magma code base, and the community of contributors to the software, so the platform can evolve to serve more users.

Appendix

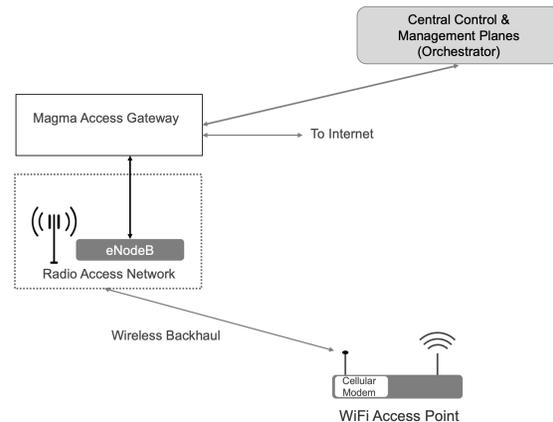

Figure 10: Wireless backhaul to WiFi hotspots provided by Magma. This is the network architecture used by AccessParks in their deployment: end users connect to WiFi access points via standard mechanisms, and traffic is backhauled from the hotspot via a co-located cellular modem to the LTE RAN supported by Magma. Note that nothing in this design precludes an end user from directly connecting to the LTE network, if appropriately configured and allowed to do so by the network operator.

Acronym	Definition
MME	Mobility Management Entity
HSS	Home Subscriber Server
PCRF	Policy and Charging Rules Function
SGW	Serving Gateway
PGW	Packet Gateway
AMF	Access and Mobility Function
SMF	Session Management Function
PCF	Policy Control Function
UDM	Unified Data Management
AUSF	Authentication Server Function
S1AP	S1 Access Protocol
NGAP	Next Generation Access Protocol
SCTP	Stream Control Transmission Protocol
NAS	Non-Access Stratum
RAN	Radio Access Network
LTE	Long Term Evolution
3GPP	Third Generation Partnership Project
UE	User Equipment (a phone or other cellular client)
eNodeB	The “access point” for an LTE network
gNodeB	The “access point” for an 5G network
AGW	Access Gateway
AAA	Authentication, Authorization, and Accounting
RADIUS	Remote Authentication Dial-In User Service

Abstract

In this paper, we present **LinkLab 2.0**, a completely programmable and controllable IoT testbed with the support of edge devices and cloud infrastructures. To be more specific, LinkLab 2.0 leverages a tiered architecture for the programmable devices and the management system to achieve scalability. To better support the integrated experiment among IoT, edge and cloud, LinkLab 2.0 provides one-site programming support and leverages the customizable offloading with serverless functions. Moreover, LinkLab 2.0 proposes a device-involved multi-tenancy approach to ensure responsiveness for concurrent requests. Furthermore, targeting 24/7 availability for experimenters, LinkLab 2.0 leverages proactive and reactive anomaly detection to improve the reliability of the testbed. Finally, we describe the supported research experiments and the outreach usage by external users. We also report lessons learned from the four-year operation. LinkLab 2.0 has supported experiments for 2,100+ users. The accumulated usage time across all the devices exceeds 17,300 hours.

1 Introduction

Many modern IoT systems are deeply integrated with edge and cloud platforms. New edge computing platforms like NVIDIA Jetson, and new computing technologies like computational offloading [41, 47] and serverless computing [27, 51] greatly enhance the capabilities of IoT systems [9, 26, 30, 49] and will eventually usher in an era of *Internet of Everything*. For example, in an industrial machine power monitoring scenario [34], hundreds or thousands of IoT devices monitor and collect energy data at a high frequency. To reduce the bandwidth usage and improve the real-time performance, edge devices are usually required to perform data preprocessing and analytics before forwarding the data to the cloud.

However, a major challenge is the lack of a fully programmable testbed for allowing the community to deeply explore new cloud/edge technologies and their “sweet spot”

[†]Co-primary authors

with a *large* number of IoT devices and *highly heterogeneous* computing platforms.

We notice that there exist multiple sensor network testbeds such as MoteLab [67], Indriya2 [7], and FIT IoT Lab [1], allowing the research community to experiment with various sensor/IoT hardware and IoT software. *Unfortunately*, they do not fully address the aforementioned challenge. Specifically, these testbeds do not natively support edge/cloud integration. Most testbeds do not support the device-edge-cloud communication path and do not allow programming on the edge devices. Moreover, they do not have good support for multi-tenant and high concurrent online experiments with a growing need for teaching and research purposes in the COVID-19 era. In this paper, we present **LinkLab 2.0**, a multi-tenant IoT testbed with edge-cloud integration, aiming to address the following systems and engineering challenges:

(1) **How to support device-edge-cloud integrated experiments?** Towards this, LinkLab 2.0 enables *one-site integrated programmability and control* for IoT, edge and cloud devices with several front-end and back-end supports. LinkLab 2.0 also supports new computation paradigms by supporting *customizable offloading with serverless functions*. Moreover, the

above programming support requires a separate and reliable channel to deploy experiments onto the devices. Hence, LinkLab 2.0 employs a *vNIC-based bandwidth reservation mechanism* on edge and cloud devices to guarantee the timeliness for controlling the devices (§3.2).

(2) How to ensure dynamic and dedicated usage with a high level of concurrency and multi-tenancy? The *Kubernetes-based architecture* makes LinkLab 2.0 adaptive to highly fluctuating usages (§3.1). Furthermore, considering the concurrent programming requests in the online education scenario, LinkLab 2.0 leverages a *device-involved multi-tenancy* technique to divide a proportion of services and devices as a tenant for dedicated usage. LinkLab 2.0 also provides a nimble configuration interface for administrators to manage the tenants (§3.3).

(3) How to ensure a high level of reliability, especially for the IoT devices? In accordance with the complicated potential root causes of IoT devices, LinkLab 2.0 uses a *proactive and reactive problem detection approach* to detect whether the devices are broken and locate the error as soon as possible. For the whole testbed, LinkLab 2.0 detects anomalies by automatically analyzing the *multi-model logs* during the operation of the testbed (§3.4).

Figure 1 shows the overall architecture of LinkLab 2.0. LinkLab 2.0 consists of three layers: device layer, edge layer and cloud layer. In each layer, there are various programmable devices to facilitate different levels of programmability and control for users. Besides programmable devices, there are dedicated devices and services to manage the programmable devices, namely LinkLab 2.0 Device Center (LDC). There are three different data paths among different layers. The experimental data path is used in the experiments conducted by users. The control data path is used for programming and controlling the devices of LinkLab 2.0, while the monitoring data path is used for experimental data collection and system monitoring of LinkLab 2.0 which is important for guaranteeing 24/7 availability.

Currently, LinkLab 2.0 is equipped with 420+ real IoT/edge devices of 14 different types. Furthermore, LinkLab 2.0 supports theoretically unlimited virtual devices with device-level simulation and a web-based IDE for easier access to the devices. The controller-server-client architecture of LDC allows LinkLab 2.0 to scale easily to accommodate substantial IoT devices at different physical sites. Table 1 compares the functionality of LinkLab 2.0 with other well-known testbeds.

LinkLab 2.0 (<https://linklab.emnets.cn>) facilitates researchers to conduct a broad range of experiments to ex-

plore new system designs. It incorporates various embedded computing platforms (e.g., Arduino, ESP32), IoT protocols (e.g., LoRa, MQTT, COAP) and techniques for edge computing (e.g., container-based service composition, edge AI). Furthermore, during the four-year operation, we extend LinkLab 2.0’s ability to better serve the community, especially for educational purposes. In §5, we exemplify the supported experiments and outreaches of our testbed to showcase the various capabilities of LinkLab 2.0.

2 Basics and Usage of LinkLab 2.0

Building and managing a testbed with numerous heterogeneous devices from the device, edge and the cloud layer at the same time need a prudent design. In this section, we first present the bird’s-eye view and the usage of LinkLab 2.0, then we compare LinkLab 2.0 with the existing testbeds.

LinkLab 2.0 in a nutshell. Towards the aforementioned goal, as Figure 1 shows, LinkLab 2.0 exhibits a three-layer architecture for both hardware and software, namely the IoT device layer, edge layer and cloud layer. LinkLab 2.0 supports both *real* and *virtual* devices for users to program with.

Currently, LinkLab 2.0 includes over 420 real devices for IoT, edge and cloud programming. The IoT devices are deployed in various environments (e.g., multi-hop scenario) as shown in Figure 2. These devices also incorporate various sensing peripherals and networking technologies for users. Another key hardware building block is the programmable edge devices and cloud server (also listed in Table 2), which is currently not well-supported by other testbeds such as FIT [1] and CloudLab [18]. For the programmable cloud server, LinkLab 2.0 provides users with a built-in cloud infrastructure with general-purpose computing resources (i.e., CPU, GPU). Moreover, LinkLab 2.0 supports users to use the public cloud service such as Microsoft Azure or the users’ own server as the cloud node in their experiment.

In addition to the real devices, LinkLab 2.0 also introduces *virtual devices* to support the experiments that are *large-scale* or *trace-driven*. We propose two kinds of virtual devices: code-level and message-level. The code-level virtual device accepts the same code as the real node and simulates all behaviors of the device. The message-level virtual device only simulates the network behavior such as MQTT publish, which enables a theoretically unlimited number of devices for large-scale experiments. Furthermore, LinkLab 2.0 also supports binding time-stamped datasets to virtual devices to reproduce an experiment with a pre-recorded trace.

Lifecycle of an experiment. LinkLab 2.0 provides comprehensive support for users to carry out experiments. Conducting experiments contains the following steps:

(1) *Project Creating and Resource Claiming:* Users should first create a project, select the hardware and claim the occupation time via our web portal. The experiment automatically terminates when the requested time quota runs out.

(2) *Programming and Provisioning:* For IoT devices, users

could simply upload the experiment binary via our web portal. Furthermore, LinkLab 2.0 also provides a web-based IDE and online compiling services to allow users to conduct experiments anytime and anywhere. For programming the edge and cloud, LinkLab 2.0 supports both programming with serverless functions and Docker-based development.

(3) *Data Collection Configuring*: The experimental data collection of LinkLab 2.0 is based on logging "channels". Each channel represents a specific category of experimental data. Currently, LinkLab 2.0 provides three channels: console logs, network traffic and energy measurement (for some devices that are connected to a Monsoon Power Monitor).

(4) *Experiment Execution*: Once finished the provisioning, users could start the experiment by clicking the "start" button. During the experiment, users could select one or more devices to view the serial/console outputs instantly and adjust the configurations from the web portal.

(5) *Report Acquisition and Data Processing*: After the execution, users could download the experimental report from the web portal and use data processing tools such as Python or R to perform further analysis.

Comparison to other testbeds/infrastructure. We compare the development process of LinkLab 2.0 with the one using FIT IoT Lab (for IoT device deployment) and FIT Cloud Lab/Microsoft Azure (for edge/cloud development) in Figure 3 and summarize the differences as follows. (1) LinkLab 2.0 is the only testbed that includes the IoT, edge and cloud, which facilitates users to do a one-stop development. Users are not asked to login with multiple credentials and the inter-device network is automatically configured. Users of FIT IoT Lab will spend a long period configuring the border router and setting up the connectivity between IoT and the cloud. (2) Furthermore, thanks to our integrated program-

ming support (§3.2), users could have a bird's-eye view when selecting devices and the networking parameters are shown when programming, which could shorten the development time. (3) The Web-based IDE and built-in online compilation environment enable the one-key provision of developed experiments. However, using FIT and Azure, developers could only separately write code for the IoT and cloud and manually deploy the program, which both need much coordination efforts between platforms.

3 Designs of Management Services

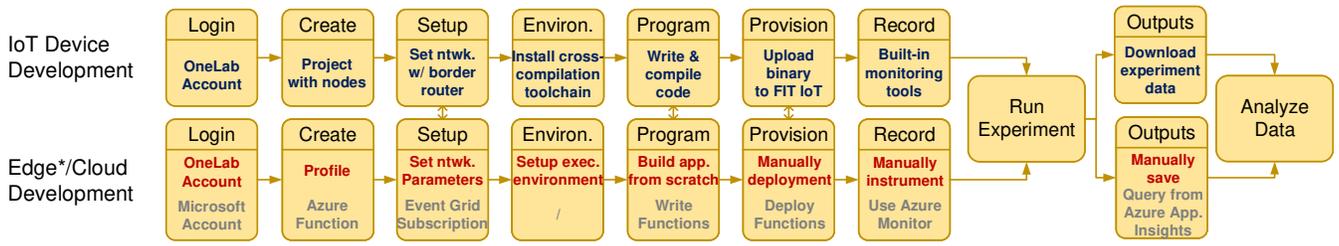

Managing such a multi-tiered testbed with various heterogeneous devices faces several non-trivial challenges. In this part, we will present the challenges and solutions from the basic architecture design to programming and reliability issues.

3.1 Overview of Management Architecture

As shown in Figure 4, all the IoT, edge and cloud devices are managed by a three-tier architecture named LinkLab 2.0 Device Control (LDC). LDC contains three building blocks: the controller, the server and the client. The LDC controller is the top-level management service, which is responsible for gathering the programming and controlling tasks from the users. The LDC server takes the experiment tasks as input, assigns the tasks to the devices and forward the binaries or configurations to the LDC client (for IoT devices) or directly to the programmable devices (for the edge/cloud). The LDC client is at the lowest level, which directly interacts with the IoT devices and provides device control interfaces (e.g., program, reset, and keep-alive) to the LDC server via the network.

Kubernetes-based management services. The architectural design of LinkLab 2.0 does not happen overnight. We next elaborate on the alternatives and our considerations dur-

Development process of FIT IoT Lab + FIT Cloud Lab and FIT IoT Lab + Microsoft Azure

*FIT Cloud Lab and Microsoft Azure do not support edge devices currently.

Figure 3: Development process of FIT IoT Lab (for IoT), FIT Cloud Lab or Microsoft Azure (for cloud) against LinkLab 2.0.

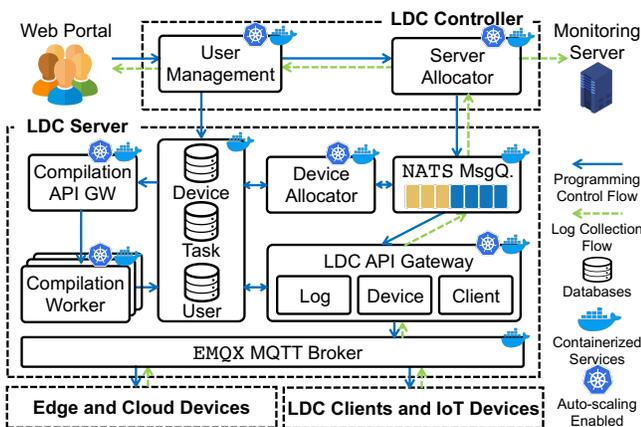

Figure 4: Kubernetes-based management services.

ing the development of such a heterogeneous and large-scale testbed.

Monolithic or cloud-native? In retrospect, LinkLab 2.0 is originally built in a native, monolithic way, which means the management functionalities are centralized in a handful of monolithic services and bare-metally deployed on the server with binaries. Nevertheless, after a few irritating experiences of migrating the services between servers or establishing sub-sites, we decided to adopt a cloud-native architecture (see Figure 4), which means decoupling functionalities to microservices and deploying them with containers. The rationale is we frequently build sub-sites to extend LinkLab 2.0’s coverage and community, which makes us value the ease of service management and migration brought by cloud-native more than the extra overhead brought by containerization.

Be adaptive to highly fluctuating workloads. Since one of LinkLab 2.0’s usage scenarios is online education, we observe a highly fluctuating workload during the operation of LinkLab 2.0, i.e., many concurrent requests during classes while few users are active at night. Simply over-provisioning the management services is too conservative and uneconomical, hence LinkLab 2.0 leverages Kubernetes for adaptivity.

Kubernetes [53] is an open-source system that enables the

automated scaling of containerized services by instantiating service replicas. As Figure 4 shows, all the key services are containerized and managed by Kubernetes (except NATS, EMQX and databases because they have their own scaling policy). The addition of a *server allocator* makes LinkLab 2.0 scalable for building LDC servers in multiple remote sub-sites.

Benefits. This Kubernetes-based management architecture is scalable to user requests. Once the user request bursts, services shown in Figure 4 will automatically scale up to handle the requests and scale down to save the resources when there are few requests.

Tiered management of devices. Due to the different programming approaches between IoT and edge/cloud devices, LinkLab 2.0 employs tiered management of the devices.

IoT devices. The real IoT devices are connected to a Raspberry Pi (RPI), which the LDC client deployed on, via USB serial. LDC client includes a programming service based on the burning tool provided by the manufacturers of the devices (e.g., *avrdude* for Arduino-series boards). An alternative is using the Over-The-Air (OTA) technology to update the binaries, while we gave up this idea due to the scarce storage space on IoT devices and the wireless interference.

The management of virtual devices is akin to the real nodes. The only difference is the addition of creating and deleting interfaces for users to adjust the number and type of simulated devices, and the managing commands are transmitted via the network rather than USB serial.

Programmable edge and cloud. The management of the programmable edge/cloud devices differs from IoT devices in two ways: (1) LinkLab 2.0 leverages network-based controlling instead of USB serial because the transmission speed of USB serial (115.2Kbps) is generally much slower than the network (>100Mbps), while the data size for provisioning edge device is mainly in gigabyte magnitude. (2) The LDC client is directly deployed on the programmable edge/cloud devices because they have enough computing ability to handle the management commands.

Hence, LinkLab 2.0 develops a runtime for the edge/cloud (Figure 5) to support the programming, controlling and moni-

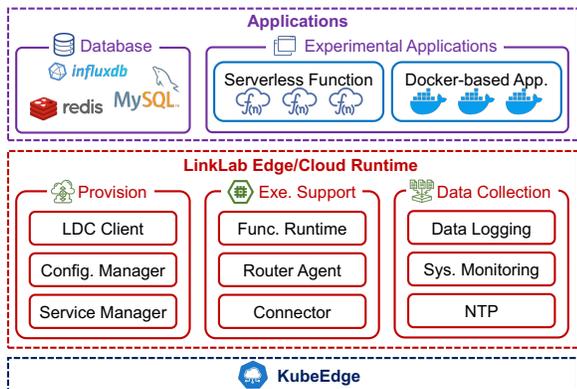

Figure 5: LinkLab 2.0 edge/cloud software stack.

toring tasks. The LDC client is part of the edge/cloud runtime and responsible for handling the commands sent by the LDC server and reports the status of the edge device. Once the LDC client receives an experiment deployment configuration, the *configuration manager* parses it and deploys the experiment. After provisioning, the lifecycle of the services of the experimental application is managed by a *service manager*, including starting, restarting and destroying the instances.

Benefits. This tiered management system as well as the distributed design of LDC client and server dramatically reduces the efforts for adding the devices to LinkLab 2.0. Users who intend to add new IoT devices only need to deploy an LDC client and plug the device into the client. Without these designs, adding devices requires plugging them into the same hardware device that the LDC server lies on, which reduces the scalability for deploying the IoT devices in the wild or physically remote from the LDC management cluster.

3.2 Achieving IoT-Edge-Cloud Integration

We now introduce how LinkLab 2.0 achieves the integrated programming for IoT, edge and cloud and how to guarantee the reliable programming of the multi-layered devices.

Integrated programming for IoT, edge and cloud. The most important feature of LinkLab 2.0 is to facilitate one-site programming for IoT devices, edge and cloud. Moreover, LinkLab 2.0 also supports serverless functions and computation offloading to lower the threshold for experiencing cutting-edge programming paradigms.

One-site programming for the three layers. In order to facilitate the one-site programming for IoT, edge and cloud, LinkLab 2.0 optimizes each step of conducting an experiment. (1) During the selection of devices, LinkLab 2.0 provides users with the hardware network topology. With this view of topology, users could choose devices from different layers with fully aware of the connectivity between devices. (2) For the programming step, users could use a Web-based IDE of LinkLab 2.0 to write code directly in the web browser and leave the compilation and deployment to LinkLab 2.0 backend services. LinkLab 2.0 also automatically handles the network between devices and shows the networking parameters (e.g.,

IP address) for each device during users’ programming. (3) During the experiment execution, LinkLab 2.0 supports the customization of configurations, especially the parameters for inter-layer communication, which could not be easily configured in other testbeds such as FIT IoT Lab. The programmable configurations include connectivity settings (e.g., round-trip time, bandwidth, packet loss rate) and performance settings (e.g., resource quota of services, docker priority).

Customizable offloading with serverless functions. Recent advances in serverless computing [60, 61, 74] allow users to focus on the application logic other than wasting time on the configuring environment and parallelism from scratch. Hence, besides the basic Docker-based development, users of LinkLab 2.0 could decompose their experiment logic into serverless functions and deploy them on edge or cloud devices. Moreover, to further simplify the serverless programming in the IoT-edge-cloud scenario, LinkLab 2.0 provides *device-interaction APIs* for serverless functions to read data from an IoT device.

Based on the serverless functions, LinkLab 2.0 provides systematic support for function offloading. Primarily, users could use @remotable annotation to mark the function that could be offloaded. Moreover, a large amount of related research [36, 50] concentrates on the offloading policy. Therefore, LinkLab 2.0 presents a *customizable offloading framework* to enable users to define and test their own offloading policies. Towards this, LinkLab 2.0 first decouples the offloading policy module from the offloading handler, which is responsible to intercept the function execution and transmit it to the offloading destination. Second, LinkLab 2.0 provides customization interfaces for users to define their own policies.

Timely edge control based on vNICs. As we stated before, LinkLab 2.0 uses the network to manage the programmable edge and cloud, which is the same data channel that most experiments use. Suppose an experiment intends to occupy as much bandwidth as it can (which most experiments do), the management delay of this device will dramatically increase, or even the device will stop responding to management commands. Existing cloud testbeds could alleviate this by employing a dedicated network interface card (NIC) for management and control. Nevertheless, most of the COTS edge devices only have one NIC and are not customizable after manufacture.

Hence, we develop a software-based tool, *resGuard*, to ensure the responsiveness of the management service under any circumstances. (1) For outbound traffic, the *resGuard* first uses *cgroup* to categorize the key management tasks (processes) and other user tasks. Then, *resGuard* leverages *tc rate* to guarantee the minimum bandwidth of management tasks. (2) For inbound traffic, however, the aforementioned approach is not applicable because *tc* only implements an egress packet queue and *cgroup* could not classify the inbound traffic to its destination process. Hence, *resGuard* takes advantage of the *ifb* virtual NIC mechanism of Linux.

```

1 tenant:
2   name: NSDI2023
3   user: "alice", "bob"
4   hardware_exclusive: "AMega-1", "AMega-2", "ESP32-1", "RPI-1"
5   hardware_shared: "ESP32-2", "ESP32-3", "RPI-2"
6   services: "$all$" # enable all services
7   service_quota:
8     - compiling: 10 # unit: req/s
9     - burning: 5 # unit: req/s

```

Figure 6: Example configuration to create a tenant.

The `ifb` vNIC is a message queue by implementation and any packet that is redirected to `ifb` will return to its original NIC automatically after traffic shaping. Therefore, `resGuard` redirects all the inbound traffic to `ifb` and uses `tc` to prioritize the packet from the IP addresses which host the management services. Note that `resGuard` only prioritizes the management service, the experiments could only utilize all the resources if there is no management task. In addition, `resGuard` also reserves CPU quota for management tasks via `cgroup`.

3.3 Achieving Multi-tenancy

During the COVID-19 pandemic, we make LinkLab 2.0 available to teachers and students for educational purposes. However, this scenario poses new concurrency and multi-tenancy challenges for LinkLab 2.0, which is guaranteeing a dedicated and responsive usage of services and devices during a certain period of time. This is because the programming requests are expected to be handled immediately in a limited class time.

The containerized architecture of our management services (Figure 4) is a good start for achieving multi-tenancy for its scalability and isolation property. However, the programmable devices, which are one of the building blocks of LinkLab 2.0, are not included in this isolation framework. Hence, LinkLab 2.0 proposes *device-involved multi-tenancy*. With this technique, operators could easily create a new tenant for a dedicated usage, and LinkLab 2.0 assures the programming responsiveness of services and devices within a preset quota.

Device-involved multi-tenancy. Services in Figure 4 are reconstructed to support multi-tenancy. First of all, each database owns a `TenantID` field for other services to look up. To avoid the interference of the tasks from different tenants, the device allocator creates waiting queues for each tenant and launches an appropriate number of instances to handle the requests. Other services will subscribe the task from NATS once they are assigned to a tenant.

Once a new request of a user is received, LinkLab 2.0 will first query which tenant the user belongs to and put the request to the corresponding queue. Then, the device allocator searches for if there are idle devices that meet the user request and belong to the requesting tenant. If so, the request will be assigned to the device. Furthermore, this device-involved multi-tenancy is also a lightweight approach to IoT device virtualization. When creating a new tenant, administrators could assign devices to the tenant in the “exclusive” or “shared” manner. “Exclusive” means the device could only be accessed by the users of the tenant, while “shared” means the device

is shared with other tenants. There are primarily sensing and actuation IoT devices in LinkLab 2.0. If a sensing device is set to “shared”, we can multiplex its sensing data to multiple tenants if necessary. On the other hand, the actuation devices cannot be shared after being allocated to avoid conflicting operations.

We also leverage an accounting mechanism for the containerized services in Figure 4 to record the resource usage of each tenant. If a tenant exceeds its preset quota, the user management will reject the new request from this tenant.

Tenant management. We build a command-line interface (CLI) for administrators to manage tenants, such as creating a tenant or to moving a device/user to an existing tenant. As Figure 6 shows, administrators could allocate users, hardware resources, and software services with quota in a YAML configuration file when creating a new tenant. Then use our management CLI with `LinkLab 2.0-manage tenant -c <config>.yaml` to create (-c) a new tenant to LinkLab 2.0. Besides adding new tenants, LinkLab 2.0 also supports modifying (-m) and deleting (-d) tenants.

3.4 Achieving Reliability

Reliability is the principal requirement of a testbed that is used for both academic and educational purposes. To achieve 24/7 availability, LinkLab 2.0 employs an anomaly detection system. The goal of the monitoring system is to keep two groups of reliability problems away from LinkLab 2.0: (1) Device-related problems, such as unexpected offline and abnormal sensor readings; (2) Service-related problems, such as improper resource occupation and service breakdown.

Proactive and reactive device anomaly detection. Towards the device-related problems, we use both proactive and reactive detection to catch the exceptions as soon as possible.

Reactive detecting. Basically, the devices in LinkLab 2.0 are monitored reactively, which means we only use the data that is non-intrusively collected from the IoT device. Such as we monitor the working state of the peripherals using the readings piggybacked from users’ experiment applications.

Proactive probing. To monitor the devices that are used infrequently and improve the coverage of device problem detection, LinkLab 2.0 also employs proactive probing. We create a benchmark set for each kind of IoT device that covers most of the functionalities of the device. Once a device is idled for a period of time (empirically set to 2 hours), our monitoring system programs the benchmarks to the devices and analyzes the output. Note that we make the regular user requests could preempt the execution of probing benchmarks for a better device utilization. Once abnormal behavior occurs, our monitoring system will send an alarm to the operators.

Benefits. Besides alarming the maintainers of device failures, our device anomaly detection approach is also beneficial to the reproducibility of experiments conducted on LinkLab 2.0. To ensure the correctness and accuracy of the experiments, we pay attention to the result consistency and abrasion

of our devices by correlating the piggybacked sensor data in the reactive detection with the environmental data collected by the maintainers and the outputs of proactive probing with our pre-defined ground truth.

Service anomaly detection via multi-model log fusion.

In this part, we introduce how LinkLab 2.0 detects service abnormalities through log analysis during system operation.

Multi-model system runtime data collection. The runtime log is an implicit indicator of the system’s health. LinkLab 2.0 collects both structured and semi-structured runtime data for further anomaly detection.

(1) Structured key performance indicators (KPIs). KPIs are the quantitative metrics that reflex the operating status of the system. For each layer of LinkLab 2.0 (IoT, edge and cloud), we collect different KPIs according to the intrinsic difference of each layer. (a) For the edge/cloud layer, we collect the network throughput, CPU, memory, etc., as the KPIs. (b) For devices of the IoT layer, the connectivity of each device (indicated by its heartbeat message to the LDC client) is recorded. The KPIs are periodically collected by our monitoring system. The interval is empirically set to 2min in the current deployment.

(2) Semi-structured event logs. Each building block of LinkLab 2.0, especially the management services in Figure 4, reports the underlying behavior of the component via the semi-structured event logs. These logs are mainly service-specific outputs with timestamps and labels of severity levels such as FATAL and ERROR. Our monitoring system collects these logs from each layer of LinkLab 2.0 for further analysis.

Multi-model log fusion based anomaly detection. The collected KPIs are time-series data, which are eligible for further processing. Nevertheless, the collected semi-structured event logs also need to be structured for anomaly detection. We propose the simFDT approach, which extends the widely-used fixed depth tree (FDT) model with the ability to parse logs in variable lengths using the similarity between logs and templates, to cope with diverse logs generated by heterogeneous devices. After parsing by simFDT, we employ a sliding window to count the different events in a period of time as vectors and feed the vectors to our anomaly detection algorithm.

We employ Autoencoder (AE) to detect abnormal events of our entire system using the KPIs and the vectors parsed by simFDT. AE is widely used for anomaly detection on time-series data [13, 42, 55]. In order to reduce the overhead of transmitting monitoring data, we leverage multi-level detection by separately training anomaly detection AEs for each layer and deploying the models on the nearest upper layer of the devices/services being monitored. For example, the AE for IoT devices is deployed in the LDC client cluster and the AE for the LDC client cluster is on LDC servers.

Operational findings of anomaly detection. We have implemented and deployed the aforementioned anomaly detection approaches to our production environment to achieve 24/7 reliability. Up to now, LinkLab 2.0 achieves 98.2% hard-

Table 3: Detected anomalies during the operation of LinkLab 2.0 (sorted by the occurrence in descending order). Dev. and Svc. mean the device- and service-related problems, respectively.

#	Type	Root causes of detected anomalies
1	Svc.	Docker images of services are recycled by Kubernetes.
2	Svc.	Failed deployment of a newly developed feature.
3	Dev.	The power supply of an edge/IoT device is broken.
4	Dev.	Loose connection between devices and peripherals.
5	Svc.	Disconnection of the reverse proxy to the cluster.
6	Dev.	The peripheral/pinout of an IoT device is broken.
7	Svc.	Network fluctuations for hours or days.
8	Svc.	Deletion of key files caused by maintainer’s misoperation.
9	Svc.	Power outage in the equipment room of LinkLab 2.0

ware available time across the IoT, edge and cloud layer since the introduction of this system, and Table 3 shows the detected anomalies. We can see from the table that our anomaly detection approaches could recognize the abnormal states for services, devices and the entire system.

Nevertheless, we observe false positives (FPs) and true negatives (TNs) during the long-term deployment. Here, we will elaborate on the occurrence of FPs and TNs, and discuss how LinkLab 2.0 evolves to cope with the problems.

The observed FPs include: (1) The number of testbed usages increases sharply, which leads to the false warning due to unusual high resource usage. (2) The regular operational actions by the maintenance team run out of the resources (i.e., deploying a new version, too many concurrent proactive tests for anomaly detection). (3) The false warning on unprecedented low resource usage after a server upgrade. The rationale behind these FPs is the data sources of the anomaly detection are inadequate. Hence, we subsequently improve the detection system by correlating the detection results with the operational data (e.g., active user, deployment status) and the domain knowledge of operators (e.g., server upgrade).

The TNs are mainly short-time service unavailability (usually for a few to tens of seconds) incurred by the network fluctuation. These TNs could be easily addressed by shortening the interval of KPI collection and proactive probing. We argue that the selection of the interval in the current deployment exhibits a good tradeoff between detecting accuracy and overhead, and we will adjust the interval for the time-sensitive situations such as supporting live classes and exams.

4 System Performance

We test our system to answer the following questions: (1) Is LinkLab 2.0 scalable? (2) Whether the resGuard of LinkLab 2.0 is reliable for programming edge/cloud devices and what is the performance? (3) How does the multi-tenant design of LinkLab 2.0 perform?

Effectiveness of the scalable architecture. In this part, we evaluate the scalability of LinkLab 2.0’s architectural design by simultaneously issuing hundreds of concurrent requests and see how many resources that used by LinkLab 2.0.

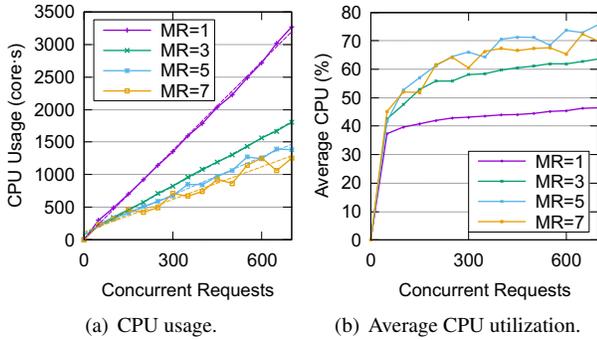

Figure 7: Resource usage of management services for different concurrencies. MR is the maximum number of service replicas (i.e., the number of containers instantiated to serve the requests of a service) when auto-scaling.

Figure 7(a) illustrates the usage of the CPU. Note that we use the product of CPU utilization and time as the metric of CPU usage in order to illustrate the overall usage during a period of time rather than the instant usage, and we omitted the illustration of memory usage because it shares almost the same distribution to the CPU and page limit. We can observe in Figure 7(a) that the relationship between CPU usage and the concurrent request is *linear* across all the settings, which is scalable because the per-user resource is stable even under extreme concurrencies. Another observation is that the CPU usage seems to be decreasing when the maximum number of replicas (MR) increases. To investigate more on the reason for the decrease, we go into the average CPU utilization of each setting, as Figure 7(b) shows. We can see that the CPU is under-utilized with lower MR, which may be because the tasks have to wait longer when there is no worker replica to process them. Nevertheless, the benefit of auto-scaling also has its upper bound. In our setting, the upper bound is 5 replicas, which we can see in both Figure 7(a) and 7(b), because the management services of LinkLab 2.0 are deployed on a cloud cluster with *five* nodes (each has a 2.5GHz CPU core).

Effectiveness of *resGuard*. In this part, we evaluate the programming reliability of the IoT devices and edge/cloud devices with our three-tiered management system.

For the IoT devices, there are only 504 (1.9%) failed trials in 27,216 programming tasks from May 2020 to January 2021. For edge/cloud devices, we conduct an experiment to evaluate the effectiveness of the *resGuard* we introduced in §3.2. The evaluation methodology is that we attempt to deploy a new experiment on the edge device while another experiment is still running on that device, and we adjust the bandwidth occupation of the existing experiment to see how the deployment time varies under different situations. We use two jobs as new deployment tasks: (1) the user deploys an InfluxDB and views the logs, and (2) the user deploys a Kafka logging service to the edge device. Figure 8 shows the results. We can see that the deployment time increases rapidly without *resGuard* while the deployment times stay still with *resGuard* when the existing experiment takes up more than

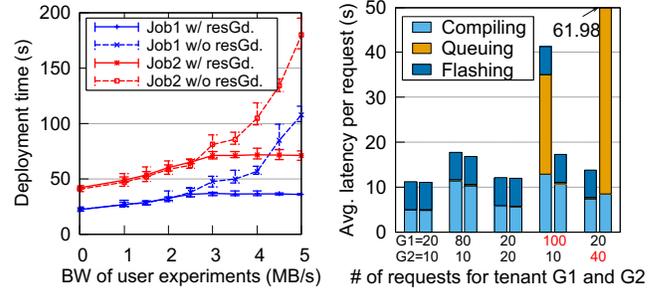

Figure 8: Provisioning time of new experiments when another experiment is running on the edge device with and without *resGuard*.

Figure 9: Average programming latency different concurrent request for tenant G1 (80 devices maximum) and G2 (20 devices maximum).

3MB/s bandwidth.

Effectiveness of multi-tenancy. To evaluate the effectiveness of multi-tenancy, we use 100 devices of LinkLab 2.0 and separate them into two tenants: G1 and G2. Then we emit concurrent requests on behalf of the two tenants in different distributions and record the latency per request of each stage in LinkLab 2.0. We set the device quota as: G1 has 80 devices and G2 has 20 devices. Figure 9 shows the results. We can observe that once the request number exceeds the device quota of the tenant (e.g., G1=100>80, G2=10<20), its per request latency increases greatly while the latency of the other tenant is not affected. Moreover, the increased time is mainly spent on waiting for allocation, which is a piece of direct evidence that the tenants would not preempt the resources of others.

5 Representative Use Cases

LinkLab 2.0 facilitates various new usages in addition to the basic wireless and embedded experiments supported by existing IoT testbeds [3, 7, 28, 57]. Furthermore, during the evolution of LinkLab 2.0, we extend it from an academic testbed to an innovative learning and examining platform for schools and individuals. We summarize the representative use cases of LinkLab 2.0 in Table 4 and Table 6 and will elaborate on both the research usages and outreaches in the rest of this section, respectively.

5.1 Supported Research Experiments

Potential research domains. We summarize the potential research domains that LinkLab 2.0 could support in Table 4. Besides traditional wireless and embedded experiments, researchers could conduct experiments with respect to serverless computing, edge AI and other research topics easily and holistically with the integrated architecture, heterogeneous devices and various deployment methods of LinkLab 2.0. Furthermore, with the involvement of edge and cloud, researchers could extend the networking protocol experiments to the IoT domain and obtain data from both the server and client.

While implementing all the research above is beyond the scope of this paper, we internally developed three represen-

tative experiments that could evaluate the functions and lead the further usage of LinkLab 2.0. Code and tutorials of these experiments are publicly available¹.

Experiment 1: Cloud-Edge-IoT integrated application.

We use a programming framework for smart spaces named dSpace [21] as an example to show the potential of LinkLab 2.0 for deploying cloud-edge-IoT integrated research.

Implementation. We directly deploy the open-source dSpace runtime [20] on the cloud. A home automation framework (Home Assistant in our implementation) is deployed on the edge to manage the IoT devices locally and provide device-controlling APIs for the dSpace runtime.

Findings. (1) The original version of dSpace only takes the COTS IoT devices into consideration. With the help of LinkLab 2.0, could explore a larger design space by obtaining more detailed data on network traffics and energy consumption by deploying instrumented codes on the prototyping devices of LinkLab 2.0. (2) The integrated architecture of cloud-edge-IoT and the docker/serverless-based programming approach of LinkLab 2.0 facilitate users to explore the "sweet spot", and this dSpace case is an ideal example. To be more specific, users could easily move the Home Assistant module between edge and cloud to evaluate the tradeoff between deploying the Home Assistant module on the edge (unreliable edge-cloud connection but shorter local control latency) and cloud (responsive device-controlling APIs but higher device control latency).

Experiment 2: Edge AI. Recently, Edge AI is recognized as one of the emerging technologies by Gartner [22] since

¹ <https://linklab.emnets.cn/tutorials>

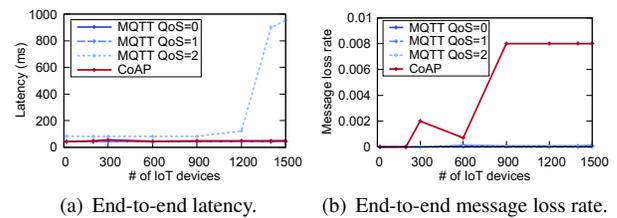

Figure 10: Collected performance of IoT protocols.

it could provide lower latency and better privacy for users. In order to illustrate how LinkLab 2.0 facilitates Edge AI experiments, we conducted an example experiment based on HRank [45] which prunes the AI model to make it feasible to be executed on the resource-constrained edge devices.

Implementation. For model pruning, HRank first generates the rank of each layer of the model by performing the training process with a very small portion of the dataset. Then, HRank prunes the less important filter by retraining the original model with the generated rank. With LinkLab 2.0, users could simply apply for an edge device, deploy the rank generation and pruning algorithm, and evaluate the accuracy degradation of inference with the serverless functions or native dockers. Table 5 shows the comparison of the execution time, model size and inference accuracy of HRank on heterogeneous edge devices, namely Xavier AGX (AGX for short) and Raspberry Pi (RPI for short).

Findings. (1) During our reproduction of HRank, we encountered an abnormal result. It is known that AGX’s CPU is more powerful than RPI’s, and AGX is also featured with a GPU-like accelerator. Nevertheless, the rank generation time on AGX is much longer than on RPI (see Table 5), which is unusual. After our investigation, we finally found the reason as follows. The HRank code leverages a GPU-based matrix algebra library named MAGMA to accelerate the rank generation, but it does not have an ARM distribution for AGX. Hence, on the AGX, HRank must move the intermediate variables during training from GPU to CPU to calculate rank and move back to the GPU, which leads to massive performance degradation. We attribute this interesting finding to LinkLab 2.0’s various and heterogeneous edge devices that could be used to obtain a

Table 6: Outreaches of LinkLab 2.0. Similar to Table 4, F1~F4 represent LinkLab’s features and S/D represent serverless/Docker.

more thorough view of the performance of the algorithms. (2) In addition to the above experiment, LinkLab 2.0 also allows users to build edge AI applications with the real-world sensing data which could be acquired from our IoT devices and test the performance brought by unstable wireless networks, which are currently not supported by other testbeds.

Experiment 3: Measurement of IoT protocols. Different from the dominance of HTTP for web applications, there is no unique protocol that could serve all the diverse application scenarios of IoT. Hence, conducting measurement studies on IoT protocols under different scenarios is worthwhile, especially before the actual deployment of IoT applications.

Implementation. As [59] illustrates, we compare the two most-used IoT protocols, MQTT and CoAP, using LinkLab 2.0. To make the measurement closer to the real-world application, we leverage the widely-used EMQX message broker on the cloud for both CoAP and MQTT. With respect to the clients, we develop the client based on libcoap and paho. Figure 10 shows the measured end-to-end latency (device-edge-cloud-device) and message loss rate against the increasing number of devices.

Findings. (1) By virtue of the LinkLab 2.0’s theoretically unlimited number of virtual IoT devices, users could easily simulate large-scale, real-world IoT applications to evaluate the performance of edge cases. (2) With the help of LinkLab 2.0’s bandwidth management, users could measure the performance of protocols under different network conditions.

5.2 Outreaches

We now report the three types of external users for non-academical usages as shown in Table 6.

Educational institutions. The most valued and long-acting outreach of LinkLab 2.0 is supporting the IoT programming practices of the relevant courses in schools, especially after the outbreak of the COVID-19 pandemic.

As shown in Table 4, the usage of LinkLab 2.0 covers regular IoT curriculum (E1) to fieldwork courses (E2). A and B are both technical colleges that teach students both theoretical expertise and practical skills, and students of these colleges mainly choose to serve the local economy for non-academic jobs after their graduation. To cope with this teaching objective, LinkLab 2.0 decides to establish a series of experiments to better train students from various knowledge and socioeconomic backgrounds ready for job markets.

(a) Online virtualization (b) Tabletop model (c) Tabletop schematics

Figure 11: Online-offline integrated smart elderly care education toolkit for College B.

We use our cooperation with college B, which is proficient in serving the local smart elderly care industry, to exemplify how LinkLab 2.0 works with the institutions and builds curricula for their students. To initialize the cooperation, we set up seminars with teachers in college B to introduce the functionalities of LinkLab 2.0 and co-create a basic version of the experiment series that fulfills the knowledge points of the courses. Then we support students for one semester’s usage, collect operational data for each experiment (e.g., average completion time, retry counts) and discuss again with the teachers to adjust the difficulty of each experiment or extend the experiments to cope with the changing demands of the job market. The above process is performed recursively in the last three academic years. Up to now, the outcome of our collaboration with College B includes (1) a set of lab experiments for the technical school students who major in IoT, and (2) an online/offline integrated education toolkit for smart elderly care (see Figure 11). The toolkit includes an offline tabletop model containing necessary sensors and actuators for students to realize their ideas on smart elderly care, as well as an online simulated environment to remotely test their programs in a visualized way with the identical program to the offline realization.

Furthermore, thanks to the cloud-native architecture, LinkLab 2.0 also jointly built an IoT laboratory (E3) with University C in a short time, which contains a cabinet of devices with LinkLab 2.0’s containerized management software pre-installed. This laboratory is used for the experiments, exams and research of all the IoT-related curricula in University C.

Commercial cooperation. LinkLab 2.0 also draws the attention from commercial institutions. LinkLab 2.0 facilitates an online IoT device playground named HaaS Lab (C1) for Merchant D, which releases a new IoT development board named HaaS (Hardware-as-a-Service). HaaS Lab allows users to try the features of the HaaS board online before buying it

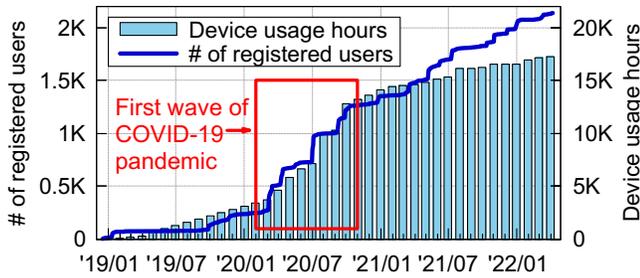

Figure 12: Illustration of the number of registered users and accumulated working hours of devices of LinkLab 2.0.

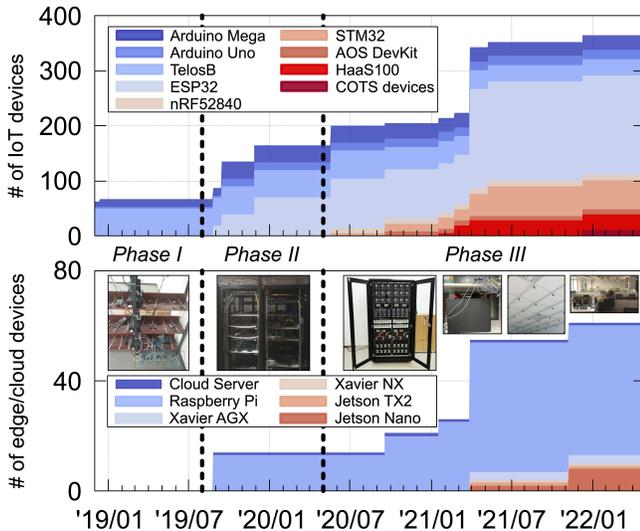

Figure 13: Evolution of LinkLab 2.0.

and Merchant D initiates HaaS Lab to promote its sale. Moreover, LinkLab 2.0 also supports an IoT engineer certification program (C2), which contains a qualifying exam and a lab exam, by creating a dedicated examination tenant.

Third-party individuals. There are 1,000+ *third-party individuals* that use LinkLab 2.0. According to the questionnaire we collected when users are registered, geek developers and self-learners take a large proportion of individual users. The geek developers use our testbed to prototype their new ideas without buying the actual hardware (T1), and the self-learners study rudimentary IoT developments (T2) with LinkLab 2.0.

6 Evolution and Lessons Learned

We are excited to see a broad use of LinkLab 2.0 in diverse scenarios since December 2018. Figure 12 illustrates the number of registered users and the device usage hours of LinkLab 2.0. We can see from the figure that LinkLab 2.0 has over 2,100 registered users and they have conducted 17,300 hours of experiments in total. We also noticed that during the first wave of the COVID-19 pandemic in the first half of 2020, both the new user registration and experiment hours of LinkLab 2.0 increased rapidly. Before January 2020, the concept of online education of IoT is not widely recognized

and most of the experiments are occasionally conducted for research purposes.

We have progressively extended the functionality of LinkLab 2.0 since its first public release. According to the different focuses of the LinkLab 2.0's development, we divide the four-year operation into three phases, as shown in Figure 13.

Phase I (2018/12~2019/8): IoT device testbed. In this phase, we focus on the basic building blocks of LinkLab 2.0 as an IoT device testbed, such as device management, on-line compiling, and the web-based programming interface. Because of the diversity of the IoT hardware used in IoT applications, we investigated popular online IoT forums and academic projects, then selected five far-reaching development boards that cover the mainstream IoT ISAs (i.e., ARM, AVR, MSP and Xtensa).

Phase II (2019/8~2020/5): Integration with cloud and edge. Based on our experience in IoT application development and the requests from LinkLab 2.0's user community, we realized that the cloud and edge were indispensable for a complete IoT application. Therefore, we started to bring cloud and edge devices to LinkLab 2.0 and refactored the management software to cope with this architectural change. In this phase, we continue to increase the number of IoT devices. To better cope with the community's demand and avoid the waste of investments, we leverage an expenditure utilization metric with the device usage per day and the cost of a device to assess how to allocate the purchase budget of hardware.

Phase III (2020/5~now): Cloud-native and multi-tenancy. Advancing to the third phase, we extended LinkLab 2.0 with Kubernetes-based scalability and multi-tenancy. Moreover, we continued to enrich the list of supported IoT devices in this phase, such as the nRF52840 and COTS IoT devices.

During this four-year evolution, we have learned a lot while developing and operating LinkLab 2.0 on a broad scale. Hence, we report five lessons learned as follows.

Lessons Learned ①: It is not easy to support heterogeneous devices for online experimentation. Before LinkLab 2.0, we experienced a smooth development process using a sensor network testbed with about 100 TelosB motes. However, it is not a plain sailing when we try to bring more heterogeneous IoT devices to LinkLab 2.0.

For example, ESP32 boards can not automatically enter the programming mode because the flashing signal issued by the uploading software is too short. We finally came up with the idea of adding a 10 μ F electrolytic capacitor to the EN port of ESP32 to lengthen the flashing signal, which works properly. Unfortunately, we failed to attach some boards that need to manually switch to the programming mode or restart the device by pushing an on-device button (e.g., TI CC2650 DK and HiSilicon Hi3861). This manual intervention leads to the human-in-the-loop problem and does not conform to the design principle of LinkLab 2.0.

According to our operational experience, we summarize a *checklist on what device could be attached*, which is: the

devices (1) do not need a manual restart, (2) owns the interface to get operational logs, and (3) support compilation and upload via a command-line interface. We believe this checklist is favorable for the operators of existing or blueprinting testbeds that use IoT devices, and the researchers that intend to conduct large-scale experiments automatically.

Lessons Learned ②: It is difficult but important to support CI/CD (continuous integration/deployment) as well as online monitoring for providing 24/7 continuous services. We planned to adopt the CI/CD process at the beginning of developing LinkLab 2.0. However, building a proper testing environment for CI/CD is challenging for LinkLab 2.0. Specifically, a complete testing environment of LinkLab 2.0 includes various devices and cloud servers with the proper software. It is not easy to build such an environment for each developer, especially those who worked remotely in a different city during the pandemic. Therefore, CI/CD was not supported in LinkLab 2.0 during Phase I. However, after experiencing problems like software incompatibilities and devices offline, we added CI/CD support to LinkLab 2.0 in Phase II.

Specifically, we set up a testing environment with dedicated cloud servers and a representative subset of devices for CI/CD. Note that compared with the cloud servers, the IoT/edge devices are much more problematic. Therefore, using a subset of operating devices instead of using dedicated testing devices can significantly increase the similarity between the testing environment and the operating environment. To further avoid the interference of automatic testing to the operating devices, a device will only be selected to act as a testing device without any adjacent tasks.

Even with CI/CD, online monitoring is also important for quality assurance. Device malfunctioning, wireless connection instabilities, and bursty usages are inevitable for an IoT testbed. Hence, LinkLab 2.0 performs online monitoring for all its software components and devices constantly. In case of any problems, alerts will be sent to maintainers automatically.

Lessons Learned ③: Cloud-native is not optional, but necessary. As shown in Figure 12, the number of LinkLab 2.0's users surges during the COVID-19 pandemic. Without the containerized architecture, resource management became painful due to the busy usages (e.g., concurrent experiments of a class of students) and various QoE requirements (e.g., time constraints for online exams). Table 4 gives such examples including classes (E1) and exams (C2). Therefore, during Phase III, LinkLab 2.0 became fully cloud-native by containerizing all services and using Kubernetes for on-demand auto-scaling, service provisioning, etc.

An unexpected benefit of becoming cloud-native is that it is one of the necessities to support multi-tenancy. After using LinkLab 2.0 for experiments or teaching, some users started to ask for dedicated devices instead of shared ones, for performance and privacy considerations. Therefore, we extended LinkLab 2.0 to support multi-tenancy (e.g., E3 and C1 in Table 4 are two typical tenants), which was straightfor-

ward with cloud-native. With multi-tenancy, we could divide a certain proportion of services and devices into a dedicated tenant to meet various requirements of the usage scenarios.

Lessons Learned ④: Incorporating open-source projects can not always accelerate the development process. LinkLab 2.0 builds on top of a large body of open-source projects, such as the Kubernetes for service management and EMQX for message dispatch. However, open-source software is not always ready for out-of-the-box usage, and an active community is profoundly important. For example, we build our web-based IDE based on Eclipse Theia [19], but we have to extend it for interacting with remote IoT devices and many other features, which means massive modifications. With an active community like Theia's, some of the modifications may be inspired by the existing discussions or solved by submitting issues. Unluckily, some modifications are unprecedented to the community and should be conducted by a developer who knows this open-source project well. Nevertheless, gigantic projects like Theia are too complicated to know everything about, especially for student developers.

Lessons Learned ⑤: Plan for obsolescence. For a long-term project, the availability of underlying open-source software could change unexpectedly. The first example is an IoT OS named AliOS Things gives up the support of ESP32, STM32 and other boards after a version iteration due to their adjustment of commercial strategy. To make things worse, they also stopped the maintenance of the compilation toolchain for the old version, which influences LinkLab 2.0's online compilation and flashing service. To this end, we managed to rebuild the obsolete tools with public documentation and older versions, which costs much labor work. The second one is the API obsolescence in open-source projects, which occurs when we update Theia from v0.8 to v1.1. After the update, most of our WebIDE components work improperly. Afterward, we check our entire code base for external dependencies, persist the current version to avoid the discontinuance impact, and be cautious when adopting newer versions.

Hence, according to the above five lessons learned, our suggestions for future testbed stakeholders are four-fold. (1) The devices which satisfy the checklist in lessons learned 1 are easier to attach into the testbed. (2) Take fully advantages of the cloud-native micro-service software architecture to better cope with bursty requests and minimize the maintenance overhead. (3) Try to incorporate the open-source software which owns an active community and has been tested by time. (4) Always remember to leave a copy of external resources such as compiling tools to avoid the obsolescence.

7 Future Directions

In this section, we envision the potential future directions and our plans for Phase IV of LinkLab 2.0.

Firstly, we plan to attach more types of devices in LinkLab 2.0. Recently, more kinds of heterogeneous devices are used in edge computing scenario. For example, the FPGA-based edge devices are widely used [68, 70] because they

exhibit excellent performance on accelerating specific tasks while keeping high energy efficiency. However, FPGA devices have limited support for multi-tenancy, which is a key feature of LinkLab 2.0. We plan to borrow the partial reconfiguration approach [33] to provide concurrent programming support and design a shim [16] for our LDC client to manage the FPGAs. Another important group of devices are the boards featured with the trusted execution environment (TEE) such as Arm Trustzone [8]. Such devices are used for secure AI model training [52], sensor data collection [48, 58], etc. Nevertheless, developing a TEE-based application is different from existing development process because it requires to develop the trusted and untrusted part of the application separately and deploy them individually. Hence, we plan to embrace the new programming pattern of TEE-based applications and attach more devices facilitated with TEE to serve a broader research community.

Secondly, we also consider improving the granularity and performance of our monitoring system as the next milestone of LinkLab 2.0. As the number of supported devices and core services grow continuously, configuring our monitoring system becomes more difficult and requires more human-on-the-loop efforts. This is mainly because the current metrics-based and log-based monitoring system is not fine-grained enough to track the micro-service invocation of each request. Recently, the micro-service observability based on eBPF (extended Berkeley Packet Filter) is widely studied both in academia and industry [10, 12, 46]. It can provide more fine-grained monitoring by leveraging user-space programmable kernel extensions. Hence, we plan to incorporate eBPF with our monitoring system to achieve more fine-grained and low-overhead anomaly detection.

8 Related Work

With the proliferation of IoT technology, applications and research of IoT grow rapidly. Several testbeds are proposed to ease IoT research and application developments.

Device-edge/cloud integrated testbeds. FIT IoT Lab testbed [1], proposed by the FIT consortium, is a large-scale wireless sensor network testbed deployed across France. Except for the full programmability of the sensor devices, FIT IoT Lab also provides researchers with energy monitoring and network sniffing infrastructure to obtain the experiment data from multiple perspectives. Another testbed that consists of experiments for both edge/cloud and IoT devices is COSMOS [56], deployed in New York. COSMOS focuses on supporting the experiments of advanced wireless technologies such as mmWave and dynamic spectrum sharing.

LinkLab 2.0 differs from the above testbeds which also include the programmability on both IoT and cloud/edge devices in the following: (1) LinkLab 2.0 is the only testbed that supports the one-site development for IoT, edge and cloud. (2) For edge/cloud experiments, existing testbeds only provide bare-metal development, while LinkLab 2.0 supports both Docker- and serverless-based development. The above two

differences accelerate the experiment setup process for the users of LinkLab 2.0.

IoT and sensor network testbeds. MoteLab [67] is a wireless sensor network testbed maintained by Harvard University. MoteLab includes 30 MicaZ motes and a web interface. Indriya2 [7] is a sensor network testbed with 41 TelosBs and 17 CC2650 sensortags that enables users to upload the executable, monitor the outputs of the devices and obtain data from the database. SmartSantander [57] is a city-scale testbed containing thousands of sensors with IEEE 802.15.4 or RFID connections that deploy across Santander city. Users could both work with the sensing data and program the sensors with executables to for their experiments. GioTTO [3, 4, 66] is a campus-scale sensor testbed deployed at scale on the UCSD and CMU campuses across several buildings. With the data accessing APIs and the machine learning layer of GioTTO, users could build intelligent inference applications without writing much code.

Compared with these testbeds, LinkLab 2.0 proposes a novel multi-tiered architecture for managing and controlling IoT devices to achieve high deployment extensibility. Furthermore, LinkLab 2.0 leverages the containerized management services for elastic scaling to enable the concurrent experimentation of multiple users.

9 Concluding Remarks

We introduce LinkLab 2.0, a fully programmable testbed that facilitates the integrated experiment with IoT devices, edge devices and the cloud infrastructures. LinkLab 2.0 achieves multi-tenancy and scalability by leveraging the container-based architecture and the auto-scaling technique of Kubernetes. Moreover, our multi-level monitoring system ensures the 24/7 availability for both the hardware infrastructure and software services. Since its public availability in December 2018, LinkLab 2.0 has supported over 17,000 submissions of experiments from 2,100+ users, and the accumulated usage time across all the devices exceeds 17,000 hours. From the four-year operational experience of LinkLab 2.0 for academia and education, we summarize five key observations and lessons learned concerning the device support, CI/CD process and open-source projects adoption, which we believe is favorable for other projects and testbeds requiring the integration of cloud, edge and IoT.

Push-Button Reliability Testing for Cloud-Backed Applications with Rainmaker

Yinfang Chen, Xudong Sun, Suman Nath[†], Ze Yang, Tianyin Xu

University of Illinois at Urbana-Champaign [†]Microsoft Research

Abstract

Modern applications have been emerging towards a cloud-based programming model where applications depend on cloud services for various functionalities. Such “cloud native” practice greatly simplifies application deployment and realizes cloud benefits (e.g., availability). Meanwhile, it imposes emerging reliability challenges for addressing fault models of the opaque cloud and less predictable Internet connections.

In this paper, we discuss these reliability challenges. We develop a taxonomy of bugs that render cloud-backed applications vulnerable to common transient faults. We show that (mis)handling transient error(s) of even one REST call interaction can adversely affect application correctness.

We take a first step to address the challenges by building a “push-button” reliability testing tool named Rainmaker, as a basic SDK utility for any cloud-backed application. Rainmaker helps developers anticipate the myriad of errors under the cloud-based fault model, without a need to write new policies, oracles, or test cases. Rainmaker directly works with existing test suites and is a plug-and-play tool for existing test environments. Rainmaker injects faults in the interactions between the application and cloud services. It does so at the REST layer, and thus is transparent to applications under test. More importantly, it encodes automatic fault injection policies to cover the various taxonomized bug patterns, and automatic oracles that embrace existing in-house software tests. To date, Rainmaker has detected 73 bugs (55 confirmed and 51 fixed) in 11 popular cloud-backed applications.

1 Introduction

Modern applications have been emerging towards a cloud-based programming model where applications depend on cloud services for various functionalities. Such “cloud native” practice greatly simplifies application development and deployment, and realizes cloud benefits (e.g., scalability, availability, and cost efficiency). Today, all major cloud providers offer various cloud services to support cloud-based programming, e.g., storage, database, and machine learning [5, 10, 14]. These cloud services have been increasingly adopted, e.g., the .NET SDK of Azure Storage services has tens of thousands of daily downloads [70]. We term the applications that rely on cloud services *cloud-backed applications*.

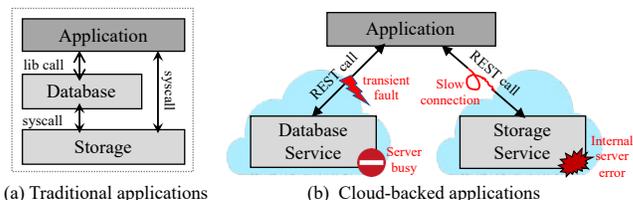

Figure 1: Fault domains of (a) traditional applications and (b) cloud-backed applications (the subjects of this paper).

Cloud-backed applications interact with one or more cloud services, usually through REST APIs over HTTP/HTTPS. To ease programming, cloud providers typically offer SDKs on top of the REST APIs to support applications written in different programming languages. For example, AWS provides SDKs in 12 languages, such as .NET, Java, Python, and C++.

Despite the attractive benefits, cloud-based programming imposes emerging reliability challenges introduced by the fault models of opaque cloud backends and less predictable connections between the application and cloud services. Figure 1 compares the fault model of cloud-backed applications with traditional applications backed by local services. Unlike traditional applications that have simple, shared fault domains as the system services with well-specified APIs (e.g., POSIX), the fault domains of cloud-backed applications are more heterogenous, unpredictable, and opaque. It is reported that cloud-backed applications commonly experience transient errors and network delays [22, 42, 81, 88].

In this paper, we unravel the reliability challenges faced by cloud-backed applications. We show that there is a lack of standards and consistencies of existing cloud services on what errors are communicated by cloud service APIs, and how SDKs handle the errors. As a consequence, it is challenging for application developers to anticipate and correctly handle myriad faults that could occur during the application’s interaction with the cloud services, resulting in critical bugs. For example, many SDKs employ automatic retries to handle transient errors; however, retries on non-idempotent APIs, if not done correctly, could result in elusive behavior, such as silent semantic violations and unhandled exceptions (see §3).

Contributions. We take a first step to address the emerging reliability challenges by building a “push-button” reliability testing tool named Rainmaker, as a basic SDK utility for any cloud-backed application. Rainmaker helps developers

easily and *systematically* test their applications' correctness, in the face of various errors under the cloud-based fault model. Rainmaker does not need developers to write policies, oracles, or test cases. It directly works with existing test suites and is a plug-and-play tool for existing test environments. Rainmaker is generic to any type of cloud-backed applications.

Designing Rainmaker is challenging. Despite the rich literature on fault injection techniques and error-handling analysis (see §7), we find that no technique can support a push-button solution for cloud-backed applications. Many existing tools provide only the basic randomized fault injection policies and basic crash oracles [6, 37, 47] that can miss critical bugs, and application-specific techniques are not widely applicable (e.g., checking data consistency for databases [16, 52] and file systems [20, 69]). Techniques that address program faults (exceptions and `errno`) and component faults (e.g., node crashes) are too coarse-grained to capture the nuances of complex interactions between the application and cloud services.

Rainmaker puts its focus on *transient* errors faced by cloud-backed applications. Basically, Rainmaker injects transient faults (e.g., temporary service unavailability and request timeouts) by intercepting outbound REST API calls from the application to the cloud service at the HTTP layer. HTTP-layer interception makes it easy to capture fine-grained interactions (including those triggered by SDK-level retries) and is transparent to applications under test. Hence, Rainmaker requires no modification of application source code and can be directly applied to an existing test environment.

A key component of Rainmaker is its *automatic* fault injection policies that define 1) *what* faults to inject and 2) *where* (e.g., at which REST calls) to inject faults. The former determines the effectiveness and validity of the injected faults, while the latter also affects test efficiency. Rainmaker's fault injection policies are guided by a bug taxonomy we developed to describe how error handling could go wrong under the cloud-based fault model. The taxonomy is simple: it considers transient error(s) that can occur during *one* REST API call initiated by the application (and the corresponding retries by the SDK); yet, it captures common bug patterns and shows that error (mis)handling of even one REST call can have major impacts on application correctness. Rainmaker uses a small set of injections to cover all taxonomized bug patterns.

Rainmaker also enables efficient testing to achieve high testing coverage with a small number of test runs. Rainmaker employs automatic dynamic instrumentation to record the application's calling context of each REST API call and to inject call-site information in the HTTP header of outgoing requests; Rainmaker's HTTP-layer fault injection uses the information to selectively inject faults based on a desired code coverage metric. The calling context also enables Rainmaker to build diagnosis support to help developers debug application behavior under fault injection (when a bug is detected).

Finally, Rainmaker includes automatic oracles to flag a fault-injection test outcome as a likely bug, with low false pos-

itives. The oracles utilize exceptions and assertions of existing software tests. For exceptions, Rainmaker does not naïvely report any exception that fails a test as a bug, but checks whether the exception is consistent with the injected fault—an inconsistent exception indicates that the fault was handled intentionally, but inappropriately (at least insufficiently).

Key results. We have implemented Rainmaker for .NET applications. Rainmaker supports a number of cloud services: Azure Storage (including Blob Storage [7], Queue Storage [11], and Table Storage [12]), Azure CosmosDB [9], AWS Simple Storage (S3) [1], and AWS Simple Queue (SQS) [4]. Supporting a new cloud service only takes the configuration of the SDK API namespace and the request-ID tag. Rainmaker is fully transparent to the application under test. We evaluate Rainmaker with 11 popular .NET applications that use the supported cloud services. Rainmaker found 73 new bugs in total, among which 55 have been confirmed, and 51 have been fixed (after we reported them). Many of the bugs have severe consequences, such as unexpected application termination, data loss/inaccessibility, and resource leaks. Rainmaker's test oracles are mostly accurate, with a very low false-positive rate (1.96%), making its test results trustworthy.

Summary. The paper makes the following contributions:

- We unravel emerging reliability challenges of cloud-based programming, faced by cloud-backed applications, under the existing design of cloud service APIs and SDKs;
- We present a taxonomy to systematically understand error-handling bugs that render cloud-backed applications vulnerable to transient errors under the cloud-based fault model;
- We develop Rainmaker, the first push-button reliability testing technique for cloud-backed applications, which can effectively and efficiently detect bugs of myriad patterns;
- We have made Rainmaker publicly available at <https://github.com/xlab-uiuc/rainmaker>, with instructions to reproduce all discovered bugs.

2 Background and Motivation

We discuss the emerging reliability challenges faced by cloud-backed applications as the background and motivation of our work. Ideally, cloud-based programming should *not* be different from traditional application programming using native libraries. Unfortunately, as we will show in this section, this is rarely the case in practice—handling errors under the cloud-based fault model is challenging and error-prone.

2.1 Errors in Cloud-backed Applications

There are three key components related to how cloud service related errors are exposed to the applications.

Error responses from cloud services. A request from the application can fail due to a client-side error (e.g., local network timeout) or a service-side error (e.g., temporary service

SDK	Retry (HTTP Status Codes)	(API)	Notes
Azure Storage (Blob/Queue/Table)	408, 429, 500, 502, 503, 504	Any	Only 429 and 503 are retried before v12.3.0
Azure CosmosDB (HTTP mode)	403, 404, 408, 503	Read	Only enabled for multi-region (no retry for single-region)
AWS S3 / AWS SQS	500, 502, 503, 504	Any	Inconsistencies in different lang. SDKs (e.g., Java versus .NET)

Table 1: The retry policies of different cloud services. Besides the HTTP status codes, SDKs could also retry on error messages, e.g., the Azure Storage SDK also retries on messages including `InternalServerError`, `OperationTimedOut`, and `ServerBusy`.

unavailability). In the latter case, the service returns an error response indicating the error type. Most cloud services are RESTful, and their APIs reuse HTTP response status codes defined by the HTTP/1.1 standard. HTTP status codes 4XX and 5XX indicate “client errors” and “server errors” respectively. In addition, a cloud service can include service-specific error codes in response payload to indicate fine-grained error types. For example, Azure Blob Storage can return 44 different error codes (e.g., `BlobImmutableDueToPolicy` and `BlobAlreadyExists`) with the same HTTP status code 409 (`Conflict`) [8]. The practice is also used by other cloud services, e.g., CosmosDB [15], S3 [3], and SQS [2]. Applications use these codes to understand the nature of the errors and take error-handling actions accordingly.

Retry on transient errors. When a request fails due to a *transient* client- or service-side error (e.g., network timeout and server overload), an application may retry the request, hoping that it would eventually succeed. Cloud-backed applications mostly use the SDKs provided by the cloud service providers to interact with the cloud services. Besides offering easy-to-use, expressive APIs, SDKs also include error handling logic with the goal of providing a native programming experience. For example, when a REST API call to a cloud service fails due to a transient error, the SDK tries to mask the error from the application by retrying the request [67].

Propagating errors up to the application. If the retry efforts fail or if the error is of a *permanent* type, the SDK propagates the error up to the application in a way that is consistent with a native programming experience. For example, .NET and Java SDKs propagate errors to applications as exceptions.

2.2 Emerging Reliability Challenges

2.2.1 A lack of standards and consistencies

Our analysis of multiple cloud service APIs and SDKs from Azure and AWS reveals a lack of standards and behavior consistencies in all three components above, across cloud services and SDKs from the same/different cloud providers.

Unanticipated errors. We observe many undocumented and inconsistent error codes returned by cloud services. For example, as of September 2022, common HTTP error codes such as 408 (`RequestTimeout`) and 429 (`TooManyRequests`) that can be returned by Azure Table Storage [78] are absent from its official documentation [66]. We also observe that the same error can be represented by different error codes across services. For example, Azure Queue Storage represents the error

`QueueNotFound` by the code 404, while AWS SQS uses the code 400 for the same error. We even reported and fixed multiple typos in error messages in Azure Storage SDKs.

Second, whether an error will be masked by the SDK (with retries) and whether an error will be propagated to an application vary widely across different services, different versions of the same service, and different language support of the same version. Table 1 shows that SDKs of different cloud services implement different retry policies. Azure Storage .NET SDKs before v12.3.0 only retry on error codes 429 and 503; the later versions add retry for 408, 500, 502, and 504 [28]. The .NET SDK for AWS retries on `LimitExceededException`, but the Java SDK does not. Finally, whether an error is propagated to the application varies even across SDKs from the same provider. The `DeleteMessage` API of Azure Queue propagates an exception to the application when a 404 is returned by the service. On the other hand, the `DeleteEntityAsync` API of Azure Table silently ignores 404 errors and returns success.

The inconsistencies make it hard for developers to anticipate whether a cloud service will return a specific error and whether the SDK will propagate it to the application.

Note that, unlike libraries and system services for traditional applications, a cloud service neither is a part of the application nor has standard APIs such as POSIX.

Retry and non-idempotent APIs. While retry is a common practice to mask transient errors, the retry may introduce subtle errors. In particular, a retry on a non-idempotent cloud service API can cause elusive effects, such as remote data corruption, which can remain latent or lead to additional errors (more details in §3). However, we observe that each service implements different retry logic, with no standard practice or discipline. As a result, the semantic of SDK APIs, under error conditions, is often opaque and inconsistent.

2.2.2 Rarity and large space of faults

Developers often miss error-handling bugs with small-scale, short-duration functional tests because cloud-based faults, which could expose such bugs, are rare. Fault-injection tools allow developers to simulate error scenarios during testing. However, although it is not hard to implement fault-injection mechanisms [35, 44], the key challenges lie in specifying *policies* about what faults to inject, where and when to inject them, and *oracles* about what post-fault conditions indicate a likely bug for developers to inspect. The space of possible fault policies and oracles is large, if not infinite.

2.3 Our Goal

Our goal is to address the emerging reliability challenges faced by cloud-backed applications by (1) systematically understanding the bug patterns, and (2) building practical tooling to systematically test whether a cloud-backed application can correctly handle the myriad errors that may happen during interactions with the cloud services it depends on. We emphasize a “push-button” technique that can be directly used by application developers in an existing testing environment, without the need of writing additional code or configurations.

3 Bug Taxonomy

To systematically understand the patterns of error handling bugs of cloud-backed applications and to guide the design of the Rainmaker tool, we develop a bug taxonomy to describe how error handling could go wrong under the cloud-based fault model. Figure 2 depicts the bug taxonomy as a tree. An important trait is that the taxonomy considers transient error(s) that occurred during *one* REST API call interaction initiated by the application. It does not reason about multiple independent REST API calls.

3.1 No Error Handling

In this pattern, the application simply does not handle certain transient errors. This can happen due to the inconsistencies mentioned in §2.2.1. An application may not anticipate a cloud service to return a specific error or may mistakenly expect the SDK to mask a known transient error. For example, an application using Azure Storage’s .NET SDKs before v12.3.0, which do not retry on certain transient error codes, may mistakenly assume that *all* transient errors are masked by the SDK and hence not handle them. As a result, some transient error from the cloud service can lead to application crashes or other undesirable behavior.

3.2 Throwing Unrelated Exceptions

In this pattern, (mis)handling of an error results in a new unhandled error that is usually *unrelated* to the root-cause fault. A common example of this pattern involves request retries. When a request to a cloud service fails with a timeout, the SDK or the application cannot determine whether the timeout happened on the request path or on the response path. SDKs commonly treat timeout as a transient failure and retry. However, if the timeout happened on the response path (in which case, the original request was executed by the service successfully), the retry can fail with a new error (different from the original error) since the original request has invalidated the precondition of the retry. This new error, if not handled properly, can lead to undesirable effects.

Figure 3 shows an example of such bugs [32] detected by Rainmaker in Microsoft BotBuilder [17]. BotBuilder stores logs in the Azure Blob Storage service. Each log operation

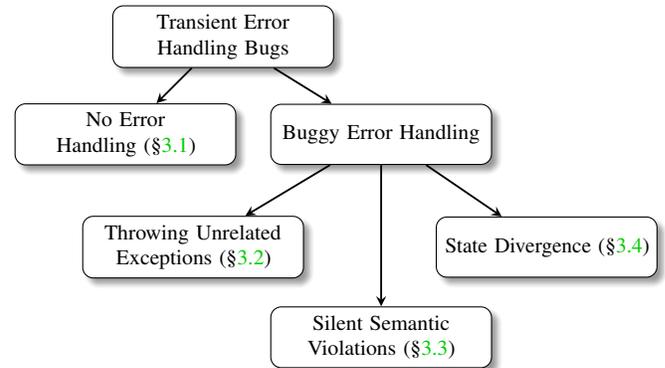

Figure 2: Taxonomy of error handling bugs in cloud-backed applications. The taxonomy addresses the handling logic of transient error(s) that occurred during the interaction of one REST API call.

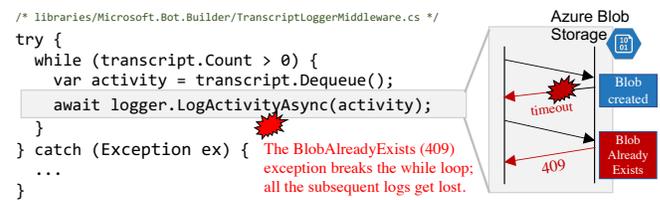

Figure 3: A bug of throwing unrelated exceptions in Microsoft BotBuilder detected by Rainmaker (confirmed and fixed). The Azure Storage SDK automatically retries on timeouts, which returns a 409 error because its precondition is invalidated by the first request.

calls an SDK API to create a new blob. If the API call successfully creates the blob, but the response times out, the Azure Storage SDK automatically retries the request (§2). However, since the blob has already been created by the first request, the retry operation fails with a 409 (BlobAlreadyExists) error. The SDK propagates this *permanent* error to the application. BotBuilder does not anticipate or handle the error. This breaks the execution of a loop that is supposed to upload a list of logs to the Blob Storage service, resulting in a loss of subsequent log data. Note that the exception seen by the application is unrelated to the root cause (a transient timeout).

In the next two categories, the buggy error handling does not immediately throw an exception. Rather, it causes unexpected (local or remote) state changes that may cause visible symptoms (e.g., exceptions) during subsequent execution.

3.3 Silent Semantic Violations

In this pattern, mishandling of a transient error causes semantic violations of the REST API specification, without observable symptoms. The REST call returns successfully, and hence the application executes in a happy path. However, the silent semantic violation may eventually result in data loss/corruption, or other incorrect application behavior. One common example of this pattern is manifested by a similar root cause as the one in §3.2: response timeout. Differently,

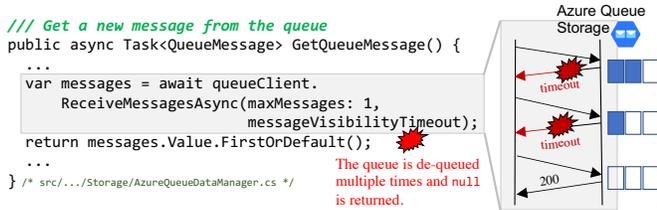

Figure 4: A silent semantic violation bug in Microsoft Orleans detected by Rainmaker. Azure Storage SDK automatically retries multiple times on timeouts, and mistakenly empties the queue.

in this pattern, the retry operation succeeds, and the SDK successfully hides the transient error from the application.

Figure 4 shows a silent semantic violation [71] detected by Rainmaker in Microsoft Orleans [13]. Orleans uses Azure Queue Storage service to manage messages. It implements a method `GetQueueMessage()` to dequeue one message from the queue. As shown in Figure 4, the method calls the SDK API `ReceiveMessagesAsync` to dequeue a message from the remote service. The corresponding HTTP request is non-idempotent and should not be naïvely retried [76], because each retry changes the contents of the queue. However, the SDK API automatically retries the request on a transient fault. If a request successfully dequeues a message but its response times out, the SDK retries the request multiple times, each of which, if successful, can dequeue a message. If the last retry/response succeeds, the API successfully returns the message. The application does not handle this corner case, even though the API documentation mentions it. Such behavior violates the semantic of the `GetQueueMessage()` API which is documented to only “get a message from the queue” [62]. In fact, repeated retries can dequeue all the messages from the queue, in which case the SDK API returns `null`; Orleans does not expect such behavior and would dereference the `null` pointer and crash. Note that `ReceiveMessagesAsync` is not the only method that has such behavior. If we replace it with `SendMessageAsync`, the above example can enqueue more messages than expected, which may lead to silent resource leaks on the cloud service. Such silent semantic violations are hard for application developers to fix or even detect, as the retries are done by the SDK and are agnostic to the application.

3.4 State Divergence

In this pattern, a mishandled transient error leads to divergence of the local state (in the application) and the remote state (in the cloud service). There is no API semantic violation as in §3.3, but the state divergence could lead to undesired application behavior, e.g., exceptions and resource leaks.

State divergence can happen when an application *optimistically* updates a local state that is correlated with the success of a cloud API call made after the update. The bug manifests if a transient fault fails the request (so no change on the cloud side), but the application does not restore the optimistic up-

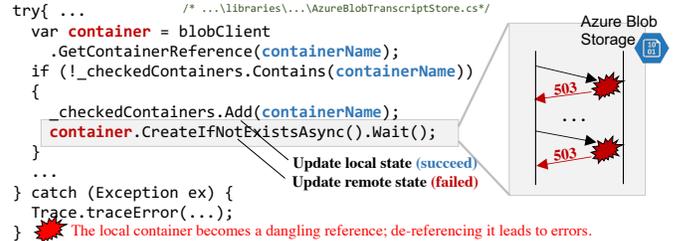

Figure 5: A local-state divergence bug in Microsoft BotBuilder detected by Rainmaker (confirmed and fixed). Azure Storage SDK automatically retries multiple times (for 503).

date. The updated state makes the application behave as if the REST API call succeeded, while it actually failed.

Figure 5 shows a state-divergence bug [30] from Microsoft BotBuilder [17] detected by Rainmaker. BotBuilder uses Azure Blob Storage to store blob data which is organized into containers. To create a container, BotBuilder calls REST API `CreateBlobContainer`. When transient errors (e.g., 503 ServerBusy errors) occur on the request path of a `CreateBlobContainer` call, BotBuilder swallows the exception in the catch block. However, BotBuilder adds the container into its local state of created containers *before* calling `CreateBlobContainer`. As a result, the local state is corrupted with a dangling container pointer, which leads to crashes when BotBuilder dereferences the pointer (e.g., with a list operation). The bug has the same essence as file system bugs that violate update dependencies [39]. On the other hand, transient errors are likely more frequent than file system crashes.

State divergence can also happen when a request changes the remote state, but the application is unaware of the change. Such bugs can manifest when a transient fault breaks the *return path* of a REST call that has changed the remote state. If not handled correctly, the application would assume the call never succeeded, leading to inconsistencies of states.

4 Rainmaker

4.1 Overview

Rainmaker is a “push-button” reliability testing tool for applications that use RESTful cloud services, such as Azure Storage, Azure CosmosDB, and AWS S3. It checks whether the application under test can correctly tolerate or handle common transient errors under the cloud-based fault model (e.g., temporary service unavailability and request timeouts), and detects bugs like the ones described in §3. Its “push-button” nature comes from the automatic fault-injection policies (§4.2) and oracles (§4.3), which are generic and applicable to any application that uses the supported cloud services.

A developer can directly apply Rainmaker as a “plugin-and-play” tool to their existing test suites in their existing testing environments, without writing additional code or configurations. The plugin-and-play nature is achieved by its fault

injection mechanism—Rainmaker injects errors by intercepting outbound REST API calls made by the application to the cloud service at the HTTP layer. It includes a standalone HTTP proxy component to do the interception. For example, to inject a 5XX error on the request path of a REST call, the proxy blocks the request from reaching the service and responds with an HTTP response containing the 5XX error code. To inject a timeout on the response path, the proxy lets the request go to the service; however, on receiving the response, it introduces a delay to force a timeout at the application.

Compared with injecting faults directly into application code (e.g., in the forms of exceptions), intercepting at the HTTP layer brings a number of technical benefits: 1) it allows intercepting *fine-grained* REST calls made by the application, including those triggered by SDK retries. As we discussed in §3, injecting errors into retry requests and responses is crucial for exposing certain categories of bugs; 2) error handling in cloud-backed applications depends on not only exception types but also HTTP status codes; 3) it makes the fault injection mechanism transparent to the application under test and work irrespective of the application language and architecture; 4) HTTP requests/responses are highly interpretable, and errors can be uniformly injected by manipulating HTTP responses, with no need to understand external dependencies (e.g., complex exception objects with multiple fields).

Usage. Rainmaker takes as input an existing testing suite that uses RESTful cloud services such as Azure Storage services or their emulators [68], and a desired coverage metric (§4.2.2). Rainmaker first installs a local HTTP proxy that can intercept and manipulate HTTP traffic to and from cloud services (or their emulators). It then selects and executes a minimal set of tests required to achieve the target coverage. As tests are executed, Rainmaker injects faults into their REST API calls according to automatic fault-injection policies. After each test is executed, Rainmaker’s oracles analyze the test outcomes and raise alerts as potential bugs are detected.

We envision Rainmaker to be a standard, widely-used testing utility as a part of cloud service SDKs.

4.2 Fault Injection Policy

A fault injection policy specifies *what* faults to inject and *where* (at which REST API calls) to inject them. Rainmaker’s fault injection policies are designed with two main objectives.

First, the policies should be *effective*. This requires them to 1) inject only *valid* faults and 2) cover the myriad bug patterns of the taxonomy (§3). One common policy is *randomized* fault injection (e.g., selecting a random fault at a random REST call). However, randomized injection can hardly be effective. As shown in §3, to expose certain bug patterns needs multiple specific faults injected along the interaction of a REST API call—randomized injection is unlikely to hit the specifics. In fact, randomized injection cannot even guarantee valid faults. For example, returning a 503 (ServiceUnavailable)

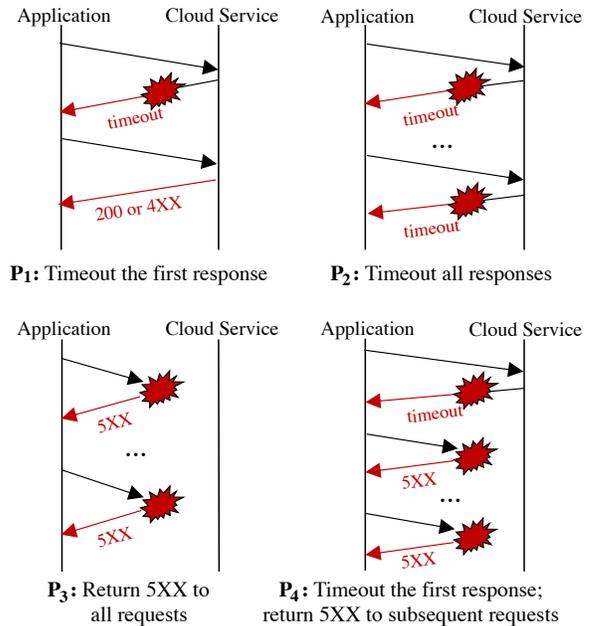

Figure 6: Fault injection policies of Rainmaker that cover all the bug patterns in our taxonomy (see Table 2). Arrows represent HTTP requests and responses for a *single* REST call (and retries). 5XX represents an error code for transient service-side failure. For a REST call with no retry, the four policies are reduced to two.

error after a write request is successfully executed is invalid, because this is inconsistent with the cloud service contract.¹

Second, the policies should enable *efficient* testing—achieving high testing coverage with a small number of test runs. Exhaustively injecting all possible faults at every REST call could be prohibitively expensive, because one test could issue thousands of REST API calls (see §5.3), and many different faults are possible for each call. This is further aggravated by the fact that each fault injection may require a separate test run because injecting the first fault might disrupt a test’s subsequent execution.

We next discuss how Rainmaker achieves the two objectives in §4.2.1 and §4.2.2, respectively. Note that Rainmaker can be easily extended to support new policies.

4.2.1 What faults to inject (for a REST API call)?

Rainmaker injects transient faults that occur during the interaction of one REST API call, following the taxonomy in §3. However, the fault space is large even for a single REST call. This is because each of the large number of possible faults may occur on the request or the response path of the original request or subsequent retries issued by the SDK. Interestingly, we find that a small set of four policies (Figure 6) are sufficient to cover the taxonomized bug patterns, as shown in Table 2. For REST calls that do not retry, the four policies are

¹In practice, a cloud service backend can have bugs to return such an inconsistent response [23]. However, we do not consider buggy cloud services.

Bug Pattern	Fault Injection Policies
No error handling	P ₁ , P ₂ , P ₃ , P ₄
Throwing unrelated exception	P ₁
Silent semantic violation	P ₁ , P ₂
State divergence	P ₁ , P ₂ , P ₃ , P ₄

Table 2: The mapping from the bug patterns and the error injection policies that can potentially expose each bug pattern.

reduced to two: 1) return a transient error code to the request, and 2) timeout the response. The four policies are:

- **P₁** (Timeout the first response). This policy forces a retry that can expose bugs related to invalidated preconditions. Since the timeout is at the response path after the request takes effect at the cloud service, the retry could trigger bugs of throwing unrelated exceptions, silent semantic violation, and/or state divergence, depending on the REST API semantics and the handling logic.
- **P₂** (Timeout all responses). This policy presents an entirely timed-out REST call to the application, while the REST call has taken effects (potentially multiple times) at the cloud service. It could trigger bugs of silent semantic violation and state divergence.
- **P₃** (Return transient error codes to all requests). Under this policy, the REST call does not reach the cloud service as all requests are returned with transient service-side errors. The policy can potentially expose bugs of state divergence, if the local state is optimistically changed before the REST call, but not restored after the call fails.
- **P₄** (Timeout the first response and return transient error codes to all subsequent requests). This policy presents a failed REST call (with a transient error code in response) to the application, which on the contrary has been successfully executed exactly once at the cloud service. It could trigger bugs of state divergence.

Rainmaker by default injects 503 (`ServiceUnavailable`), as the transient fault(s) for request failures. For the responses, Rainmaker injects a timeout fault. These two types of transient faults are common and safe to inject and thus are valid faults on the request and response path, respectively. In comparison, error codes like 500 (`InternalServerError`) have undefined semantics and service-side behavior. The error code can be further customized for specific cloud services and their SDKs based on their definitions of transient faults and retry policies.

Rainmaker identifies all the retried requests and their responses of each REST API call by checking the unique request ID in the HTTP header (e.g., `x-ms-client-request-id` for Azure Storage services). The request ID is provided by the SDK to identify the specific REST call request and is shared by all the subsequent retried requests and responses.

One design choice we make is to avoid encoding specifications of REST/SDK APIs in policies (e.g., idempotency of a

Coverage Metric	
C ₁	Cover all tests; for each test, select the first REST call.
C ₂	Cover all unique call sites of the application code; if a call site is exercised by multiple tests, select the cheapest test.
C ₃	Cover all tests and all unique call sites in a pairwise manner.
C ₄	Cover all unique call sites of every test; if multiple REST calls exercises the same call site, select the first call to inject.

Table 3: The coverage metrics supported by Rainmaker. We use C₄ as the default metric. Note that injecting faults in every REST call in every test is prohibitive (see §5.3).

REST API and retry behavior of an SDK API). Leveraging API information can help optimize test efficiency. However, it is known that specifications are expensive to maintain and are often incomplete and outdated in practice. Rainmaker minimizes its assumption on the REST/SDK APIs.

4.2.2 Which REST API calls to inject faults?

A test suite may generate an excessive number of REST calls; injecting faults into all of them can be prohibitively expensive, even with the above optimized policies (it could take several machine-months for one application, §5.3). In fact, many REST calls can be redundant (e.g., invoked by the same application code location) for the purpose of covering new error-handling code. Rainmaker therefore selectively injects faults into a small number of REST calls, which achieves certain coverage metrics and optimizes testing resources.

Coverage metrics. Rainmaker supports four different coverage metrics (Table 3). While C₁ measures coverage in terms of the REST calls, C₂–C₄ involves call sites of cloud service APIs. We use the term *call site* to denote a location in the application code that invokes an SDK API that eventually makes one or more REST calls (typically, one SDK API invokes one REST API [26, 27]). Call sites reside in the application code, while REST calls are constructed by the SDK. Hence, C₂–C₄ are more intuitive to developers than C₁.

However, computing C₂–C₄ is challenging for Rainmaker and for any other tools that inject faults via a separate HTTP proxy [37, 47]. This is because the proxy process does not have visibility of call sites within the test/application process.

Making call sites available to the HTTP proxy. Rainmaker addresses this challenge with two techniques using automated instrumentation. First, Rainmaker enables a test to communicate with the HTTP proxy through headers of outgoing HTTP messages. Given test binaries, Rainmaker automatically instruments their outbound HTTP calls. An instrumented call can put its call site information in the header of an outbound HTTP request, so the HTTP proxy can retrieve the information. This can be done automatically since outbound HTTP calls are usually made with a small number of standard core APIs. For example, one needs to instrument only four HTTP client API families (e.g., `HttpClient.SendAsync`) provided by .NET core libraries to intercept outgoing HTTP calls from *all* Azure SDKs (see §4.5).

Second, an outbound HTTP call needs to automatically find its call site to put in the HTTP header. If the application were single-threaded, the instrumented HTTP call could identify the call site by taking the caller of the bottom-most SDK function in the call stack. But, modern applications are multi-threaded, and an HTTP call usually happens asynchronously in a child thread created as a result of executing the call site. In this case, a call stack taken at an outbound HTTP call does not capture the call site that resides in a different thread.

To solve this problem, Rainmaker utilizes inheritable thread-local storage (ITLS) supported by modern languages such as .NET [64] and Java [49]. Any data stored in the current thread's ITLS automatically propagates to all its child threads. Rainmaker automatically instruments all call sites (identified by SDK namespace) so that at runtime, they store their location information in the current thread's ITLS. When a call site eventually invokes an instrumented, outgoing HTTP call, in the same thread or in a child thread, the call retrieves the call site information from its ITLS and puts it in the HTTP header for the proxy process to examine.

Test planning. With the call site information available at the HTTP proxy, Rainmaker can inject faults according to the specified coverage metric in Table 3. Each coverage metric is a tradeoff between completeness and cost.

To plan the fault injection runs, Rainmaker first performs a *reference run* of the test suite with no fault injection. During the reference run, Rainmaker measures the time taken by each test and observes, by using its HTTP proxy, the REST calls made by different tests. It then selects the tests that issue REST calls as candidate tests for fault injection. Rainmaker then performs an offline analysis to generate test plans containing the minimum number of fault-injection target REST calls (and their tests) in order to achieve target coverages. It also outputs an approximate running time of each plan using the time of the tests in the reference run and, if any, the delays to be injected to create timeout errors. The time helps a developer choose the right coverage metric by understanding the tradeoff between completeness and cost.

Given the time taken by each test and the set of REST calls each test makes in the reference run, it is straightforward to implement the policies C_1 , C_2 , and C_4 . For C_3 , Rainmaker models it as a linear programming (LP) problem of generating a set of pairs that cover all N tests and M unique call sites (with each test covering a subset of call sites), while minimizing the total test running time (each test has different running time). It then uses an LP solver to generate a plan.

Note that test planning, including the reference run and LP solving, is done offline as a one-time effort. The results can potentially be reused across test runs in CI/CD environments.

4.3 Test Oracles

A test oracle checks whether the outcome of a fault injection test run indicates a bug. A trustworthy oracle catches

```

/// test code
public async Task
Should_be_able_to_send_if_container_was_not_found()
{
    ...
    await plugin.BeforeMessageSend(message); ...
} /* ServiceBus.AttachmentPlugin.Tests/When_sending_message_using_connection_string.cs */

/// application code
public override async Task<Message>
BeforeMessageSend(Message message)
{
    ...
    try {
        await container.CreateIfNotExistsAsync();
    }
    catch (StorageException ex) {
        // intentionally swallow and continue
    }
    ...
    await blob.UploadFromByteArrayAsync(...);
    ...
} /* ServiceBus.AttachmentPlugin/AzureStorageAttachment.cs */

```

The diagram shows a call stack with two levels. The top level is the test code, which calls `BeforeMessageSend`. The bottom level is the application code, which calls `Container.CreateIfNotExistsAsync`. An exception (404) is thrown from the application code, which is captured by Rainmaker. The exception is inconsistent with the injected fault (503).

Figure 7: An exception captured by Rainmaker to detect a state-divergence bug in ServiceBus AttachmentPlugin. The exception that fails the test (404) is inconsistent with the injected fault (503).

different types of bugs with no false alarms so that developers can focus their investigation only on true bugs.

With the goal of being generic and widely applicable to any cloud-backed application, Rainmaker does not use any application-specific oracle. Instead, it devises a set of application-agnostic oracles on top of the existing test oracles encoded in developers' test code. These oracles are effective in identifying various types of bugs, with low false positives.

4.3.1 Exception Oracle

This oracle flags a fault-injection test outcome as a potential bug if 1) the test fails with an exception, 2) the exception is created in application code rather than in test code, and 3) the exception is inconsistent with the injected fault. We now explain the rationale behind the three conditions.

When a test fails with an exception as a result of an injected fault, it may not always mean a bug. For example, in the applications we use for our evaluation, many tests directly interact with a cloud service (e.g., to setup the test environment) but without proper error handling. If Rainmaker injects faults into such REST calls, the test will fail with an exception. However, the failure does not indicate application bugs. Rainmaker applies the second condition to filter out test failures due to exceptions created in test code, based on the exception call stack. Note that Rainmaker avoids injecting faults into REST calls with call sites from the test code.

However, not all test failures due to exceptions created in application code are bugs. For example, a utility method of an application may intentionally propagate an exception to the upper layer and expect it to be handled there. When a test for this utility fails due to not handling the exception, the test failure is expected, and it does not indicate a bug.

Rainmaker applies the third condition to only report bugs when the final exception that causes the test failure is inconsistent with the injected fault (by searching the injected HTTP

```

public async Task Receive_SendOne_Received()
{
    ...
    messages = await client.ReceiveAsync(queue);
    Assert.Contains(messages,
        m => m.tag == tag);
} /* Trio/MessagingTest.cs */

```

timeout
Assertion failure:
Expect: True; Actual: False
(tag not found in messages)

Figure 8: An assertion utilized by Rainmaker to detect a bug of silent semantic violation in Storage.NET backed by AWS SQS. When timeouts are injected, ReceiveAsync dequeues multiple times, causing an empty message list returned, which fails the assertion.

status code or error code in the exception stack). The intuition is that, if the test fails due to an error different from the injected fault, it indicates that the fault was once handled (it shows the developer’s intention to handle it), but the handling is inappropriate (at least insufficient) and causes a different error that fails the test. This oracle can capture bugs of throwing unrelated exceptions as well as silent bugs of semantic violations and state divergence which do not cause immediate exceptions but result in exceptions eventually. Figure 7 shows such an example, where a 503 fault injected to CreateIfNotExistsAsync leads to a 404 exception from UploadFromByteArrayAsync and fails the test.

Note that the oracle is incomplete. If an application misses error handling (§3.1), exceptions exposed by the test could be a bug. However, at the unit test level, it is indeterminate.

Relaxing the oracle. With all three conditions, the oracle above is conservative. One can relax it to identify other types of likely bugs. If the developer is testing an application or running a system test (instead of a unit test), she can disable the third condition so that Rainmaker flags any failure (e.g., crash) due to exceptions from application code as a bug. This is because Rainmaker only injects transient faults that are expected to be handled gracefully.

4.3.2 Assertion Violation Oracle

This oracle flags a fault-injection test outcome as a potential bug if the test fails due to an assertion violation (*and* not an unhandled exception). Intuitively, transient faults injected by Rainmaker should not impair semantic correctness of application code; hence existing assertions should not be violated if the faults are properly handled. The assertions in test code could be brittle to fault injection [45], i.e., an assertion violation is not a bug, but caused by the fault injection changing application runtime behavior. In practice, we find such brittle assertions are small in numbers, as discussed in §5.2. The assertion oracle can capture bugs of silent semantic violations and state divergence. Figure 8 shows how Rainmaker leverages the existing assertion to capture a silent semantic violation in Storage.NET [19].

4.4 Diagnosis Support

Associating source-code information with faults. Diagnosing and localizing bugs in application code triggered by

HTTP-level faults can be challenging without source-code context. This can be true even when the developer knows the fault-injected REST API or SDK API (via instrumentation), because they can be invoked by multiple program locations.

To help developers debug the test failures, Rainmaker associates the fault injection with source-code information in the form of the call site, together with the call stack of runtime exceptions or assertions (§4.3). We find the REST API call site and exception/assertion call stack are critical to debugging. They help developers to understand what and where fault(s) were injected and reason about the error propagation inside application code. One can further apply existing techniques to automatically reconstruct the failure execution (e.g., [85]).

Reproducing bugs. Rainmaker can reproduce a reported bug because all fault injections for a test are determined by the test planner (§4.2.2). If an injected fault exposes a bug, Rainmaker can rerun the planned fault injection to reproduce the triggered bug. If the test is nondeterministic, it may take several runs to reproduce the bug. In our experience, the error handling behavior for REST calls is typically local to the call and is rarely affected by nondeterminism of test execution.

4.5 Implementation

We have implemented Rainmaker for Windows. Its HTTP interception is implemented using MockServer [18], with fault-injection policies implemented as MockServer rules in Java. Rainmaker registers a system proxy for Windows Internet Services to forward all HTTP traffic to the MockServer proxy. This enables Rainmaker to inject faults to *any* application that issues REST APIs. The oracles are implemented in Python, which analyzes the raw test results and logs.

Rainmaker currently supports coverage metrics C_2 – C_4 for .NET applications only, which needs dynamic instrumentation to record and propagate call site information (§4.2.2). The instrumentation is implemented using the .NET profiling API [65] that enables changing bytecode of a method before it is JITed. Rainmaker inserts call site information in HTTP headers by instrumenting four HTTP API families from the .NET core library that cover all outgoing HTTP messages. We believe the same mechanism can be implemented for Java.

To support a new cloud service in Rainmaker only takes two inputs in the form of configurations: 1) the SDK namespace (e.g., Azure.Storage* for Azure Storage SDK) and 2) the request-ID tag of the cloud service (e.g., x-ms-client-request-id for Azure Storage services and amz-sdk-invocation-id for AWS S3). The former instructs Rainmaker what call sites to record, and the latter identifies a request and its retries (they all have the same request ID).

5 Evaluation

Our evaluation addresses the following questions: 1) Can Rainmaker find new bugs in real-world cloud-backed applications? 2) Are Rainmaker’s testing results trustworthy? 3)

Application	Cloud Service	# Stars	# LOC	Selected Tests
Alpakka	Queue	106	14K	9
AttachmentPlugin	Blob	67	1.3K	32
BotBuilder	Blob, Queue	758	18K	67
DistributedLock	Blob	838	17.1K	30
EF Core	CosmosDB	11.7K	842.4K	420
FHIR Server	CosmosDB	897	112.8K	202
Insights	Blob, Queue, Table	20	51.7K	147
IronPigeon	Blob	255	5.4K	7
Orleans	Blob, Queue, Table	8.8K	187K	155
Sleet	S3	276	18.7K	2
Storage.NET	Blob, Queue, S3, SQS	567	12.4K	36

Table 4: The cloud-backed applications used in our evaluation.

What is the tradeoff between running time and coverage?

- **§5.1:** Rainmaker finds 73 new bugs in all 11 evaluated cloud-backed applications, which represent a swathe of reliability issues. So far, 55 of them have been confirmed, and 51 have been fixed by the developers.
- **§5.2:** Rainmaker’s test oracles have a low false-positive rate (1.96%) with regards to test failures.
- **§5.3:** Rainmaker significantly reduces running time compared to exhaustive fault injection with coverage guarantee.

Evaluation setup. We evaluated Rainmaker on 11 popular .NET applications that use six different cloud services from two cloud service providers, Azure and AWS (Table 4). These applications are mature and widely used; many are maintained by software companies, such as Orleans, BotBuilder, EF Core, FHIR Server from Microsoft, Insights from NuGet, and Alpakka from Petabridge. They use six cloud services: Blob Storage [7], Queue Storage [11], Table Storage [12], and CosmosDB [9] from Azure, and Simple Storage Service (S3) [1] and Simple Queue Service (SQS) [4] from AWS. We configure Rainmaker to support these services (§4.5).

We apply Rainmaker to existing test suites of the applications. Rainmaker automatically selects tests that interact with the cloud services from the test suite by monitoring HTTP traffic during the reference run (§4.2.2). The number of selected tests varies from 2 to 420 across the applications (Table 4), including both unit and system tests. We differentiate unit and system tests based on their naming conventions.

All the tests that interact with Azure cloud services are run with emulators: Azurite [68] for Blob, Queue, and Table and the CosmosDB emulator [63] for CosmosDB. The tests that interact with AWS are run with the real S3/SQS services; we did not find an official AWS emulator.

5.1 Finding New Bugs

Rainmaker finds a total of 73 *new* bugs in the evaluated applications (Table 5). Those bugs include all the bug patterns in the taxonomy (§3): 29 bugs of no error handling, 23 bugs of throwing unrelated exceptions, four bugs of silent semantic violations, and 17 bugs of state divergence. Rainmaker finds bugs in *every* application, showing the error-proneness of

Application	No Error Handling	Throw New Exception	Semantic Violation	State Divergence	Total

Table 5: New bugs detected by Rainmaker across the applications.

handling transient faults with cloud-based programming. We have reported 66 (out of 73) bugs. So far, 55 of them have been confirmed, and 51 of them have been fixed.

Many of the detected bugs have severe consequences, such as unexpected application termination, data loss/inaccessibility, and resource leaks (Table 6). All these consequences are triggered by transient faults against *one* REST API call.

Rainmaker detects bugs that are unlikely to be exposed by randomized fault injection. For example, a bug [36] in DistributedLock is only triggered when timeout happens to the response of a specific SDK API call site. The test used for detecting this bug issues 900+ requests in total; only four requests are from that specific call site. Rainmaker can consistently detect this bug as it systematically exercises the call sites of the REST API calls (§4.2.2).

Table 7(a) shows that all four fault injection policies (Figure 6) employed by Rainmaker are effective in finding bugs. The four policies address different fault scenarios and are complementary to each other. No policy detects all the bugs. Similarly, Table 7(b) shows that oracles are complementary to each other. For example, all the semantic violation bugs are captured by assertions as they do not cause exceptions.

The 73 bugs cause 2,654 test failures in total. To inspect them, we cluster test failures based on (a) the application call site that invokes the REST API where fault(s) are injected and (b) the exception stack trace in the application namespace, or assertion. For two test failures with both (a) and (b) being the same, they are considered to have the same root cause, i.e., injecting to the same API call site causes the same exception stack trace in application namespace or assertion violation.

No error handling. Rainmaker found 29 bugs of this type, where neither the SDK nor the application handles the injected faults. These bugs are all from applications that use Azure Storage SDK with versions before 12.3.0 and the CosmosDB SDK; the former does not retry timeouts, and the latter does not retry with our single-region setting. The applications using these SDKs are expected to handle transient errors but do not have error handling. These bugs are manifested in system tests when Rainmaker injects faults into the REST calls.

Consequence	Example	# Bugs
Externalizing unrelated exception	IronPigeon-133: Deletion operations perform on non-existent resources [46].	36
Operation failure	AttachmentPlugin-277: Containers cannot be created due to transient error [24].	35
Incorrect results or states	BotBuilder-5787: The timestamp metadata of blobs is not set correctly [31].	13
Application crash	FHIR Server-2732: FHIR Server can crash unexpectedly upon transient faults [38].	11
Data loss or inaccessibility	BotBuilder-6407: Activities that should be logged are lost [32].	4
Resource leak	Orleans-7790: Redundant messages were added incorrectly to the Queue service [72].	2

Table 6: Consequences of the bugs found by Rainmaker. One bug can lead to multiple consequences.

Throwing unrelated exceptions. Rainmaker found 23 bugs of this type. Rainmaker triggers these bugs by injecting timeout to the response path after a request takes effect at the cloud service (see Figure 3). While the bug in Figure 3 is captured by an assertion on the number of created blobs, many other bugs are captured by the exception oracle (the exception is mostly inconsistent with the injected fault). Such bugs can be avoided if the cloud service can collapse the retries: If the first attempt is successful, the cloud service should ignore the following retries of the same SDK API call. This requires the cloud service to identify the retries of each SDK API call, which can be specified by the SDK when it issues a retry.

Silent semantic violations. Rainmaker found four bugs of this type. All of them are caused by retrying non-idempotent REST APIs (e.g., `ReceiveMessagesAsync` in Figure 4). Rainmaker detects these bugs by injecting timeout to trigger non-idempotent retries and leveraging assertions to catch semantic violations (as in Figure 8). Different from traditional system services (e.g., file systems), cloud services seldom have standard API specifications like POSIX for file system APIs; documents are often outdated or incomplete. Without precisely understanding the semantic and side effect of each REST API, it is difficult for developers to avoid silent semantic violations.

State divergence. Rainmaker found 17 bugs of this type. Some applications maintain local data structures to reflect the state of the remote resources hosted by the cloud service. Rainmaker triggers state divergence by injecting 5XX error codes to the request path or timeout to the response path (e.g., Figure 5). Although the inconsistencies do not immediately lead to exceptions, Rainmaker can still catch them when the test throws exceptions (e.g., Figure 7) or fails assertions.

5.2 False Positives

While identifying bugs with its test oracles, Rainmaker introduces a very low false positive rate of 1.96% (52/2,654). It reports in total 2,654 test failures for the evaluated applications. Among the failures reported, only 52 of them were false alarms. The low false positive rate is attributed to Rainmaker’s exception oracles (see §4.3.1). If Rainmaker directly reports exceptions thrown by unit tests, it would have reported 3.07

Application	Fault Injection Policy				Test Oracle		
	P ₁	P ₂	P ₃	P ₄	Exp (Unit)	Exp (Sys)	Assert.
Alpakka	2	1	1	0	0	0	2
AttachmentPlugin	0	1	2	1	2	0	0
BotBuilder	2	1	2	1	3	0	1
DistributedLock	2	0	0	0	2	0	0
EF Core	7	n/a	7	n/a	0	7	0
FHIR Server	11	n/a	11	n/a	0	11	0
Insights	10	0	0	0	10	0	0
IronPigeon	1	0	0	0	1	0	0
Orleans	17	11	11	11	16	0	2
Sleet	2	0	0	0	2	0	0
Storage.NET	13	12	12	12	2	11	1
Total	67	26	46	25	38	29	6

Table 7: The breakdown of the number of bugs captured by the fault injection policies (left) and oracles (right). For EF Core and FHIR Server, the four policies are reduced to two, because CosmosDB SDK does not retry in our setting (single region). For the exception oracle (“Exp”), we differentiate unit tests and system tests. Note that one bug can be exposed by multiple fault injection policies.

times more test failures. To validate that the oracles filter out little true alarms, we randomly sample a hundred exceptions that are filtered out by Rainmaker’s exception oracle and find that none of them indicates a bug.

Among the 52 false alarms, 10 of them come from five tests of Insights. These tests exercise scenarios where a client issues invalid requests and expects the return of certain error codes (e.g., 404 Not Found). Since Rainmaker injects 5XX on the request path (P₃ and P₄ in Figure 6), the REST call fails by assertions on the original error codes. To avoid those false alarms needs to understand those REST calls, e.g., based on information from the reference run. Note that Rainmaker does not inject faults on an HTTP response that already has an error code.

The other 42 false alarms were caused by 14 tests from Alpakka and IronPigeon. Those tests use a small connection timeout that was exceeded due to the fault injection, resulting in either assertion failures or inconsistent exceptions. These tests are considered flaky tests in software testing literature [54]. Strictly speaking, flaky tests should not be counted as false alarms. However, detecting flaky tests is not a goal of Rainmaker, and the flakiness is indeed triggered by fault injection (it can also be triggered by slow connections).

5.3 Running Time with Coverage

Rainmaker takes 0.57–212.77 hours to test each application under coverage metric, C₄ (Table 3), as shown in Table 8. All the experiments were run on a Windows 10 Pro with AMD Ryzen 9 5900X 3.70 GHz CPU and 32 GB memory. Over 93.54% of the running time is spent on executing fault injection test runs. Rainmaker also spends 0.02–16.61 hours to 1) conduct the vanilla run and 2) generate the test plan. The test plan generation using a linear programming (LP) solver takes only 1.46–3.67 seconds across the applications and is negligible compared with the time for vanilla test runs. The numbers of constraints and variables range from 14 to 241 and

Application	Running Time (Machine Hours)			# Fault Injection Test Runs
	Test Planning	Fault Injection	Total	
Alpakka	0.02	0.97	0.99	196
AttachmentPlugin	0.04	2.83	2.87	416
BotBuilder	0.32	10.36	10.68	888
DistributedLock	0.13	4.97	5.10	572
EF Core	10.65	159.60	170.25	4786
FHIR Server	16.61	196.16	212.77	6428
Insights	0.36	10.97	11.33	3056
IronPigeon	0.06	0.51	0.57	120
Orleans	2.57	53.17	55.74	3804
Sleet	0.11	0.63	0.74	72
Storage.NET	2.30	40.27	42.57	1512

Table 8: Running time of Rainmaker in machine hours, for the most expensive coverage metric C_4 . Test planning includes both the vanilla test run and test plan generation (the latter takes seconds).

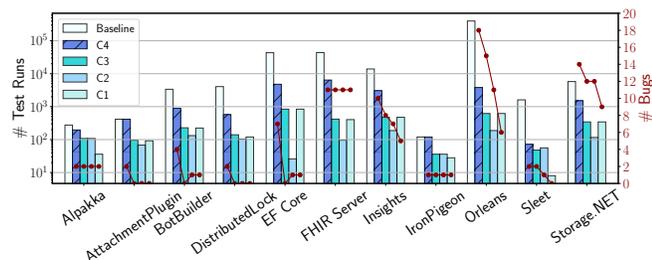

Figure 9: The number of fault injection test runs of each coverage metric, C_1 – C_4 in Table 3 (bars) and the number of bugs detected by each coverage metric (dots). Baseline refers to exhaustively injecting faults to all the REST API calls of all the tests.

from 18 to 3214, respectively. Note that test plan generation is a one-time effort and is done offline; fault injection takes multiple test runs and is more time-consuming.

Rainmaker’s test planning avoids exhaustively injecting faults in every REST call (the baseline). Figure 9 shows the number of fault injection test runs each coverage metric can reduce, compared to the baseline. Overall, Rainmaker with C_4 (default coverage) reduces on average 64.47% of test runs for each application compared to the baseline. In particular, C_4 reduces 394,172 (99.04%) test runs for Orleans alone because Orleans has stress tests that repeatedly exercise the same SDK API call site in large loops. C_4 reduces fault injection runs by “deduplicating” REST calls with the same call site. Without the reduction, Rainmaker would take 588 days to test Orleans.

In terms of bug finding effectiveness, C_4 covers all the tests and REST calls that are covered by C_1 – C_3 . Thus, C_4 detects all the bugs that are detected by C_1 – C_3 .

6 Discussion and Limitation

Rainmaker’s effectiveness depends on the adequacy of the existing test suite, in particular, tests that interact with cloud services. Such tests may not be abundant (Table 4). For example, in Microsoft Orleans, only 155 out of 7,002 tests interact with cloud services. A more common testing practice is to mock REST APIs [53]. Our future work is to auto-rewrite mocked tests into tests that can be utilized by Rainmaker.

Rainmaker is not cheap. It may need to run a test multiple times, each injecting different fault(s) or to a different REST call. For big test suites, Rainmaker would need significant machine hours (Table 8). In fact, our evaluation shows that many bugs trigger multiple test failures (§5.1). A future work is to reduce the cost using test selection techniques [83].

Rainmaker currently only targets faults that occur in one interaction of REST API call initiated by the application and the subsequent retries (§3). We are investigating how to inject faults to multiple *correlated* API call interactions which has a larger fault space and a more complex fault model.

Rainmaker can be extended to test applications under potential cloud service bugs. In our evaluation, we find that cloud services have various correctness issues. For example, we observe that the same REST API of AWS S3 has different consistency guarantees at different regions [25], which can break application assumptions. Also, the error behavior is often opaque and hard to reason, e.g., the side effect of a non-idempotent API call when it returns 500 (InternalServerError).

Not every bug found by Rainmaker is easy to fix. For example, timeouts on the response path make it hard for SDK/application to know whether the failed request has taken effect at the cloud service. Server-side support such as versioning (e.g., based on HTTP ETag) and transaction-like API support could potentially help non-idempotent APIs. Moreover, SDKs should not blindly retry non-idempotent APIs, which however is not an uncommon practice, as shown in Table 1.

Our current prototype of Rainmaker focuses on .NET applications. We believe that the prototype can be generally extended to support applications in other languages as well. The high-level idea of injecting faults with an HTTP proxy is independent of the programming language of the target application. The only .NET-specific component in our prototype is the one that computes the coverage metrics C_2 , C_3 , and C_4 (in Table 3) by using .NET profiling API [65] for dynamic instrumentation and .NET inheritable thread-local storage (ITLS) [64] for propagating call-site information. Neither dynamic instrumentation nor ITLS is unique to .NET; they are already available or can be supported in other languages and runtimes such as Java.

7 Related Work

Our work focuses on push-button tooling to help developers address emerging reliability challenges of cloud-backed applications. The techniques that embody Rainmaker have lineages of error-handling analysis and fault injection.

- **Error-handling code analysis.** It is known that error handling is a main root cause of production failures of software systems [40, 41, 84]. Prior work developed static analysis for error-handling code to search missing logs and TODOs in error-handling code [84, 86], check error specifications [48], and understand error propagation [41, 77, 82].

- **Fault injection.** Prior work developed fault injection techniques for traditional software applications [29, 35, 59, 87] and for distributed backend systems (e.g., storage and data processing systems) that empower modern cloud services [16, 20, 21, 33, 34, 40, 43, 51, 55–57, 69, 73, 80]. They implicitly or explicitly target error-handling code. Moreover, many existing fault injection tools support injection at the HTTP layer [37, 47].

Unfortunately, we realized that none of the above techniques support a push-button tool that is generic, widely applicable to cloud-backed applications because they all have one or more of the following limitations. First, many fault injection tools only provide mechanisms without fully automatic policies beyond randomization or oracles beyond crashes [6, 21, 35, 40, 43, 44, 51, 58, 61, 73, 75]. Developers need to manually implement them, which is nontrivial. Second, many techniques use application or domain knowledge to devise policies and oracles [16, 20, 33, 34, 55, 56, 69, 80]. For example, fault injection for distributed databases checks consistency and isolation properties by injecting node crashes and network partitions [16, 52]. These techniques cannot be used as a common, basic utility for diverse types of applications. Third, fault injection at the program level [35, 50, 59, 60, 87] is fundamentally limited to cloud-backed applications: 1) program errors (exceptions and errno) are too coarse-grained to expose certain bug patterns (e.g., silent semantic violations) which need fine-grained injection at the HTTP layer; 2) it is nontrivial to construct exception objects—error handling of cloud-backed applications is based on not only exception types, but also HTTP status codes (Table 1); 3) few program fault injection considers cloud states, but assumes a single program. Rainmaker instead injects faults at the REST interface, effectively addressing the above three limitations.

The early form of cloud-backed applications is mobile apps that interact with cloud backends via REST APIs. Unlike today’s cloud services, the cloud backend is specific to an app and is not widely used as a building block of generic application development. Most fault injection tools for mobile apps focus on GUI testing [74, 79]; few considers app-cloud interactions. Rainmaker applies to cloud-backed mobile apps.

8 Concluding Remarks

Rainmaker serves as a first step tooling to help developers test application reliability under the cloud-based fault model conveniently, when writing cloud-backed code. Despite being a simple tool, Rainmaker can effectively detect bugs in many existing cloud-backed applications, indicating the challenge and error-proneness of correctly handling transient errors. Our goal is to make Rainmaker a basic utility running against every cloud-backed application to detect critical bugs at development time. We hope to inspire more advanced, specialized tooling and raise discussions on cloud service support and SDK designs to eliminate reliability threats in the first place.

Test Coverage for Network Configurations

Abstract

We develop NetCov, the first tool to reveal which network configuration lines are tested by a suite of network tests. It helps network engineers improve test suites and thus increase network reliability. A key challenge in developing a tool like NetCov is that many network tests test the data plane instead of testing the configurations (control plane) directly. We must be able to efficiently infer which configuration elements contribute to tested data plane elements, even when such contributions are non-local (on remote devices) or non-deterministic. NetCov uses an information flow graph based model that precisely captures various forms of contributions and a scalable method to infer contributions. Using NetCov, we show that an existing test suite for Internet2, a nation-wide backbone network in the USA, covers only 26% of the configuration lines. The feedback from NetCov makes it easy to define new tests that improve coverage. For Internet2, adding just three such tests covers an additional 17% of the lines.

1 Introduction

As critical infrastructure, networks must be highly reliable but, unfortunately, network outages are common. A primary culprit is networks' reliance on complex, low-level configuration that dictates how routers select best paths and forward traffic. Day-to-day updates to network configuration are error-prone, leading to outages that knock off important online services (e.g., banking), ground airplanes, and disable critical communication (e.g., emergency calls) [3, 33, 34, 39, 45].

To improve network reliability, automatic testing and verification of configurations is becoming commonplace. Today, network operators have at their disposal many tools with increasing sophistication that can scale to large networks and check various aspects of network behavior [5, 23, 40, 49, 51].

However, using such tools is not sufficient by itself; one must also use them *effectively*. Outages can occur despite automated testing when the test suite is poor and does not cover key aspects of network configuration. This was the case with the massive Facebook outage during which Facebook, WhatsApp, Instagram, and Oculus were unavailable for six hours [35]. Current tools have pushed the limits of *what can be tested* but left open the question of *what needs to be tested*.

Without tool support, it is difficult for engineers to know if they are effectively testing network configurations. In industrial networks with possibly millions of lines of configurations,

engineers' understanding of network behavior and dependencies is necessarily incomplete. It is even harder to update an existing test suite after the network evolves because the engineers likely do not know what the old test suite is or is not testing for the updated network.

Recent work has proposed data plane coverage [47] to reveal testing gaps. It shows which data plane elements, such as forwarding rules, are exercised by a test suite. However, well-tested data plane does not imply well-tested configurations. Data plane elements are the output of network's configurations (which define its control plane) and the current operating environment (failures, external routing information). Testing a given data plane only tests configuration elements that are exercised in that particular environment. Other configuration elements are not tested. We demonstrate this empirically via a scenario where testing *all* data plane elements leaves over half of configuration lines untested.

We develop *configuration coverage* to provide comprehensive and precise feedback to network engineers on test suite quality. Our goal is to identify exactly which configuration lines are tested and which ones are not. We want to consider all configuration elements, not only those that contribute to the current data plane. Revealing exactly which lines are untested helps improve tests—add tests that target untested lines—which in turn can improve network reliability. This is similar to how code coverage tools help improve tests and software reliability [9, 11, 22].

A major challenge we face is that many network tests do not exercise configurations directly. Instead, they reason about the data plane elements produced by configurations. We need to infer the configuration elements that contribute to the tested data plane elements. This inference is complicated because contributions can be non-local and non-deterministic. In a distributed control plane, a piece of tested routing information may have been propagated and transformed multiple times along its path, and both local and non-local configurations may have contributed to its existence. For example, the path attributes of a BGP route is shaped by routing policies on each and every hop that it traverses. Further, not all contributions are deterministic. For instance, any one of possibly multiple sub-prefixes can lead to the route of an aggregate prefix. We must scalably account for local and non-local contributions and for non-deterministic contributions.

Our solution is to model the contribution between configuration elements and data plane elements as an *information*

flow graph. An IFG is a directed acyclic graph (DAG) where vertices denote network elements and edges denote contributions. In addition to direct contributions from configuration elements to data plane elements, we also model contributions between data plane elements (from predecessors to successors). For instance, a BGP route contributes to the BGP message that derived from it. Indirect contributions are thus modeled by multi-hop paths in the DAG. When contributions exhibit non-determinism, we use special *disjunctive* nodes to organize possible DAG paths that may contribute to a given data plane element.

We build a tool called NetCov based on this model. It annotates which configuration lines and logical elements are tested by a given test suite and produces aggregated coverage statistics. To efficiently map tested data plane element to the set of contributing configuration elements, it materializes the IFG lazily, instead of tracking contributions proactively, during data plane generation. This design avoids the cost to compute and store contributions for transient or untested data plane elements. NetCov is open-sourced on GitHub [30].

We evaluate NetCov on Internet2, a nation-wide backbone network in the USA, and on synthetic data center networks. We show that test suites proposed in prior work can have poor coverage. The three tests proposed by Bagpipe [44] covered only 26% of the configuration lines of Internet2. We also show how surfacing untested configuration elements suggests new tests that improve coverage. By adding just three such tests to the Internet2 test suite based on NetCov’s feedback, we could improve coverage to 43%, and more similar tests can be added to further increase coverage. NetCov performs reasonably well. The time to compute coverage is 1.2 hours for the largest network that we study, which has over 2 million forwarding rules. This time is an order of magnitude less than the time to execute tests.

Stepping back, we note that networking is not alone in its reliance on configuration. Today, a lot of infrastructure and distributed applications are deployed by composing existing components using configuration (e.g., infrastructure deployment using Terraform, and application deployment using containers and service meshes). These configurations are central to correct behavior, which is why there is an intense focus on testing them properly [21, 38, 43]. As for networks, there are no tools to help engineers discover how well the configurations are tested. The techniques developed in our work, the IFG-based contribution tracking and its lazy traversal, can provide a starting point toward better testing of infrastructure and distributed application configuration as well.

2 Background on Network Testing

In networks with distributed control planes, each device runs one or more routing protocol (e.g., BGP, OSPF) instances. Each instance exchanges routing messages with its neighboring instances. Routing messages contain attributes of paths

that the sender is using to various destinations. A routing instance may learn multiple paths to the same destination via different neighbors. It selects the best one (or multiple best ones if multipath routing is enabled) based on its policy and stores that path in its protocol RIB (routing information base). Multiple routing protocol instances on a device may have best paths to the same destination. The device selects the best one(s) based on the relative preference of the protocols and stores the selection in its main RIB. Information in the main RIB is used to forward packets.¹

Network engineers can control many aspects of the computation above using device configuration. This includes the routing protocol instances that are running; the peering between instances; the destination prefixes that are announced by each routing protocol instance; how routing messages are transformed prior to sending (export policy) and upon reception (import policy); and the preference function for best path selection. Naturally, thus, how the network forwards packets is intimately dependent on device configurations.

Given the importance of configurations to correct network behavior, network engineers use automatic testing to find bugs and gain confidence in their correctness. Network tests come in two flavors. *Data plane tests* analyze the computed data plane state (*i.e.*, RIBs), e.g., checking that node A can reach B and that route to a particular destination is present at node C. *Control plane tests* directly analyze device configuration, e.g., checking that the import policy blocks routing messages for private address space (such as 10.0.0.0/8) and BGP peerings are correctly configured.

3 Configuration Coverage: Overview

Network engineers today create data and control plane tests based on past outages and their knowledge of which behaviors are important to test. There are no tools to provide feedback on how well they are testing configurations and which aspects of the configuration are untested. We aim to build such a tool. Given the complexity of real-world networks, it is difficult for humans to know if they have covered all important elements of configurations. As with software, high coverage is necessary but not sufficient for a good test suite. In addition to exercising all key behaviors, the tests must also properly assert that those behaviors match intent. This latter task is not our focus.

Our goal is to reveal which elements of the network configuration are covered by a suite of data and control plane tests. Before discussing our approach, we define what it means for a configuration element to be covered.

¹In reality, for fast forwarding, routers have a forwarding information base (FIB), which maps each main RIB destination to its outgoing interface, by recursively resolving next hop information (which may be an IP address). The difference between main RIB and FIB is not material for our work, and we use the term main RIB for the table that has forwarding information.

3.1 Defining coverage

We deem a configuration element to be covered if it *i*) is tested directly by a control plane test; or *ii*) contributes to the production of a data plane state element (i.e., an entry in the protocol or main RIB) tested by a data plane test. For now, assume that contributions are deterministic. We discuss non-deterministic contributions in the next section.

Figure 1 illustrates configuration coverage as a result of a data plane test. It shows parts of the two routers' configuration. R1's configuration defines one interface (Lines 1-2) and one BGP peer (192.168.1.2, which is R2's address), and it specifies the import and export policy to use. The import policy (R2-to-R1 at Lines 6-11) denies routing messages for a particular prefix and sets the preference for another.

R2's configuration defines two interfaces, a BGP peer (R1) and routing policies. At Line 13, it states that the prefix 10.10.1.0/24 should be announced to BGP peers *iff* it is in the main RIB.² In our example, 10.10.1.0/24 will be in the main RIB as it corresponds to the eth1's prefix. (Address statements like Line 4 encode the IP address and prefix length. For eth1, given the address 10.10.1.1 and prefix length of 24, the prefix is 10.10.1.0/24.) Routers add interface prefixes to the "connected" protocol RIB, from where those prefixes can enter the main RIB. The resulting RIBs on the two routers are shown in the figure. Each entry includes the next hop and source routing protocol ("conn" = connected).

Suppose the entry for 10.10.1.0/24 at R1 was tested by a data plane test. The covered configuration elements are highlighted. On R1, the BGP peer configuration and import policy binding (Lines 3-4) are covered because the tested entry came via that peering and passed through that policy. Parts of the routing policy R2-to-R1 relevant to the tested state (Lines 6, 9-11) are also covered. The interface definition (Lines 1-2) is covered because it enables the BGP peering to be established. In contrast, the export policy R1-to-R2 and unexercised parts of R2-to-R1 (Lines 7-8) are not covered.

There are covered configuration elements at R2 as well. These include the interface definitions—eth0 enables the BGP edge and 10.10.1.0/24 was announced due to eth1—and BGP peering, the export policy, and the BGP network statement.

Alternative definitions of coverage. One may consider an alternative definition of coverage that disregards non-local configuration elements. But we posit that including non-local elements is more meaningful. These elements, such as the BGP network statement on R2's Line 13, are just as key to the existence of 10.10.1.0/24 at R1 as the local elements.

Another definition of coverage is based on mutation [4]: a configuration line is deemed covered if its mutation alters the test result. Compared to the definition of coverage we adopt, mutation-based coverage will report an additional class of configuration elements as covered—configuration elements

²Different router vendors have different semantics for BGP network statements. We are assuming Cisco semantics.

192.168.1.0/30	eth0	conn	192.168.1.0/30	eth0	conn
10.10.1.0/24	192.168.1.2	bgp	10.10.1.0/24	eth1	conn

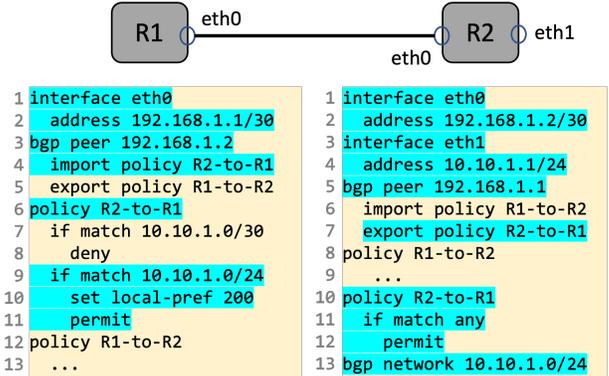

Figure 1: An example network with routing tables and configurations. The highlighted configuration lines are covered when the route to 10.10.1.0/24 is tested at R1.

that de-prioritize (or reject) the competitors of the tested data plane element. Mutation-based coverage tends to be significantly harder to compute [24], and its results can be hard to interpret. In developing the first tool in this space, we decided to focus on a simpler, more direct definition of coverage. We will explore more sophisticated definitions in the future.

3.2 Our approach

While it is straightforward to identify configuration elements covered by a control plane test, it is not so for data plane tests. Data plane tests analyze the "output" of the control plane, and we need a scalable way to compute which configuration elements contributed to tested data plane state. The relationship between these inputs and outputs is complex. How a particular RIB entry comes about relies on many configuration elements across multiple devices. The need to map tested outputs to input space sets computation of configuration coverage apart from data plane coverage and software coverage, for both of which the coverage domain is the same as test domain.

To motivate our approach to solving this problem, let us first sketch two strawman approaches. One potential approach is to express control plane computation declaratively, e.g., in Datalog. This enables identification of contributing inputs for a given output using a form of backward-reasoning [46, 52]. However, network control plane computations can be quite complex (e.g., non-monotonic behaviors [16, 36]). While declarative encodings may work in special cases [27], it is generally hard to get high-fidelity, performant encodings. That is why most control plane analysis tools use an imperative approach [12, 31, 32, 49].³

³Batfish [12], a widely used control plane analysis tool, originally used Datalog to encode network control planes but switched to imperative simulations due to expressiveness and performance challenges.

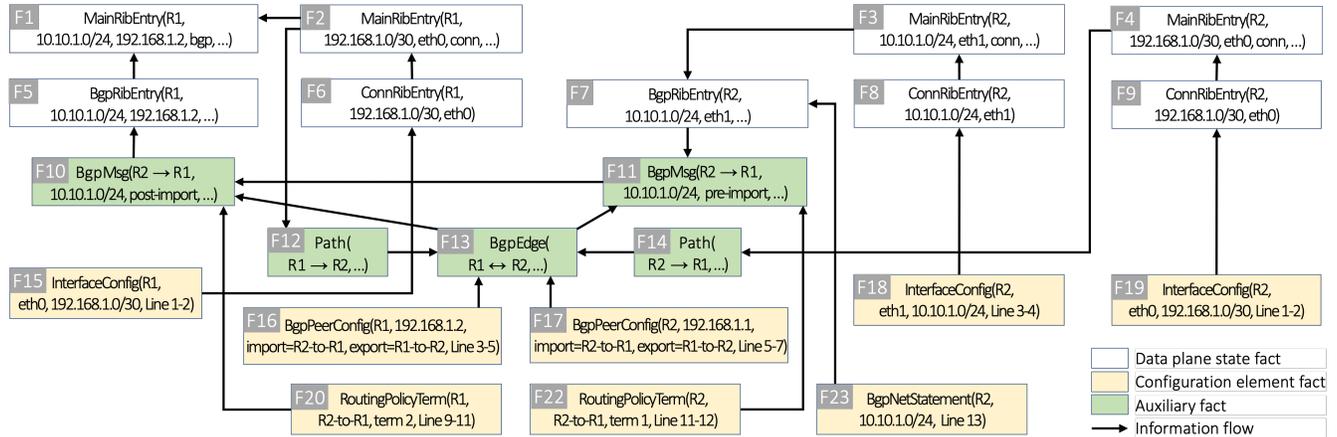

Figure 2: Subset of the IFG for the [Figure 1](#) example. It tracks configuration elements that contribute to the tested RIB entry (F1).

Another potential approach is to use simulation-based forward reasoning, i.e., simulate the control plane (imperatively) and track which configuration elements feed into each part of the data plane state. However, this approach has scalability limitations. Network simulation is time and memory intensive [12, 32, 49], and it will become significantly worse if it needed to track all necessary information along each hop.

Our approach is based on two observations. First, for the purposes of computing coverage, we do not need a full computational model of the control plane. We need to only track which configuration elements contribute to tested data plane state (i.e., taint analysis [41]), not the exact input-output relationship; and we need to reason only about the stable state (i.e., the the of devices once they have settled on best paths), not the transient states. Data plane testing [19, 23, 25, 26, 48] assumes that the analyzed state is stable. Our second observation is that the stable state contains enough information for us to infer contributions of configuration elements after the fact, based on the semantics of the control plane. This inference is vastly cheaper than tracking contributions towards all data plane state entries, independent of whether they are tested.

To model contributions to the stable state, we use an *information flow graph* (IFG). [Figure 2](#) shows a subset of the IFG for the example in [Figure 1](#). Each node is a *fact* and arrows denote information flow from the tail to head. IFGs have three types of facts: *i*) data plane state, *ii*) configuration elements, and *iii*) auxiliary facts that capture intermediate dependencies between data plane state and configuration elements.

The main RIB entry 10.10.1.0/24 at R1 (F1) is derived from the corresponding BGP RIB entry (F5), which in turn is derived from the BGP message from R2 (F10). This message exists because of the BGP edge between R1 and R2 (F13), the source message sent by R2 (F11), and the relevant configuration element within import policy (F20). R2 sent the BGP message because of the same BGP edge (F13), its export policy elements (F22), and the BGP RIB entry (F7). This

BGP RIB entry exists because of the configuration element (F23) and the RIB entry (F3), which exists because of the connected route (F8). The BGP edge (F13) exists because of the configuration elements that define the peering (F16, F17) and paths between R2 and R1 that enable the BGP session to be established. The paths depend on the RIB entries (F2 and F4, respectively), the contributions to which can be similarly traced. In this manner, the IFG captures all configuration elements that led to the tested RIB entry (F1).

We do not track IFG dependencies proactively but infer them on-demand based on control plane semantics, using a mix of backward-forward reasoning. Backward inference infers the parent (tail) of the edge from its child (head). The information in child nodes is not enough to fully recover the parent nodes, but is often enough to select them from the known stable state. For instance, we can compute the BGP RIB entry F5 from the main RIB entry F1—the main RIB entry indicates that its source routing protocol is BGP, and we thus look up the BGP RIB for 10.10.1.0/24.

Lookup-based inference does not always work. For instance, given a BGP message which has passed through an import policy, we cannot compute backwards which terms of the import policy were exercised (F10 ← F20). Another parent of F10, the pre-import BGP message (F11) cannot be looked up either because it is not part of the input and needs to be computed on-the-fly. To address these limitations, we combine backward and forward inference. When a parent can not be directly looked up, we first look up the prerequisites of the parent. For instance, we can look up F7 based on F10. Next, we use targeted simulations to compute non-existing facts and to select relevant facts exercised in a control plane process or data plane process. For instance, given the BGP route at R2 (F7), we simulate its processing through the export policy, which allows us to derive the pre-import BGP message (F11) and find the policy term exercised during the export process (F22). Once F11 is computed, we conduct another targeted

simulation to discover the policy term exercised in the import process (F20). Unlike a full control plane simulation, these targeted simulations are fast. They have limited scope (e.g., best path selection is not simulated) and are done only for messages of interest, not all messages.

By combining backward and forward inference, atop the stable state IFG, we can scalably discover all covered configuration elements. We describe this approach in detail next.

4 Design of NetCov

NetCov takes as input configuration files, data plane state (protocol RIBs, main RIB and active routing edges) of the network. The data plane state may be pulled from live network or produced by control plane analysis tools [12, 32, 49]. In addition, NetCov takes as input what is tested: data plane entries that are tested by data plane tests, and configuration elements that are tested by control plane tests. This information is produced by network testing tools [12, 47].

Based on these inputs, NetCov computes which configuration elements are covered. The core of this computation efficiently mapping a data plane fact to configuration elements that contribute to it. We describe this computation next.

4.1 Information flow model

IFGs are directed acyclic graphs whose nodes denote network facts and edges denote information flow between facts. Table 1 shows the types of network facts modeled by NetCov and the information flow between different types. Data plane state has three subtypes: main RIB entries, protocol RIB entries, and access control list (ACL) entries.

Auxiliary facts have three subtypes: routing edges, routing messages, and paths of routing messages. These facts are not strictly necessary, but they help create a compact IFG and speed up graph walking. For instance, the routing messages of many protocol RIB entries depend on the same path which in turn may depend on many main RIB entries. Adding an explicit fact for the path avoids the need to add all pairs of edges between routing messages and main RIB entries.

In our model, the auxiliary facts for routing messages represent messages between routing protocol instances across devices as well as within a device, i.e., redistribution [10]. This uniform treatment is a modeling convenience. In reality, explicit messages are not exchanged during redistribution (though redistribution is subject to routing policies akin to messages between cross-device routing instances).

The last column of Table 1 shows how information flows among different types of facts. A main RIB entry stems from a protocol RIB entry and optionally another main RIB entry (when its next hop is an IP address whose corresponding output interface needs further resolution). A protocol RIB fact stems from a routing message (for protocols such as BGP), a configuration element (for connected interfaces and static

Network fact	Information flow
Configuration element (c)	None
Main RIB entry (f)	$f_i \leftarrow r_j$ $f_i \leftarrow r_j, f_k$
Data plane state	$r_i \leftarrow m_j$ $r_i \leftarrow c_j$ $r_i \leftarrow f_j, c_k$ $r_i \leftarrow \{r_{j_1}, \dots\}, c_k$
ACL entry (a)	$a_i \leftarrow \{c_{l_1}, \dots\}$
Routing message (m)	$m_i \leftarrow r_j, e_k, \{c_{l_1}, \dots\}$ $m_i \leftarrow m_j, e_k, \{c_{l_1}, \dots\}$
Auxiliary	Routing edge (e) $e_i \leftarrow \{c_{j_1}, \dots\}$ $e_i \leftarrow \{c_{j_1}, \dots\}, \{p_{k_1}, \dots\}$
Path (p)	$p_i \leftarrow \{f_{j_1}, \dots\}, \{a_{k_1}, \dots\}$

Table 1: Information flow model: Types of facts and all possible information flows for each type. $\{t, \dots\}$ denotes a set of facts.

routes), a main RIB entry accompanied with a configuration element (such as when a BGP network statement populates a main RIB entry into BGP RIB) or a set of RIB entries accompanied with a configuration element (for aggregate routes). ACLs facts stem from configuration facts and have no other dependencies. Routing messages stem from a RIB fact or another message (e.g., post-import-policy message depends on pre-import-policy message), and they also depend on routing edges and routing policy configurations. Inter-device routing edges stem from paths that enable sessions to be established and configuration facts that define peerings; Intra-device routing edges stem from configuration facts that define redistribution. Finally, path facts depends on main RIB facts and ACL facts that impact routing traffic along the way.

For correct computation of coverage, the IFG model must be sound and realizable. Soundness means that it includes all relevant dependencies (per control plane semantics) and no more. Realizable means parents (tails) along all information flow edges can always be inferred, via lookup or simulation or a mix. Our model is sound to our knowledge; and that we are able to use it to compute coverage, using the framework described next, points to its realizability.

4.2 Inferring the IFG on demand

Based on the information flow model, NetCov uses a backward-forward inference framework to lazily materialize the IFG from any set of facts whose coverage need to be tracked. The framework is abstracted using a set of *inference rules* and an iterative construction algorithm. Each inference rule is function that takes a materialized IFG node as input and materializes a set of its ancestor nodes as well as the

Algorithm 1: Rule to infer BGP RIB entry from main RIB entry.

```
1 def infer_from_main_rib_entry(f,
  ↪ stable_state):
2   if not (f is MainRibEntry and f.protocol ==
  ↪ 'bgp'):
3     return []
4   bgp_entry = stable_state.bgp_rib.lookup(
5     host=f.host,
6     prefix=f.prefix,
7     nexthop=f.nexthop,
8     status='BEST'
9   )
10  return [(bgp_entry, f)]
```

edges the allows the ancestors to reach the input node. These nodes and edges will be merged into the materialized IFG by the construction algorithm. The implementation of these functions uses one or both of the *lookup-based inference* and *simulation-based inference*. Let us elaborate.

Lookup-based inference. The computation of data plane state is lossy. While a main RIB entry may be derived from a BGP RIB entry, we cannot infer the complete BGP RIB entry from the main RIB entry because BGP specific attributes (e.g., AS-path) are not preserved in the main RIB.

To handle this information loss, our inference takes two steps. It first infers attributes that can be known from heuristics (we know such heuristics from control plane semantic, e.g., the BGP RIB entry should have the same prefix as the main RIB entry derived from it). Next, we look up all entries in the stable state that match the inferred attributes. For instance, [Algorithm 1](#) shows the simplified function to infer the BGP RIB entry that led to a main RIB entry. Based on control plane semantics, if a main RIB entry indicates its source protocol to be BGP, it must have stemmed from a BGP RIB entry on the same router with the same `prefix` and `nexthop` attributes (Lines 5-7). Besides, the BGP RIB entry should have been selected as the best route (Line 8). Such information is enough to uniquely identify the parent within the known stable state. The return value (Line 10) is a list of tuples denoting the IFG edges materialized by this rule.

Simulation-based inference. Lookup-based inference falls short in two scenarios. First, when a parent fact is absent from the known stable state (e.g., routing messages), and second, when the heuristics fail to infer enough information so as to uniquely identify the parents (e.g., we cannot know which policy clauses are used in the production of a BGP route by looking at the resulted route). We use local simulations to complement lookup-based inference. But simulations can only be performed in the forward direction, i.e., to compute a fact using simulations, we first need to know its parent. We use

Algorithm 2: Rule to infer ancestors of a post-import BGP message.

```
1 def infer_from_bgp_message(m, stable_state):
2   if not (m is BgpMsg and m.is_post_import):
3     return []
4   bgp_edge = stable_state.bgp_edges.lookup(
5     recv_host=m.host
6     send_ip=m.nexthop
7   )
8   origin_entry = stable_state.bgp_rib.lookup(
9     host=bgp_edge.send_host,
10    prefix=r.prefix,
11    status='BEST'
12  )
13  pre_import_msg, export_clauses =
  ↪ policy_simulation(
14    input=origin_entry,
15    policy=bgp_edge.export_policy
16  )
17  _, import_clauses = policy_simulation(
18    input=pre_import_msg,
19    policy=bgp_edge.import_policy
20  )
21  return [(pre_import_msg, m), (bgp_edge, m)]
  ↪ +
22  [(cl, m) for cl in import_clauses] +
23  [(origin_entry, pre_import_msg), (bgp_edge,
  ↪ pre_import_msg)] +
24  [(cl, pre_import_msg) for cl in
  ↪ export_clauses]
```

a generalized version of lookup-based inference to discover grandparent facts of a known fact, and then use simulations with the grandparents to infer their children (i.e., parents of the original fact).

[Algorithm 2](#) shows the simplified inference rule that infers the ancestors of a post-import BGP message. Line 13 demonstrates the use of simulation-based forward inference to compute a missing parent fact on the fly. The two prerequisites to simulate the BGP message—the grandparent BGP RIB entry (`origin_entry`) and the BGP edge—are discovered via lookup-based backward inference, on Line 8 and Line 4 respectively. The simulation returns the derived BGP message after applying the routing policy, as well as the policy clauses exercised during the process. The second forward-simulation (Line 17) is to discover the policy clauses that are hit during the import process. The return value includes the inferred IFG edges that connect to the input node `m` as well as ones that connect to parent `pre_import_msg`. The former corresponds to information flow $m_i \leftarrow m_j, e_k, \{c_{l_1}, \dots\}$ in [Table 1](#) and the latter corresponds to $m_i \leftarrow r_j, e_k, \{c_{l_1}, \dots\}$.

IFG construction. Next, we detail IFG materialization using inference rules. Assume for now that the information flow

Algorithm 3: IFG lazy materialization

Input: Initial nodes $\{v_i\}$; Inference rules $\{\phi_i : v \mapsto \{(u_i, v_i)\}\}$;
Output: Materialized IFG (V, E)
Data: Stable state data plane state (main RIB and protocol RIBs);
Routing edges; Configuration elements;

```

1 Procedure BuildIFG( $\{v_i\}, \{\phi_i\}$ )
2    $V, E \leftarrow \{v_i\}, \emptyset$ 
3    $V_{prev} \leftarrow \{v_i\}$  // dirty nodes of previous iteration
4   while  $|V_{prev}| > 0$  do
5      $V_{curr} \leftarrow \emptyset$  // dirty nodes of current iteration
6     foreach  $c \in V_{prev}$  do
7       foreach  $\phi \in \{\phi_i\}$  do
8          $E' \leftarrow \phi(c)$ 
9         foreach  $(u_i, v_i) \in E'$  do
10          if  $u_i \notin V$  then
11             $V \leftarrow V \cup \{u_i\}, V_{curr} \leftarrow V_{curr} \cup \{u_i\}$ 
12          if  $v_i \notin V$  then
13             $V \leftarrow V \cup \{v_i\}, V_{curr} \leftarrow V_{curr} \cup \{v_i\}$ 
14          if  $(u_i, v_i) \notin E$  then  $E \leftarrow E \cup \{(u_i, v_i)\}$ 
15      $V_{prev} \leftarrow V_{curr}$ 
16   return  $(V, E)$ 

```

is deterministic; the next section discusses how we handle non-determinism.

As shown in Algorithm 3, the IFG initially contains only the nodes representing the tested data plane state facts from the input and does not have any edges (Line 2). It is then iteratively expanded by applying inference rules on existing nodes. In each iteration, all inference rules are applied to the dirty nodes derived from the previous iteration (Line 8). The new nodes and edges inferred during such process are collected and merged (with deduplication) into the IFG (Line 9-14). The computation repeats until no new facts can be derived in an iteration.

4.3 Handling uncertainty

There are situations where it is not certain which stable state facts contributes to a given fact. One such scenario is BGP aggregation, where a prefix (e.g., 10.10.0.0/16) is added to the RIB iff at least one more of its more specific prefixes (e.g., 10.10.1.0/24) is present. When multiple more specifics are present, we do not know which one triggered the aggregate. Another such scenario is when multiple paths are available for a routing edge to be established, which can happen when the network uses multipath routing. Here, we do not know which path is actually used by routing messages.

It is important to model and report such uncertainty because the notion of contribution is different. Unlike deterministic contribution, when the contribution is non-deterministic, one or more parent facts can disappear without impacting the outcome represented by the child. Our experiments have scenarios where 78% of the configuration lines have non-deterministic contribution, and the tested fact would not be

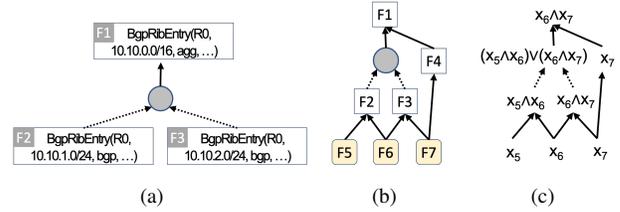

Figure 3: Modeling uncertainty. (a) BGP aggregate (F1) has two potential contributors. (b) F5 is weakly covered but F6 and F7 are strongly covered. (c) The predicates of IFG nodes.

impacted if any of them did not exist. Not separating such uncertain contribution would lead to misplaced confidence in how well configurations are tested.

We model contribution uncertainty using *disjunctive* nodes in the IFG. This node points to the parent fact (e.g., the aggregated RIB fact) and the multiple contributors to the parent point to this node. See Figure 3(a) for an example where a BGP aggregate could be triggered by either of the two more specific prefixes. When our inference rules encounter uncertainty during IFG materialization, they produce a disjunctive node and attach all contributors to it as children.

We introduce the notion of *weak* coverage to capture the configuration elements whose contribution to the tested facts is not critical. We define a contribution as non-critical if the tested fact will not be affected by deleting the configuration element from the IFG. In Figure 3(b), F5 is weakly covered when F1 is tested because F1 can be derived without any contribution from F5, via F2 and F6. On the other hand, F6 is strongly covered because, without it, neither F2 nor F3 can be derived and thus the disjunctive node cannot be derived. F7 is also strongly covered because it contributes to F4, which is essential to F1.

NetCov labels each covered configuration element as strong or weak after the materialization of the IFG. The label is determined as follows. We first assign a Boolean variable to each configuration element in the IFG. Next, we build a Boolean predicate of each IFG node on top of these variables. The predicate of a fact depends on the predicate of its ancestors in the IFG: A normal node depends on the conjunction of its immediate parents, and a disjunctive node depends on the disjunction of parents. Therefore the predicate of any IFG node is ultimately composed of the variables associated with configuration elements that lead to it, denoted as $\Gamma(v) = F(x_1, \dots, x_n)$. Figure 3(c) shows the predicates of IFG nodes in Figure 3(b). We represent these Boolean predicates using Binary Decision Diagrams (BDDs) [8] and build BDD predicates by traversing the IFG. By definition, a configuration fact (denoted as x_i) is strongly covered if and only if there exists a tested data plane state fact (denoted as v), v is reachable from x_i in the IFG, and x_i is a necessary condition of $\Gamma(v)$. Therefore, once the predicates are built, we test graph reachability and logical necessity between each pair of configuration facts and

tested data plane facts. Necessity $\neg x_i \Rightarrow \neg \Gamma(v)$ is equivalent to unsatisfiability of $\neg x_i \wedge \Gamma(v)$. While (un)satisfiability is NP-Complete in general cases, we note that it is efficient in our case—it can be reduced to computing the cofactor $\Gamma(v)|_{x_i=0}$ and testing whether the cofactor is constant false, both of which are efficient using BDD operations.

We further reduce the size of BDD predicates by precluding configuration facts that can reach tested facts via a path with no disjunctive node, such as node F7 in Figure 3(b). These configuration facts must be strongly covered so their necessity do not need to be tested. Besides, their validity variables can be replaced with constant true when building BDD predicates, which will not affect the strong/weak classification of other configuration elements. We empirically find this heuristic to be effective in reducing the number of variables used for weak coverage computation.

4.4 Future Extensions

Our current model tracks the contribution of configuration elements to concrete data plane state entries. While this view aligns well with tools that perform data plane testing [50], data plane verification [25, 29], and control plane testing [12, 49], it is not applicable to control plane verification tools [1, 7] that reason about data plane symbolically (i.e., simultaneously reason about multiple data planes under different environments). Control plane verification tools turn configuration into an internal model that is used for validation. NetCov can be extended to these tools by tracking how configuration elements contribute to the model, akin to how compilers link program source information to its intermediate representations.

The current implementation of NetCov supports BGP, a path vector protocol, and static routes. Other protocols, including link state protocols (e.g., OSPF) and label switching protocols (e.g., MPLS) can be supported with appropriate extensions. Such extensions require defining protocol-specific configuration elements and data plane state facts (such as label information base entry for MPLS) as well as all new information flows.

5 Implementation

We implemented NetCov with 4,000 lines of Python code. A total of 18 lambdas (Python functions) encode the IFG inference rules. NetCov uses Batfish [6] to extract configuration elements from configuration files and to run targeted simulations, and it uses CUDD [37] for BDD operations.

NetCov supports several major router vendors supported by Batfish, including Arista, Cisco, and Juniper. It builds a vendor-neutral representation of configuration elements using vendor-specific information provided by Batfish. Table 2 lists the configuration elements that NetCov currently analyzes.

NetCov may not consider all components of a device’s configuration. One category of such components is device

Type	Purpose
Interface	Interface and its settings (e.g., addresses)
BGP peer	BGP peer settings (e.g., IP address, AS number)
BGP peer group	BGP peer settings inherited by one or more peers
Route policy clause	One clause in an export or import route policy
Prefix list	List of prefixes, used in route policy clauses
Community list	List of BGP communities for route policy clauses
AS-path list	List of AS-path expressions for route policy clauses

Table 2: Configuration elements analyzed by NetCov.

management configuration (e.g., login settings), which does not impact data or control plane functionality. The second category is control plane components that are not currently modeled by NetCov. This includes IPv6 (which is not modeled by Batfish currently) and routing protocols other than BGP (e.g., OSPF). The presence of unconsidered components does not imply that NetCov cannot be used for that network. As we show in the next section, NetCov provides helpful coverage information for parts that are considered.

After constructing the IFG, which yields information on which configuration elements are covered, NetCov computes which lines are covered. NetCov leverages the Batfish parser to map configuration elements to line numbers. Each element typically spans multiple configuration lines, and when an element is covered, it deems all of those lines as covered.

Based on element and line coverage, NetCov produces three main outputs. The first is a coverage report at the granularity of individual lines (or elements). We produce this report in the `lcov` format, which is supported by common code coverage tools and enables users to visualize coverage results as annotations on configuration files. See Figure 4(a) for an example. The second is coverage aggregated at the file level, generated with the help of GNU LCOV [17]. See Figure 4(b) for an example. The third output is coverage aggregated by the type of configuration element, which shows what fraction of elements of each type are covered.

These outputs help users uncover testing gaps and improve their test suites in different ways. The aggregate results help identify systematic gaps such as "router A is poorly covered" or "routing policy clauses are poorly covered." The line-level results help them zoom in to specific gaps and develop tests that target them. The case study in the next section demonstrates this test suite improvement process.

6 Case Studies

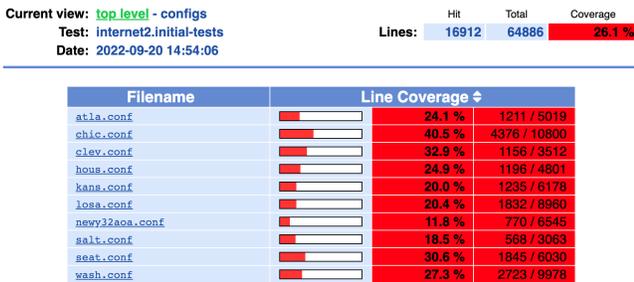

We present case studies of using NetCov on two disparate networks, one a wide-area backbone and another a datacenter. In each case, using realistic test suites, we show that NetCov provides insight into what is and is not covered and how these insights help improve the test suites.

```

6880 policy-statement SANITY-IN {
6881   /* Reject any BGP prefix if a private AS is in the path */
6882   term block-private-asn {--
6883   }
6884
6885   /* Reject any BGP NLRI=Unicast prefix if a commercial ISP's AS is in the path */
6886   term block-commercial-asn {--
6887   }
6888
6889   term block-nlr-transit {--
6890   }
6891
6892   /* Reject BGP prefixes that should never appear in the routing table */
6893   term block-martians {
6894     from {--
6895     }
6896     then reject;
6897   }
6898
6899   /* Reject BGP prefixes which Abilene originates */
6900   term block-internal {--
6901   }
6902 }

```

(a) Line-level coverage. Green background denotes covered lines, and red denotes uncovered lines. Some lines are collapsed for simplicity.

(b) File-level aggregate coverage. The overall coverage is at top right, and the coverage for individual files (devices) is in the table.

Figure 4: Example NetCov outputs.

6.1 Case Study I: The Internet2 backbone

Internet2 is a nation-wide network that connects over 60,000 US educational, research and government institutions. The routing design of Internet2 is typical of backbone networks. It has 10 BGP routers spread across the country. The routers are organized as a single autonomous system (AS), and they establish iBGP full mesh on top of internal reachability provided by the IS-IS protocol. The Internet2 routers connect to 279 external BGP peers, and heavily use route import and export policies. The import policy for an external peer has multiple policy statements, some specific to the peer and some shared within the same peer group. Peer-specific policies tend to specify a list of allowed prefixes from this peer, and others are used for sanity checking, preference setting, etc. Export policies are similarly structured.

Internet2’s configurations that we study have 96,672 lines (in Juniper’s JunOS format) across all routers. Of these, NetCov’s coverage computation considers 64,886 lines. The bulk of the unconsidered lines correspond to device management, IPv6, and IS-IS protocol.

We do not have the data plane state of Internet2, which is needed to run data plane tests. We approximate it using Route Views [42], a repository of BGP routes from over two hundreds ASes worldwide. This data helps approximate BGP messages that external peers of Internet2 send to it. Consider a peer with AS number X . If we find a prefix P in Route Views with AS-path $[A, X, Y]$, we assume that the peer sends

P to Internet2 with AS-path $[X, Y]$. The existence of AS-path $[A, X, Y]$ means that AS A must have a route to P with AS-path $[X, Y]$, which it announces to its neighbors. If we find multiple AS-paths for a prefix, we pick the one with fewest AS hops.

We use these BGP messages that each peer sends to Internet2 as inputs to simulate Internet2’s control plane using Batfish. The data plane state produced by this simulation is a coarse approximation of the real version, but it suffices to meet our goals of running data plane tests and characterizing configuration coverage.

6.1.1 Test suite coverage

To study how NetCov analyzes coverage for realistic test suites, we use the test suite proposed in Bagpipe [44]. It has three tests to validate Internet2’s BGP configuration.

- *BlockToExternal*: ensure that BGP routes with BTE community are not announced to any external (eBGP) peer.
- *NoMartian*: ensure that incoming BGP messages from external peers for prefixes in the private address space ("Martian") are rejected.
- *RoutePreference*: ensure that if multiple routes to the same prefix are accepted from multiple external neighbors, the selected route belongs to the most preferred neighbor. The neighbor’s preference depends on commercial relationship [13]. *Customers* are most preferred, followed by *peers*, and then *providers*⁴.

We implemented these tests using Batfish. *BlockToExternal* and *NoMartian* are control plane tests. *BlockToExternal* evaluates all BGP export policies on a set of BGP routes carrying the BTE community and asserts that the result be rejection. We generate the test cases by sampling BGP routes from the data plane state and attaching the BTE community to them. *NoMartian* evaluates all BGP import policies on a set of BGP routes destined for Martian addresses and asserts that the results be rejection. *RoutePreference* is a data plane test. It focuses on destination prefixes available via multiple neighbors and asserts that their local preferences reflect commercial relationship. We use CAIDA data [28] to infer commercial relationship between Internet2 and its BGP neighbors.

After running this test suite on Internet2, we find that it covers only 26.1% of configuration lines across all devices. Only a tiny fraction of configuration lines (0.5%) are weakly covered, so we do not separate weak/strong coverage for this case study; we will do that in the next one.

⁴As a not-for-profit network, Internet2 treats its member institutions as customers and other not-for-profit networks (such as ESNet) as peers. Internet2 does not have providers in its routing preference model.

To help understand what is and is not covered in more detail, NetCov enables network engineers to look at the data from multiple perspectives. Figure 4(b) shows per-device coverage. We see notable variation across devices, from 11.8% to 40.5%. As we show below, the test suite has systematic gaps, and the cross-device variation stems from different devices having different fractions of covered configuration elements.

Figure 5 shows the coverage broken down by the type of configuration elements. For simplicity, we create four buckets of element types, as shown in the legend. The bottom bar shows the fraction of reachable configuration lines in each bucket. The "Test Suite" bar shows the covered fraction of those lines, and the top three bars show the coverage of individual tests. The total coverage of individual tests is 0.6%, 0.9% and 24.7% respectively. *BlockToExternal* and *NoMartian* cover only one type of configuration element (routing policies), and even within this type, they cover a small fraction. *RoutePreference* covered all four buckets but its overall coverage is still limited.

Finally, NetCov reports that 27.9% of configuration lines are "dead code" that will never be exercised. They include defined BGP peer groups with no members and defined routing policies that are never used for any peer.⁵

With 69% of BGP configurations, 85% of interfaces, 88% of routing policies, and 57% of route attribute match lists being completely untested, this test suite is clearly under-testing the network. This leaves the network vulnerable to bugs in untested configurations elements. Prior to NetCov, it was not possible for network engineers to get any insight into the quality of their test suite. It was also not possible for them to get help toward systematically improving tests. We demonstrate this test suite improvement process next.

6.1.2 Coverage-guided test development

NetCov's feedback enables a test suite development process that enables users to systematically improve coverage, which helps test more critical aspects of the network and prevent outages. This process is iterative. In each iteration the user first identifies specific testing gaps and then creates new tests to target those gaps. We demonstrate the process using three iterations that focus on different types of gaps.

Iteration 1. We saw that routing policy coverage of *NoMartian* test is low (Figure 5) despite that it checks the import policies for all external peers. To investigate, we look at the structure of Internet2 import policies and find that routers have a policy named `SANITY-IN` which is shared by the majority of external neighbors. Figure 4(a) shows this policy with annotated coverage. Each router has an independent copy of

⁵Per best practices, these lines should be deleted. Or, at a minimum, they should be tested lest someone start using an unused, erroneous policy. When it comes to testing, such lines can never be exercised by data plane tests, though control plane tests may be written for them.

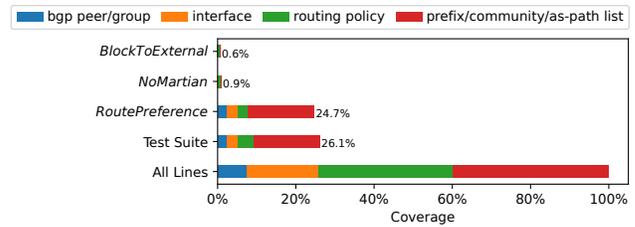

Figure 5: Coverage of the initial test suite broken down to each individual test and configuration type.

this policy, but the copies and the coverage results are identical across routers. Of the five clauses in the policy, the clause `block-martians` starting at line 6,896 is the only clause that is covered. This coverage result confirms that the *NoMartian* test did its job, and more importantly, it revealed a systematic testing gap—the other four classes of forbidden routes are not being tested.

Once we know the gap, the solution suggests itself. We added a new test, *SanityIn*, to enforce that the other four classes of received BGP messages should be rejected. After adding this test, we used NetCov to confirm that this testing gap had been addressed. Routing policy coverage was improved by 0.6% and all five terms of `SANITY-IN` were covered by the new test suite. The quantitative improvement is low because `SANITY-IN` is just one of many policies in the network. With feedback from NetCov, network engineers can identify testing gaps in other routing policies and add more tests in a similar way.⁶

Iteration 2. BGP peer configuration coverage of *RoutePreference* test in Figure 5 is surprisingly low, given that all external BGP peers are supposed to be checked. Upon further investigation we find that the uncovered peers have permitted prefix-lists that do not overlap with other peers' lists, which left these peers untested.

We added a new test, *PeerSpecificRoute*, to check that BGP announcements received from external peers should be accepted if their prefixes is in a peer-specific prefix list. This test improved BGP peer coverage from 32% to 46%. The rest of untested BGP peers are either not allowed to send BGP routes to Internet2 or is intended for other internal use, such as monitoring and management. This test also improved prefix-list coverage from 45% to 63%. The remaining of untested prefix-lists are mostly (30% out of 37%) ones that are defined by never referenced.

Iteration 3. The low coverage of interface configuration in Figure 5 reveals another testing gap. *RoutePreference* is the only test in the initial test suite that checks interface configurations, and it only considers one category of interfaces—ones that are used to establish the tested BGP edges. Many other

⁶Automatic test generation based on coverage feedback will further help engineers. We will investigate this in the future.

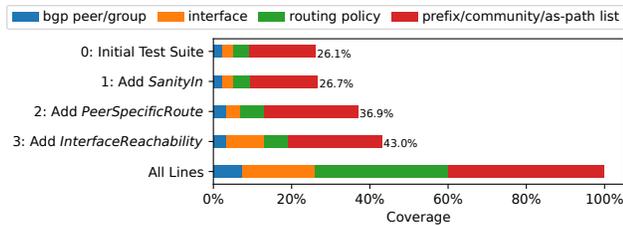

Figure 6: Coverage improvement with test suite iterations.

interfaces remain untested, including but not limited to ones that associate with untested BGP edges and other routing protocols, and the ones that are unused.

We added a new PingMesh-style [18] test, *InterfaceReachability*, to check that the IPv4 addresses assigned to interfaces should be reachable from each router in the network. This test increased interface coverage from 15% to 53%. The rest of untested interfaces do not have IPv4 addresses assigned.

Figure 6 summarizes the coverage improvement for the three iterations of test improvement in our study. After only three iterations, the overall coverage was improved from 26% to 43%. This final coverage number is far from perfect, but our goal was not to develop the ideal test suite for Internet2; we wanted to demonstrate how coverage information helps develop new tests. Networks are complex, and we should not expect to get the job done with 6 tests. Many more tests are likely needed. With NetCov, network engineers now have a tool to develop new tests that meaningfully improve coverage.

6.2 Case study II: Datacenter networks

We study the coverage for data center networks which have a different topology and routing design. We create synthetic fat-tree [2] networks with routers across three tiers. The leaf routers at the bottom tier connect to hosts. Aggregation routers at the middle tier connect to leaf routers in a pod and to spine routers at the top tier. The spine routers connect to the wide area network (WAN). The WAN is not part of the tested network. Each leaf router is assigned a /24 prefix which is advertised inside the data center through eBGP. Spine routers receive a default route (prefix 0.0.0.0/0) from WAN via eBGP and propagate it to lower tiers. At each spine router, the entire address space of the network is summarized into a /8 prefix and is announced to WAN. Multipath routing (ECMP) is enabled with maximum number of paths set to 4. Routing policies are only configured at spine routers to white-list the default route received from WAN peers. We synthesize the configurations of these networks in Cisco IOS format.

We study a test suite of three tests inspired in prior works on data center network validation [18, 23].

- *DefaultRouteCheck*: ensure that each router has the default route.

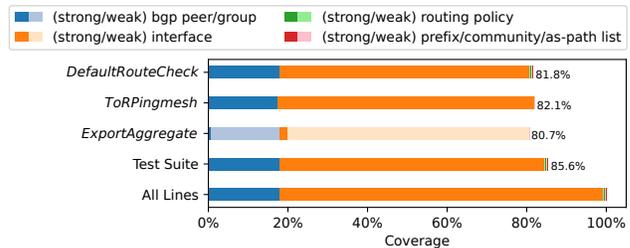

Figure 7: Coverage of synthetic datacenter network for different tests and types of configuration elements.

- *ToRPingmesh*: ensure that each leaf router’s assigned subnet is reachable from all other leaf routers.
- *ExportAggregate*: ensure that each spine router exports the aggregate route to WAN.

Figure 7 shows the coverage result when the network has a total of 80 routers. Given the uniformity of the network and the test suite, coverage results are similar for other network sizes. The total coverage of individual tests is 81.5%, 82.1% and 80.7% respectively, and the three tests together cover 85.3% of configuration lines. We find that these tests cover largely the same configuration elements—interfaces and BGP peerings between the data center routers—despite checking for seemingly different network behaviors. This result indicates that test development without coverage feedback can be ineffective in terms of covering the testing gaps.

The coverage of *ExportAggregate* shows a large proportion of weak coverage. This is because a spine router has routes to all leaf routers, so that all leaf subnets contribute to the tested aggregate route, albeit weakly. Separating out weak coverage here avoids false negatives of testing gaps—the aggregate routes would be there even if some of the BGP peering or interfaces are misconfigured, therefore testing the aggregate routes provides a weaker endorsement for the covered BGP peerings and interfaces to be bug-free.

By looking at uncovered configuration lines reported by NetCov, we learn that most correspond to host-facing interfaces on leaf routers. Adding tests that target those interfaces improves this test suite and eliminate testing gaps. We omit results of this iteration.

7 Performance Evaluation

We benchmark the performance of NetCov on both types of networks we studied above. Our test machine has two Intel Xeon CPUs (16 core each, 3.1 Ghz), 384 GiB of DRAM, and runs Ubuntu 18.04.

Figure 8(a) shows the time to compute coverage for each test in §6.1 and for the full test suite. It breaks out the time spent on simulations and strong/weak labeling, and, for reference, also shows the test execution time. We see that coverage

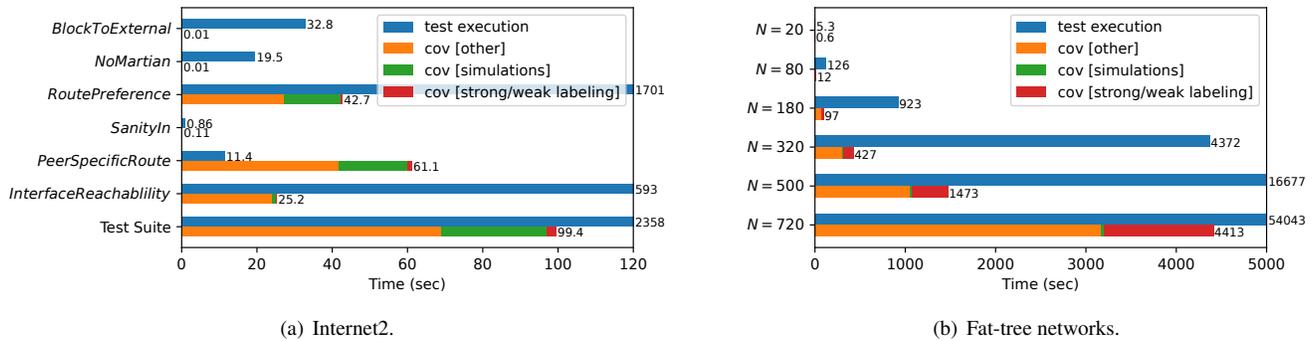

Figure 8: Time to compute coverage.

computation is reasonably fast. The full test suite takes only 99.4 seconds. In comparison, the test execution takes 2,358 seconds. The total coverage computation time is less than the sum for individual tests because facts tested by multiple tests are tracked only once. The graph also shows that simulations and strong/weak labeling are a minority component, which means that most of the time is spent on walking the IFG and doing lookups in stable state for backward inference.

Figure 8(b) shows test execution and coverage computation time for the test suite in §6.2, as a function of the data center network size. Coverage computation takes 4,413 *sec* on the largest network, which has 2,040,624 RIB entries. This time is less than 9% of the time to execute the test suite. While substantial, we deem it acceptable in practice. Configuration coverage analysis can be run in the background, as code coverage is often run. NetCov does not slow down test execution, which is on the critical path to finding configuration errors and updating the network.

However, time to compute coverage increases rapidly with network size. This is because the number of RIB entries grows quadratically and so does the number of vertices in the IFG. We find that the average time to materialize an IFG node does not change substantially because all computation is local to the node. The scaling trends suggest that to scale NetCov to much larger networks, we need a concurrent implementation of IFG materialization. Our current implementation is single-threaded (as Python interpreter is single-threaded).

8 Comparison to Data Plane Coverage

We demonstrate the unique value of control plane coverage by comparing it to data plane coverage. Following Yardstick [47], we quantify data plane coverage as the proportion of main RIB (forwarding) rules exercised. Figure 9 shows the comparison for different cases. Figure 9(a) shows the comparison for Internet2 for all tests in §6.1 and a hypothetical data plane test that inspects all main RIB rules. Figure 9(b) shows the comparison for fat-tree tests in §6.2.

Besides the obvious advantage that only control plane coverage can support control plane tests—the graphs show 0%

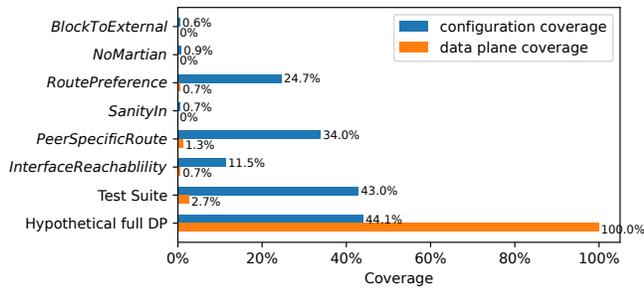

data plane coverage for these tests—there are two main advantages to using control plane coverage to guide network test development. First, it reveals testing gaps that can not be revealed by data plane coverage. Tests with high data plane coverage do not necessarily have high control plane coverage, as we can see in the last row of Figure 9(a). Covering 100% of the data plane state covered only 41% of the configuration. If the engineers were to improve the test quality under the guidance of only data plane coverage, they would not know that 59% of the configurations remain untested. The reason of this disagreement is that some configuration lines are only exercised under specific environments (failures, routing messages). For instance, list-filtered route policies apply on BGP messages within a specific range, and will only be exercised when such messages appear in the environment.

Second, testing more data plane state can sometimes be redundant in covering configurations, when the tests hit the same configuration elements. For example, the *Default-RouteCheck* test in Figure 9(b) has only 1.8% data plane coverage because it only tests default routes, which is a small fraction of all main RIB routes. However, because correct propagation of default routes incorporates many BGP peerings and interfaces in the network, this test has extensive configuration coverage (87%). The *ToRPingmesh* test covers much more data plane state (88%), but adding it atop *Default-RouteCheck* has little value because this state is derived from almost the same set of configurations lines. We do not necessarily imply that engineers should drop one of these tests, as there may be other reasons to keep both. Our observations are about their value toward configuration coverage.

9 Related Work

Our work builds on top of four lines of research.

Code coverage. We borrow from the software domain the idea of using code coverage to reveal testing gaps, quantify test suite quality, and help engineers improve their test suites [4, 15, 20]. Our coverage analysis techniques, however, are specialized to the operation of network configurations.

(a) Internet2.

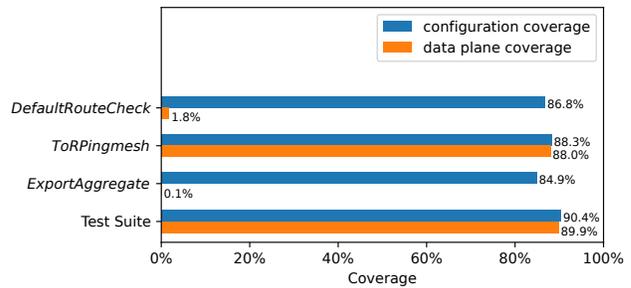

(b) Fat-tree with $k=10$.

Figure 9: Comparing control plane and data plane coverage.

Data plane coverage. Yardstick introduced data plane coverage metrics [47] that quantify the proportion of data plane elements such as forwarding rules and paths that are exercised by network tests. Configuration coverage goes further and maps tested data plane components to configuration elements that contribute to them. It provides more direct feedback because network engineers author configurations, not data plane state, and it supports testing of configuration elements that are not exercised by the current data plane state.

Network testing and verification. A range of tools can analyze properties of network data and control planes [7, 12, 14, 18, 19, 23, 25, 26, 48, 49]. NetCov borrows ideas from verification tools to concisely model the network, *e.g.*, focusing on stable state and routing protocol instances [7, 14]. However, NetCov target a different problem—reveal what is tested vs enabling testing of new properties—and uses different techniques.

Network provenance. Provenance systems can track causal dependencies of events in distributed systems. Provenance systems like ExSPAN [52] materialize provenance graphs by tracing system execution in forward direction. Negative provenance systems can reason about missing events [46] and materialize provenance graphs lazily using backward inference. NetCov too uses a graph-based model. However, it is unique in terms of accommodating network configuration into a provenance model, and this model, tailored to the stable state assumption, is more succinct. Further, it combines backward and forward inference to overcome the limitations of using only one type of inference.

Software configuration testing. As for networks, configuration testing is an important problem for software systems as well. Sun et al. developed a system that can link software tests to exercised configuration parameters [38]. They exploit dependence on configuration settings being explicit, observable via read/write operations that use standard *get/set* APIs. NetCov targets a setting where the dependencies are implicit and non-local. Routers read the entire configuration file, and their forwarding behavior depends on that file and information received from neighbors who in turn act based on their configuration files and their neighbors. That led us to develop

a different approach to tracking configuration dependencies. We will investigate in the future if our approach can be extended to software systems where dependence between tested runtime behavior and configuration is not explicit.

10 Summary

NetCov reveals which configuration lines are tested by a suite of network tests. It uses an information flow model based on control plane semantics to track which configuration lines contribute to tested data plane state. It accounts for non-local and non-deterministic contributions, and for performance, it discovers the graph lazily. Our experiments showed that NetCov successfully reveals coverage gaps for real-world networks and test suites, and these tests can have surprisingly low coverage, *e.g.*, 26% of configuration lines for Internet2. They also showed how its feedback helps improve coverage.

Abstract

Network load tester is important to daily network operation. Motivated by our experience with a major cloud provider, a practical load tester should satisfy two important requirements: **(R1)** stateful protocol customization, and **(R2)** real network traffic emulation (including high-throughput traffic generation and precise rate control). Despite the success of recent load testers, we found they fail to meet both above requirements. This paper presents Norma, a practical network load tester built upon programmable switch ASICs. To achieve the above requirements, Norma addresses three challenges: (1) modeling stateful protocols on the pipelined architecture of the ASIC, (2) generating replying packets with customized payload for stateful protocols, and (3) controlling mimicked traffic in a precise way. Specifically, first, Norma introduces a stateful protocol abstraction that allows us to program the logic of the state machine (*e.g.*, control flow and memory access) on the programmable switch ASIC. Second, Norma proposes a novel multi-queue structure to generate replying packets and customize the payload of packets. Third and finally, Norma coordinates meters and registers to construct a multi-stage rate control mechanism capable of offering precise rate and burst control. Norma has been used to test the performance of our production network devices for over two years and detected tens of performance issues. Norma can generate up to 3 Tbps TCP traffic and 1 Tbps HTTP traffic.

1 Introduction

Understanding whether the network meets expected performance is essential to today's cloud providers, especially for performance-sensitive services such as live streaming and edge cloud games [30, 35, 57]. For example, in edge cloud games, the players complain about their unsmooth feelings if the network latency reaches 50 ms, and cannot play the games when the latency exceeds 100 ms [54].

Network load tester is one of the most important testing tools that checks the performance of network devices by proactively generating various testing packets including different protocols, rates, and traffic patterns [7, 13]. A network load tester could be used by the operator to test the performance of devices, debugging the root causes of packet loss. In a typical network load testing scenario, the tester generates user-defined traffic and sends it to the Device Under Test (DUT). After receiving the testing packets, the DUT processes the traffic and forwards it back to the tester for further processing, such as dropping or replying to the incoming packets.

Based on the analysis of the outgoing and incoming traffic, the tester can evaluate the performance of the DUT in multiple aspects, including throughput, latency, and packet loss.

As a major cloud provider, we also deploy load testers in production networks to test pre-online network devices and functions. Load testers have become indispensable for daily network operation tasks, such as performance monitoring, failure troubleshooting, and stress testing. Building a *practical* load tester that works for large-scale cloud networks should satisfy the following important requirements from our network operators.

- **(R1) Stateful protocol customization.** Besides switches and routers which work in a stateless way, cloud networks also have complex and stateful network functions, such as stateful packet filters and L4/L7 load balancers. The protocols used by these network functions might be stateful (*e.g.*, HTTP) or self-defined by the cloud provider. To provide the all-around testing capability, a practical load tester should be able to generate packets with not only stateless protocols (*e.g.*, UDP) but also stateful (*e.g.*, TCP) and customized (*e.g.*, private tunnel protocols) protocols.
- **(R2) Real traffic emulation.** As the scale and single-port bandwidth of cloud networks grow fast, a practical load tester should be able to mimic real, cloud-grade traffic in a cost-effective way: (1) it can generate Tbps-level traffic, and (2) it can create and send precise rate packets with customized payload and burst patterns.

A number of previous efforts have focused on network load testing [7, 9, 13, 18, 24, 31, 32, 47, 53, 55, 59]. While these state-of-the-art systems can work well in principle, in reality in our situation, they fail to simultaneously satisfy the above two requirements (see Table 1). Specifically, software load testers [9, 18, 24, 31, 32, 47] and FPGA-based load testers [60] are unable to generate Tbps-level traffic or control rate precisely (*i.e.*, fail **R2**). On the other hand, hardware load testers (*e.g.*, Keysight [7] and Spirent [13]) can only generate and emulate fixed types of protocols (*i.e.*, unable to support the customized protocols **R1**). Recently, researchers have developed load testers based on programmable switch ASICs [53, 55, 59], which are capable of sending Tbps-level traffic and are customizable. While these pioneer systems have shown the potential to partially solve the above problems, they cannot customize stateful protocols or provide precise rate control, *i.e.*, partially failing **R1** or **R2**.

We, therefore, decided to build a practical load tester to

satisfy our operators' requirements for their daily usage.

Our approach: Norma. This paper presents Norma, a high-performance network load tester, based on the RMT-based¹ programmable switch ASIC. The key idea of Norma is to execute load testing based on template packets derived from tested protocols, which enables Norma to achieve **R1** and **R2** simultaneously. First, template packets continuously loop in the pipeline and can be conditionally replicated to generate testing packets of both stateless and stateful protocols. Operators can flexibly customize headers and payload of template packets; thus, Norma can be used to test various cloud network functions. Second, through controlling rates and patterns of replicating template packets, Norma can generate load testing traffic that faithfully mimics realistic traffic. Besides programmable switch ASIC resource limitations [33, 38, 39, 41, 50–52, 56], building Norma nevertheless requires us to address the following challenges.

Challenge 1: First, RMT-based programmable switch ASICs are unfriendly to modeling stateful protocols (e.g., TCP and HTTP), since the ASIC architecture is implemented as a pipeline that processes packets in a sequential way and only supports accessing states once per packet. However, most stateful protocols need to read and write a state multiple times. This, therefore, makes it difficult to model or customize stateful protocol behaviors on current programmable switch ASICs. On the other hand, testing the performance of stateful protocols (e.g., stateful load balancer, DDoS defense, and ACL) is crucial, which accounts for the majority of our load testing requirements and tasks. To the best of our knowledge, none of the prior work solved this problem. Existing load testers based on programmable switch ASICs like HyperTester [59] can only support stateless protocol customization. To address this challenge, we introduce a new data structure, named *stateful protocol abstraction*, to enable programming the logic of the state machine (including control flow and memory access) on programmable switch ASICs. We construct a state machine framework via the stateful protocol abstraction. In the framework, packets are looped inside the ASIC, and each round corresponds to a step in the state machine of the emulated stateful protocol. We can use this framework to emulate arbitrarily complex protocols (including both stateful and stateless), as long as the hardware resources of the ASIC are sufficient (§4.1 and §4.2).

Challenge 2: Load testers need to reply according to state machines when receiving packets of stateful protocol from DUT. Replying packets involves packet generation with customized payload as well as header modification, which presents the second challenge. The programmable switch ASIC uses PHV² resources to add, delete, and modify packet

headers and payload. Due to limited PHV resources, the capability of load testers to generate and modify packets with a large payload and statefully complex headers is inherently constrained. To address this challenge, we propose an efficient multi-queue structure based on registers³ inside the programmable switch ASIC. In this structure, the stateful packet will enqueue to trigger the corresponding type of template packet to dequeue. In this way, Norma supports generating replying packets with customized payloads for most stateful protocols (§4.3 and §4.4).

Challenge 3: The final challenge is that programmable switch ASICs is hard to offer precise control of the packet rate and burst, thus resulting in unrealistic traffic emulation. The above two control capabilities are important requirements of our daily operation and testing; however, we have not seen any of state of the art systems that can achieve the above goals. The rate control relies on the specific hardware named meter; however, in practice, the speed limit of the hardware meter is coarse-grained, i.e., not all target rates can be precisely achieved, which results in an error in the control of packet rate. In addition, the programmable switch ASICs do not support the generation of traffic bursts with given patterns. To address this challenge, we proposed a multi-stage rate control mechanism based on the coordination of meters and registers in the programmable switch ASIC. The meters provide coarse-grained rate control, which will be further tuned by the follow-up registers in a fine-grained manner. In this way, the special requirements of the tester for rate and burst control can be satisfied with great precision (§5).

Norma has been used to test the performance of pre-online devices that would be deployed in our production network for over two years. For example, we used Norma to test the forwarding capability and ARP learning rate of L2/L3 switches and tested stateful gateways by generating L4/L7 flows. Evaluation results show Norma can generate up to 3 Tbps TCP traffic and 1 Tbps HTTP traffic while maximizing the use of pipeline bandwidth. Experiments also show that Norma can achieve precise rate control and burst capability. The relevant rate error does not exceed 0.01% in the worst cases.

Contributions. We make the following contributions:

- It is new for us to implement the stateful responder into the programmable switch ASIC to support stateful protocols. The pipeline-folded switch ASIC and the queue implemented in P4 are the keys to make it possible.
- We propose high-precision packet rate and burst control method. This provides us the ability to reproduce traffic at accurate rates and desired burst patterns.
- We use Norma to test our pre-online devices. Norma is useful for our network developers and operators to find performance issues and system bottlenecks.

¹RMT (Reconfigurable Match Tables) is a reconfigurable pipeline-based architecture for programmable switch ASICs. Each pipeline consists of a parser, multiple match-action stages, and a deparser [22, 40].

²PHV (Packet Header Vector) stores and transits parsed headers or meta-data between neighboring stages. More details can be found in [10, 22].

³Registers are memory blocks attached to each stage, whose data can be shared by multiple packets across different ports inside a pipeline [10, 22].

Ethics. This work does not raise any ethical issues.

2 Background & Motivation

This section details our operators' requirements and discusses related work.

2.1 Requirements for Production

Based on the experience of our operators, we summarize the requirements of our network load tester in Table 1.

(1) Supporting protocol customization. In cloud networks, traffic can be carried via non-standard private protocols. These protocols are usually defined and experimentally developed by the cloud providers, *e.g.*, QUIC [42] and Multipath QUIC [28, 58], which provide great extensibility of network functions and can be quickly iterated according to the needs of upper-layer applications. These non-standard protocols and traffic are not supported by commercial hardware network testers.

In particular, the majority of protocols we need to test are stateful. The DUT keeps the state of L4/L7 sessions for stateful protocols. For example, an L4 gateway may perform a TCP relay or SYN proxy, and an L7 load-balancer balances the load of the HTTP traffic according to the HTTP header of the first packet. In these cases, the load tester should be able to emulate the establish, transmission, and release processes of a session, and reply to the incoming packets according to the specification of the protocol.

(2) Emulating realistic traffic. During the development and operation of network devices, our operators need to evaluate the device or optimize configurations by emulating realistic traffic. The volume of mixed traffic flows can be as large as O(1 Tbps), or O(1 Gpps) for small packets. It is essential to emulate the traffic similar to the realistic load. We have observed the case that a DUT works well in the experimental development with simple traffic, but suffers from continuous packet drop after it goes online. It is not acceptable for cloud providers.

To test the DUT with emulated traffic under heavy loads, the tester should support sending traffic at the line rate of DUTs. Besides, the tester needs to emulate various traffic patterns and mixed traffic flows for network operators to determine the optimal configuration like hash function, CPU allocation, and queuing policy of devices. The traffic is expected to be cheap in terms of hardware cost, power consumption, and rack size. Plus, in cloud network testing, the value of the field in the packet header is required to be editable. For example, one may expect the source IP address to be randomly chosen from the prefix 10.0.0.0/16.

In addition, since a network load tester is usually used for network checking, debugging, and troubleshooting, it is required to control the sending rate based on the determined configuration. In other words, the tester should be able to generate the random burst traffic and emulate the failure scenarios precisely. All of the testing data are collected by measuring the incoming and outgoing traffic in multiple dimensions,

such as throughput and packet drops. A network load tester is required to support fine-grained bidirectional measurement of the large volume of traffic.

2.2 Related Work

Table 1 shows the comparison between Norma and the state-of-the-art load testers in terms of our production requirements.

Software network testers. Software solutions [9, 18, 24, 31, 32, 47] are highly flexible. The early software network testers [6, 11, 17, 23] are based on the standard Linux IO API which limits the performance and accuracy. There are many works [9, 18, 31, 47] that utilize the IO frameworks such as DPDK [2], Netmap [47], and PF_RING ZC [8] that are working on accelerating packet processing on various CPU architectures. However, the computing bottleneck makes it difficult to apply to 100 Gbps network test scenarios. The state of the art such as MoonGen [31] needs over 14 2.4 GHz cores to generate 64-byte packets at 100 Gbps, corresponding to only one port capability of Norma. In addition, software solutions are not stable when testing complex packet processing due to the indefinite packet processing time [59]. Therefore, they are not scalable and cost-effective in industrial scenarios that require Tbps-level load testing.

Commodity hardware testers. Vendors like Keysight [7] and Spirent [13] provide network infrastructure performance tests using their test suites with hardware-based modules. These commercial hardware testers [7, 13] are able to emulate standard traffic demands by providing rich testing functions. There are also application and security tests that cover the L4 protocols. Benefiting from the specially designed software and hardware, it achieves high throughput and accuracy on packet generation and measurements. Commercial hardware tester uses dedicated ASICs from the vendors to accelerate network traffic generation, which can provide O(1 Tbps) traffic for stateless protocols.

However, the commercial hardware tester is a black box, which makes it hard to adapt to the agile development of self-defined protocols. The vendors are aiming to provide standard tests thus the customizability of user-defined packet structures and protocols is lacking. Besides, they are expensive to deploy in a large-scale system (*e.g.*, \$100,000 for a 100 Gbps dual-port packet generation module [59]) which requires a large number of testers.

Programmable hardware testers. To achieve a balance of programmability and performance, some network testers [19, 27, 48] using programmable hardware such as NetFPGA [60] are proposed. These works achieve accurate rate controlling and precise measurement results. However, the NetFPGA-based testers are still expensive to achieve Tbps-level test traffic (*e.g.*, a NetFPGA board costs \$5,341 with two 100 GbE interfaces [1], and a programmable switch ASIC with 32 100 GbE interfaces only costs \$2160 [5]). And it is non-trivial to develop new functions on FPGA boards.

Table 1: The required properties of a tester listed by our network operators, and the comparison between Norma and prior work.

Requirements	Meaning	Norma	CHT	ST	HT	NetFPGA
Stateful Protocol Support						
Generation	Whether the traffic of stateful protocols (<i>e.g.</i> , HTTP) can be generated?	✓	✓	✓	✗	✓
Customization	Whether the stateful protocol can be fully customized by users?	✓	✗	✓	✓	✓

CHT=Commercial Hardware Testers ST=Software Testers HT=HyperTester

Programmable switch ASICs like Intel Tofino [16] provide customizable packet processing logic via programmer-friendly P4 language [21]. HyperTester [53, 55, 59] leverages the recirculate primitive in P4 language and packet replication engine to generate packets. It can generate stateless traffic at the rate of 1.6 Tbps. HyperTester confirms the feasibility to implement a stateless hardware tester via Tofino’s programmable switch ASICs and proves the traffic quality via microbenchmarks. However, HyperTester cannot emulate the data plane behavior of the stateful protocol. We cannot use HyperTester to test a stateful L4/L7 gateway, because HyperTester cannot generate and maintain the session as what the TCP/HTTP specification describes. In addition, HyperTester cannot emulate realistic traffic in a high-fidelity way. We analyze the reason and conduct experiments in §9.2. Inspired by HyperTester, IMap [43] uses programmable switch ASICs for network scanning. It is not a network load tester in a general sense.

Stateful packet processing. Many works are providing stateful packet processing to offload networking functions into hardware. FlowBlaze [46], FAST [44], and OpenState [20] define state machine abstraction to describe network functions, while Domino [49], dRMT [26], SDP [34], and Ibanez *et al.* [37] propose customized RMT-based architecture using FPGA to achieve the processing ability of the stateful packet. These works are orthogonal to Norma. Norma focuses on emulating high-throughput stateful traffic to test the performance of the DUT, instead of implementing every detail of stateful protocols. This gives us the chance to implement the state machine on programmable switch ASICs like Tofino. None of the prior work focuses on this.

3 Norma Overview

Norma is a practical cloud network tester for load testing. We use the programmable switch ASIC to leverage its large capability of packet processing and programmability. In this part, we explain the reason for using the pipeline-folded [14, 15, 45] programmable switch ASIC first (§3.1). Then, we introduce the high-level architecture of Norma (§3.2). This architecture illustrates how our testing functions are arranged in the ASIC and work as a practical network tester.

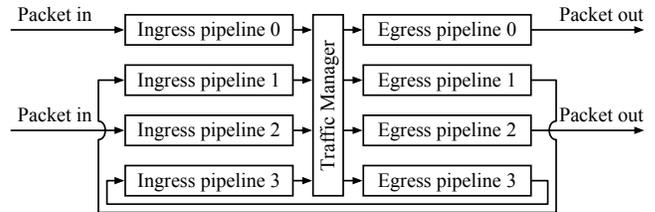

Figure 1: The packet path of pipeline-folded programmable switch ASICs. Half of the pipelines are in loopback mode.

3.1 The Pipeline-Folded Switch ASIC

As shown in Figure 1, the pipeline-folded programmable switch ASIC we use (*i.e.*, BFN-T10-032Q [5]) has $64 \times 100G$ ports with maximum port bandwidth of 3.2 Tbps. It has four physical pipelines in total, but only two of them are connected to front panel ports (*e.g.*, pipeline 0/2, namely *external pipeline*). The remaining two pipelines are connected to the internal loopback ports, whose egress direction is wired to the ingress direction inside the ASIC (*e.g.*, pipeline 1/3, namely *internal pipeline*).

Norma chooses the pipeline-folded programmable switch ASIC for three reasons. (1) The internal pipelines and external pipelines can be programmed with different P4 programs. By dividing functions such as basic switching, packet editor, stateful responder, *etc.* into the above two groups, Norma can support all of them simultaneously with the limited hardware resources inside the ASIC. (2) Besides the recirculation capability provided by P4 primitives, internal pipelines provide 3.2 Tbps extra loopback bandwidths. Therefore, high-throughput traffic generation can be achieved without affecting the front-panel port throughput. (3) The folded pipelines double the stages we can use. That means we can implement more complex processing logic than the unfolded one, which is the fundamentals of stateful packet processing. The RMT-based programmable switch ASIC guarantees that these additional stages do not affect the processing rate of the traffic and only introduce negligible latency.

3.2 Norma’s Architecture

Norma takes advantage of the pipeline-folded programmable switch ASIC and arranges all required functions in the architecture shown in Figure 2. The input and output represent the front-panel ports of the switch. The basic switching logic (omitted in figures) and measurement functions are imple-

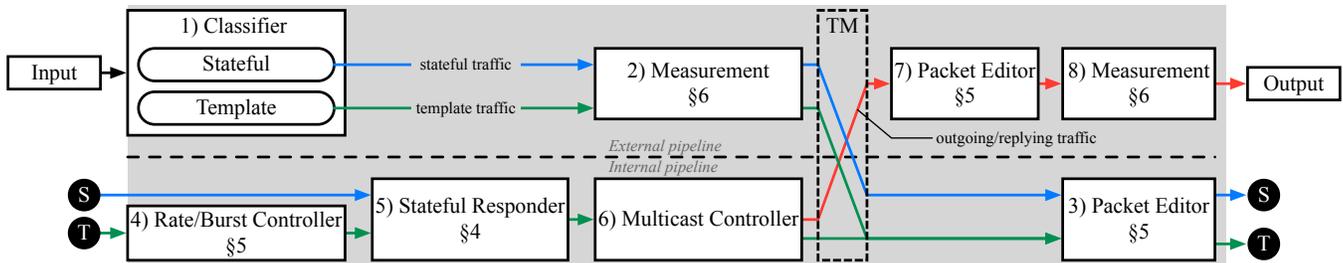

Figure 2: The function models and workflow of Norma. Different colors of arrow lines represent different traffic types. Nodes S and T are loopback ports.

mented in external pipelines, while other functions are implemented in internal pipelines. The **S** and **T** nodes represent two loopback ports in internal pipelines, allowing packets to travel from the egress back to the ingress. The traffic manager (TM) is responsible for packet replication and forwarding.

Traffic. Norma needs to classify incoming traffic to decide which function to enable according to the user’s test task. We detail three kinds of traffic shown in Figure 2 as follows.

- **Stateful traffic** includes incoming packets of stateful protocols such as TCP and HTTP, represented as blue lines. Once received, these packets will be preprocessed by the packet editor (*e.g.*, updating the TCP sequence number) and then handled by the stateful responder, which triggers replying traffic.
- **Template traffic** includes template packets sent from the control plane, represented as green lines. Control plane programs construct template packets according to the user’s test task and send them to the ASIC via PCIe. Then Norma keeps these packets looping all the time in loopback ports of internal pipelines. If a template packet is marked by the multicast controller, it will be replicated by the packet replication engine (PRE) in the ASIC’s TM module. Then the replicated packet will be forwarded to the DUT as outgoing traffic via external egress pipelines. In this way, Norma can generate line rate traffic on the data plane, though there is no memory for the ASIC to store packets. The looping template packets determine what kind of traffic can be generated.
- **Outgoing/Replying traffic** is represented as red lines. The two traffic types can be regarded as the same because they go through the same paths. The replying traffic is triggered by the stateful responder, while the outgoing traffic is not.

Modules and workflow. We now show the function modules of Norma in turn by the following workflow.

- 1) **Classifier.** The traffic is classified by the classifier first. Norma mainly focuses on stateful traffic and template traffic. Other traffic is also classified, but omitted in Figure 2.
- 2) **Measurement.** All traffic enters the measurement module and is measured according to the user’s measurement rules. Measurement functions are described in §6.

- 3) **Packet Editor.** Stateful traffic and template traffic are forwarded to internal egress pipelines. The packet editor preprocesses the stateful traffic or modifies template packet fields. The packet modification function is introduced in §5.
- 4) **Rate/Burst Controller.** After looping back to internal ingress pipelines, the rate/burst controller marks template packets to control the rate and burst pattern of the generated traffic. This part is detailed in §5.
- 5) **Stateful Responder.** Norma uses the extended finite-state machine (EFSM) [25] to abstract the stateful protocol. The stateful responder triggers the EFSM according to the input stateful traffic. The replying traffic is generated with the help of the template traffic. This part is detailed in §4.
- 6) **Multicast Controller.** The multicast controller marks the template traffic and forwards it to the internal egress pipeline it comes from to complete the high-speed looping of the template traffic. In addition, the marked template packets are replicated to the target output port through TM.
- 7) **Packet Editor.** Outgoing traffic needs to go through the packet editor on the external egress pipeline one more time. The supported actions of these two packet editors are different for sophisticated traffic generation capabilities.
- 8) **Measurement.** Finally, all outgoing traffic enters the measurement module in the egress direction.

4 Emulating Stateful Protocol

The essence of emulating a protocol is to run the processing program on the programmable switch ASIC. Although, it is not easy to port programs that originally run on CPUs to the ASIC. The protocol implemented on Norma for testing the DUT can be reduced to a human-descriptive sequence of packet interactions, as long as the DUT does not perceive the differences. Therefore, our high-level idea is to convert such a program into a state machine and write it into the match-action table.

In this section, we first introduce the EFSM [25] abstraction of stateful responder, which helps us establish a general stateful protocol programming pattern for Norma (§4.1). Then we take the HTTP protocol as an example to show the implementation details of the stateful responder in three steps: executing

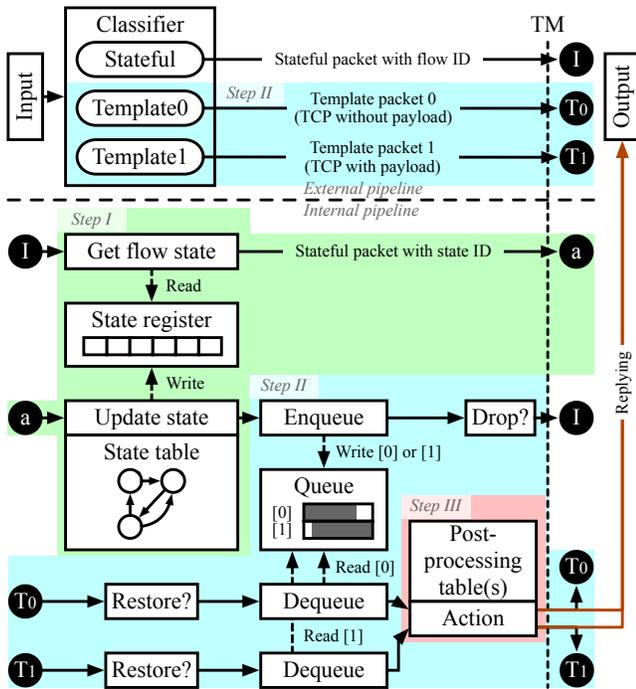

Figure 3: A detailed view of the components of the stateful responder. The classifier is not included in the stateful responder but used to describe where the inputs come from.

the state machine (§4.2), generating replying traffic (§4.3), and postprocessing of the replying traffic (§4.4). The brief packet path and table placement are shown in Figure 3.

4.1 The Stateful Protocol Abstraction

To handle stateful protocols, we need to program the processing logic of the protocol in the programmable switch ASIC. The main process is to generate replying packets according to the flow state and stateful packets, and the abstraction of this process can be represented by the EFSM.

EFSM abstraction of Norma. An EFSM in Norma is defined as a 7-tuple $M = (I, O, S, D, F, U, T)$. S is a set of flow states. I is the current flow state. O is the next flow state. D is a set of variables, such as packet fields, metadata, and registers. F is a set of enabling functions that trigger transitions based on the variables ($f_i : D \rightarrow \{0, 1\}$). U is a set of update functions that update variables ($u_i : D \rightarrow D$). T is a transition relation ($T : S \times F \times I \rightarrow S \times U \times O$). Table 2 shows the state table of the EFSM that handles HTTP GET requests. The conditions are the enabling functions in set F , and the actions are update functions in set U .

Hardware bases and limitations. The EFSM abstraction provides an interface for users to customize stateful protocols. Specifically, users need to construct the following three parts in Norma to realize the EFSM. The first part is variables D and flow states S . The parser and deparser provide the ability to locate packet fields and metadata. Because programmable switch ASICs natively support registers, the flow states are

Table 2: A part of the simplified HTTP state table.

Curr S	Condition	Next S	Action
0	RST	0	ig_md.skip_mc = 1;
0	SYN	2	hdr.tcp.flags = R;
0	Unknown	1	hdr.tcp.flags = R;
1	SYN	2	hdr.tcp.flags = S A;
1	Unknown	1	ig_md.skip_mc = 1;
2	RST	0	ig_md.skip_mc = 1;
2	HTTP GET	3	hdr.payload = 0x48...
2	Unknown	1	hdr.tcp.flags = R;
			...

saved in registers and updated by register actions [14].

The second part is conditions F . The conditions can be implemented as keys in the match-action table. State transitions and actions are triggered by matching the variables like the current flow state and the input stateful packet. However, it should be noted that the matching ability of the key is limited. The relationship between keys in a table can only be a logical AND relationship, so complex matching rules need to be expressed using multiple entries.

The final part is actions U . The actions modify and send the template packets to reply to the stateful packet. It should be noted that the implementation of actions is limited by the resource constraints of the programmable switch ASIC. Excessive register action and table execution may exceed the number of stages in the switch. And it is hard to implement actions that require iteration, such as sorting headers in a packet. A possible solution is splitting the action that requires iteration into multiple steps. The stateful packet loops in the internal pipeline through node I in the internal pipeline in Figure 3 and executes these steps. But this solution reduces the throughput of the flow processing.

4.2 Executing State Machine

Implementing the EFSM on programmable switch ASICs is challenging due to limitations on registers, and table actions. Next, we will introduce the details of the state machine implementation, as shown in Figure 3 Step I.

State register. Norma stores the state of each flow in a register array. Initially, a flow ID is assigned by the classifier to each flow and used as an index to access registers. Then, the stateful packet is forwarded to the internal pipeline with its flow ID for indexing its state register. The flow state registers store current state ID in Table 2 and other flow information such as TCP sequence number, which can be read by the template packet directly for generating the replying packet.

A side benefit of the flow ID is that it releases the fields of 5-tuples and MAC addresses in the stateful packet. When we generate the replying packet, these fields can be retrieved via a post-processing table with flow IDs. Therefore, we can write the flow ID and other bridged metadata⁴ into these fields to avoid additional bandwidth consumption when the packet

⁴Bridged metadata is a temporary header carrying the data calculated in current and previous pipelines to the next pipeline [14].

carries the metadata looping from egress pipelines to ingress pipelines.

State updating. As described in §4.1, the state table stores the conditions for state transition. For the stateful packet, it first reads its state ID from the state registers. Then, it gets the next state ID and action ID from the state table. And finally, the stateful packet writes a new state ID back into the register. However, this process cannot be done simply because of the register access restriction that a register cannot be accessed more than once in one pass (a packet goes through the ingress pipeline and egress pipeline). Reading and updating are two accesses that cannot be merged into one due to complex dependencies. To break this limitation, our idea is to let the stateful packet do another pass. In the first pass, the stateful packet reads the state register to get the state ID. In the second pass, the stateful packet gets the new state ID through the state table and then writes back to the state register. Note that this design can make state register updating non-atomic, further discussed in Appendix A.

State machine bypass. Some protocols can be implemented with state machine bypass. Taking the SYN flood test as an example, the tester receives a SYN packet and replies with an RST packet. The SYN packet can be preprocessed by the packet editor to obtain the action ID. Then, the packet skips Step I in Figure 3 and directly passes the relevant packet information to generate replying packets. For the stateless traffic generation like UDP and ARP reply, the entire stateful responder can be skipped.

4.3 Generating Replying Packets

Norma generates replying packets by replicating the template packet looping in the internal pipeline, as shown in Figure 3 Step II. Take the HTTP GET test task as an example. Norma needs to generate a PUSH packet when receiving an ACK packet. The PUSH packet has a 1460-byte payload, and the ACK packet does not. If the programmable switch ASIC can add or delete the payload, we can generate these two kinds of packets by modifying the input stateful packet. However, PHV resources limit the total length of packet headers that can be parsed. The 1460-byte payload cannot be completely stored in the PHV. So we have to prepare ACK template traffic and PUSH template traffic with 1460-byte payload separately to generate corresponding traffic. Since the stateful packets and template packets do not share packet fields and metadata, Norma needs to transfer information from the stateful packets to the template packets, such as the sequence number and action ID. Then in post-processing tables, Norma can modify the template packets according to the transferred information to generate required replying packets.

Next, we will detail the approach to transferring information across different packets.

A strawman solution. A straightforward way to transfer information across packets is using a queue. The incoming stateful packet pushes necessary information into the queue, and then

the template packet pops the information to its corresponding fields or metadata. The register array in programmable switch ASICs can be used to implement the queue. Besides the register array for the elements, the queue needs three more registers to maintain the data structure, one for the head pointer, one for the tail pointer, and one for the queue length. Compared with the common queue data structure, the one in programmable switch ASICs has two critical limitations.

First, the template packet cannot decide whether to dequeue according to the head element. To dequeue according to the head element, the tester must first check whether the queue length is zero, then read the queue element via the head pointer, and finally decide whether to decrease the queue length. In this way, the queue length register is accessed twice in one packet path, which is not allowed by programmable switch ASICs. Since template packets will inevitably take out information from the queue, the queue cannot be shared by multiple types of template packets.

Second, there is no way to prevent the queue from overflowing. Since the packet paths of the stateful packet and the template packet are parallel, to ensure parallel safety, the instructions for dequeuing and enqueueing must be executed in the following order. For dequeuing, reading elements must occur after decreasing the queue length; and for enqueueing, writing elements must occur before increasing the queue length. To ensure that the queue does not overflow, the queue length is compared with its capacity to get the enqueueing permission first. Then the stateful packet writes its information to the queue. And finally, the queue length increases. In this way, the tester accesses the queue length register twice. So there is no method to check the queue length before enqueueing.

In Norma, the consumer of the queue is the template packets, and the producer of the queue is the stateful packets. Template packets poll from the queue to generate replying packets. For example, the PUSH template packets poll the queue for ACK packets. Therefore we must ensure that the polling rate is higher than the arrival rate of the stateful packets to avoid queue overflowing.

Multi-queue for multiple template traffic types. Because of the limitations of the queue, only the stateful packet can choose what kind of template packets to reply to. It is straightforward to allocate a queue for each type of template packets. As shown in Figure 3 Step II, the stateful packet enqueuees using queue ID which is obtained from the state table and then triggers the corresponding type of template packet to dequeue. Compared to the strawman solution, there are two changes to the multi-queue data structure. The first change is that three register arrays are used as head pointers, tail pointers, and queue lengths. Each queue ID identifies an element in these register arrays. The second change is that the index of the queue elements needs to be re-planned. A typical method is using some lower bits of the pointer to represent the queue ID, and the remaining bits to represent the element offset in the queue. For example, one register array with a capacity of

256 is used as 16 queues. The lower four bits are the queue ID and the higher four bits are the offset.

Modifying payload. For some test cases where the complete or partial payload of the template packet is capable to be parsed in the PHV, we can treat this payload as a normal packet header. First, the parser needs to parse the payload as a header according to the *total length* in the IP header. Before entering the post-processing table, the previously added payload header must be set to invalid to avoid adding payloads repeatedly. Second, the payload header needs to participate in the calculation of the TCP checksum, which should be implemented in both the parser and the deparser. In this way, Norma can add, delete, and modify the payload without queues.

4.4 Post-Processing

As shown in Figure 3 Step III, post-processing tables are used to modify the template packet and finally generate the replying packet. First, the stateful packet enqueues the flow ID and action ID. Then, the template packet obtains the action ID from the queue and executes state actions according to this action ID in post-processing tables. State actions must implement the following functions: (1) restoring the MAC addresses, IP addresses, and TCP ports according to the flow ID; and (2) setting the correct egress port to the replying packet. Other instructions such as updating the TCP sequence number depend on the user’s testing requirements.

5 Emulating Realistic Traffic

Now we introduce how Norma emulates realistic traffic. We have two requirements for real traffic generation. First, the types of outgoing traffic generated by Norma cover our test scenarios (§5.1). The packet editor can modify the fields of the outgoing packet fields according to the user’s test tasks such as port scanning and host probing. Second, the rate of outgoing traffic controlled by Norma covers our test scenarios (§5.2). Norma leverages the packet header compression technique to overcome the bandwidth bottleneck caused by bridged metadata conveyance, thus achieves the line-rate traffic generation (Appendix B). On this basis, the rate/burst controller is able to control the outgoing traffic rate accurately and the burst pattern can be customized by the controller to emulate the network traffic in corner cases.

5.1 Two-Stage Packet Editor

If the resources of the external pipeline are sufficient, the packet editor only needs to be implemented on the external egress pipeline. However, most resources of the external pipeline has been occupied by switching functions. There are no more stages available to support register operations like generating random numbers and execution of the packet editor table actions like packet field assignment.

We propose a two-stage editing mechanism to overcome this limitation. Instead of editing the outgoing packet on the external egress pipeline only, Norma splits the packet editor

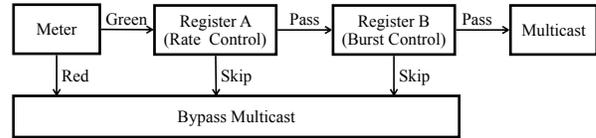

Figure 4: The multi-stage rate control mechanism. Meters and registers determine whether to multicast the template packets or not to control the traffic rate and burst pattern.

into two parts. Because the internal egress pipeline is not used by the switching function and measurement functions. We implement a major packet editor that edits the template packets on the internal pipeline first to complete most of the work. However, modifying the template packet alone is not enough. The outgoing traffic on multiple front-panel ports is identical if these modified packets are replicated to these ports through the PRE. So there is a minor one that edits the outgoing traffic on the external pipeline to differentiate them on each port. We leave implementation details in Appendix C.

5.2 Precise Rate & Burst Control

The traffic rate is an important feature in realistic traffic emulation. Norma is required to send the traffic exactly at the configured rate with diverse burst patterns. The meter [36] (usually implemented by a token bucket) is a common rate control component provided by the programmable switch ASIC. In Norma, the meter first colors the template packets that loop in the internal pipeline at line rate to red or green. The multicast controller then marks the drop flag to the red packets and writes the multicast metadata to the green packets to generate outgoing traffic at the target rate. But the following two limitations make the meter not quite practical. 1) The meter colors the packets of the stable traffic with an equal time interval. It is impossible to generate burst traffic where packets are expected to be sent in batches. 2) The target rate has a finite precision, *i.e.*, not all target rates can be precisely configured. The actual rate of the meter can be different from what we set, and the error grows even larger if we choose a shallower bucket depth to avoid unexpected bursts.

Norma proposes a multi-stage rate control mechanism in the rate/burst controller to obtain the ability of accurate rate control and bursts. As shown in Figure 4, the mechanism is based on a meter, appended with multiple register units (*e.g.*, 2 units in the figure). Each unit is implemented in the same way, which skips the following m packets after passing n successive packets. These units are connected in a cascaded way, and the parameters m and n can be configured individually. Next, we show how the design solves both two problems.

First, for the case of accurate rate control, the user wants to generate 10 Gbps traffic. However, the two closest rates supported by the meter are 9.9 Gbps and 10.1 Gbps. In this case, we can configure the meter to the larger rate. The parameters m and n of register A in Figure 4 are set to 1 and 100, respectively, which means skipping 1 packet after passing 100 packets. Therefore, the final rate becomes $\frac{10.1 \text{ Gbps} \times 100}{1+100} = 10 \text{ Gbps}$.

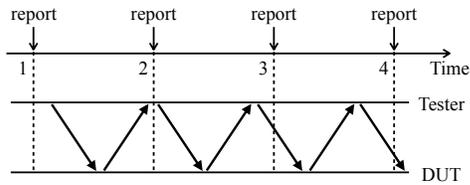

Figure 5: Cross-interval packets make counters out of sync. In time 2-3, the tester sends two packets and reports one is lost, but it receives the lost one in time 3-4.

Second, for the case of burst pattern control, the user wants to send burst traffic whose peak rate and average rate are 10 Gbps and 4 Gbps, respectively, which means there are 1,000 packets in a burst batch. To meet this goal, we only need to configure the m and n of register B to 1,000 and 1,500, respectively. These registers can be used flexibly. We can use two or more registers together to get a more precise rate or to construct complex burst patterns.

6 More Practical Considerations

To use Norma in practice, we also need to address some engineering challenges. For a load tester, measurement is one of the most important engineering challenges, since it is used to estimate the performance of tested networks. We have two requirements for the measurement. First, the measurement must be accurate, which means that the measurement must be done on the data plane as much as possible. Second, the measurement should not affect the functionality of the DUT and the pattern of the outgoing traffic. This means that the outgoing packet should not carry additional headers to store information such as timestamps.

This section first presents a measurement technique based on a flapped version bit, which can obtain high-precision traffic metrics in real time (§6.1). Then, we detail the blind measurement technique used in the delay measurement that avoids adding extra information to the outgoing packets (§6.2).

6.1 High-Precision Real-Time Measurement

A straightforward way is to let the programmable switch ASIC periodically report the counter value to control plane programs. Then, the metrics (*e.g.*, throughput) can be calculated as the quotient of the counter value difference and the reporting period. However, this method is inaccurate for complex metrics relying on bidirectional measurements. Consider the measurement of packet drop rate in Figure 5, which counts in both ingress and egress directions and reports the difference. Note that there is a *cross-interval packet* that is sent before the third report (at time 3) and received after it. Thus the ASIC knows that there are two packets sent in total and only one packet received during the reporting interval 2-3, and reports “one packet is lost” to the control plane at time 3. But in fact, there is no packet loss.

Norma synchronizes the counters in two directions by embedding a version bit in packet headers (*e.g.*, one bit in the

IPv4 *identification* field). The version bit flaps every time a report happens. For example, in Figure 5, the version bit values in three reporting intervals can be (1,0,1) or (0,1,0), respectively. In the meanwhile, each original counter will be replaced by a counter group composed of two counters, corresponding to two versions. When receiving a packet, the ASIC reads the version it belongs to from the packet header, and updates the counter indexed by the version. Choosing the reporting period to a value larger than the maximum forwarding time of the DUT, the cross-interval packets will disappear.

While Norma achieves high-precision real-time measurement, it also adds a delay in reporting period to the data report. In addition, the SRAM used by counters is doubled.

6.2 Blind Measurement of Forwarding Delay

Typically, the forwarding delay can be measured by embedding a timestamp at the end of the packet. When Norma receives it, the timestamp will be parsed out and then compared with the current timestamp. However, this method cannot be applied to the programmable switch ASIC, whose pipelines are unaware of the packet payload. An alternative way is to embed to timestamp between the headers where the ASIC can parse, but it does not work for stateful protocols. For example, the HTTP header cannot be parsed by the ASIC due to the variable header length, and such embedding inserts the timestamp between the TCP header and the HTTP header. When the DUT (*e.g.*, an L7 gateway) receives the packet, it incorrectly treats the timestamp as an HTTP header. Another way is to embed the timestamp in packet headers, but there is not enough room for a 32-bit nanosecond timestamp, which is necessary for measurement precision.

Norma proposes the *blind measurement* technique, which does not embed or add a timestamp into the packet but sends blindly. Our approach is based on the synchronization framework (§6.1). Within each reporting interval, the ASIC records the timestamp of the first outgoing packet in a register and regards the value as base timestamp B_o . For following outgoing packets in the interval, the ASIC calculates relevant time as the difference between its timestamp and the base timestamp and adds it to a time register. Here we use the relevant time to avoid arithmetic overflow and denote T_o and P_o as the sum of relevant time and the outgoing packet number, respectively. The ASIC processes the incoming packets in the same way, and we denote corresponding values as B_i , T_i , and P_i , respectively. When the interval passes, the ASIC reports the all above values to the control plane, and then the control plane calculates the average delay d as: $d = (B_i + T_i/P_i) - (B_o + T_o/P_o)$. It is noticeable that packet loss can affect the precision of blind measurement. We leave the analysis in Appendix D.

We use the example in Figure 6 to illustrate how it works. Assume that the base timestamps of outgoing and incoming packets are 1000 and 1005, respectively. Three outgoing packets are sent at the time 1010, 1020, and 1030, so the time

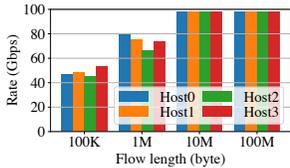

Figure 7: CDN load balance throughput.

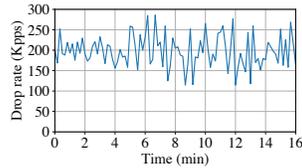

Figure 8: Packet drop on the traffic manager.

register of outgoing packets is added by 10, 20, and 30, respectively, which sum up to 60. Similarly, the time counter of incoming packets is 360. Therefore, the control plane calculates the average delay as $(1005 + 360/3) - (1000 + 60/3) = 105$.

7 Implementation

Different from prior work, Norma depends on the pipeline-folded programmable switch ASIC, and therefore, is built from scratch. We write about 1,200 and 1,000 lines of P4 code to implement HTTP and TCP traffic responding functions, respectively. Except that, we write about 8,400 lines of P4 code to implement the rest of the data plane, as well as basic switch functions such as routing and ACL.

The control plane of Norma is implemented with about 2,500 lines of Python code and runs in a SONiC-like operating system [12]. It uses internal gRPC to communicate with the ASIC and provides HTTP APIs to users for job management. With these APIs, users can create a traffic-sending job with a desired packet header stack, traffic rate, burst pattern, measurement, stateful responder, *etc.*, and then submit it to Norma. After that, the job manager automatically allocates loopback ports (Appendix E) to these jobs and starts sending packets, until the job is terminated by users.

8 Case Study

Norma has been used to test our pre-online devices for over two years. We present three real usage experiences.

CDN load balancer stress test. In a CDN system, the load balancer (LB) is responsible for distributing user requests to backend servers and then returning the servers' responses to the user. The LB, therefore, needs to afford a large amount of traffic. Its performance is critical to the CDN system. In one of our production pre-deployment, the load balancer employs four 100 Gbps links to connect to the ISP network and uses the other four 100 Gbps links to connect to the backend servers. To test the LB, we used Norma to emulate the traffic from both the ISP network and the backend servers. The

traffic of the emulated HTTP clients was sent to the ISP ports of the LB, and the traffic of the emulated HTTP server was sent to the backend server ports of the LB. Norma initiated and maintained 4,000 HTTP connections. If one connection ends normally, Norma re-initiates the connection; if one connection ends abnormally, Norma shuts down the connection. Therefore we changed the connection establishing frequency by tuning the flow length to test whether there existed any performance issue. As shown in Figure 7, we observed that when the flow length was greater than 10 MB, the throughput of each backend server was close to 100 Gbps; however, when the flow length was less than 1 MB, the throughput was lower than 80 Gbps due to the limitation of the HTTP connection establishment capability of the LB. We therefore successfully measured the performance specifications of the LB under different types of loads.

Traffic manager burst traffic test. In another LB setup, our switch should connect to the ISP network with two 100 Gbps links and 32 backend servers with 25 Gbps links. Normally, the throughput of the user requests from the ISP to the backend servers should be 50 Gbps. These requests trigger about 90 Gbps replying traffic, and 200 Mbps synchronization traffic from each backend server to other servers. But long-term operation in practice showed that there was packet loss on the LB. In troubleshooting, we find that requests sometimes generate bursts of 7 Gbps lasting 9-10 ms on one host, and drive the burst of synchronization traffic. Even with the bursts, this level of traffic should not cause a significant packet loss on the DUT. However, the QAC (Queue Admission Control) drop counters of backend servers increased irregularly.

The root cause is the improperly configured traffic manager. The burst traffic can rapidly fill the queue up and then cause packet loss. To tune the traffic manager configuration, we set the burst mode to sending 3,000 packets at 2.5 times the average throughput intermittently on the request traffic and the synchronization traffic, which can reproduce the bursts and packet loss. Figure 8 shows our result. There were about 197,000 packets dropped by the traffic manager every second. And therefore, Norma assisted our operators to optimize the traffic manager configuration.

ARP learning rate test. We have deployed many programmable switches in our network. We need to ensure the correctness and speed of L2/L3 forwarding functions. To this end, we used Norma to connect these DUTs (*i.e.*, tested programmable switches) with two links. On one link, Norma generated ARP-reply traffic at line rate. It announced the MAC address of a segment of free IPs as the tester itself's. On another link, Norma generated UDP traffic at line rate, where the destination IPs were the free IP addresses announced by the ARP traffic. The DUTs must be able to learn ARP entries correctly first. Second, the DUTs need to forward UDP traffic according to the learned ARP entries. Finally, Norma judged whether the DUTs had learned all ARP entries by measuring the throughput of the forwarded UDP traffic, and then

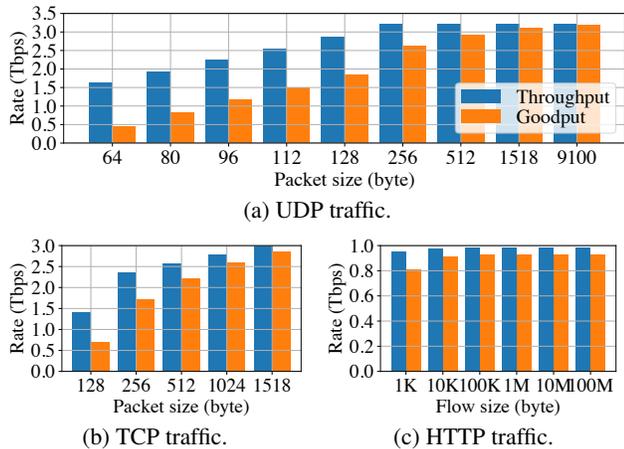

Figure 9: Maximum throughput of Norma.

calculated the ARP learning rate.

In our testing, Norma showed that when the number of tested IP addresses was 2^{13} , the learning rate was about 462 ARP entries per second. However, when the number of IP addresses reached 2^{14} , the DUTs failed to learn all ARP entries. After our troubleshooting, we found that the control plane used a hash value of the entry to locate the ARP entry. If a hash conflict of ARP entries occurred, the control plane returned an exception. In addition, the control plane only supported up to 2^{14} entries, which made our test trigger hash collisions. These bugs were hard to find in unit tests because the number of ARP entries in unit tests is limited. No assertion can be triggered without hash collision.

9 Evaluation

All of our experiments were conducted in two programmable switches with Tofino programmable switch ASICs, where one was the tester, and the other was the DUT. Two switches were connected via 32 100 Gbps optical fibers, which provided 3.2 Tbps bidirectional bandwidth in total.

The traffic quality of Tofino ASICs and software testers has been well-learned in HyperTester [55] (see Appendix F). So we omit these experiments in the evaluation. Norma generates traffic only via dedicated hardware, rather than software. Therefore, the traffic generated is quite stable and very easy to reproduce. We got exactly the same results from multiple runs in our experiments.

9.1 Traffic Throughput

In this part, we evaluated the maximum throughput of three typical traffic, including UDP, TCP, and HTTP. Packets or flows with different sizes were required to generate to test the performance limit of Norma. And loopback ports were allocated by the algorithms in Appendix E. Unless otherwise specified, the Ethernet header and frame check sequence are taken into account when we describe packet or flow sizes, while the inter-packet gap and preambles are not.

UDP traffic. We first evaluated Norma’s throughput of UDP traffic with different packet sizes, including small packets ranging from 64 to 512 bytes, MTU-sized packets (1518 bytes), and jumbo packets (9100 bytes). The allocation of loopback ports was straightforward for UDP, whose outgoing packets were directly multicast from template packets, and did not need other packets to trigger. Therefore, only one loopback port was occupied by template packets.

Figure 9a shows our results. Norma can generate traffic at the rate of at least 1.6 Tbps and reaches 3.2 Tbps for packets longer than 256 bytes. Two bottlenecks limit the performance of Norma. For small packets, the throughput was bounded by the operating frequency of the ASIC because there were more headers for the pipelines to process. And for large packets, however, the throughput was bounded by the 100 Gbps port rate. We used goodput to represent the transmission rate of the payload. As the packet size increased, the proportion of the packet header decreased, so the goodput increased. These results indicated that Norma’s performance reached the limit of ASIC’s capability. In the meanwhile, HyperTester can generate UDP traffic at the rate of 1.6 Tbps [55] and can be simply extended to 3.2 Tbps for large packets, similar to Norma.

TCP traffic. Next, we evaluated Norma’s throughput of TCP traffic with state machine bypass. The TCP packet received was forwarded to the loopback pipeline where packet information was enqueued directly. Then the template packets looped in the pipeline read the information from the queue and generated a replying packet based on TCP flags. For example, when receiving a pure ACK packet, Norma would send back a PUSH packet with the payload of a specified size. Since the size of ACK packets was much smaller than that of PUSH packets, one loopback port was enough to process the ACK traffic received from multiple front-panel ports. For example, one loopback port processing ACK packets can support three front-panel ports that sent out 256-byte PUSH packets. That means, every four loopback ports can support up to 300 Gbps TCP traffic.

Figure 9b shows our results. According to the loopback port allocation algorithm in Appendix E, the expected throughput of PUSH packets sized by 128, 256, 512, 1024, and 1518 bytes was 1.6, 2.4, 2.6, 2.8, and 3.0 Tbps, respectively. However, the throughput of 128- and 256-byte packets was slightly lower than expected due to pipeline throughput limitations. For the rest of the PUSH packet sizes, each front-panel port generated near-line-rate TCP traffic.

HTTP traffic. Finally, we evaluated Norma’s throughput of HTTP traffic by emulating HTTP sessions with different flow sizes, ranging from 1 KB to 100 MB. There were two types of packets in one HTTP session. One was the packets with HTTP content, and the other was the TCP control packets. Norma generated the packets with HTTP content by duplicating the template packets with the 1024-byte payload. For other packets, Norma used the template packet with no pay-

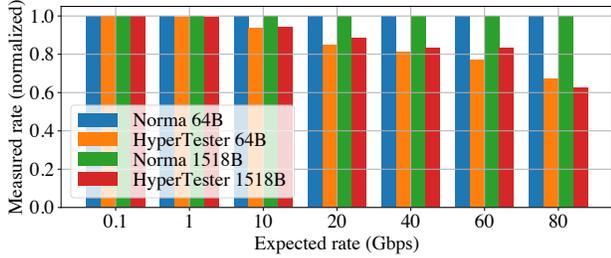

Figure 10: Comparison of rate control accuracy.

load. To achieve the maximum throughput, in each 16-port internal pipeline, five ports were used for reading state registers, five ports were used for writing state registers, five ports were used for generating PUSH packets, and one port was used for generating TCP control packets. Therefore, we expected that Norma should generate 1 Tbps HTTP traffic.

Figure 9c shows our results. Norma generated HTTP traffic with over 950 Gbps throughput, which was slightly lower than expected. This was because of the gap between the looping frequency of large template packets (*e.g.*, 11 Mpps) and the arrival frequency of small packets (*e.g.*, 150 Mpps), which made the enqueue time and dequeue time unaligned. For example, a small HTTP control packet may wait in the queue for triggering a large data packet. This phenomenon was obvious when small packets dominate in short HTTP sessions and led to lower throughput.

Stability. We evaluated the stability of Norma by sending UDP, TCP, and HTTP traffic continuously over 24 hours, at the rate of 3.2, 3.0 and, 1.0 Tbps, respectively. We recorded the throughput of Norma periodically and found that it kept stable during the long-term run.

9.2 Traffic Control

In this part, we evaluated the traffic control capabilities in Norma in terms of rate control accuracy and traffic bursts.

Rate control. We evaluated rate control on two types of UDP traffic generated by Norma. One was composed of 64-byte packets and the other was MTU-sized packets. We measured the actual throughput of generated traffic and compared it with the expected rate. For clarity, the actual throughput was normalized by the expected rate. As shown in Figure 10, Norma achieved nearly 100% accuracy in all cases. However,

Table 3: The rate error of our multi-stage rate control and pure meter when generating packets of different sizes.

Rate (Gbps)	64 Bytes		1518 Bytes	
	Multi-Stage	Pure Meter	Multi-Stage	Pure Meter
0.1	6×10^{-6}	3×10^{-3}	2×10^{-5}	1×10^{-3}
1	9×10^{-7}	2×10^{-3}	4×10^{-6}	5×10^{-4}
10	8×10^{-8}	4×10^{-3}	1×10^{-6}	3×10^{-3}
20	5×10^{-8}	4×10^{-3}	4×10^{-8}	3×10^{-3}
40	3×10^{-8}	4×10^{-3}	2×10^{-7}	3×10^{-3}
60	5×10^{-5}	3×10^{-3}	2×10^{-6}	8×10^{-4}
80	2×10^{-4}	4×10^{-3}	1×10^{-7}	3×10^{-3}

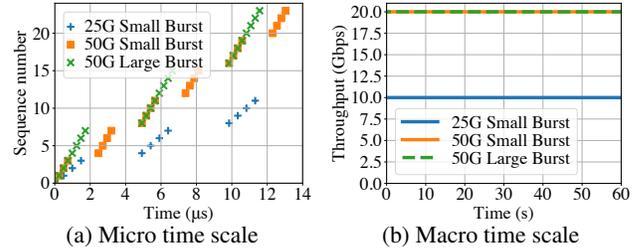

Figure 11: The traffic generated by Norma's burst control.

the actual throughput of HyperTester became inaccurate as the expected rate grew larger. For example, the rate error reached 38% when the expected rate was 80 Gbps.

HyperTester controlled the rate of generated traffic by comparing the timestamp gap with a dropping threshold, which was calculated based on the expected rate. For any two successive packets, if the packet gap was less than the threshold, the second packet would be dropped. However, considering the scenario when the expected rate was more than half of the full rate, the dropping threshold would always be larger than the transmission time of a single packet. It meant there was always one packet being dropped for any two successive packets, and the actual rate cannot exceed 50% of the full rate. When the expected rate reached 80 Gbps, the actual rate of HyperTester was $80 \text{ Gbps} \times 62\% \approx 50 \text{ Gbps}$, which was the same as what we measured above.

We further evaluated the accuracy of our multi-stage rate control. We used the meter-based rate limiter provided by the programmable switch ASIC as a baseline. The actual rate is measured by a counter that counts how many packets pass through the egress pipeline in a range of time. The error is the ratio of the difference between the actual rate and the target rate to the target rate. For Norma, the rate control accuracy can be further guaranteed by our multi-stage rate control design. As shown in Table 3, the error of the meter-based rate limiter ranged between 0.1% and 1%, because the rate to limit supported by the hardware meter was not continuous. After applying the multi-stage rate control, the accuracy was promoted by at least $10\times$, and the rate error was less than 0.01% in the worst cases.

Burst control. To test the burst control, we made the Norma to generate three kinds of traffic with different burst patterns. For traffic A, B, and C, we set the expected average rate to 10 Gbps, 20 Gbps, and 20 Gbps, and the burst scale (*i.e.*, the number of packets in a burst batch) to 4, 4, and 8, respectively. In addition, the burst rate (*i.e.*, peak rate) of all the traffic was required to be $2.5\times$ the average rate. The performance of burst control was evaluated on two scales. The micro time scale showed the packet-level burst pattern, while the macro time scale showed the traffic-level throughput. For the micro time scale, we gave each packet an increasing sequence number and recorded their transmission time. The result was shown in Figure 11a. In the two burst patterns with an average rate of

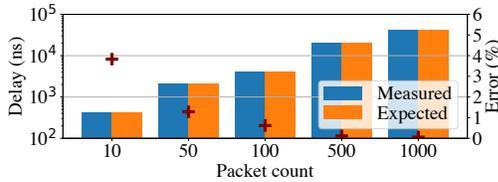

Figure 12: The packet delay when DUT meets bursts.

50 Gbps, there were 8 packets sent continuously in each batch under the large burst setting, and there were 4 packets under the small burst setting at the same rate with half the batch size. For the burst pattern with an average rate of 25 Gbps, there were 4 packets sent continuously at half rate in the same batch size as the 50 Gbps large burst pattern. At the macro time scale shown in Figure 11b, they all stayed at the target average rate.

9.3 Measurement

In this part, we combined traffic generation and burst control to evaluate the measurement function of Norma. First, Norma was connected to the switch under test and generated 100 Gbps line-rate UDP background traffic. The switch then forwarded background traffic back to one specified port of the tester. Second, Norma generated burst traffic at 100 Gbps with different burst scales. And burst traffic was also forwarded by the switch back to the same port of the tester. The packet size of burst traffic and background traffic was both 1024 bytes. Finally, Norma measured the average delay of packets in the burst traffic and compared it with the expected queuing time to judge the error of Norma’s measurement.

Note that in this case, both burst traffic and background traffic were queued at the same egress port of the switch. We denoted the burst scale as n packets, and then the theoretical average packet queuing time was $\frac{(1024+20) \text{ Bytes}}{100 \text{ Gbps}} \times \frac{n}{2}$ ⁵. In addition, the delay measured by Norma included the link propagation time, which is about 1454 ns.

Results are shown in Figure 12, where the link delay has been removed. For all of the burst scales, the queuing delay measured by Norma was very close to the theoretical value. When the burst scale was greater than 10 packets, the error of the average delay was less than 4%. The larger the burst size, the more accurate the measurement of average delay was.

10 Limitation & Discussion

Can Norma emulate full functions of stateful protocols? It depends on the complexity of the protocol. Besides the hardware limitations we detail in §4.1, the hardware resources also constrain the implementation of the stateful protocol. A stateful protocol in Norma consists of its state transitions, the replying traffic types, and the state actions. The capacity of the state table determines how many state transitions Norma can support. The loopback ports determine how many template packet types Norma can support and the maximum throughput

⁵The inter-packet gap and preambles (20 bytes) should be considered.

of replying traffic Norma can generate. And most importantly, the state action may be too complex to implement into the programmable switch ASIC, because the switch resource allocation algorithms and related optimizations in compilers are unknown to developers. Without trying to implement the protocol and compile it, it is hard to know whether a stateful protocol can be fully emulated. Therefore, for complex protocols, we need to simplify them under the premise of being able to complete the test task.

Can Norma support testing customized protocols? Users can customize the packet structure and the processing logic of the protocol in most cases. For example, if we want to measure the forwarding performance of the GPRS tunneling protocol [3], we can modify the parser and deparser to support it. If we want to measure the RDMA write-only throughput of a host, things become complex. The process of exchanging information, congestion control algorithm and packet loss recovery are difficult to express with the EFSM. Even if possible, it is difficult to implement within limited instructions. Our approach is to retain only the process of transferring content in RDMA and remove other logic such as congestion control. However, Norma cannot support protocols with encryption due to the limitation of programmable switch ASICs, unless the encrypted data can be regarded as a fixed payload, or special acceleration cards such as IPU [4] are available.

Can Norma localize the root cause of performance issues? Norma cannot localize the root cause of performance issues because the DUT is typically a black or gray box that cannot be simply modeled. For example, a performance problem can come from misconfigurations, ASIC capabilities, bottleneck of switch CPUs, and even signal strength when wireless links involve. It might be possible to extend Norma to root cause localization if sufficient information is provided.

11 Conclusion

We present Norma, the first practical network load tester used in production. Norma employs the programmable switch ASIC to support stateful protocol generation and customization and realistic traffic emulation such as high precise rate control. Norma has been used in our operation for over two years and successfully detected many performance issues.

APPENDIX

Appendices are supporting material that has not been peer-reviewed.

A Non-Atomic State Updating

The state updating we detailed in §4.2 is non-atomic, which brings two drawbacks. First, this inevitably consumes an extra loopback port and increases the packet processing delay. Second, because the updating of the state registers is done in two passes, if the new state ID is too late to be written to the state register, the next stateful packet may read the old one. In this situation, the state register can be mistakenly written with the wrong value. Because the programmable switch ASIC does not provide the ability to schedule packets, this error can only be avoided by locking the state register and delaying the processing of the following stateful packets. This will bring more problems like keeping following stateful packets looping in the internal pipeline buffer and then handling them in order, which makes it impractical. Therefore, a more acceptable solution is to take the continuously incoming packets into account when designing the EFSM.

B Full-Speed Traffic Generation

How to eliminate bandwidth consumption of bridged metadata? Norma generates traffic by multicasting the template packets that loop inside the internal pipeline. However, there is no extra bandwidth reserved for the bridged metadata when the loopback port conveys the packet from the egress back to the ingress, so all metadata must be packed into the packet, which increases the length of the packet and forms a bandwidth bottleneck. For example, consider the scenario when we want to send outgoing traffic composed of 64-byte small packets at the rate of 100 Gbps from one front panel port. Assume the egress of the loopback port adds 12-byte metadata to the template packet, so the packet loops at the rate of $\frac{100 \text{ Gbps}}{(64+20+12) \times 8} = 130 \text{ Mpps}$. Although the ingress will parse and remove the metadata header, the packet rate could not increase anymore. As a result, the throughput of outgoing traffic is only $130 \text{ Mpps} \times (64 + 20) \times 8 = 87 \text{ Gbps}$. This is a severe problem for the network tester, which makes it impossible to test the DUT under 100% workload.

The key idea of Norma is to compress the packet header. We noticed that the bandwidth bottleneck only exists in the internal pipeline, instead of the external pipeline, because only the internal pipeline has egress-to-ingress forwarding. This enables Norma to borrow some header bits to temporarily store the metadata in the internal pipeline, and pay them back at the egress of the external pipeline. The key point is to find the “traffic/port-invariant” fields, whose value is determined once the flow ID and outgoing port are given. Practically, Norma compresses the Ethernet header and borrows 12 bytes in total.

- The 2-byte *Ethernet Type* field can be compressed to one byte. This field indicates the type of the next header in the

packet. For example, 0x0800 represents the IPv4 header. In cloud scenarios, there are no more than 10 possible values for this field, which can be encoded in one byte.

- The *Src MAC* and *Dst MAC* fields can be compressed together to one byte, which occupy 12 bytes in the original Ethernet header. MAC addresses are usually fixed given the traffic ID and the outgoing port, so storing the 1-byte traffic ID is enough. When the traffic arrives at the egress of the external pipeline, these fields can be recovered.

How many template packets are needed in one loopback port? In the RMT-based programmable switch ASIC, one template packet is not enough to make full use of the hardware pipeline of a loopback port. Multiple template packets are required to guarantee the line-rate looping. But unfortunately, the exact number of template packets we need depends on many factors, including the packet size, the packet header depth, and how the compiler arranges P4 tables, which makes it hard to predict. Based on our experience, the number of template packets can be represented as a function like $y = Ax^{-B} + C$, where A , B , and C are unknown constants, and x is the packet size. When the packet type and the P4 program are fixed, the function can be determined via curve fitting. In general, 10 and 120 packets are enough when packet sizes are 1500 and 64 bytes, respectively.

C Implementation Details of Packet Editors

The major editor can apply step-based or random-based field editing. There are five modes Norma supports:

- 1) The **direct step mode** simply adds a constant to the initial value. If the value exceeds the bound provided by the user, it will be subtracted by the bound.
- 2) The **indirect step mode** is similar to the direct step mode. Differently, the value is not directly outputted but used as an index to access a register array, which saves the real value to the output provided by the user.
- 3) The **cascaded step mode** can be regarded as a combination of two editors working in the direct step mode. The first one works as normal, but the second one is triggered only when the bound excess happens in the first one.
- 4) The **direct random mode** simply fills some bits of a field with random bits. For example, filling the rightmost 8 bits of the source IP field means randomly choosing an IP address under a /24 prefix.
- 5) The **ranged random mode** also relies on random bits. Differently, Norma is required to choose a number from a given range. For example, choose a number for the source port field uniformly from the range 2000-3000.

Among all these modes, the ranged random is the most complex one. It is the random bit instead of the random number that is provided by the programmable switch ASIC, which

means the length of the range must be a power of 2. For example, with 8 random bits, we can only get a uniform random number from 0 to 255, instead of any other range. A straightforward way is to keep trying until a number in the required range is acquired. However, it is not suitable for the ASIC, because there is no cheap way to emulate the while-loop. So we need a concise method that does not rely on loops. Norma solves this problem by using the equation $n := (n' + r) \bmod l$, where n' is the random number generated in the last execution, stored in the corresponding field of the template packet. Here, r is a k -bit random number generated by the ASIC satisfying $2^k \leq l$, where l is the length of the range. Note that the mod operator is not supported by the ASIC, but the restriction to k makes it representable with no more than one subtraction and thus can be implemented in the ASIC. We evaluated the quality of generated random numbers as follows.

We applied the packet editor to UDP packets, whose source ports were randomly chosen from the range 0-999, so the length of the range was 1000, and k (*i.e.*, the number of random bits) should be set to a number no more than 9 to satisfy the constraint $2^k \leq 1000$. From Figure 13a and Figure 13b, we can observe that the quality of the generated random number improved as k becomes larger, benefiting from more random bits provided. Figure 13c shows the frequency of each number generated from 100,000 packets. Each number occurred at a frequency of around 0.1% as expected, which indicated the uniformity of the generated numbers.

D Analysis of Blind Measurement

We use the sets \mathbb{S} and \mathbb{R} to represent the packets sent by the egress pipelines, and received from the ingress pipelines, so we have $\mathbb{R} \subseteq \mathbb{S}$, and $drops = |\mathbb{S}| - |\mathbb{R}|$ is the number of packets dropped by the DUT. The real average delay can be represented as $delay = \frac{1}{|\mathbb{R}|} \sum_{i \in \mathbb{R}} (r_i - s_i)$, where the dropped packets are excluded due to incomplete information. However, the blind average delay becomes $delay' = \frac{1}{|\mathbb{R}|} \sum_{i \in \mathbb{R}} r_i - \frac{1}{|\mathbb{S}|} \sum_{i \in \mathbb{S}} s_i$. Now, we define the absolute measurement error e as the difference between $delay$ and $delay'$, and we have

$$\begin{aligned} e &= |delay' - delay| \\ &= \left| \frac{1}{|\mathbb{R}|} \sum_{i \in \mathbb{R}} s_i - \frac{1}{|\mathbb{S}|} \sum_{i \in \mathbb{S}} s_i \right| \\ &= \left| \frac{1}{|\mathbb{S}|} \left(\sum_{i \in \mathbb{R}} s_i + \sum_{i \in \mathbb{S} \setminus \mathbb{R}} \left(\frac{1}{|\mathbb{R}|} \sum_{j \in \mathbb{R}} s_j \right) \right) - \frac{1}{|\mathbb{S}|} \left(\sum_{i \in \mathbb{R}} s_i + \sum_{i \in \mathbb{S} \setminus \mathbb{R}} s_i \right) \right| \\ &= \left| \frac{1}{|\mathbb{S}|} \sum_{i \in \mathbb{S} \setminus \mathbb{R}} \left(\frac{1}{|\mathbb{R}|} \sum_{j \in \mathbb{R}} s_j - s_i \right) \right| \leq \frac{1}{|\mathbb{S}|} \sum_{i \in \mathbb{S} \setminus \mathbb{R}} \left| \frac{1}{|\mathbb{R}|} \sum_{j \in \mathbb{R}} s_j - s_i \right| \\ &\leq \frac{|\mathbb{S}| - |\mathbb{R}|}{|\mathbb{S}|} \left(\max_{i \in \mathbb{S}} s_i - \min_{i \in \mathbb{S}} s_i \right) = \frac{drops}{ppsr_x}, \end{aligned}$$

which means, the more the packets are dropped, or the slower the packets are sent, the larger the error could be.

E Loopback Port Allocation

As shown in Figure 1, Norma uses two internal pipelines and each of which contains 16 loopback ports. Each loopback port

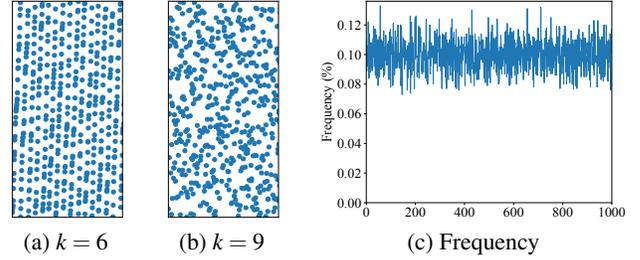

Figure 13: Pseudo-random ports ranging in 0-999.

has a maximum BPS rate (*e.g.*, 100 Gbps) while each pipeline has a maximum PPS rate shared by all ports belonging to it.

Norma models the loopback port allocation as a satisfiability problem, which can be solved efficiently by SMT solvers such as Z3 [29]. Consider there are n flows using loopback ports. We use zero-one variables $x_{i,j,k}$ to indicate whether flow i should be placed to port k in pipeline j . The BPS rate and PPS rate of flow i are represented as b_i and p_i , respectively. The maximum BPS rate of a port and the maximum PPS rate of a pipeline are represented as B and P , respectively. Then loopback port allocation can be modeled as the following integer linear satisfiability problem:

$$\sum_i \sum_k x_{i,j,k} p_i \leq P \quad \text{for each } j, \quad (1)$$

$$\sum_i x_{i,j,k} b_i \leq B \quad \text{for each pair of } (j,k), \quad (2)$$

$$\sum_k x_{i,j,k} = \sum_k x_{i',j,k} \quad \text{if } i \text{ shares data with } i', \quad (3)$$

$$\sum_j \sum_k x_{i,j,k} = 1 \quad \text{for each } i. \quad (4)$$

Equations (1) and (2) describe the constraints of the PPS rate and BPS rate, respectively. Equation (3) enforces flow i and flow i' in the same pipeline if they share data via registers, such as the enqueueing flow and dequeueing flow in §4.3. Equation (4) guarantees that each flow will be placed to a port and a port is allowed to be shared by more than one flow.

For all of the cases we met, the satisfiability problems were solved by Z3 in less than 1 second. Then Norma can allocate loopback ports according to the solved variables $x_{i,j,k}$.

F Performance of Software Testers

Zhang *et al.* [55] evaluated software testers such as MoonGen [31] and TRex [18]. Results are summarized as follows. First, software testers cannot generate traffic at more than 300 Gbps due to PCIe bandwidth limitations. For small packets, even with 12 CPU cores, software testers can only generate traffic at about 40 Gbps. Second, the rate control of MoonGen relies on NIC meters, which means not all target rates can be precisely configured. TRex uses software timestamps for rate control, which leads to unstable inter-packet gaps. These results show that software testers cannot generate precisely-controlled high-speed traffic.

μ Mote: Enabling Passive Chirp De-spreading and μ W-level Long-Range Downlink for backscatter Devices

Abstract

The downlink range of backscatter devices is commonly considered to be very limited, compared to tremendous long-range and low-power backscatter uplink designs that leverage the chirp spread spectrum (CSS) principle. Recently, some efforts are devoted to enhancing the downlink, but they are unable to achieve long-range receiving and low power consumption simultaneously. In this paper, we propose μ Mote, a μ W-level long-range receiver for backscatter devices. μ Mote achieves the first passive chirp de-spreading scheme for negative SINR in long-range receiving scenarios. Further, without consuming external energy, μ Mote magnifies the demodulated signal by accumulating temporal energy of the signal itself in a resonator container, and meanwhile it preserves signal information during this signal accumulation. μ Mote then leverages a μ W-level sampling-less decoding scheme to discriminate symbols, avoiding the high-power ADC-sampling. We prototype μ Mote with COTS components, and conduct extensive experiments. The result shows that μ Mote spends an overall power consumption of 62.07μ W to achieve a $400m$ receiving range at a $2kbps$ data rate with 1% BER, under $-2dB$ SINR.

1 Introduction

Backscatter communication has significant advantages over active radio in terms of power consumption. The recognized drawback of conventional backscatter devices [10, 46] is their insufficient communication range of only a few meters. In the last decade, a number of long-range backscatter techniques [23, 35, 37, 51, 54, 55] are proposed that can significantly increase the uplink backscatter range to hundreds of meters or even more than $1km$. Their main idea is to reflect the Chirp Spread Spectrum (CSS) signal. When this chirp signal is de-spread by the gateway receiver, it will incur a processing gain for the receiver, and therefore more interference immunity and longer communication range.

Nevertheless, the downlink range of this type of long-range backscatter devices [18, 37] is limited to less than 20 meters [17]. As they still use the conventional envelope detector

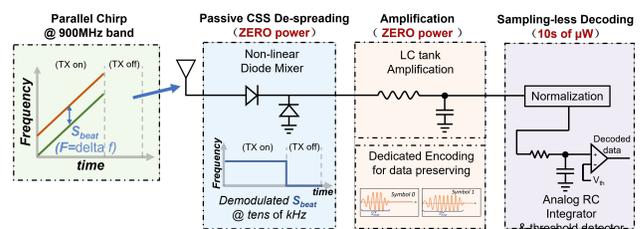

Figure 1: The high-level block diagram and basic principle of μ Mote.

as a receiver [15, 30], rather than de-spreading the chirp signal. In the last two years, two efforts are devoted to extending the downlink range. Saiyan [17] leverages an RF band-pass filter (with $6dB$ signal strength loss) to assign an envelope to the chirp signal, and subsequently uses an envelope detector to detect the assigned envelope. This demodulation method does not de-spread the chirp signal, so it cannot obtain processing gain and extend the downlink range. Instead, to extend the range, Saiyan uses an LNA (Low Noise Amplifier) and an OP AMP (Operational Amplifier) to amplify the signal [16, 21, 40] and gains a receiving range of $180m$. However, these two amplifiers consume about $88mA$, which is similar to the current consumption of active radio, and 176 times that of the typical backscatter device [46]. Passive-DSSS [31] employs two envelope detection channels to transmit DSSS (Direct Sequence Spread Spectrum) spreading codes, enabling anti-interference receiving. However, it strictly requires a positive SINR. Besides, due to the performance limitation of the envelope detector, its downlink range is limited to about 50 meters, far less than the uplink range of existing long-range backscatter devices. Therefore, to the best of our knowledge, none of existing envelope detector-based receivers can achieve long-range receiving with low power consumption.

In an IoT network consisting of backscatter devices and a gateway, insufficient downlink range will be the bottleneck of network coverage. When a backscatter device is placed far away from the gateway, the incapability of downlink communication can lead to the failure of essential network func-

tions, including ACK and re-transmission [13], multi-access control [13], network association [27], over-the-air firmware switching or updating [59,60], and device authentication [41].

Conventional methods to improve the downlink range can be classified into two categories. The one is to employ spread spectrum communication to suppress interference, so as to demodulate the signal at low SINR (signal-to-interference-plus-noise ratio) or even negative SINR. The other one is to use amplifiers (i.e., LNAs) [58] to enhance the receiver sensitivity and combat signal strength loss during propagation. De-spreading the spread spectrum signal, e.g., the CSS signal, requires a local-generated carrier and correlated de-spreading signals, which will incur very high power consumption (e.g., more than $7mW$ [6]). As for LNAs, by their nature (see Sec. 2.1), they commonly consume $10mW$ to more than $100mW$ [14, 47]. In summary, these two solutions are very power-consuming, and therefore cannot realize on backscatter devices whose overall power consumption is commonly less than $1mW$ [46].

In this paper, we present $\mu Mote$, a μW -level reMote receiver with hundreds of meters of receiving range, which can effectively work even under negative SINR. The high-level idea incorporates three key designs, as shown in Fig. 1: a novel Passive Chirp Spread Spectrum (Passive-CSS) de-spreading design to combat interference, a magnification scheme to magnify the demodulated signal with zero external power consumption to combat signal strength loss, and an efficient decoding design with only tens of μW .

More specifically, $\mu Mote$ addresses the following key challenges.

(1) How to address interference or even negative SINR with extremely low power? We try to leverage Chirp Spread Spectrum (CSS) technique to resist interference, which has been widely used in backscatter transmitters. Existing chirp de-spreading techniques, however, consume very high power consumption, as we describe above. To this end, we present the first Passive Chirp Spread Spectrum (Passive-CSS) technique, which removes the conventional power-consuming chirp demodulation and de-spreading processes. The basic idea is a parallel chirp modulation scheme for the gateway and then a passive chirp de-spreading circuit with zero power. Thus, we can passively decode the chirp signal while retaining the long-range and interference-resilient features.

(2) How to increase the signal amplitude without external power, and meanwhile preserve signal information? Traditional amplification solutions, such as LNAs, commonly consume more than ten mW of power. To solve this problem, we leverage an LC resonator (also called LC tank) as a container to accumulate the energy of demodulated signal so as to magnify the signal amplitude. However, when the signal energy is stored in such an LC tank, the corresponding signal information that is supposed to be in chronological order can be overlapped and distorted. To preserve the information, we expect a new encoding method that can embed information

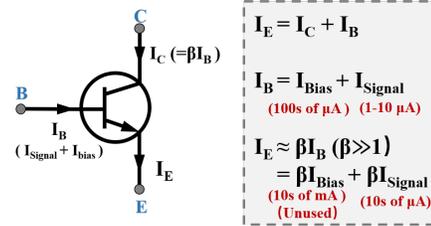

Figure 2: Amplification principle and current consumption of an LNA.

into the accumulated signal. Inspired by PIE (Pulse Interval Encoding), we propose a software/hardware co-designed encoding scheme that leverages the duration of the magnified signal to represent symbols.

(3) How to efficiently decode symbols conveyed by the magnified signal? Existing receivers usually employ ADC for high-speed sampling and decoding. This accounts for the vast majority of the power consumption of backscatter devices. For example, a widely used low-power integrated ADC IC [49] typically consumes hundreds of μW power. In this paper, we present an analog RC integrator to decode without the need for ADC. This significantly reduces the power consumption to several μW . Specifically, we introduce a low-power energy integrator to identify the symbols based on the level of symbol energy. Moreover, the above circuit is designed to be programmable to achieve ADC-free symbol synchronization before decoding. Besides, we present a normalization scheme to address the “dynamic symbol energy” problem caused by the diversity of signal strength.

Summary of the contributions and results:

- We propose the design of $\mu Mote$, a novel μW -level low-power receiver with hundreds of meters of receiving range which can effectively resist interference and work even under negative SINR.
- We address the fundamental challenges for realizing the receiver. We realize a passive-CSS communication technique on passive circuits, enabling zero-power chirp de-spreading and demodulating. We present the zero power magnification scheme by accumulating the energy of the demodulated signal itself. And we propose the design of a sampling-less analog energy integrator for μW symbol decoding.
- We prototype $\mu Mote$ with COTS components and conduct extensive experiments. The results demonstrate that $\mu Mote$ reaches a communication range of more than $400m$ at a 1% Bit Error Rate (BER) with an average working power of $61.07\mu W$. Compared to the literature of existing works [17, 31], $\mu Mote$ improves the downlink range by $2.5\times$ to $8.65\times$, with a power consumption reduction of at least 63.2%. Under the case of narrowband

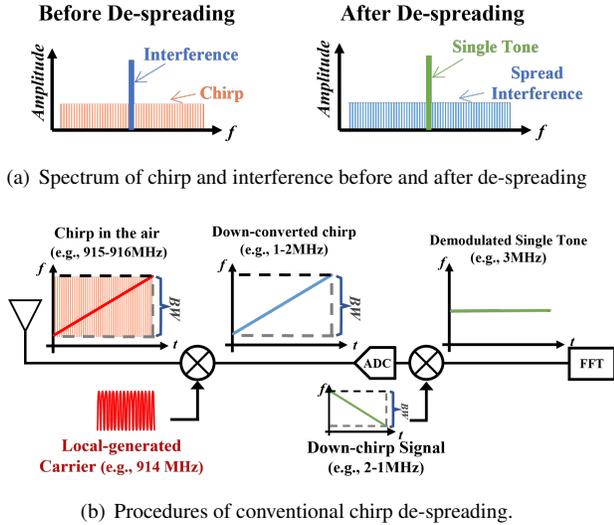

Figure 3: Principle of conventional chirp de-spreading, in which the power consumption of carrier generation is not affordable for backscatter devices.

interference, μMote can work at -2dB SINR or above. To the best of our knowledge, this is the first receiver that can work under negative SINR with μW -level power.

2 Background and Motivation

Before presenting our design, it is worth investigating why existing receivers cannot achieve long-range receiving with low power consumption. We classify existing approaches to long-range receiving into two categories: amplifying the signal and spreading spectrum technique.

2.1 Amplifying the Signal

Receivers usually use LNAs to amplify the received signal strength, as LNAs' low noise figure can minimize the noise caused by the amplification process. An LNA usually consists of multiple triodes and peripheral analog circuits. Its function of signal amplification is performed by the triodes. Fig. 2 depicts the principle of a triode. By leveraging the external current injected to its collector (I_C), it can amplify small base current (I_B) by β times, and the amplified current is output as emitter current I_E , i.e.,

$$I_E = I_C + I_B = \beta I_B + I_B \approx \beta I_B (\beta \gg 1)$$

where the β inherently depends on the transistor and can be typically large up to 100.

However, the practical power efficiency of such triodes is very low. As shown in Fig. 2, the I_B contains not only the signal current (I_{Signal}), but also a bias current (I_{Bias}) that is significantly larger than I_{Signal} . The I_{Bias} contains no signal information but can ensure that the triode works within the

linear active region (amplifying region). After amplification, the amplified I_{Bias} will be removed. In the widely used commercial LNA ICs [7, 8], the I_{Bias} is commonly hundreds of μA or even more than 1mA . Hence, amplifying the I_{Bias} makes commercial LNA ICs consume several mA to even hundreds of mA of external current. As a comparison, the total power consumption of a typical backscatter device is $470\mu\text{A}$ [46].

2.2 Spread Spectrum Technique

Spread spectrum techniques, such as Chirp Spread Spectrum, has been widely used in LPWAN (Low Power Wide-Area Network) and backscatter transmitters due to their interference immunity and long communication range. In brief, the basic idea of CSS is "don't put all the eggs into one basket". Specifically, by transmitting or reflecting the wide-band chirp signal, the information (e.g., a symbol) is distributed to the chirp's band (the red shaded area in Fig. 3(a) and Fig. 3(b)). Hence, the narrow-band interference is unable to cover the entire band, even if it has a stronger signal strength, as shown in Fig. 3(a).

The receiver needs to de-spread the chirp to gather the distributed information. As shown in Fig. 3(b), the chirp is down-converted to a relatively low frequency (e.g., $1\text{--}2\text{MHz}$) and then multiplied by a down-chirp signal, incurring a single tone signal which sums the frequency of the down-chirp and the down-converted chirp. Meanwhile, the narrow-band interference is also multiplied by the down-chirp signal, but then its energy is spread into the entire chirp's band. This means the single-tone signal gains high SINR and can be easily recognized by FFT (Fast Fourier Transform) operation (as shown in Fig. 3(a)). With the FFT results, the receiver knows whether a chirp is transmitted or not, even if the chirp has lower strength than that of the interference.

Nevertheless, the conventional chirp de-spreading process is power-consuming, as it requires the receiver to generate the high-frequency carrier for down-conversion and perform FFT operation. Generating the carrier needs power-consuming components, such as the VCO (Variable Crystal Oscillator) and the PLL (Phase Locked Loop), and performing FFT requires high-speed computing. These operations inevitably incur high power consumption that is undesirable for backscatter devices [29, 34]. Hence, chirp de-spreading has never been implemented on backscatter devices.

2.3 Motivation

After revisiting existing solutions and their power consumption, we aim to design a receiver with interference resistance, long-range receiving (high receiving sensitivity), and low-power consumption. We are motivated to take the following strategies to solve those problems, respectively.

Interference resilience: When the receiver is far away from the gateway, the received signal becomes susceptible

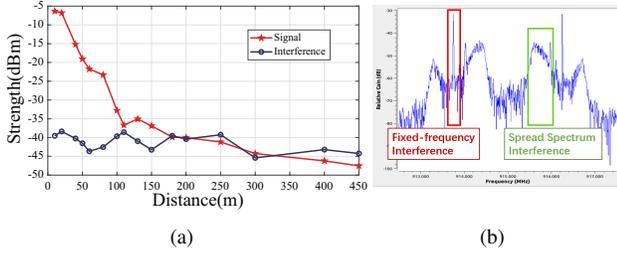

Figure 4: (a) Site survey for the strengths of ambient interference and downlink signal in the campus environment, and (b) Then measured spectrum of interference signals.

to interference. This significantly decreases the receiving performance in practice, especially for non-noise-resistant envelope detectors. Hence, we are motivated to present a passive chirp de-spreading design to combat interference.

Low-power Magnification: Amplification can combat signal strength loss and improve receiving range. However, using LNAs can cause enormous power consumption. Thus, we present the LNA-free magnification scheme with zero power consumption, which helps to extend the receiving range.

Low-power decoding: Conventional symbol decoding solution is high-speed ADC sampling. However, it typically consumes hundreds of microwatts, accounting for the major part of the power consumption of a backscatter device [46]. Hence, we expect a power-efficient decoding mechanism without high-speed ADC sampling.

3 Passive Chirp De-spreading

The envelope detector is widely used in low-power receivers as it requires no high-power-consuming components and computing tasks. However, the envelope detector is subject to interference. When the interference is stronger than the downlink signal, it will misidentify the envelope of interference as the envelope of the downlink signal, thereby incurring communication failure. To better understand this, we conduct a preliminary site survey in a campus environment. As illustrated in Fig. 4(a), at the distance of 250m, 350m and above, the interference strength is stronger than that of the signal. In those environments, the envelope detector fails to work.

This motivated us to implement CSS downlink on backscatter devices to combat interference and extend the receiving range. However, as we have introduced in Sec 2.2, the power-limited backscatter device is unable to afford the power consumption of carrier generation and signal down-conversion. Therefore, implementing chirp de-spreading seems to be infeasible on backscatter devices.

3.1 Passive Chirp De-spreading Design

With an understanding of the major cause of high power consumption in conventional chirp de-spreading, preliminarily,

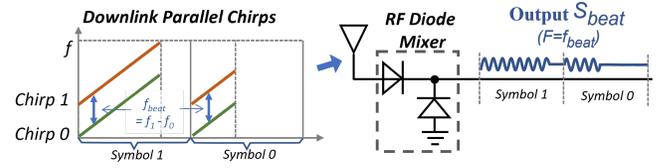

Figure 5: Transmitted two chirps and circuit for passive chirp de-spreading.

we explore uploading the task of carrier generation and down-chirp generation to the gateway. Specifically, we arrange the gateway to transmit two wide-band chirp signals into the air. By multiplying one chirp with another one, the receiver can achieve down-converting and de-spreading without the requirement of a locally generated carrier and the down-chirp signal.

The transmitted chirp signals are shown in Fig. 5, which are denoted by ‘chirp_0’ and ‘chirp_1’, respectively. They have the same chirp rate (i.e., frequency increasing rate whose unit is Hz/s), and hence there is a constant frequency difference between them. Unlike narrow-band signals, such as ASK signals or BFSK signals, these two wide-band chirp signals will not be covered by narrow-band interference.

These two chirps transmitted to the receiver can be written as:

$$chirp_0(t) = \cos [2\pi (f_0 t + 1/2 u t^2)] \quad (1)$$

$$chirp_1(t) = \cos [2\pi (f_1 t + 1/2 u t^2)] \quad (2)$$

where u is their chirp rate; f_0 and f_1 are their initial frequencies, respectively.

The receiver de-spreads these two chirps by multiplying them with each other using a passive, non-linear diode mixer. In practice, we use two diodes so as to receive the signal from the positive and negative terminals of the antenna. The result of signal mixing is expressed as:

$$\sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} a_{mn} \cos \{2\pi ([m(f_1 + ut) + n(f_0 + ut)])t\} \quad (3)$$

According to the property of non-linear mixing, we ignore the high-order harmonics as they have very low energy levels. Thus, we only consider the low-order harmonics, e.g., the first, second and third-order harmonics. More specifically, we can obtain a high-frequency signal and a low-frequency beat signal (denoted by S_{beat}) whose frequency is equal to the frequency difference $f_1 - f_0$. Instead of using FFT to detect the single tone, we use the LC resonator introduced in the next section to filter out the high-frequency signal.

Therefore, the only signal that can remain is the S_{beat} . If the receiver detects the presence of the S_{beat} , it can infer that the gateway is transmitting that two chirps. Moreover, by measuring the duration of the S_{beat} , the receiver can know the transmitting duration of the two chirps. This further allows

us to encode different symbols by varying this transmitting duration, as shown in Fig. 5.

3.2 Interference Resilience Analysis

From the measured spectrum shown in Fig. 4(b), it can be seen that the interference can be classified into two categories, i.e., narrow-band interference, and the spread spectrum signals. We consider signals using ASK, FSK and PSK modulation to be narrow-band signals, because they are composed of one or multiple narrow-band signal components with fixed frequencies.

Narrow-band interference: As we have introduced, narrow-band signals will be spread into the chirp’s band in de-spreading process. More specifically, considering that there is a narrow-band interference with a fixed frequency f_n passes through the mixer with the two chirp signals, the resulting signals contain multiple components, including multiple high-order harmonics, the spread interference, and the envelope of all these signals. For example, if the interference signal is mixed with chirp_0 (Eq. 1), the generated signals are

$$\sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} a_{mn} \cos \{2\pi [m(f_0 + ut) + n f_n] t\}. \quad (4)$$

where the high order harmonics and the spread interference with increasing frequency term (i.e., the ut in Eq. 4) cannot pass the following filter (i.e., the LC resonator). As for the envelope, it can hardly pass the filter unless it has the same frequency of $f_1 - f_0$. We argue that this case can hardly occur in practical scenarios.

Moreover, we should note that we also encountered strong out-of-band interference in our experiment (whose strength is about $12dB$ higher than that of chirp signals), and the passive mixer can only output the interference envelope instead of the desired beat frequency. This can be fixed with a SAW (Surface Acoustic Wave) filter.

Spread spectrum interference: Theoretically, our design can be interfered with by a specific type of chirp spread spectrum interference. This chirp signal should have the same chirp rate as the chirp signals transmitted by the gateway. Besides, the frequency difference between this interference chirp and one of the chirp signals transmitted by the gateway should be equal to $(f_1 - f_0) / 2^n$ (where $n = 0, 1, 2, 3, \dots$). According to our experiment, facing this type of interference, its anti-interference performance is similar to that of an envelope detector without an anti-interference design.

4 LNA-free Signal Magnification

Amplifying the received signals can enhance the receiving sensitivity and improve the receiving range. Receivers typically employ the LNA to achieve this. As we have introduced in Sec. 2.1, even the latest LNAs we can find, still consume

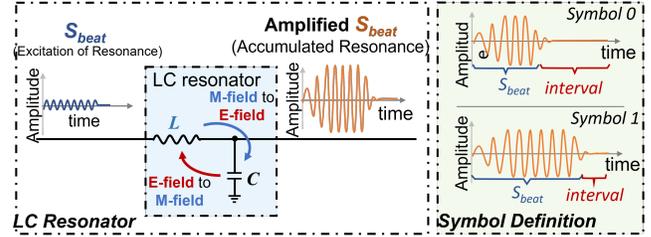

Figure 6: Block Diagram of LNA-free Magnification.

several mA to hundreds of mA of external current. Hence, we are motivated to propose a signal magnification method with ultra-low power to replace the amplifier.

To achieve this, we explore accumulating the energy of the signal to implement magnification instead of consuming external current. We leverage an LC resonator to realize a container to accumulate energy. Conventionally, the LC resonator is used as high-frequency RF elements, e.g., on RF receiving antennas. It relies on tuning antenna impedance [3] to improve signal receiving efficiency at a particular frequency [1, 50]. Differing from these conventional uses, $\mu Mote$ ’s LC resonator works at relatively low frequencies (tens of kHz) and is used to accumulate the signal energy to magnify signal amplitude. Besides, when the signal energy is being accumulated, the signal’s physical characteristics (e.g., frequency, amplitude, and phase which are used to carry data) will be destroyed. Thus, we should address the issue of information preservation during energy accumulation.

4.1 Magnifying by Accumulating Energy

In $\mu Mote$, the LC resonator is placed after the passive-CSS and consists of an inductor in series and a shunt capacitor, as shown in Fig. 6. The energy in this circuit will be alternatively transformed in the manner of magnetic and electric fields between the capacitor and inductors. The principle behind is the energy entered the magnetic field of the inductor can be used to charge the electric field on the capacitor plates, and vice versa. Similar to a pendulum or a swing, this “energy reciprocating” has its natural resonance frequency, which can be written as:

$$f_{res} = \frac{1}{2\pi\sqrt{L \cdot C_{res}}}$$

where C_{res} is the capacitance value of the capacitor in the resonant circuit.

The input signal of LC circuit is S_{beat} , the demodulated beat signal output by the passive-CSS circuit. If S_{beat} has the same frequency as $f_{resonant}$, its energy will be accumulated in the form of resonance for magnification, as shown in Fig. 6. Thus, the resonator acts as a magnifier and band-pass filter which only magnifies the voltage of S_{beat} whose frequency is f_{res} .

Table 1: Candidate LC resonators for different symbol rates

Symbol Rate	L	C_{res}	R_{inner}	Q	T_{dis}	V_{out}/V_{in}
$1 \sim 2kbps$	0.05H	270pF	273Ω	49	600μs	40×
	0.05H	270pF	384Ω	35	250μs	23×
	0.05H	270pF	734Ω	18	100μs	15×
$5kbps$	0.05H	470pF	1.1kΩ	9	70μs	10×
	0.05H	470pF	1.3kΩ	7.9	30μs	7×

4.2 Preserve the Information

Unfortunately, this magnification scheme based on LC circuit can destroy the physical characteristics of the signal, e.g., the phase, the frequency and the amplitude of the signal. For instance, symbols in PSK (Phase-Shift-Keying) or ASK (Amplitude-Shift-Keying) manner can be destroyed as the phase and amplitude are instantaneous physical characteristics that cannot be preserved in an energy container. Therefore, we need to retain the encoding information in the energy accumulating.

Inspired by PIE (Pulse Interval Encoding), we leverage the duration of the magnified S_{beat} signal (i.e., S_{beat} 's energy) to represent the binary value of a symbol. The symbols representing binary bit "1" and binary bit "0" are shown in the right portion of Fig. 6. For simplicity, we refer to them as symbol "1" and symbol "0" respectively. Besides, in each symbol, there is an interval between two consecutive symbols. As the duration of S_{beat} in symbol "1" is longer than that in symbol "0", the symbol "1" contains more energy than symbol "0". The energy difference can further be distinguished by energy integration schemes introduced in Sec. 5.

To separate symbols, each symbol's energy should be released from LC circuit to avoid affecting the next symbol. In our scheme, we can separate symbols by assigning an interval between two symbols, as shown in the right portion of Fig. 6. In detail, during the symbol, the LC circuit has energy input and keeps resonating. During the interval, the energy of the current symbol stored in the LC resonator should be discharged by the circuit's internal resistance, or controlled discharging, see Sec.8.

4.3 Symbol Rate vs. Magnification Performance

From the symbol definition, we can see that a higher symbol rate requires a shorter interval, and fast discharging of LC . If the LC is not discharged completely, the residual energy will make the next symbol misidentified. Thus, we need a small Q factor to ensure sufficient discharging. On the other hand, a small Q means the weak magnification capability of the LC circuit. There is a trade-off between the magnification times and the symbol rate.

The Q factor is defined as

$$Q = 2\pi \frac{E_{store}}{P_{diss}T}$$

, where P_{diss} is the average dissipation power during a resonant period T , and E_{store} is the energy currently stored in LC . Hence, a higher Q factor means more energy can be preserved in LC , or more time to release the stored energy, i.e., discharge the capacitor in LC . On the other hand, the Q factor of the LC resonator can be calculated as:

$$Q = \frac{1}{R_{inner}} \cdot \sqrt{\frac{L}{C_{res}}}$$

where R_{inner} is the inner resistance of the LC resonator. From the two formulas, it can be seen that we can hardly calculate or measure the time constant of an LC resonator [48] to determine the required time interval for discharging. Further, it is also difficult to find COTS "L" and "C" components with the exact optimal value in practice. Hence, we empirically study LC resonators of different Q factors with available COTS components, and practically measure their discharging time.

We present the parameters of candidate LC resonators for different symbol rates in Table 1. In the table, " V_{out}/V_{in} " means the magnification ratio that the resonator can magnify the voltage of input S_{beat} , and the " T_{dis} " is the measured discharging time. For example, for a symbol rate of $2kbps$, we can choose parameters of the third resonator, whose discharging time is more than $100\mu s$. It means that the time interval of symbols should be more than $100\mu s$ also.

5 Low-power Decoding

With LNA-free magnification, we can get the magnified signals as well as symbols. The next step is to extract binary bits from the symbols. Mostly, ADC (Analog-to-Digital Conversion) is used for symbol decoding, but ADC will introduce high power consumption due to two reasons.

First, to ensure decoding accuracy, the ADC has to perform sampling tens of times when decoding each symbol. Based on Nyquist's theorem, the sampling rate should be twice the frequency of S_{beat} . Second, every single sampling operation of ADC consists of several complicated steps, e.g., extracting analog samples from a continuous signal, amplifying those analog samples to improve converting accuracy, integrating the amplified samples, and converting integration results to digital values. All aforementioned steps are controlled by an MCU or custom IC. As a result, even a well-known energy-efficient ADC [49] will consume more than a couple of $100 \mu W$, which is two to three times higher than the total power consumption of our $\mu Mote$ including signal amplifying and symbol decoding.

In $\mu Mote$, we carefully make use of the signal duration of S_{beat} and interval to represent symbols, as shown in Fig. 6. For

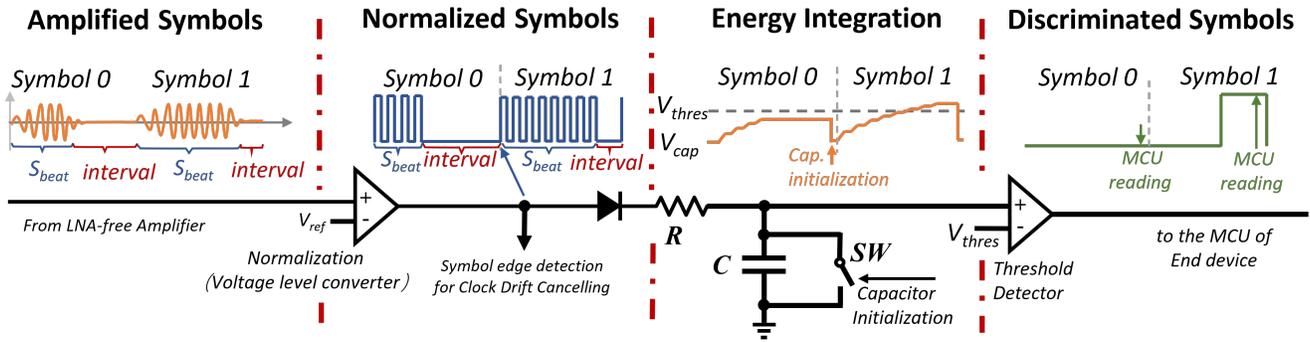

Figure 7: Procedures for energy integration-based decoding.

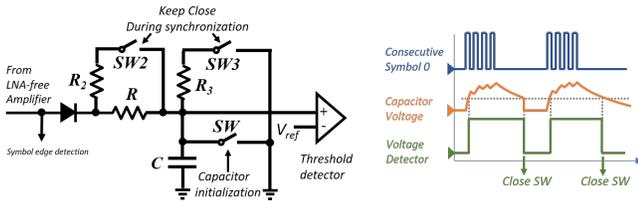

Figure 8: The practical decoding circuit for symbol synchronization.

example, symbol “1” has a shorter interval and longer signal duration than symbol “0”, thus the energy of symbol “1” is higher than symbol “0”. Different symbols to an *energy integrator* can result in different energy levels which can be used to discriminate symbols. Thus, a simple energy integrator can be employed to replace the ADC for decoding each symbol with only a single integration operation and low power consumption. *RC* (Resistance Capacitance) circuit is a typical realization of energy integrator as illustrated in Fig. 7. In order to save power, we can suppress the internal current to several μA with high resistance, and reduce the power consumption of integration to about $10\mu\text{W}$. As shown in Fig. 7, the signal S_{beat} can charge the capacitor “C” through the resistor “R” upon decoding. Because of the longer signal duration, symbol “1” can charge the capacitor to a higher peak voltage, which can be detected and converted to “1” by a threshold detector, and vice versa.

Apart from the basic design, there are several practical problems that need to be addressed.

Dynamic signal strength. In practice, the charged peak voltage in capacitor “C” is not only determined by S_{beat} ’s duration, but also affected by S_{beat} ’s strength. For example, if the receiver is placed close to the gateway, the incident signal power is high and hence the time to charge the capacitor would be short. In this case, a symbol “0” might be identified as a symbol “1”. Conversely, if the receiver is placed far away, a symbol “1” may also be incorrectly identified as a symbol “0”. To address this problem, we normalize S_{beat} ’s amplitude after magnification. Specifically, we place a voltage level converter after the *LC* circuit and before the *RC* integrator,

normalizing the amplitude of S_{beat} to a predefined reference voltage, as illustrated in the left part of Fig. 7. The detailed implementation of this circuit is introduced in Sec. 6 and its power consumption is discussed in Sec. 7.4.

Capacitor discharging. The binary value of each symbol is determined by how much S_{beat} charges the capacitor C. So the capacitor should be discharged fast and completely before the arrival of the next symbol to avoid inter-symbol interference. Intuitively, we can leverage the self-discharging of the capacitor. However, this is quite slow and thereby significantly slowing down the symbol rate. To address this problem, we add an NMOS switch to connect the positive plate of the capacitor to Ground (GND). At the end of each symbol, we make the capacitor directly connected to the Ground for fast discharging.

Symbol synchronization. To decode the symbol, the MCU should know exactly the end time of a symbol and read the output of the threshold detector at the time. Otherwise, the MCU may get the wrong integration results and misidentify symbols. In other words, it should be synchronized with the symbols sent by the gateway. Intuitively, we can make the gateway transmit preamble symbols for synchronization. However, if it is not synchronized, the decoding circuit and MCU cannot decode any symbols.

To achieve synchronization, the decoding circuit is programmed to switch to another structure which can detect preamble symbols. Specifically, two resistors and two NMOS switches are added to the circuit, as shown in the left portion of Fig. 8. Upon receiving the preamble, $SW2$ and $SW3$ are closed by the MCU so that resistors R_2 and R_3 are connected to the circuit. At this time, R and R_2 form a smaller resistor, accelerating the charging speed of the capacitor. With these resistors, a symbol “0” can rapidly charge the capacitor to the threshold of the detector, and the charged voltage can be released via R_3 and $SW3$ before the next symbol “0” arrives, as illustrated in Fig. 8. Thus, we can use a series of symbol “0” as the preamble, and the detector will output corresponding high voltage levels (the green line shown in Fig. 8) to inform the MCU that the preamble has arrived. The reason we do not use symbol “1” is that the duration of its S_{beat} signal is

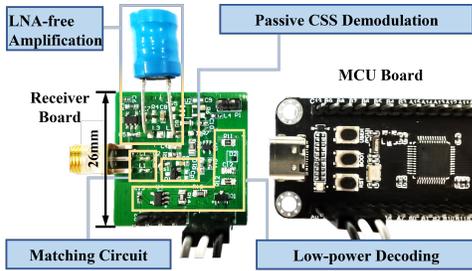

Figure 9: $\mu Mote$ prototype.

too long, so even with the presence of R_3 , the voltage in the capacitor cannot be fully released before the next symbol “1” arrives.

Clock drift canceling. The clock on the backscatter device drifts over time, leading to synchronization and decoding errors. To address this, we present a method to cancel the clock drift. At the end of a symbol, we detect the first rising edge of the following symbol, as shown in Fig. 7. This rising edge represents the exact starting time of a symbol, which can be used to calibrate the clock on the device.

Power consumption. The decoding process requires three operations at the end of a symbol, i.e., reading the threshold detector, discharging the capacitor, and canceling the clock drift. These operations can be accomplished with less than 100 instructions, which incurs $< 1\%$ duty cycle and several μW power consuming. The necessary timing circuit to wake up the MCU and control the duty cycle is included in the MCU hardware, and the MCU only consumes nW -level power in low power mode [49].

Power optimization of RC circuit. We reduce the charging current to save power. The charging current can be written as

$$I_{charge} = \frac{V_{ref} \cdot \exp(-t/RC)}{R}$$

, where V_{ref} is the charging voltage on the capacitor and is equal to the reference voltage in S_{beat} normalization. To suppress I_{charge} , we increase R and reduce C , and keep the product RC unchanged. For a symbol rate of $5kbps$, the proper values of R and C are $220k\Omega$ and $330pF$, and the power consumption of the RC circuit is $12\mu W$. The concrete evaluation results can be found in Sec. 7.

6 Implementation

We prototype $\mu Mote$ with COTS components on a $2.4cm \times 2.6cm$ PCB, as shown in Fig. 9. We introduce the hardware implementation as follows.

Matching circuit and passive-CSS demodulation: The matching circuit is composed of a series capacitor and a shunt inductor, as RF signals can easily pass through the capacitor but cannot go through the inductor to the Ground (GND). The matching circuit achieves reflection loss lower than $-20dB$ in the $913 - 916MHz$ frequency band, which is wide enough

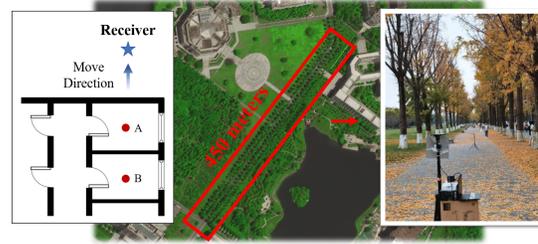

Figure 10: Indoor and outdoor experiment environment.

for receiving the two chirps. We use Skyworks SMS7630-005LF RF diodes as the passive mixer for down-conversion and de-spreading.

LNA-free Magnification: We implement $\mu Mote$ prototypes of three symbol rates. For $1kbps$ and $2kbps$, we choose the third resonator shown in Table 1. For $5kbps$, we choose the fifth one. The corresponding resonant frequencies of these two are $43kHz$ and $32.8kHz$. Before the LC resonator, we place a capacitor in series for DC-AC conversion, as the LC resonator requires AC input.

Normalization circuit: We employ a voltage level conversion circuit to normalize the magnified S_{beat} . In practical realization, we have two choices: (i) NCS2200, a comparator which has a relatively low power consumption of $18\mu W$ and can work on passive backscatter devices [64]. (ii) MAX9914, which is actually a power-efficient operational amplifier which can also work as a voltage level converter. It can provide an extra sensitivity gain of $8dB$ with a power consumption of $51.17\mu W$, therefore further extending the receiving range. We use MAX9914 to realize the $\mu Mote$ prototype to explore the maximum range of our design. Besides, we use NCS2200 to realize a low power version of $\mu Mote$, which is named as “ $\mu Mote-$ ” (i.e., “ $\mu Mote$ minus”). Compared with $\mu Mote$, $\mu Mote-$ loses $8dB$ sensitivity but gains $33.17\mu W$ power saving.

RC Decoding circuit: We employ different combinations of R and C to build RC circuits for different symbol rates. The detailed values are introduced in Sec. 7.4. After the RC circuit, we use an S-1000C16 and an NLSV1T244 to build the threshold detector with a total power consumption of $1\mu W$. And we use GPIO ports of STM32L476 MCU to record the decoded data and control the circuit via three DMG2302UK NMOS switches. The MCU runs at a 1% duty cycle as we introduced in Sec. 5.

7 Evaluation

In this section, we first introduce the experiment setup in Sec. 7.1. Then we introduce benchmarks for subsequent evaluation in Sec. 7.2. Further, we evaluate communication ranges of $\mu Mote$ and benchmarks in Sec. 7.3. The power consumption comparison among our design and benchmarks, as well as $\mu Mote$ power breakdown, are illustrated in Sec. 7.4. Then we introduce interference experiments using interference signals

recorded in practice environments in Sec. 7.5.

7.1 Experiment Setup

We leverage a USRP-2922 to build the gateway’s transmitter with an ADL5605-EVALZ [9] RF amplifier. Thus, the gateway can transmit up to $30dBm$ power, near the ImpinJ R420 RFID reader. The two downlink chirp signals are in $915MHz$ ISM band and their bandwidths are $1MHz$. The frequency difference (i.e., the frequency of S_{beat}) between the two chirp signals is set to the resonant frequencies of LC circuit, i.e., $43.3kHz$ for $1kbps$ and $2kbps$ symbol rates, and $32.8kHz$ for $5kbps$.

7.2 Benchmarks

- WISP5 [45]: a very widely known backscatter tag with an envelope detector-based receiver and an ADC for sampling. It has no amplification and anti-interference design. To favor the communication range test for the WISP5, we connect it with a $1.8V$ power supply module, instead of using its RF energy harvester which has an energy harvesting range of only several meters.
- Saiyan [17]: the very recent work that achieves LoRa symbol receiving with an envelope detector. Saiyan converts chirp symbols to amplitude-modulated signals via a SAW (Surface Acoustic Wave) filter, and uses an LNA for amplification. Following the literature [17] and the BOM (Bill of Material) list of their project document [16], we implement Saiyan hardware with a TQP3M9008 LNA and an OPA810 operational amplifier for signal amplification.
- Passive-DSSS [31]: an envelope detector-based design which employs two envelope detection channels for DSSS spreading codes to address interference. Besides, passive-DSSS employs a TLV9001 operational amplifier of $180\mu W$ to improve sensitivity and range.

Those benchmarks use their original encoding mechanisms, respectively, i.e., PIE for WISP5, chirp symbols for Saiyan, and DSSS spreading codes for passive-DSSS. For comparison, we manually set the symbol rate of those benchmarks to $1kbps$.

7.3 Communication Range

In this section, we first evaluate the receiving sensitivity of $\mu Mote$ and benchmarks using laboratory tests. Then we conduct outdoor experiments to evaluate their practical communication ranges in LOS (Line-of-Sight) scenario, i.e., a roughly straight road on campus, as shown in Fig. 10. Finally, we evaluate the communication range and packet throughput of

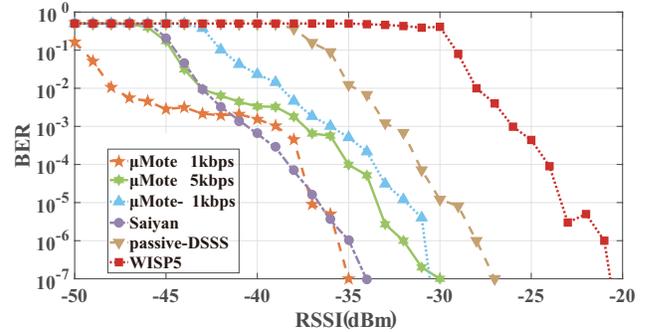

Figure 11: Receiving sensitivity of $\mu Mote$ and benchmarks.

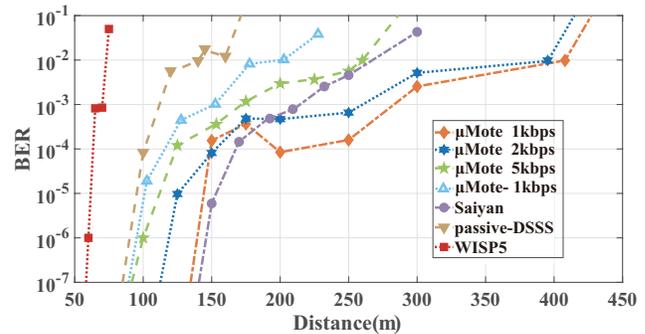

Figure 12: Communication range in the outdoor LOS scenario.

$\mu Mote$ in the NLOS (Non-Line-of-Sight) scenario. The NLOS experiment field is illustrated in the left portion of Fig. 10.

Receiving Sensitivity: Without interference, the receiving sensitivity theoretically determines the receiving range. In experiments, we measure the receiving sensitivity as the lowest received signal strength with a corresponding physical layer Bit Error Rate (BER) lower than 1%. To precisely control the signal strength, we connect the transmitter (i.e., USRP) and receiver with an RF cable and employ one or two $30dB$ RF attenuators in the cable. Thus, the receiving signal strength can be precisely controlled by setting the transmitting signal strength and the number of employed attenuators. Besides, to ensure accuracy, we leverage a professional signal strength meter [28] to calibrate the transmitting power of USRP. For each round, we measure the BER by sending 1,280,000 bits.

The measured receiving sensitivities are shown in Fig. 11. It can be seen that the $\mu Mote$ has the best receiving sensitivity of $-48dBm$ at $1kbps$ symbol rate. According to theoretical estimation [10], its receiving range can reach 500 meters with the maximum transmitting power of our transmitter ($30dBm$). The receiving sensitivities of WISP5, replicated Saiyan, and passive-DSSS are $-28dBm$, $-43dBm$, and $-35dBm$. Similarly, we estimate their theoretical receiving ranges are $80m$, $250m$, and about $160m$, respectively. The sensitivity of $5kbps$ $\mu Mote$ prototype is $-43dBm$, due to the relatively low Q factor of LC circuit. The future solution to this is discussed in Sec. 8. Besides, $\mu Mote$ has a sensitivity of about $-38dBm$, which is similar to Saiyan and better than passive-DSSS.

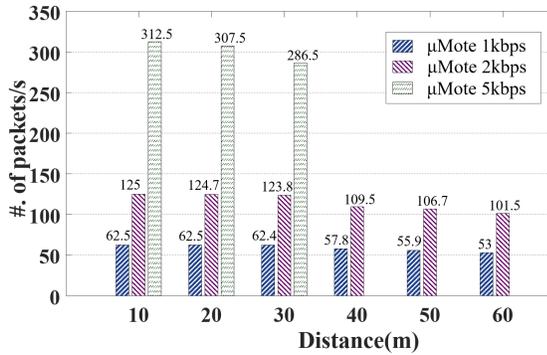

Figure 13: Throughput of μ Mote for different bit rates when twin-CSS signal penetrates one wall.

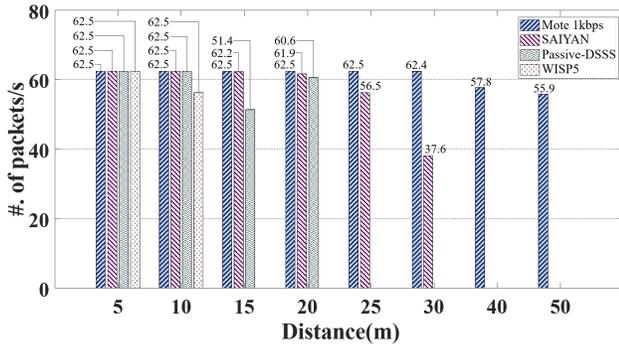

Figure 14: Throughput of μ Mote 1kbps and benchmarks when the signal penetrates one wall.

LOS Experiments: To evaluate the practical communication ranges of μ Mote and three benchmarks, we conduct outdoor experiments in LOS scenarios. The USRP transmits 30dBm RF signals through a 6dBi gain antenna, while each of the receivers uses a receiving antenna with 3dBi gain. We test μ Mote at different symbol rates of 1kbps, 2kbps, and 5kbps. Each BER value is obtained by counting misidentified bits in 1,280,000 received bits.

The practical receiving ranges are shown in Fig. 12. At symbol rates of 1kbps and 2kbps, μ Mote achieves a similar receiving range of 400 meters, because at these symbol rates, the LC circuit has the same high Q factor and similar magnification performances. We do not reach the estimated 500m range, because we encountered strong in-band interference that came from unknown wireless devices and exceeded the anti-interference capability of our prototype. The practical ranges of WISP5, Saiyan and passive-DSSS are 70m, 250m, and 140m, which are similar to our estimations. We think that the reason is at these ranges, they do not face interference signals significantly stronger than signals transmitted by USRP. And the range of μ Mote 5kbps is 260m which is an expected result considering its sensitivity. Besides, μ Mote— achieves a maximum range of about 200m.

NLOS Experiments: We also measure the practical receiving ranges of μ Mote and benchmarks in the indoor NLOS scenarios, as a number of IoT devices are deployed in doors

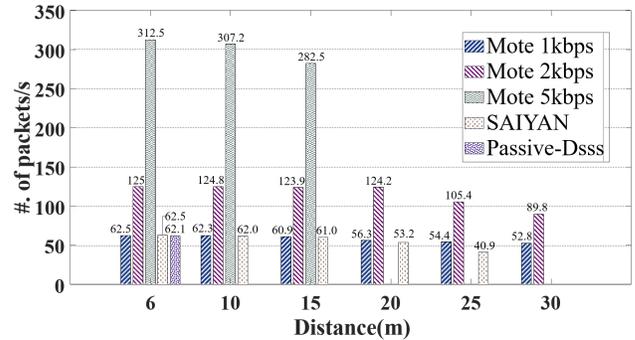

Figure 15: Packet throughput of μ Mote and benchmarks when the signal penetrates two walls.

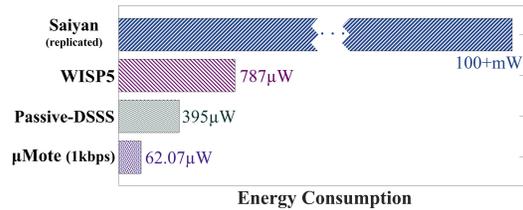

Figure 16: The power consumption of μ Mote prototype and benchmarks.

and signals have been attenuated by walls. The dots A and B represent where the gateway’s USRP transmitter is located, and the star indicates where the receiver is placed. When the gateway is placed at the A , the transmitted signals have to penetrate one wall. When the gateway is at the dot B , the signals penetrate two walls. The star can be moved far or close to the transmitter to make different downlink ranges. We test three symbol rates with μ Mote and one symbol rate with benchmarks, and record each of the error bits in 1,280,000 received bits.

Leveraging the recorded error bits, we calculate the packet throughput at different ranges, which can better represent the communication performance in actual environments. For example, even if there is only one error bit, the packet will become unrecognizable and is therefore discarded. The packet is defined as a 16-bit string, and thus the *packet throughput* refers to the number of received packets being correctly recognized. The test data is a packet which is sent for 10,000 times in a loop.

When there is one wall, the measured packet throughput of μ Mote at different symbol rates are shown in Fig. 13. With 60m downlink range, the μ Mote receiver achieves 53 packets/s at 1kbps, and 101.5 packets/s at 2kbps. The maximum range for 5kbps is 30m and the corresponding throughput is 286.5 packets/s. We can learn from this result that for μ Mote, a LC resonator with high Q factor is crucial to achieving long range.

We also measure the packet throughput of benchmarks when their downlink signals penetrate one wall, and then compare them with μ Mote at 1kbps. The results are plotted

Table 2: Power breakdown of two prototypes

Modules	Despreading	Magnification	Regulator	RC Decoding (1kbps)	MCU (1% duty cycle)	Total
μ Mote	0 μ W	0 μ W	51.17 μ W	3.4 μ W	7.5 μ W	62.07 μ W
μ Mote-	0 μ W	0 μ W	18 μ W	3.4 μ W	7.5 μ W	28.9 μ W

Table 3: Parameters of RC decoding circuit for different symbol rates

Bit rate	R value	C value	E/symbol	Power
1kbps	910k Ω	330pF	2.40nJ/bit	3.4 μ W
2kbps	470k Ω	330pF	2.36nJ/bit	3.72 μ W
5kbps	200k Ω	330pF	2.51nJ/bit	13.55 μ W

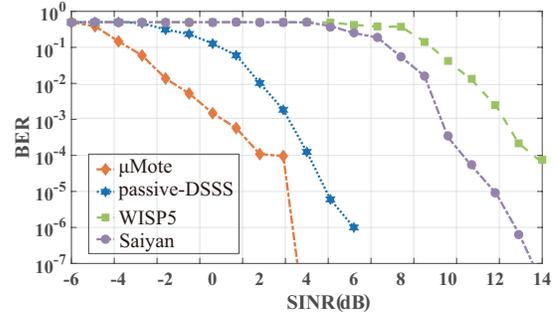

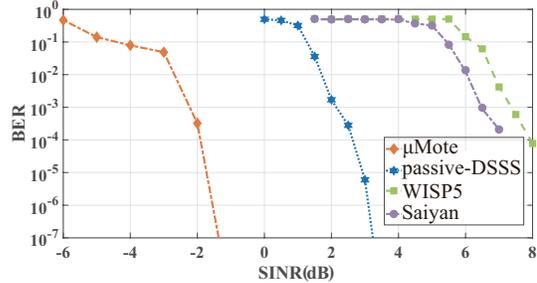

in Fig. 14. Among these benchmarks, Saiyan has the longest range of 30m with a packet throughput of 37.6 packets/s, this range is half the range of μ Mote (i.e., 60m at 1kbps).

When there are two walls between the gateway and receivers, the receiving ranges are further decreased, as shown in Fig. 15. At the range of 30m, μ Mote has acceptable throughput values of 52.8 packets/s at 1kbps and 89.8 packets/s at 5kbps. Saiyan and passive-DSSS can receive at the ranges of 25m and 6m, with packet throughput values of 61.6 packets/s and 62.1 packets/s, respectively. WISP5 cannot receive its downlink signal.

7.4 Power Consumption

μ Mote vs. Benchmarks: To demonstrate the power-efficiency of our design, we measure the practical power consumption of μ Mote prototypes and benchmarks using a sub- μ A-level power monitor [52]. The results are plotted in Fig. 16. We can see that the total power consumption of μ Mote (1kbps) is 61.07 μ W, which is the lowest. WISP5 and passive-DSSS have a power consumption of several hundreds of μ W, as we take the power consumption of ADC sampling and the MCU for ADC control into account. We replicated Saiyan prototype according to the BOM extracted from their project files [16, 17]. At its maximum receiving range, the power consumption of the Saiyan prototype is 446mW. We believe the cause of this high power consumption is their use of two amplifiers [21, 40].

μ Mote power breakdown: Table 2 shows the power breakdown of the μ Mote prototype. The de-spreading circuit and magnification circuit consume zero power as they are driven by the received signal. For different symbol rates, the corresponding power consumption of RC decoding circuit (including the threshold detector) is illustrated in Table 3. It can be observed that at different symbol rates, the energy budget for decoding one bit remains roughly unchanged. The cause is that the energy budget is related to capacitance. The MCU average power consumption is about 7.5 μ W with 1% duty cycle.

Figure 17: Receiving BER of μ Mote and benchmarks under LoRa interference.Figure 18: Receiving BER of μ Mote and benchmarks under RFID interference.

7.5 Interference Resilience

We evaluate the interference resilience of μ Mote under interference in 900MHz ISM band, such as RFID and LoRa. We use the interference-resilient receiver, i.e., passive-DSSS, as benchmarks. We also evaluate WISP5 and Saiyan for comparison, which are not interference-resilient. We choose the impinj R420 RFID reader and EBYTE E32-915T30S Lora transceiver as the interference source. Then we use USRP to record practical signals transmitted by these two devices, so we can manually amplify or attenuate the recorded signals to make interference with different strengths. Finally, we leverage RF cables to transmit twin-CSS signals as well as those interference signals to μ Mote receiver to measure receiving BER values. Both μ Mote receiver and passive-DSSS receiver are set to 1kbps symbol rate. The bandwidths of RFID and LoRa interference are set to 100kHz and 500kHz, respectively.

Fig. 17 and Fig. 18 show the BER measurement under LoRa and RFID interference signals. The results demonstrate that the μ Mote prototype can operate under negative SINR caused by RFID or LoRa interference. In detail, at BER of

1%, the corresponding SINRs caused by LoRa or RFID signal are about $-1dB$ and $-2.7dB$, whereas at BER of 0.1% the SINRs caused by LoRa or RFID signal are about $-1dB$ and $-2.2dB$. We can learn $\mu Mote$ can operate under negative SINR caused by LoRa and RFID interference. Passive-DSSS has SINR improvement over classic WISP5 which has no anti-interference design, but it cannot work under negative SINR.

8 Discussion and Limitations

Accessing multiple devices or gateways: To date, $\mu Mote$ cannot support concurrent transmissions from the gateway to multiple backscatter devices, as $\mu Mote$ has no frequency division or other multiple access designs. A feasible solution is to employ time division on the MAC layer, similar to RFID protocols. In addition, $\mu Mote$ fails to work in the face of the hidden node problem, which occurs when multiple gateways want to talk with a certain receiver, but they are unaware of each other's existence.

Strength loss: The gateway transmitter needs to split its power across both chirps, and therefore it may require more transmitting power than it would have been needed to transmit to a device at the same distance using a conventional active receiver. Although $\mu Mote$ mixes the two chirps, the generated harmonics will also result in a loss of signal energy.

Spectrum efficiency: The bandwidth consumed in our design is about $1.04MHz$ ($1MHz$ chirp and $43kHz$ S_{beat}). Most spectrum bandwidth is spent on spectrum spread to resist interference. Compared with LoRa receivers, our $\mu Mote$ consumes similar spectrum bandwidth but achieves power consumption three orders of magnitude lower than LoRa.

Improving symbol rate: As the trade-off introduced in Sec. 4, in this paper, we cannot achieve the highest symbol rate and best magnification performance simultaneously. Improving the magnification performance requires increasing the interval time for discharging the LC resonator, while improving the symbol rate requires decreasing the interval time. Hence, we explore a discharging mechanism to the LC resonator. Specifically, when the symbol synchronization is completed, we can discharge the LC resonator at the middle (to discharge the energy of symbol "0") and the end of a symbol. Thus, the energy in LC can be discharged more rapidly to allow a higher symbol rate, even for LC of very high Q factor to gain high magnification performance. Moreover, we also plan to explore whether we can add more threshold detector modules ($< 1\mu W$ per module) with different thresholds, and then the symbols can be quantified into more characters, thereby increasing the bit rate.

9 Related Work

Diode-based mixer. Similar to $\mu Mote$, there are two existing works [11, 42, 43] that use the diode mixer [4] to mix two RF signals and achieve low-power subcarrier generation or very high-speed receiving. The differences between our work and them are three-fold. The first difference is waveform modulation. In $\mu Mote$ design, we employ Chirp Spread Spectrum (CSS) signals as downlink signals, and thus our work can combat interference and even work under negative SINR. The second difference lies in $\mu Mote$'s system design. The passive chirp de-spreading scheme should be used in conjunction with the LC resonator which acts as a magnifier and filter, otherwise the signal strength loss due to chirp mixing would decrease the receiving range, and the receiver cannot filter or detect the generated beat signal. The third difference is our design has the benefit of a relatively long receiving distance.

Long-range backscatter communication. To resist interference and improve communication range in low-power IoT systems, tremendous backscatter innovations [23, 35, 37, 51, 54, 55] leverage CSS modulation on LoRa, extending the uplink range to more than one kilometer. Nevertheless, these designs cannot receive spread spectrum signals on the downlink, as spread spectrum signal demodulation and de-spreading involve high-power local carrier generation and computing-intensive correlation for synchronizing local de-spreading codes or de-spreading signals. This fact causes unbalanced communication ranges and robustness on uplink and downlink. Moreover, tunnel diode can be employed in backscatter transmitters, further increasing the communication range of backscatter devices [56].

Saiyan [17] employs a SAW filter to re-shape the envelope of chirp signals, enabling an envelope detector to receive LoRa signals on the downlink. But this method does not de-spread chirps so it cannot gain the communication range and robustness improvements of CSS, and instead, it has to use LNA to boost range. Passive-DSSS [31] receives both spreading codes and synchronized de-spreading codes from the transmitter, first achieving the DSSS communication on envelope detector-based receivers. Compared with $\mu Mote$ which employs a passive mixer to de-spread two parallel chirps, Passive-DSSS relies on envelope detectors to receiver signal, and hence it cannot receive CSS signals and work under negative SINR. Moreover, Passive-DSSS does not contain any low-power signal magnifying scheme (e.g., the LC resonator) and low-power ADC-free decoding scheme, resulting in a relatively limited receiving range and relatively high decoding power.

Signal magnification techniques. The most commonly used signal amplification means is the LNA. As we introduce in Sec. 2.1, even the latest commercial LNA ICs consume more than several mW of power. To magnify signals with low power, recent researches leverage the principle of *Voltage transforming* or *Impedance tuning* to get signals with mag-

nified voltages. For example, XSHIFT [43] leverage a coil voltage transformer to magnify the voltage of demodulated signals by 5 times. Besides, LC circuits are also used to boost the voltage of received RF signal by adjusting the antenna impedance [1, 50]. However, these two methods cannot magnify the instantaneous power of RF signals or demodulated signals, so their improvements in receiving sensitivities are relatively limited, compared to our design.

Backscatter communication. Our work is also related to backscatter communication techniques, as $\mu Mote$ characteristics have potential benefits existing backscatter devices. For LoRa backscatter devices [23, 35, 37, 51, 54, 55], it can make up for their limited downlink performance in terms of range and robustness against interference, with only μW -level power. For other tremendous backscatter innovations features of high data rate [53], high-throughput [24, 25, 42], robustness [57], large system scale [19], simplified hardware [30, 43, 62], and ambient-signal-compatible [2, 5, 12, 22, 26, 27, 32, 33, 35, 36, 38, 54, 61, 63], $\mu Mote$ can provide downlink connection with benefits of interference-resistant, low-power, and cost-efficiency, at the same time.

ADC-free decoding. Similar to $\mu Mote$, RFID tags [10] can decode PIE symbols without ADC. But differing from $\mu Mote$, the PIE decoder of RFID tags can extract the synchronization clock from PIE symbols by simply inverting the PIE waveform (which is illustrated in the citation [28]). However, according to the symbol definition of our design, our ADC-free decoding circuit cannot extract the synchronization clock in the same way as RFID tags. Hence, we have to explore a dedicated synchronization scheme for our decoding circuit.

Wake-up receiver. Due to the power benefit of integrated circuits, envelope detector-based wake-up ICs achieve power consumption of less than $100\mu W$ and good receiving sensitivity of lower than $-60dBm$. These receivers typically has a low power consumption of less than $100\mu W$, and provide sensitivities lower to $-60dBm$ [20, 39, 44]. There are two distinctions between our work and these ICs. First, our design enables interference-resistant communication with μW -level power. Second, employing the LC resonator and the dedicated encoding mechanism can magnify the amplitude of demodulated signals, which is a potential alternative technique for receivers to enhance the receiving sensitivity.

10 Conclusion

In this paper, we systematically investigate the issue of low-power and long-range receiving, the critical bottleneck of communication of backscatter devices. We present $\mu Mote$, an μW -power receiver with 400 meters range. We design and implement the first passive chirp de-spreading method with a simple mixer by offloading high-power carrier de-chirp generating to the gateway. Then we present a novel zero-power magnification method with a LC resonant circuit, effectively improving the receiving sensitivity. We propose an energy

integration-based decoding mechanism instead of high-power ADC sampling to reduce power consumption. We conduct extensive experiments in different scenarios. The evaluation shows that $\mu Mote$ can support up to 400m receiving range with $62.07\mu W$ power consumption at $2kbps$ symbol rate. Compared to benchmarks, $\mu Mote$ improves the downlink range by $2.5\times$ to $8.65\times$, with a power consumption reduction of 63.2% to even three orders of magnitude.

Channel-Aware 5G RAN Slicing with Customizable Schedulers

Yongzhou Chen¹, Ruihao Yao¹, Haitham Hassanieh², Radhika Mittal¹
¹UIUC, ²EPFL

Abstract. This paper focuses on 5G RAN slicing, where the 5G radio resources must be divided across slices (or enterprises) so as to achieve high spectrum efficiency, fairness and isolation across slices, and the ability for each slice to customize how the radio resources are divided across its own users. Realizing these goals requires accounting for the channel quality for each user (that varies over time and frequency domain) at both levels – inter-slice scheduling (i.e. dividing resources across slices) and enterprise scheduling (i.e. dividing resources within a slice). However, a cyclic dependency between the inter-slice and enterprise schedulers makes it difficult to incorporate channel awareness at both levels. We observe that the cyclic dependency can be broken if both the inter-slice and enterprise schedulers are greedy. Armed with this insight, we design RadioSaber, the first RAN slicing mechanism to do channel-aware inter-slice and enterprise scheduling. We implement RadioSaber on an open-source RAN simulator, and our evaluation shows how RadioSaber can achieve 17%-72% better throughput than the state-of-the-art RAN slicing technique (that performs channel-agnostic inter-slice scheduling), while meeting the primary goals of fairness across slices and the ability to support a wide variety of customizable enterprise scheduling policies.

1 Introduction

Network slicing is one of the key new features introduced in the 5G standards [3, 9, 37]. It refers to dividing network resources among different services or groups of users to create virtual customizable networks. Such virtualization enables cellular networks to expand beyond the classical “individual mobile user” use-case to a more general “groups of users” use-case which can support new applications with different requirements. These groups of users (typically referred to as enterprises in 5G) enter into service level agreements (SLA) with the network operator, which provides two features: (1) It governs the type of service and the total amount of resources allocated to each slice. For example, it can provide an ultra-reliable low-latency communication for first responders, connected vehicles, or hospitals performing remote surgeries [20]. It can provide cheap and scalable IoT connectivity for farmers using sensors to monitor crops and cities deploying sensors for traffic or air quality monitoring [18]. It can also provide high throughput connectivity for companies with multiple users as well as educational and training institutions using VR/AR [36]. (2) It allows each slice (or enterprise) to customize their virtual networks and dynamically manage their resources [22, 41]. For example, a farming enterprise might

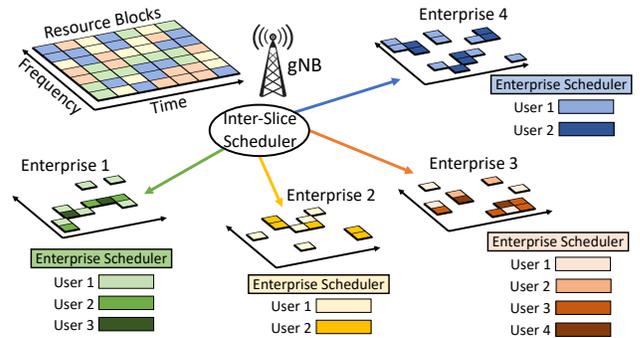

Figure 1: RAN Slicing of resources across 4 enterprises.

want to give higher bandwidth to drones collecting aerial images of crops as opposed to soil moisture sensors, or a hospital might want to prioritize traffic for critical remote surgeries at different times of the day.

Network slicing has two components: 5G RAN (Radio Access Network) slicing and 5G core slicing [11, 29, 30, 44]. This paper focuses on RAN slicing as the RAN is typically the bottleneck in cellular networks [11, 27]. The goal is to divide physical layer resources at the base station (referred to as gNB in 5G) among different enterprises with devices connected to that gNB. These resources include time slots as well as frequency sub-bands used for transmission as shown in Fig. 1. Ideally, the RAN should schedule these resources in a manner that:

- (1) Achieves high spectrum efficiency.
- (2) Ensures fairness among enterprises subject to their SLAs.
- (3) Allows enterprises to customize their scheduling policies.

Realizing the above goals, however, can be challenging in wireless networks because the throughput achieved by using a certain resource block is highly dependent on which user gets that block. In particular, the quality of the wireless channel can change drastically between frequency bands, between users, and over time. This well known phenomena is called frequency selective fading and is shown in Fig. 2 where the capacity can vary by up to $9\times$ across 100 resource blocks (frequency sub-bands) for two users in a 20 MHz LTE bandwidth. Frequency selective fading is even more prominent in 5G where the total bandwidth is expanded to 100 MHz and up to 400 MHz [6]. Allocating resources in a channel agnostic manner can lead to inefficient spectrum usage and unfairness among different slices (enterprises) [10, 22].

Past work has considered the problem of channel aware spectrum allocation [2, 4, 38, 45], channel aware hierarchical resource scheduling in WiMax [21], and RAN virtualization in the context of MVNOs (Mobile Virtual Network

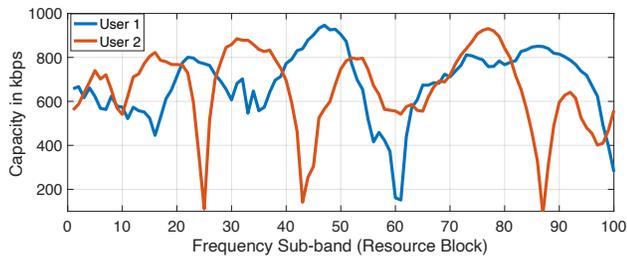

Figure 2: The channel quality across 100 RBs for two users in a 20MHz LTE downlink.

Operators)¹ [9, 22]. However, state-of-the-art techniques can only account for the channel quality between users within the same slice (as detailed in § 2). In other words, only after the inter-slice scheduler allocates resources to different slices irrespective of channel quality, each enterprise can run a channel aware scheduler. Hence, a slice can end up with resources that have bad channel quality for its users which significantly degrades the throughput as we demonstrate in §3.1.

Enabling channel aware scheduling at both the inter-slice scheduler and enterprise scheduler leads to a chicken and egg problem. The enterprise scheduler cannot allocate resources in a channel aware manner before it knows all the resources the inter-slice scheduler will give it, and the inter-slice scheduler cannot allocate resources among slices in a channel aware manner if it does not know to which user in the slice the enterprise scheduler will give a certain resource. One way to break this deadlock is to enumerate through all possible resource allocations and run the enterprise scheduler for each one. However, enumerating all possibilities leads to exponential complexity and is intractable. As a result, state-of-the-art work only uses a channel agnostic inter-slice scheduler [9, 21, 22].

In this paper, we present RadioSaber, a RAN slicing policy that enables channel aware resource allocation at both the inter-slice scheduler and the enterprise scheduler while allowing each enterprise to customize their scheduling policy. RadioSaber’s design is based on a simple idea. Since both the inter-slice scheduler and the enterprise scheduler must run at the base station for real-time scheduling, the inter-slice scheduler can use the enterprise scheduling algorithms as sub-routines in its algorithm. Both the inter-slice and enterprise scheduler can be channel aware if the inter-slice scheduler can call the enterprise scheduling algorithm with the following query: “If we give resource X to slice A, which user in slice A will get resource X?” If the enterprise scheduler is able to reply to this query independent of what other resources the inter-slice scheduler will allocate to its slice, the inter-slice scheduler can be channel aware. Specifically, the inter-slice scheduler can query the enterprise scheduler of each slice, find the user to which the resource X will be allocated and

¹Examples of MVNOs include Straight Talk, Virgin Mobile, & Xfinity mobile, which do not operate their own networks but rather run their traffic through Verizon, AT&T, & T-mobile networks.

determine the slice in which X will deliver the best channel quality.

Being able to answer this query, however, limits the space of scheduling policies that an enterprise can run. In particular, the enterprise scheduler must decide how to allocate a resource X independent of the remaining resources that have not yet been allocated to it as we show in § 4.1. Hence, its algorithm must greedily allocate one resource at a time. Most common practical policies, however, like Max. throughput [4], proportional fairness [45], QoS-aware scheduling [2, 4, 38, 39] etc., tend to use greedy algorithms that satisfy the above requirement. It is worth noting here that when allocating a resource X, the algorithms can still account for resources that have already been allocated to the slice in the past (e.g. in order to provide some notion of fairness or demand-awareness), but not account for resources that are yet to be allocated in the future. Hence, RadioSaber is able to accommodate policies that are both channel aware and flexible to the needs of different slices.

Realizing RadioSaber in practice, however, requires addressing algorithmic questions like how do we incorporate the SLA between the operator and the enterprise into the inter-slice scheduler? In what order does the inter-slice scheduler query the resource blocks to decide which slice gets the block? How do we support customizable enterprise scheduling, while restricting the schedulers to be greedy? How does the enterprise scheduler balance between channel quality and other metrics such as flow priorities? We also have to address several system level questions like what is a good and simple interface that we can provide to the enterprises to set their scheduling policies? How do we incorporate RadioSaber into the current 5G standards? We address the above questions in detail in §4.2 and § 4.3.

We have implemented RadioSaber and evaluated it using trace driven simulations. We used an open-source 5G core network [1] and a popular RAN simulator [34] that is capable of simulating both the physical layer and higher layers at the RAN. We evaluate our system using traces of cellular signals [46], that were collected using software defined radios. We compare with:(1) NVS [9, 21, 22], a popular algorithm which enables RAN slicing with channel aware enterprise scheduler and (2) a global channel aware scheduler that schedules all users without slicing.

Our results reveal that RadioSaber is able to outperform NVS, achieving 17%-72% better throughput for backlogged flows, 2× to 4× lower FCT (flow completion time) for non-backlogged flows, and 24× lower packet delays for real-time flows with constant bitrates. Unlike the global channel aware (but slicing unaware) scheduler that fails to provide any isolation across slices, RadioSaber is able to achieve desired isolation and fairness. Finally, RadioSaber is able to accommodate enterprise schedulers with various policies and number of users. Hence, RadioSaber is able to achieve the three goals of spectrum efficiency, fairness, and customizability.

The paper makes the following contributions:

- We present the first RAN slicing that is channel-aware both at the inter-slice scheduler and enterprise scheduler.
- We present a new framework for RAN virtualization that abstracts physical layer scheduling and provides an interface for enterprises to set their own schedulers.
- We implement our techniques and demonstrate significant improvement in efficiency and fairness.

2 Background & Related Work

In this section, we provide a brief background on the radio access network (RAN) in cellular networks as well as the related work for channel aware scheduling and RAN slicing.

1. Resource Blocks: In 5G RANs, the user or device is referred to as UE (User Equipment) and the base station is referred to as gNB (next generation Node B). The gNB uses OFDMA (Orthogonal Frequency Division Multiple Access) at its PHY and MAC layers in order to divide radio resources across UEs. In OFDMA, the frequency bandwidth is divided into sub-carrier frequencies that are orthogonal (i.e. do not interfere) and time is divided into equal slots called TTIs (Transmission Time Interval). A resource block (RB), which is the smallest resource unit that can be allocated to a UE, is formed of 12 frequency sub-carriers and 1 TTI slot. Hence, the RBs are organized into a 2D grid as shown in Fig. 1. In practice, however, network operators typically schedule resources in the granularity of resource block groups (RBGs) to minimize control overhead. Each RBG contains a fixed number of consecutive RBs ranging from 1 to 4 [8, 42]. In 4G, each TTI has a fixed length of 1ms and each sub-carrier has a fixed width of 15 kHz. Thus, the RB spans $12 \times 15 = 180$ kHz. 5G, on the other hand, supports 5 configurable TTI and sub-carrier intervals such that the TTI is $2^{-\mu}$ ms and the sub-carrier interval is $2^{\mu} \times 15$ kHz. μ is commonly referred to as the numerology and chosen from the values 0, 1, 2, 3, 4 depending on the band of operation [7, 35]. For example, the 5G sub-6GHz band, supports sub-carrier width of 60 KHz with a TTI of 0.25 ms for $\mu = 2$ [33, 43]. In this case, the RB spans 720 kHz.

2. Data Rate: The data rate at which a UE can transmit in a given RB depends on the channel quality which is typically defined by the SNR (signal-to-noise-ratio). The SNR determines the capacity of the wireless link and varies across time, RBs, and users as shown in Fig. 2. The SNR can be computed at the UE for each OFDM sub-carrier. For a RB or RBG made of many sub-carriers, the “effective SNR” is typically computed² as described in [16, 25, 31]. The effective SNR is then mapped to a discrete value called channel quality indicator

²The effective SNR is not the average across sub-carriers but rather a weighted exponential average that typically gives a value close to the minimum SNR across sub-carriers. This ensures that the chosen data transmission rate does not exceed the capacity of the wireless link at any sub-carrier which would otherwise result in a very high packet loss rate.

UE	User Equipment	RAN	Radio Access Network
gNB	5G Base station	TTI	Transmission Time Interval
RB	Resource Block	RBG	Resource Block Group
SNR	Signal-to-Noise Ratio	SLA	Service Level Agreement
PF	Proportional Fair	CQI	Channel Quality Indicator
MT	Max. Throughput	MCS	Modulation & Coding Scheme

Table 1: Terms used in 5G networks

(CQI) and periodically reported to the gNB [8]. The CQI is then used to determine the modulation and coding scheme (MCS) for the UE which in turn determines the data rate of the UE. The higher the SNR and channel quality, the higher order MCS can be used to increase the data rate.

3. Channel Aware Scheduling: The need for channel-aware scheduling in wireless networks has led to a number of techniques that propose allocating resources across individual users in a channel-aware manner (e.g. [2, 4, 13, 14, 38, 39, 45]). In most cases, the scheduling problem is NP-Hard and a greedy heuristic is adopted whereby RBs are allocated one at a time to the UE that scores highest on some given metric [4]. These strategies ensure low scheduling overhead and enabling fast decisions at timescales of a single TTI. Some of the most common techniques include:

- *Maximum Throughput (MT):* Assigns the RB to the UE with the largest CQI to maximize data rate irrespective of fairness.
- *Proportional Fair (PF):* Extends MT to incorporate fairness across users by weighing the CQI with the UE’s historical allocation. This is a very popular strategy in cellular networks that aims to optimize the sum of the log of throughput of UEs [17, 24, 45]. The PF metric can also be parameterized to vary the relative weights of the CQI versus historical allocation [45].
- *Incorporating QoS and delay:* The PF metric can be further extended to incorporate (i) QoS values that increase the weights of higher priority UEs [4, 13, 14, 39], or (ii) packet delays that increase weights of UEs that have been waiting longer [2, 38, 39].

Non-greedy heuristics have also been proposed for optimizing proportional fairness [17, 24]. The scheduling problem is abstracted as an NP-hard integer linear program and solved using a sub-optimal non-greedy algorithm. Such algorithms, however, are computationally very expensive and must use GPUs to compute their solutions [17].

4. RAN Slicing: The inter-slice scheduler provides each enterprise with a slice of the RAN by allocating a set of virtual RBs which it maps to physical RBs. In order to support channel aware scheduling, it also provides the enterprise scheduler with the CQIs of the UEs of this enterprise for each virtual RB. Each enterprise is then able to customize how it allocates the virtual RBs to its UEs by using virtual control functions at the gNB to specify its own scheduling policy [9, 10]. Note that both the inter-slice scheduler and enterprise scheduler run on the gNB which enables RadioSaber to expose the enterprise scheduling algorithms to the inter-slice scheduler as described in more details in §4.1.

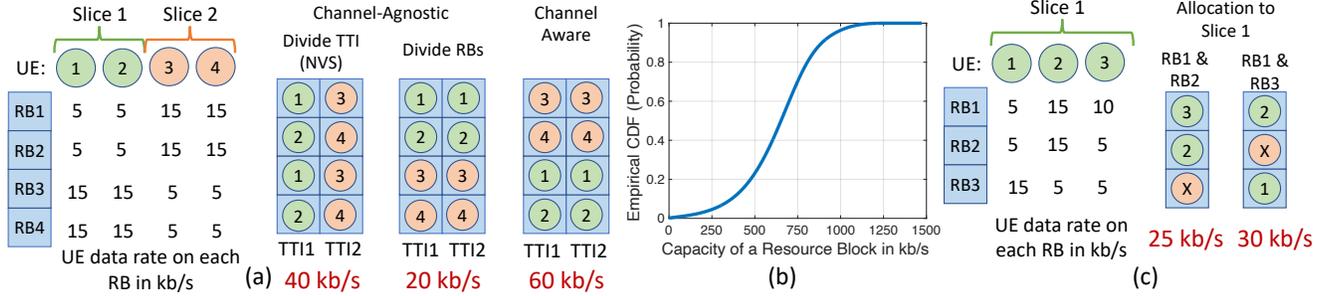

Figure 3: (a) Illustrative example showing the importance of a channel aware inter-slice scheduler. (b) Distribution of the capacity of RBs from real traces. (c) Example showing the challenge in enabling a channel aware inter-slice scheduler.

The closest to our work is NVS (Network Virtualization Substrate) [21], a popular inter-slice scheduler that is used by multiple RAN slicing schemes [9, 21–23, 26]. NVS allocates all RBs in a given TTI to a single slice independent of channel quality. It then rotates between slices in a weighted round-robin manner to satisfy the target throughput of each slice as specified by SLA. While NVS does allow the enterprise scheduler to run a channel aware policy, the inter-slice scheduler remains agnostic to channel quality which changes over time and resource blocks. We compare with NVS in §6 and show that our channel aware inter-slice scheduler can significantly improve performance.

Past work on slicing radio resources also explores supporting dynamic demands across slices [40, 47] and deadlines across slices [12, 15]. All past work, however, constraints the inter-slice scheduler to allocate virtual RBs to each slice in a channel-unaware manner. Our goal, in contrast, is to enable channel-aware scheduling at both inter-slice and enterprise levels, while still giving each enterprise enough flexibility to allocate RBs across its users.

3 Motivation and Challenges

In this section, we will explain, using illustrative examples, the importance of channel aware resource allocation at both the inter-slice scheduler and enterprise scheduler as well as the challenge in making the inter-slice scheduler channel aware.

3.1 Need for Channel-Aware Slicing

To best illustrate the need for channel-aware slicing at both the inter-slice scheduler and enterprise scheduler, consider the toy example in Fig. 3(a). In this example, there are 4 RBs $\{R_1, R_2, R_3, R_4\}$, 2 slices $\{S_1, S_2\}$, and each slice has 2 UEs: $\{u_1, u_2\} \in S_1$ and $\{u_3, u_4\} \in S_2$. The channel quality is shown in the left 2D grid in terms of the data rate each UE can achieve on each RB in kb/s. The enterprise scheduler of both slices are channel-aware and run a proportional fairness (PF) policy in order to maximize throughput while ensuring fairness between UEs.

Consider a channel unaware inter-slice scheduler. The scheduler could allocate all RBs in the first TTI to S_1 and

all RBs in the second TTI to S_2 similar to NVS [21]. In this case, the enterprise scheduler of S_1 would allocate $\{R_1, R_3\}$ to u_1 and $\{R_2, R_4\}$ to u_2 . Similarly, the enterprise scheduler of S_2 would allocate $\{R_1, R_3\}$ to u_3 and $\{R_2, R_4\}$ to u_4 . This allows each UE to achieve 10 kb/s over the two TTIs for a total of 40 kb/s. An alternative channel unaware inter-slice scheduler could have also divided the RBs between the two slices by allocating $\{R_1, R_2\}$ to S_1 and $\{R_3, R_4\}$ to S_2 for all TTIs. In this case, the enterprise scheduler of S_1 would allocate $\{R_1\}$ to u_1 and $\{R_2\}$ to u_2 and that of S_2 would allocate $\{R_3\}$ to u_3 and $\{R_4\}$ to u_4 . This allows each UE to achieve a data rate of 5 kb/s for a total of 20 kb/s. Since the inter-slice scheduler is channel-unaware, it has no way of figuring out that such an allocation is very inefficient.

Consider, on the other hand, a channel-aware inter-slice scheduler. This scheduler would allocate $\{R_3, R_4\}$ to S_1 and $\{R_1, R_2\}$ to S_2 for all TTIs. In this case, the enterprise scheduler of S_1 would allocate $\{R_3\}$ to u_1 and $\{R_4\}$ to u_2 and that of S_2 would allocate $\{R_1\}$ to u_3 and $\{R_2\}$ to u_4 . This allows each UE to achieve a data rate of 15 kb/s for a total of 60 kb/s. Hence, the channel-aware inter-slice scheduler enables $1.5 \times$ to $3 \times$ higher throughput.

There are two factors in this example that enable a channel-aware scheduler to achieve better performance than a channel-agnostic scheduler: (i) The channel quality differs across RBs for a given slice, and (ii) The two slices have complementary channel quality distribution across RBs (i.e. slice 1 has a better channel quality for the first two RBs, and slice 2 has better channel quality for the last two RBs). It is the combination of these factors that enables a smarter (channel-aware) resource allocation policy to achieve better performance. Moreover, such factors are quite common in practice as can be seen from the real traces shown in Fig. 2.

While this toy example illustrates the insight behind RadioSaber, the variation in channel quality in real systems can be quite significant as was shown in Fig. 2. Fig. 3(b) plots the cumulative distribution function (CDF) of capacity of all the RBs in a real trace collected from 4G measurements (obtained from [46]). The figure shows that the channel in real traces can vary significantly leading to a capacity that can be as high as $2.2 \times$ the median value and as low as $1/20$ of the median value. This diversity which is a result of frequency

selective fading in the wireless channel is expected to further increase in 5G as the bandwidth increases from 10-20 MHz to 100-400 MHz [6].

Our evaluation in §6 shows that due to this diversity, our simple insight from the toy example generalizes to more complex scenarios.

3.2 Challenge in Channel-Aware Slicing

In order to allocate RBs across slices in a channel-aware manner, we first need to know what channel quality each slice would achieve for each RB. While in the above toy example it is easy to see what the best channel aware allocation is, the problem is challenging in more general settings. In particular, if the inter-slice scheduler gives RB R_i to slice S_j , then the channel quality of R_i will depend on which UE belonging to S_j will use R_i which in turn depends on the enterprise scheduling policy. However, the enterprise scheduling policy itself could be channel-aware, in which case, the allocation of R_i to a given UE will depend on which RBs the inter-slice scheduler has allocated to S_j . This creates a deadlock as the inter-slice scheduler needs to know how the enterprise scheduler will allocate R_i to determine its channel quality and whether to give R_i to this slice. At the same time, the enterprise scheduler needs to know what RBs the inter-slice scheduler will give it so it can allocate them in a channel-aware manner.

Fig. 3(c) illustrates this through a toy example. Consider a slice with three UEs $\{u_1, u_2, u_3\}$. Suppose the inter-slice scheduler must allocate two RBs to this slice (as per its weighted share) and suppose the enterprise scheduling policy assigns a RB to the user which has maximum data rate for the RB, while limiting each user's allocation to a single RB. If the inter-slice scheduler allocates $\{R_1, R_2\}$ to the slice, then the enterprise scheduler would first allocate R_2 to u_2 and then allocate R_1 to u_3 . However, if the inter-slice scheduler allocates $\{R_1, R_3\}$ to the slice, the enterprise scheduler would allocate R_1 to u_2 and R_3 to u_1 . The data rate associated with R_1 for this slice is 10 kbps in the first case and 15 kbps in the second case. Hence, while determining whether to allocate R_1 to this slice or not, the inter-slice scheduler does not know the data rate that R_1 will deliver as it depend on whether the other RB allocated to the slice is R_2 or R_3 .

One way out is to enumerate through all possible combinations of inter-slice allocations, and run the enterprise scheduler for each slice for each allocation. However, this is clearly intractable with the number of possible allocations increasing exponentially with the number of slices and resource blocks.

3.3 RadioSaber's Approach

In order to break the deadlock challenge outlined in §3.2, we leverage the following insights. First, both the inter-slice and enterprise scheduler must run on the base station (gNB) to

guarantee real-time scheduling. Hence, the inter-slice scheduling algorithm can use the enterprise scheduling algorithm as a subroutine and query it to figure out how it will allocate a certain RB. Second, we can break the deadlock if the enterprise scheduler is able to reply to the following query from the inter-slice scheduler: "If I give resource R_i to slice S_j , which UE in slice S_j will get resource R_i ?"

For the enterprise scheduler to be able to reply to this query, its algorithm should determine how to allocate a RB independent of other RBs that the inter-slice scheduler might allocate to it. Restricting the enterprise scheduling algorithm to greedily allocate one RB at a time makes it independent of the remaining RBs that will be allocated to it. It may still need to account for the historical allocation of RBs (i.e. RBs already assigned to the slice) to correctly estimate the remaining demand of a user or to account for fairness. A greedy inter-slice scheduler, that assigns RBs to slices one at a time, enables the enterprise scheduler to update its scheduling state based on its allocation so far. Restricting both scheduler to be greedy thus enables the enterprise scheduler to effectively answer the query while still accounting for historical allocation, and for the inter-slice scheduler to use the result of the query to assign the RB to the slice with the best channel quality.

4 RadioSaber's Design

Objectives. RadioSaber tackles the problem of dividing N RBs (over one or more TTIs) across K slices, and then dividing the RBs allocated to each slice across the UEs within that slice, such that the following objectives are met:

(i) *Weighted fairness across slices.* Each slice must get its weighted fair share of resource blocks. We assume that the weights are known and are proportional to each slice's demand (based on the SLA between the slice owner and the cellular network operator). Prior work on RAN slicing [22] shows how SLAs can be specified either in terms of number of RBs or overall throughput, and how both can be translated to dynamic per-slice weights. We use these weights to compute a quota of RBs for each slice, as detailed in §4.1.

(ii) *High spectrum efficiency.* The system must allocate RBs across slices so as to use the spectrum efficiently and achieve high overall throughput. For this, RadioSaber uses the approach outlined in §3.3 to greedily determine which RBs are allocated to a slice to fulfill its quota in a channel-aware manner. We detail RadioSaber's greedy channel-aware inter-slice scheduling algorithm in §4.1.

(iii) *Customizable enterprise scheduler.* Each slice can have a different policy for dividing the RBs allocated to it across its UEs and flows. The system should provide an expressive interface for slice operators to specify their desired policies, and should be able to enforce them. §4.2 describes RadioSaber's framework for supporting a variety of greedy enterprise schedulers.

After describing individual components of RadioSaber’s design, we end this section with describing our overall workflow for RAN slicing in §4.3.

4.1 Inter-slice Scheduler

We divide inter-slice scheduling logic into two steps: (i) computing the quota of RBs for each slice in a TTI, and (ii) greedily allocating RBs to slices as per their quota in a channel-aware manner.³ We detail these steps below.

Computing Per-slice Quotas. In each TTI, RadioSaber first computes the quota of RBGs (the granularity at which RBs are allocated) for each slice, based on per-slice weights. Let the number of RBs and the number of RBGs in each TTI be $|\mathcal{RB}|$ and $|\mathcal{RBG}|$ respectively. A naive strategy is to simply compute the quota of slice s as $w_s|\mathcal{RBG}|$, where w_s is the normalized weight of the slice. However, there are a few practical considerations: (i) The quota for a slice computed in this manner could be non-integral (and possibly less than 1, depending on the number of other slices and their weights). We cannot have non-integral allocation of RBGs. (ii) If $|\mathcal{RB}|$ is not a perfect multiple of the default number of RBs in each group (say k), then the last RBG will have fewer RBs.

RadioSaber accounts for these aspects by maintaining an offset from the (ideal) target share of RBs for each slice, that rolls over to the next TTI. Algorithm 1 presents the pseudocode. We first compute the target share of each slice (in number of RBs) as its absolute weighted share in a TTI (given by $w_s|\mathcal{RB}|$) subtracted by its rolling offset from the previous TTIs (initialized to zero for a new slice). We then set the quota for the slice (in number of RBGs) as its target share divided by k , and round down the result. Because of the rounding down, the sum of quota across all slices would be less than the available number of RBGs. We then increment the quota of a random set of slices by one, so as to account for all of the extra RBGs. This can result in a few slices getting less than their fair share of RBs, and a few slices getting more. We capture this by updating the offset for each slice. This offset is then taken into account when computing the quotas in the next TTI – the slices that get more than their fair share of RBs in the current TTI will have a positive offset and a lower share in the next TTI, while the slices that get less than their fair share of RBs in the current TTI will have a negative offset and a higher share in the next TTI.

As mentioned above, one of the RBGs allocated to a slice may have fewer than k RBs. We account for this by adjusting the offset of the slice that is allocated the aberrant RBG when assigning RBGs to slices (we skip mentioning this step when discussing our assignment algorithm below).

Assigning RBGs to Slices. Given per-slice quotas, we next

³RadioSaber follows the standard practice of making radio resource allocation decisions at timescales of a TTI (§2). Consequently, any temporal variations in a UEs CQI is naturally accounted for when recomputing the schedule over each subsequent TTIs.

Algorithm 1 Calculating RBGs quota for slices

```

1: variable rbs_offset_
2: procedure SLICEQUOTA
3:   rbs_share = []
4:   rbgs_quota = []
5:    $k \leftarrow$  rbs_per_rbg()
6:   for  $s$  in  $\mathcal{S}$  do
7:     rbs_share[ $s$ ]  $\leftarrow$   $|\mathcal{RB}| \times w_s - \text{rbs\_offset\_}[s]$ 
8:     rbgs_quota[ $s$ ]  $\leftarrow$   $\lfloor \text{rbs\_share}[s] / k \rfloor$ 
9:   end for
10:  extra_rbgs =  $|\mathcal{RBG}| - \text{sum}(\text{rbgs\_quota})$ 
11:  while extra_rbgs > 0 do
12:    rbgs_quota[ $\mathcal{S}.\text{rand}()$ ] += 1
13:    extra_rbgs -= 1
14:  end while
15:  for  $s$  in  $\mathcal{S}$  do
16:    rbs_offset_[ $s$ ] = rbgs_quota[ $s$ ]  $\times$   $k - \text{rbs\_share}[s]$ 
17:  end for
18:  return rbgs_quota
19: end procedure

```

need to assign RBGs to slices in a channel-aware manner, so as to maximize spectrum efficiency. Even if we assume that the channel-quality (or the data-rate) associated with each slice for each RBG is known in advance (which, as illustrated in §3, is not the case), computing the optimal assignment of RBGs that maximizes the total data-rate, while adhering to the quota on RBGs for each slice is an NP-hard problem.⁴ A greedy heuristic is therefore a natural choice for finding (a potentially sub-optimal) solution to this problem. But more importantly, as discussed in §3.3, a greedy approach allows the inter-slice scheduler to effectively query the enterprise scheduler and determine the channel quality for each RBG.

The basic allocation logic then becomes relative straightforward: In each TTI, RadioSaber greedily picks a RBG and assigns it to the slice that achieves the maximum channel quality for that RBG. Once a slice has been allocated its quota of RBGs, it is no longer considered for subsequent RBGs allocation in that TTI.

The order in which the inter-slice scheduler allocates

⁴It reduces to an Integer Linear Programming problem [45].

Algorithm 2 Assigning RBGs to slices

```
1: procedure RBALLOCATION
2:   rbg_quota ← sliceQuota()
3:   rbg_assignment = []
4:   slice_user = [] ▷ Users that each slice decides to
   schedule for all RBs
5:   slice_cqi = [] ▷ Channel qualities of each slice(based
   on scheduled users) for all RBs
6:   slice_rbg = []
7:   for  $i$  in range( $|\mathcal{RBG}|$ ) do
8:     for  $s$  in  $\mathcal{S}$  do
9:        $u^* \leftarrow s$ .enterpriseScheduler( $i$ )
10:      slice_user[ $i$ ][ $s$ ] ←  $u^*$ 
11:      slice_cqi[ $i$ ][ $s$ ] ←  $u^*$ .channelQuality( $i$ )
12:    end for
13:  end for
14:  while rbg_assignment.size() <  $|\mathcal{RBG}|$  do
15:     $i^*, s^* \leftarrow \operatorname{argmax}_{i,s}$  slice_cqi and  $i$  not in
    rbg_assignment and slice_rbg[ $s$ ] < rbg_quota[ $s$ ]
16:     $u^* \leftarrow$  slice_user[ $s^*$ ]
17:     $u^*$ .allocRB( $i^*$ )
18:    rbg_assignment[ $i^*$ ] =  $u^*$ 
19:    slice_rbg[ $s^*$ ] += 1
20:    if slice_rbg[ $s^*$ ] >= rbg_quota[ $s^*$ ] then
21:      Continue
22:    end if
23:    for  $i$  in range( $|\mathcal{RBG}|$ ) do
24:       $u' \leftarrow s^*$ .enterpriseScheduler( $i$ )
25:      slice_user[ $i$ ][ $s^*$ ] ←  $u'$ 
26:      slice_cqi[ $i$ ][ $s^*$ ] ←  $u'$ .channelQuality( $i$ )
27:    end for
28:  end while
29: end procedure
```

the RBGs can impact spectrum efficiency. Fig. 4 illustrates this with an example. It shows the channel quality (datarate) associated with three slices $\{s_1, s_2, s_3\}$ for three RBGs $\{R_1, R_2, R_3\}$. Each slice has a quota of 1 RBG. Assigning RBGs sequentially in the order $\{R_1, R_2, R_3\}$ to the slice that has maximum datarate (until it exhausts its quota) results in a total datarate of 50Kb/s. In comparison, allocating RBGs in decreasing order of channel quality achieves a higher datarate of 60Kb/s as it greedily selects the best RBG-slice mapping (in terms of datarate) in each iteration. RadioSaber adopts this strategy for inter-slice scheduling.

While this greedy strategy results in a better outcome than the sequential allocation, it does not produce the optimal result. In fact, the optimal allocation for the example in Fig. 4 would have resulted in a higher datarate of 65kb/s. This sub-optimality is expected from any polynomial time algorithm, given the NP-hardness of our resource allocation problem.

Algorithm2 presents the pseudo-code for RadioSaber’s inter-slice scheduler. It computes maximum channel quality

across slices for each unallocated RBG (lines 7-13). It allocates the RBG with the highest channel quality (say i^*) to the corresponding slice (s^*) that has the highest channel quality for it (line 15). If the quota for slice s^* is not exhausted, it recomputes the channel quality for the remaining RBGs for that s^* (lines 20-24). This recomputation is needed because the previous allocation may influence how the enterprise scheduler in s^* schedules UEs for subsequent RBGs allocated to it (e.g. if a UE has met its demand or to ensure fairness across UEs). The above steps are then repeated to proceed with the allocation of the next RBG.

This algorithm has a polynomial time complexity of $O(|\mathcal{RBG}|^2(|\mathcal{S}| + T) + |\mathcal{RBG}||\mathcal{S}|T)$ in the worst case, where T is the time complexity of the enterprise scheduler for assigning an RBG to a UE (this is typically $O(|\mathcal{U}|)$ for $|\mathcal{U}|$ UEs in a slice for the greedy enterprise scheduler described in §4.2).

4.2 Customizable Enterprise Scheduling

We now describe RadioSaber’s framework for supporting different enterprise scheduling policies. Restricted by the need for the enterprise scheduler to be greedy (§3), and inspired by existing channel-aware wireless schedulers (described in §2), we adopt a metric-based allocation strategy. The enterprise scheduler computes a metric for each UE for the RBG it is assigned (or queried about by the inter-slice scheduler) and selects the UE that scores highest on that metric. These metrics are parameterized – RadioSaber exposes these parameters to the slice operators, allowing them to tune the parameters in order to express different scheduling policies.⁵

At a high-level RadioSaber allows the slice operator to specify a variety of policies based on flow priorities, fairness across UEs, channel-quality, and packet delays. It supports two scheduling paradigms:

Paradigm 1: Select User First. This paradigm assigns a given RBG i to a UE that scores the highest on the following metric (corresponding to the generalized PF [45]), and schedules the highest priority flow belonging to that UE.

$$metric(u, i) = d_{u,i}^\epsilon / R_u^\psi$$

Here, $d_{u,i}$ is the instantaneous data rate of UE u for RBG i , and R_u captures the historical RBG allocation for the UE u as an exponential weighted moving average of the user’s throughput, based on its datarate for the RBGs it has been assigned so far. The parameters, ϵ and ψ , are integers that determine the relative weightage of channel quality and historical allocation. For example, setting $\epsilon = \psi = 1$ instantiates the default

⁵RadioSaber makes an implicit assumption that each slice operator wishes to implement a customized scheduler, and accordingly specifies the scheduling parameters that allow RadioSaber’s enterprise scheduling framework to answer the inter-slice scheduler’s query and to allocate resources. For slices that do not wish to implement a customized policy, RadioSaber can initialize the scheduling parameters to reflect the default scheduling policy decided by the network operator.

PF(proportional fairness) scheduler, or setting $\epsilon = 1$ and $\psi = 0$ instantiates the MT(maximum throughput) scheduler.

Paradigm 2: Select Highest Priority First. This paradigm always assigns a given RBG i to the flow with highest priority. When the highest priority level (p) has multiple flows (across multiple UEs), it selects a flow (or a UE)⁶ based on the following metric (from [2,4]):

$$metric(u, p, i) = (\beta D_{u,p} + (1 - \beta))(d_{u,i}^\epsilon / R_u^\psi)$$

Here, $D_{u,p}$ is the queuing delay experienced by the packet at the head of the queue corresponding to UE u and priority p . β is a binary parameter that determines whether the head packet delay ($D_{u,p}$) influences the choice of UE. $d_{u,i}$, R_u , ϵ and ψ are as described above. Setting $\beta = \epsilon = \psi = 1$ instantiates the M-LWDF(Modified-Largest Weighted Delay First) Scheduler [2].

A binary parameter α allows a slice operator to pick between the two paradigms ($\alpha = 0$ picks the first paradigm and $\alpha = 1$ picks the second paradigm).

In summary, there are four parameters that RadioSaber exposes for tuning the enterprise schedulers:

- (1) α that determines whether a UE is selected first or the priority level.
- (2) ϵ that determines the weightage of channel quality.
- (3) ψ that determines the weightage of historical allocation.
- (4) β that determines whether the head packet delay is a factor.

A slice operator can tune these parameters differently to express different policies, as per their requirements and workload. These parameters are initialized when the slice operator creates the slice, and are stored in the data repository in the 5G core (as detailed in §4.3).⁷

While our enterprise scheduling approach is heavily inspired from existing wireless scheduling techniques, we introduce some new aspects. In particular, cellular schedulers typically do not consider different priority levels for a given UE. Instead, they map all flows belonging to a UE to a single queue (the default radio bearer). We introduce the notion of different priority levels for each UE, as we believe that is an important requirement for emerging applications where each UE may have different types of flows.

4.3 RAN Slicing Workflow

We now explain the RAN slicing workflow for RadioSaber.

⁶We assume each UE has a single flow at each priority level. Even if a UE has multiple flows for a given priority level, they are served in a FIFO order with respect to one another, and we can logically treat them as a single flow.

⁷We assume that the slice operators are fine with sharing their coarse-grained scheduling policies with the network operators (in the form of these parameters). Extending our system to provide a secure environment for the slice operators to schedule their UEs and to answer the inter-slice scheduler's query in manner that does not reveal the scheduling policies is an interesting future direction, that is beyond the scope of this paper.

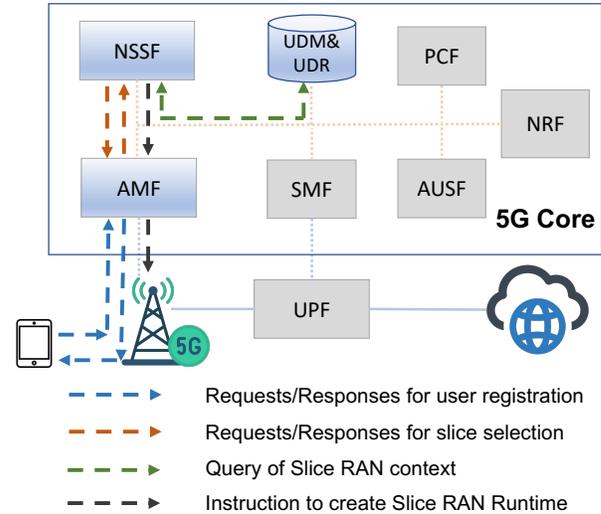

Figure 5: 5G Core network architecture, and the workflow for relaying slice context from 5G core to gNB.

4.3.1 Relaying Slice Context to gNB

The relevant slice context for RadioSaber includes the slice ID, a list of its users, the slice SLA (or weight), and the enterprise scheduling parameters. When the slice operator registers a new slice, this context is initialized and stored in the 5G core. When a user belonging to this slice attaches to a gNB, the relevant context must be relayed from the 5G core to the gNB for RAN slicing. We now describe the workflow for it.

Fig. 5 shows different modules of 5G core. The modules relevant for RadioSaber's workflow are shaded in blue. UDM & UDR (Universal Data Management & Repository) manages and stores all user-related data including slice contexts. AMF (Access and Mobility Function) manages different aspects of a UE (other than data forwarding) – these include connection, reachability, mobility, authentication, authorization, and location services. NSSF (Network Slicing Selector Function) handles slice selection request and manages the life cycle of a network slice instance.

Standard implementations for 5G core provide a framework to support core slicing. We extend it for RAN slicing with RadioSaber by adding the following workflow:

- (1) When a UE tries to connect, it issues a registration request to the gNB, which then forwards the request to the AMF.
- (2) The AMF in turn issues a request to the NSSF to fetch the slice context associated with the UE.
- (3) If the corresponding slice instance is not available at the NSSF, it means that the UE is the first to register for the slice. The NSSF then constructs the slice instance based on the slice context stored in the UDM, and passes the context to the AMF in response. If an instance for the slice is already available at the NSSF, it directly responds to AMF.
- (4) The AMF then relays the slice context obtained from NSSF to gNB through the NGAP(NG Application Protocol).
- (5) The gNB uses the information received from the AMF

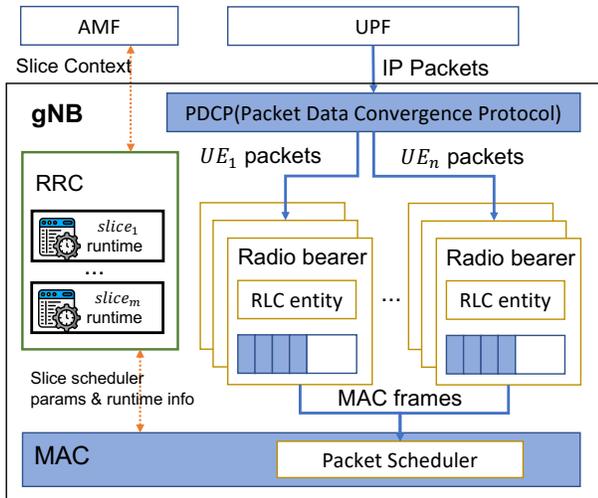

Figure 6: 5G gNB architecture: it shows how RRC maintains slice runtimes, and controls the MAC scheduler behavior.

to create a RAN slice runtime instance if that UE is the first to register for that slice at the gNB. Otherwise, it uses the information to determine the slice ID for the UE, and map the UE to the corresponding RAN slice instance.

4.3.2 Scheduling at gNB

The gNB stores the slice context obtained from the 5G core at the RRC (Radio Resource Control). The IP packets arrive at the gNB from the UPF (User Plane Function), and are intercepted by the PDCP (Packet Data Convergence Protocol). PDCP is responsible for compressing IP headers and ciphering data for integrity protection. For RadioSaber, it parses the packet priority from the DSCP field in the IP header.

Typically, a gNB maintains a single queue for each UE associated with a single QoS level (radio bearer) [32]. To support multiple priority levels within a UE, we simply allow multiple discrete priority queues (radio bearers) for each UE.⁸

Upon parsing the priority level from the packet header, the PDCP can then forward the packets to the radio bearer with the corresponding UE and priority level.

The packet scheduler in the gNB uses the slice context stored in the RRC (that includes slice weights and enterprise scheduling parameters) and the per-UE context (including its periodically updated CQI and historical allocations) to run both the inter-slice and the enterprise schedulers.

5 Implementation

5G Core Support. We extend Open5GS (an open-source 5G core) [1] to add support for the RadioSaber workflow described in §4.3.1. Open5GS already provides a framework for core slicing. We add the serialization and deserialization

⁸We expect a typical deployment to support 4-8 priority levels.

procedure of our RAN slice context, and the communication between the AMF and gNB for the construction and destruction of RAN slice runtime. This implementation comprises 530 lines of code in total.

RAN Slicing and Scheduling Logic. Due to high overhead and massive cost of deploying a base station and scaling to large number of users, we evaluate our system using trace-driven simulations. We implement RadioSaber’s RAN slicing and scheduling logic in an open-source RAN simulator [34]. By default, the simulator was configured to use LTE settings. We extend it to support 5G configuration. In particular, we configure the downlink bandwidth to 100MHz and the TTI to 250 μ s. We set the guard band to 3920KHz so there are 128 RBs and 32 RBGs in total. We also add support for some practical considerations (e.g. CQI reporting intervals). We ensure that UEs report subband CQI every 40ms, at a granularity that covers 4 RBs. We extend the simulator to support multiple priority levels for each UE. Moreover, we implement multiple scheduling policies in the simulator, including RadioSaber’s inter-slice scheduler, the inter-slice scheduling logic in NVS [22], and the enterprise scheduling policies.

As detailed in §6, we use this simulator to do trace driven simulations to evaluate RadioSaber, using traces from LTScope [46]. These traces measure LTE signal strength (SNR over time and sub-carriers) for major US mobile carriers. We extend those measurements to 5G by concatenating five randomly selected distinct measurements of the 20 MHz LTE bandwidth to generate measurements over a 100 MHz 5G bandwidth.

6 Evaluation

We use the simulator described in §5 to evaluate RadioSaber. Our evaluation results in the following key takeaways:

- RadioSaber achieves higher overall throughput than the state-of-the-art (channel-unaware) inter-slice scheduler, NVS [9, 21, 22] (§6.1).
- RadioSaber can correctly enforce isolation and weighted fairness across slices (§6.1).
- RadioSaber is able to support diverse and customizable enterprise scheduling policies. The throughput wins with RadioSaber over NVS translate to better performance on the corresponding slice-specific metrics (§6.2).
- Complementary CQI distribution across slices is required for channel awareness to produce throughput gains (§6.3).
- RadioSaber’s performance benefits hold as we vary the number of slices and UEs/slice (§6.4).
- RadioSaber performs better than NVS with non-greedy PF enterprise schedulers (§6.5).
- RadioSaber performance is very close to our (contrived) upperbound (§6.6).
- The scheduling latency of RadioSaber is within a TTI and the runtime overhead is low (§6.7).

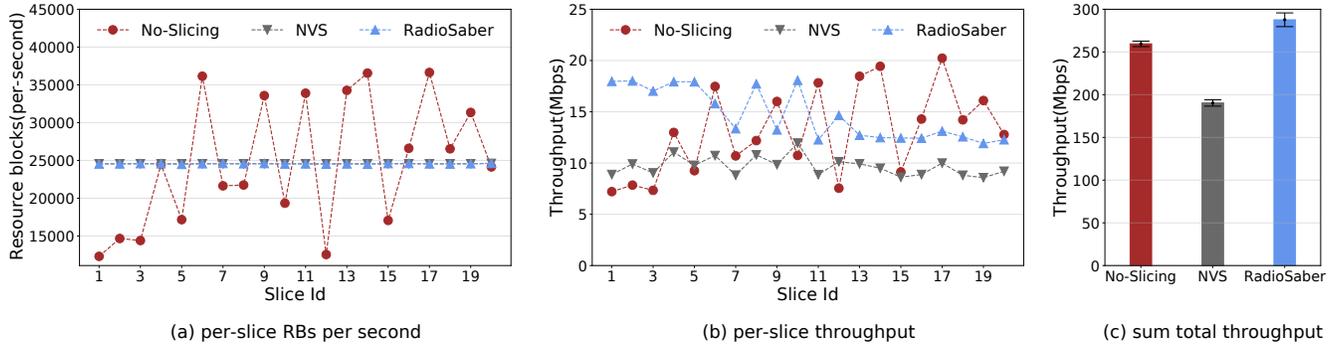

Figure 7: Comparing RadioSaber with NVS and no slicing. Number of slices is fixed to 20, with 5-15 UEs in each slice. The first 10 slices use MT and the next 10 use PF enterprise schedulers (except for no slicing, which uses a global PF scheduler).

6.1 Spectrum Efficiency and Fairness

We first evaluate how RadioSaber can achieve both high spectrum efficiency and fairness between slices. We configure our experiment to use 20 slices, and randomly assign between 5 to 15 UEs to each slice. While we expect there to be hundreds of slices, and hundreds of UEs associated with each slice, only a few of them will be active (and in the geographical vicinity) of a given gNB.

We configure all slices to have the same weight. To evaluate total spectrum efficiency of RadioSaber, we instantiate each UE with a single backlogged flow. The enterprise scheduling policy is configured to follow MT scheduling for the first 10 slices (with $\beta = 0$, $\epsilon = 1$, and $\psi = 0$), and PF scheduling for the last 10 slices (with $\beta = 0$, $\epsilon = 1$, and $\psi = 1$).

We compare RadioSaber with two baselines in this experiment: (i) NVS, with a channel-agnostic inter-slice scheduler described in §2, and the same (channel-aware) enterprise scheduling policy for each slice as described above; (ii) No-Slicing, which uses a global PF scheduler to schedule UEs without any notion of slicing.

Fig. 7(a) shows the number of resource blocks allocated to each slice over intervals of 1 second. Both RadioSaber and NVS allocate same shares of radio resources to slices since each slice is configured to have the same weight. In contrast, No-Slicing cannot guarantee the same level of fairness across slices. With No-Slicing, the allocated RBs for a slice is roughly proportional to the number of UEs in the slice.

Fig. 7(b) shows the aggregate average throughput achieved by each slice. We see that, even though NVS and RadioSaber allocate the same number of RBs to each slice, RadioSaber achieves better throughput than NVS for each slice by enabling a better (channel-aware) assignment of RBs to slices. As expected, for both RadioSaber and NVS, the first 10 slices (that use MT schedulers) achieve higher average throughput than the last 10.

Fig. 7(c) shows the overall throughput computed as the total number of bytes transmitted across all UEs and over all TTIs and divided by the total number of TTIs in the experiment run. RadioSaber achieves 51% higher throughput than

Slices	Scheduler ($\alpha, \beta, \epsilon, \psi$)	Traffic generation	Metrics
1-5	PF(0,0,1,1)	a backlogged flow	average throughput
6-10	PF(1,0,1,1)	heavy-tail distributed flows	FCT(Flow Completion Time)
11-15	PF(1,0,1,1)	heavy-tail distributed flows(25% prioritized)	FCT of prioritized flows
16-20	M-LWDF (1,1,1,1)	a 1280kbps real-time video flow	average queueing delay

Table 2: Scheduling configuration, workloads per user, and metrics to evaluate in different slices.

NVS and 11% higher throughput than No-Slicing. The higher throughput compared to NVS comes from channel-aware inter-slice scheduling with RadioSaber. The higher throughput compared with No-Slicing stems from the first 10 slices applying MT enterprise schedulers as compared to all UEs being scheduled as per the PF policy with No-Slicing (that does not have any notion of customizable per-slice scheduling).

We also evaluated a setting where slices differ in their weights. Both NVS and RadioSaber adhered to the specified per-slice weights when allocating RBs, while No-Slicing could not, and RadioSaber achieved better throughput than NVS. We present these results in Appendix §A.1.

If No-Slicing used MT instead of PF, it would have necessarily achieved a better overall throughput than RadioSaber, but would have failed to provide weighted fairness across users. In contrast, RadioSaber strives to maximize throughput while meeting this basic objective of isolation and fairness across RAN slices.

6.2 Diverse Enterprise Schedulers

We now evaluate how RadioSaber supports diverse and customizable enterprise schedulers, and maintains isolation between slices. We compare against the same baselines: NVS and No-Slicing. We consider a total of 20 slices, and randomly assign between 5-15 users to each slice. We group the slices into 4 categories, with 5 slices in each category. Table 2 summarizes the configuration for slices in each category, including the enterprise scheduler, workloads per user, and

Slices	Metrics	RadioSaber	NVS	No-Slicing
1-5	throughput (Mbps)	13.02	8.45	17.41
6-10	average FCT(s)	2.606	5.708	5.714
11-15	average FCT(s)	0.489	1.686	2.988
16-20	average queuing delay(s)	0.061	1.493	0.696

Table 3: Experiment results w.r.t different metrics in all slices of RadioSaber and baselines.

metrics: (i) Slices 1-5 use PF based enterprise scheduling policy. Every user in a slice instantiates a backlogged flow, and we measure the average aggregate throughput as the metric. (ii) Slices 6-10 also use PF based enterprise scheduling policy. Each slice in this category generates flows with Poisson inter-arrival time, arriving at an average rate of 12Mbps, following a heavy-tailed Internet flow distribution [28]. It randomly and evenly assign these flows to its UEs. We measure the FCT(Flow Completion Time) of flows as the evaluation metric. (iii) Slices 11-15 use the same workload generator as the previous category, but assigns a higher priority to 25% of the flows (that are randomly selected). We measure the FCT of prioritized flows as the key metric. (iv) For slices 16-20, each user streams a real-time video flow with 1280kbps average bitrate. Each slice applies the M-LWDF policy for enterprise scheduling, to ensure low packet delays for the real-time streaming. We compute per-packet queuing delays as the key evaluation metric. We configure the weights of slices 16-20 to be $2\times$ higher than the weights of the other slices.

Table 3 summarizes the results (aggregating the slice-specific metrics across all slices in each category). We also present the CDF of different metrics, to highlight the performance differences at different percentiles in the Appendix §A.2.

We find that RadioSaber consistently outperforms NVS across all slice-specific metrics, with $1.5\times$ higher throughput for slices 1-5, $2-4\times$ lower FCT for slices 6-15 and $24\times$ lower packet delays for slices 16-20. This shows that the throughput wins of RadioSaber directly translate to other relevant metrics such as flow completion time and packet delays. No-Slicing achieves higher throughput than RadioSaber for slices 1-5 which have backlogged flows, but fares significantly worse in the performance metrics for other slices (with $2-7\times$ higher FCT in slices 6-15 and $10\times$ higher packet delays in slices 16-20). This is because: (i) No-Slicing cannot provide isolation across slices and correctly enforce weighted fairness. Instead, it ends up allocating a larger share of RBs to the first category of slices (1-5) which have more number of active users at any given time (as they are all backlogged). (ii) No-Slicing’s PF policy is not compliant with the requirements of other slices (i.e. prioritization for slices 11-15 and low packet delays for slices 16-20)

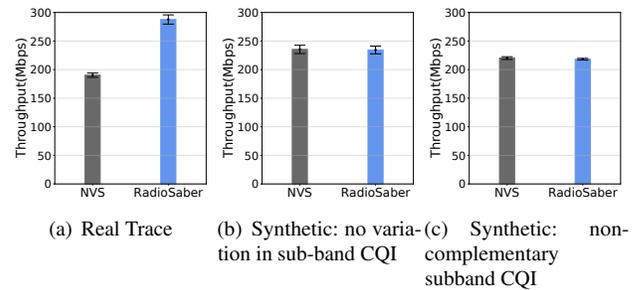

Figure 8: Experiments with different types of CQI traces

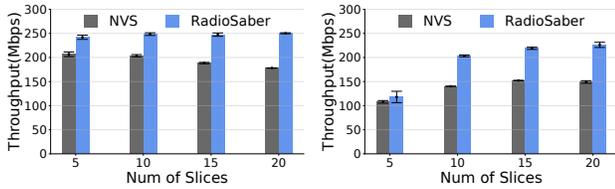

6.3 What Makes RadioSaber Win Over NVS?

We now validate the intuition discussed in §3, that the throughput gain from channel-aware inter-slice scheduling originates from the complementary channel quality distribution between slices. We use the same setting as that in §6.1, except that we generate synthetic CQI reports using the default channel propagation module in our RAN simulator that models losses due to multipath [19], path loss, penetration and shadowing [34]. Fig. 8(a) shows experiment results from real traces for comparison (these results are the same as those presented in §6.1).

In the first experiment, we exclude the multipath loss to make the channel quality same across all RBs (although the channel quality still varies across different UEs). Channel quality variations over time happen at granularity of 40ms (the CQI reporting interval), which translates to 160 TTIs. Fig. 8(b) shows that NVS and RadioSaber both achieve the same throughput. If we consider a 2D grid spanning 20 TTIs (number of slices in our setup), the channel quality for a UE neither varies in the frequency domain, nor in the time domain – so, as long as all slices are assigned RBs as per their quotas, it does not matter which RBs they get assigned.

In the second experiment, we synthetically make the sub-band channel distribution non-complementary. For this, we exclude the multipath loss, and manually decrease SNR of the first 50MHz channel by 10dB and increase SNR of the lower 50MHz channel by 10dB. What this implies is that all UEs have equally high channel quality for the first half of the RBs in the frequency domain, and equally low channel quality for the second half. Fig. 8(c) shows that NVS and RadioSaber again achieve similar throughput with this “non-complementary” CQI distribution. This is because, with both NVS and RadioSaber, each RB will produce the same data rate (that is either high or low), no matter which slice/UE it gets assigned to.

These results highlight that RadioSaber wins over NVS when (i) the CQIs differ across UEs in the frequency domain, and (ii) the CQIs for a RB across different UEs complement one another (i.e. if some UEs have low CQIs for a given RB, there are other UEs having high CQIs for it). We found this to be the case for the LTE cellular traces used in our experiments, and expect these trends to be stronger for 5G with larger bandwidths.

(a) backlogged flows (b) heavy-tail distributed flows

Figure 9: Varying the number of slices (5-15 UEs per slice).

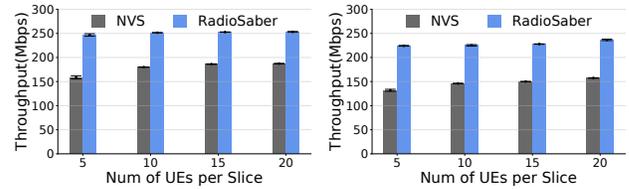

6.4 Varying Number of Slices and UEs per Slice

We next evaluate the robustness RadioSaber’s throughput wins over NVS, as we vary the number of slices and the number of users in each slice. For simplicity of analyzing the results, we configure each slice to apply the PF enterprise scheduling policy. We experiment with two types of workloads: (i) each user maintains a backlogged flow; (ii) the heavy-tail distribution of flows across UEs (as described in §6.2), and an average load of 24Mbps per slice.

Varying number of slices. We increase the number of slices from 5 to 20 and randomly assign between 5-15 users in each slice. In Fig. 9(a), we find that with backlogged flows, the aggregate throughput remains almost unchanged in RadioSaber as we increase the number of slices, but the aggregate throughput keeps dropping in NVS. It shows that the spectrum efficiency of RadioSaber remains unaffected and scales well with the number of slices. RadioSaber achieves 17.2%-40.5% higher throughput than NVS.

We find some interesting trends in Fig. 9(b), with non-backlogged flows. RadioSaber is able to make better use of the spectrum as the number of slices increase, which increases the number of active users (with diverse and complementary subband CQI distributions) that can be scheduled per TTI. NVS does not experience a similar trend, and in fact, has a significantly lower aggregate throughput compared to the backlogged flows scenario in Fig. 9(a). This is because NVS allocates all RBs in a TTI to the same slice, and since there are fewer active users in a slice in this scenario, the multi-user diversity gain reduces, which reduces the throughput achieved with the PF scheduler. RadioSaber achieves 37.3%-50% higher throughput than NVS in this context for 10-20 slices. Note that when there are 5 slices, the throughput is limited by the total incoming network traffic.

Varying number of UEs. In the second experiment, we fix the number of slices to 20, and increase the number of UEs per slice. In Fig. 10(a), the aggregate throughput of NVS increases a little when the number of users per slice increases. This is reasonable since more users bring more diverse subband channel quality distributions for the PF enterprise scheduler in NVS to allocate RBs smartly. However, RadioSaber still outperforms NVS by 35.2%-56.8%. From Fig. 10(b), RadioSaber outperforms NVS by 49.7%-72.2% when the flows are heavy-tail distributed.

(a) backlogged flows (b) heavy-tail distributed flows

Figure 10: Varying the number of UEs per slice for 20 slices.

6.5 Non-greedy Enterprise Schedulers

Our evaluation so far only considered greedy enterprise schedulers. Indeed, most proposed (and potentially deployed) radio resource schedulers employ a greedy heuristic to achieve low runtime overheads [4]. We now compare how RadioSaber (using a greedy enterprise scheduler for PF) compares against NVS using a non-greedy heuristic for PF [17]. We briefly explain the non-greedy heuristic before presenting our results.

A UE can only use a single MCS (Modulation and Coding Scheme) across all RBs that are allocated to it. The typical practice is to first assign RBs to users, and then compute the MCS based on effective SNR across these RBs. The final data-rate so achieved is less than the sum of the data-rates achieved if one could use the optimal MCS value for each RB (our experimental results take this effect into account). Given this effect, GPF [17] uses a non-greedy heuristic to co-optimize the MCS assignment and the RB allocation – it samples 300 plausible mappings between each user and a corresponding MCS value (assuming that all RBs are available for a given user), and computes the best RB allocation for each of these MCS mappings. It then selects the MCS mapping and RB allocation that achieves the highest PF metric.

We evaluate how NVS using the above non-greedy PF scheduler for each slice compares against NVS and RadioSaber using greedy PF enterprise schedulers. We fix the number of slices to 20 and vary the number of UEs in each slice. Fig. 11 reports the overall throughput across the three schemes. We find that NVS with non-greedy PF achieves 13%-19% higher aggregate throughput than NVS with greedy PF. This better spectrum efficiency results from the tactical assignment of RBGs and MCS to users. However, the aggregate throughput of NVS (non-greedy PF) is still 14%-18% lower than RadioSaber since NVS is channel-unaware.

6.6 Is There a Better Inter-Slice Scheduler?

We now evaluate two questions:

(i) What is the impact of assigning RBGs in the order of decreasing channel quality? For this, we modify RadioSaber’s inter-slice scheduler to greedily assign RBGs to the slices with maximum channel quality in a sequential order (from top to bottom). We term this strategy as "Sequential". With this approach, the inter-slice scheduler can query enterprise schedulers to determine the channel quality when it

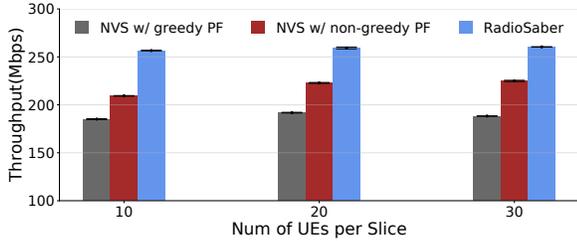

Figure 11: Comparing RadioSaber (using a greedy PF scheduler) with NVS (using a non-greedy PF scheduler). We fix number of slices to 20, and vary the number of UEs per slice.

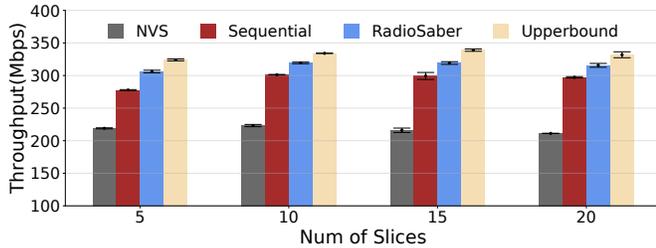

Figure 12: Comparing RadioSaber with a simple greedy inter-slice scheduler, and with a contrived upperbound. We vary the number of slices, with 5-15 random users in each slice, and use MT scheduling policy in each slice.

assigns RBGs, which avoids the need for recomputing channel quality after each allocation (as in the original inter-slice scheduling algorithm), resulting in a lower time complexity of $O(|\mathcal{R}\mathcal{B}\mathcal{G}||S|T)$.

(ii) Could we have achieved a better allocation? For this we compare RadioSaber with an impractical scheme that gives us an upper-bound on the spectrum efficiency that any inter-slice scheduler can achieve. In this scheme, we greedily allocate the RBG with the best channel quality to each slice until the slice’s quota is exhausted. However, in doing so we allow a given RBG to be repeatedly allocated to multiple slices. As a result, each slice gets its best set of RBGs, independent of the allocation for other slices. Note that this upperbound still enforces fairness between slices, and allows customizable enterprise scheduling within each slice.

To make it easier to analyze the inter-slice schedulers we configure the enterprise scheduler in each slice to use the MT policy. We evaluate the overall throughput as we vary the number of slices, with 5-15 users in each slice. Fig. 12 shows that RadioSaber performs only 4%-6% worse than Upperbound and 6%-10% better than Sequential. We see similar trends across other settings (e.g. using PF policy in each slice, varying the number of users, etc).

The key takeaways are: (a) RadioSaber’s inter-slice scheduling policy is close to optimal, and (b) Even the simple channel-aware greedy inter-slice scheduler achieves 25%-36% better throughput than channel-agnostic NVS, and is a good option if lower time complexity is required, at a cost of some throughput penalty compared to our current algorithm.

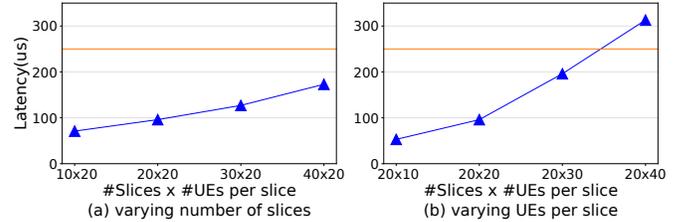

Figure 13: RadioSaber’s scheduling latency

6.7 Scheduling Latency and Overhead

To evaluate RadioSaber’s scheduling latency and runtime overhead, we implement its MAC scheduling logic on a system using a single Intel Xeon core. For simplicity of analysis, we configure each slice to apply the PF scheduling policy with backlogged users. Fig. 13(a) shows how the scheduling latency increases linearly with the number of slices when the number of UEs per slice is fixed to 20. Similarly, Fig. 13(b) shows how the scheduling latency increases linearly with the number of UEs per slice when the number of slices is fixed to 20. In both cases, the scheduling system can support as many as 600 users and make the scheduling decision within the stringent TTI constraint (250us).

7 Limitations and Future Work

- So far, we have only considered scheduling for downlink radio resources and not for uplink. The uplink channel applies SC-FDMA [5], which is similar to OFDMA and allows radio resources allocation in both time and frequency domain. This indicates that RadioSaber can be extended to uplink scheduling. However, it requires more complicated control information exchange between UEs and the base station. We leave a detailed exploration of this to future work.
- We only consider scheduling radio resources in a channel-aware manner for a single gNB. An interesting future direction is to extend our work in the context of multiple gNBs with small cells. The problem expands to a 3D allocation of frequency, time, and space resources in a channel aware manner.

Acknowledgement

We would like to thank our shepherd, Ganesh Ananthanarayanan, and the anonymous NSDI reviewers for their insightful comments and feedback. We’re grateful to Ammar Tahir, Emerson Sie for their feedback in the camera-ready version. We would also like to thank Yaxiong Xie for sharing the LTE SNR traces with us. This work was supported by Intel, Facebook, AG NIFA under grant 2021-67021-34418, and UIUC’s Smart Transport Infrastructure Initiative.

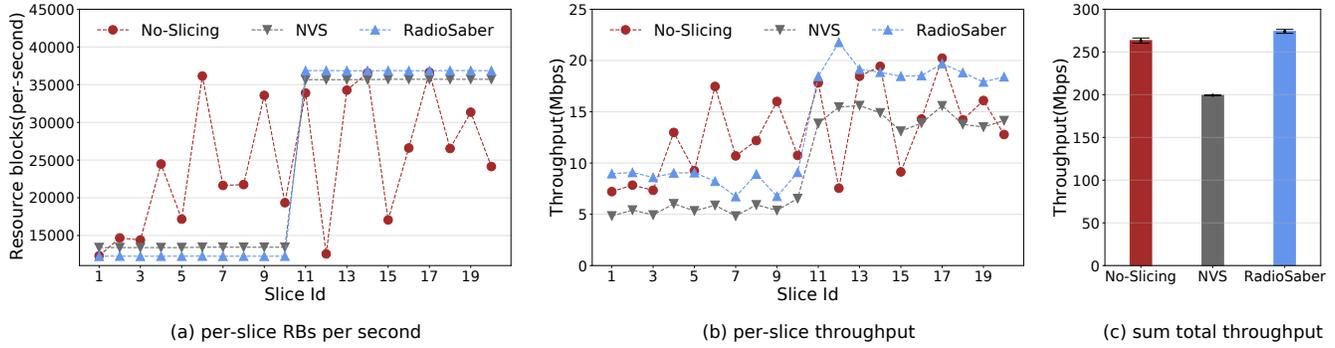

Figure 14: (a) the average allocated RBs per second to slices; (b) the average aggregate throughput of slices; (c) the sum total throughput of three systems

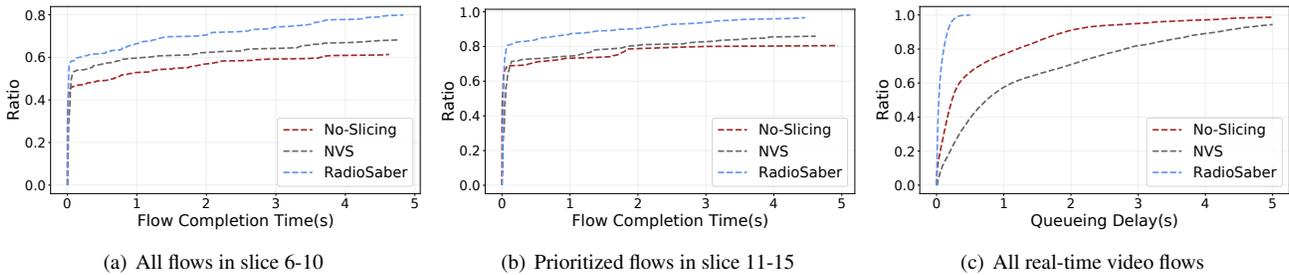

Figure 15: CDFs of (a) completion time of flows in slices 6-10, (b) completion time for the higher prioritized flows in slices 11-15, and (c) queuing delay of packets in slices 16-20. We cut the graphs at 5s to better highlight the trends.

A Supplemental Evaluation

A.1 Slices with Different Weights

§6.1 evaluated the scenario where every slice has the same weight. Here we do the same experiment but slightly modify SLAs of slices: slices with PF schedulers have 3X higher weights than slices with MT schedulers. Fig. 14 shows the experiment results. From Fig. 14(a) and Fig. 14(b), it's obvious that the last 10 slices get 3X more RBs than the first 10 slices, and approximately 3X higher throughput. Meanwhile, it's impossible for No-Slicing to meet the SLAs of slices since it doesn't support network slicing between groups of users at all.

A.2 CDF Graphs of FCT and Queueing Delay

We provide more evaluation results in §6.2. Fig. 15(a) shows the CDF of flow completion time in the slice 6-10, and Fig. 15(b) shows the CDF of flow completion time for the higher priority flows in slices 11-15, and Fig. 15(c) shows the CDF of queueing delay for slices 16-20. We cut the graphs at 5s to better highlight the trends. For flows in slices 6-15, the FCT in No-Slicing is the longest since No-Slicing cannot enforce fairness for slices in which flows arrive intermittently. NVS suffers from the longest queueing delay in slices 16-20 due to low spectrum efficiency.

RF-CHORD: Towards Deployable RFID Localization System for Logistics Network

Abstract – RFID localization is considered the key enabler of automating the process of inventory tracking and management for the high-performance logistic network. A practical and deployable RFID localization system needs to meet *reliability*, *throughput*, and *range* requirements. This paper presents RF-CHORD, the first RFID localization system that simultaneously meets all three requirements. RF-CHORD features a multisine-constructed wideband design that can process RF signals with a 200 MHz bandwidth in real-time to facilitate one-shot localization at scale. In addition, multiple SINR enhancement techniques are designed for range extension. On top of that, a kernel-layer near-field localization framework and a multipath-suppression algorithm are proposed to reduce the 99th long-tail errors. Our empirical results show that RF-CHORD can localize up to 180 tags 6 m away from a reader within 1 second and with 99th long-tail error of 0.786 m, achieving a 0% miss reading rate and ~0.01% cross-reading rate in the warehouse and fresh food delivery store deployment.

1 Introduction

Today’s major e-commerce companies like Alibaba and Amazon need to handle a package volume that is tens of billions per year [1], calling for increasingly high-performance automated logistics operations in their network. Considering a typical warehouse in which tens or even hundreds of packages pass through each checkpoint – the packages need to be verified, recorded, sorted, and tracked when checking in/out. In widely adopted barcode-based logistic networks, the worker spends 1~3 seconds on scanning one package. Although this operation can be automated by robots [2], the line-of-sight and field of view requirements of vision-based approaches limits work range and scalability fundamentally. RFID technology, since its invention, has been carrying the vision of replacing inefficient labor and automating inventory management with zero power, near-zero cost, and high throughput.

Towards a highly practical and deployable RFID empowered automated logistic network shown in Fig. 1, there are three key considerations: *i) Reliability*. The classic ROI (range of interest) reading task requires the reader to scan all the RFID tags within the ROI (*i.e.*, near-zero miss-reading rate)

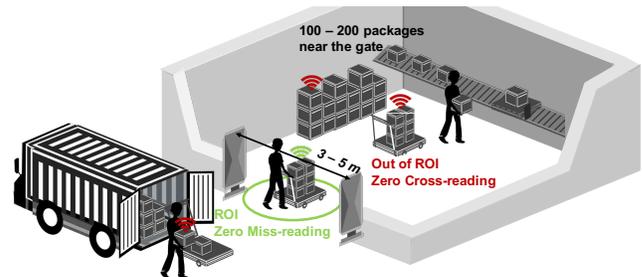

Figure 1: In a typical logistic scenario, the packages are discharged from the truck, scanned at an inventory gate and sorted for warehouse check in. The RFID-based inventory gate should meet *reliability*, *throughput*, and *range* requirements at the same time.

while excluding any tag out of the ROI (*i.e.*, near-zero cross-reading rate); *ii) Throughput*. The packages come to the checkpoint in a burst (*i.e.*, 100~200 per pallet)¹ while all the logistic operations, including verification and recording need to be finished within 2~3 seconds before check-in/out; *iii) Range*. A single reader should cover tags within 3~5 m, which is the typical width of the check-in/out aisle.

Unfortunately, today’s read-or-not inventory systems, both industrial products and research prototypes, all have limitations in meeting these three requirements simultaneously. Industry-grade RFID systems (*e.g.*, Impinj) suffer from miss-reading and cross-reading when deployed in the logistic warehouses. RFGO [3] reports 99.8% recall with 10 carrier-level synchronized antennas and neural network based classifier but limits its operating range to sub-meter. NFC+ [4] achieves a sharp inventory boundary with magnetic resonance engineering that meets the reliability (*i.e.*, miss-reading rate of 0.03% and cross-reading rate of 0%) and range (~3 m) requirements but cannot achieve the desired throughput. No current inventory-based solutions can support automatic package management in a practical logistics network.

RFID localization technique offers an alternative approach toward the same goal by filtering out the reading outside the ROI. Compared with the inventory-based system, the tag location brings a new dimension of information, which can realize a more flexible and accurate ROI reading. The reliability of

*Bo Liang and Purui Wang are the co-primary student authors. Purui Wang was affiliated to Peking University and Alibaba Group during which he contributed to this work.

¹Even though one trailer can carry up to 50 packages, the reader should be able to cover all the tags (100~200 tags) near the gate (including passed trailer and undischarged packages) to ensure to read all the passing packages.

ROI reading depends on localization accuracy. However, the legitimate narrow frequency band (*i.e.*, 26 MHz ISM band within 902~928 MHz) of RFID fundamentally limits its capacity of combating multipath and ambiguity [5]. To improve the localization accuracy, approaches like fingerprinting [6] and synthetic aperture radar (SAR) based hologram [7, 8] have been proposed. However, they suffer from prolonged latency due to lots of tag inventory, especially at scale. Cross-frequency based approaches utilize higher frequency band to overcome the bandwidth limitation (*e.g.*, 2.4 GHz [9, 10], millimeter wave [11], UWB [12, 13]) but introduce extra tag manufacturing cost due to wider frequency response and higher power attenuation. More recently, sniffer-based RFID architecture [14, 15] has been proposed to leverage the advantage of wideband (*e.g.*, 100~200 MHz) near 915 MHz to boost location accuracy without violating FCC regulation. Despite the potential, these systems either suffer from latency issues due to the lack of hardware support on multi-band parallel information capture [14], or report limited sub-meter range [15].

This paper introduces the design and implementation of RF-CHORD, an active sniffer-based wideband RFID localization system that tackles the above challenges. RF-CHORD exploits wideband signal and a hologram-based localization algorithm to realize *high reliability*. It employs lossless data stream compression and a GPU-based decoder to guarantee real-time decoding and channel estimation for *high throughput*. It utilizes a customized wideband waveform, full packet matching integration, fine-grained clock offset mitigation, and channel diversity decoding to improve SINR for *long range*.

RF-CHORD ensures *high reliability* (*i.e.*, near zero miss reading and cross reading) by high-accuracy localization. Our study (§5.1) shows that the multipath profile causes long-tail localization errors. Therefore, we design the fine-grained distance resolution hardware and multipath-suppression algorithm to handle these long-tail errors. Considering that the distance resolution is inversely proportional to bandwidth (*i.e.*, $\frac{c}{2B}$), the distance resolution of a conventional UHF RFID reader, which works on a 26 MHz wide ISM band, is only 5.78 m. RF-CHORD introduces an extra active sniffer-based reader to help UHF RFID reader realize 200 MHz parallel wideband localization (§3.2). However, the distance resolution of 200 MHz (0.75 m) is still not enough in all situations. RF-CHORD exploits a kernel-layer-based near-field localization algorithm framework to handle corner cases. The kernel function characterizes the location estimation from a single channel, and layer functions coherently combine multiple channels into a final location estimation. This framework supports choosing different kernel and layer functions suitable for various deployment scenarios to achieve multipath suppression and ambiguity reduction (§5.3). For example, in RF-CHORD's deployment in the warehouse, the work range is fixed so it can be taken as prior information for direct path enhancement to effectively suppress the multipath effect (§5.4).

RF-CHORD ensures *high throughput* by one-shot channel

measurement and one-shot location estimation. The hardware supports concurrent phase and amplitude capture across multiple antennas and wide bandwidth. Therefore, RF-CHORD can obtain the necessary information (*i.e.*, wideband channel estimation across multiple antennas) for localization within only one shot measurement. It is challenging because: i) directly capturing the wideband signal from a large array will result in a huge amount of real-time data (~64 Gbps); ii) the commercial reader does not support real time synchronization (*i.e.*, synchronizing with our sniffer-based reader at each slot [18]). Utilizing the essence that the wideband backscattered signal is a combination of scattered narrowband signals, RF-CHORD distills 4 MHz valid bandwidth from 200 MHz bandwidth to reduce the data rate by 50x without information loss (§3.4). Meanwhile, we develop a GPU-based wideband decoder to ensure real time decoding and channel estimation. In other words, the sniffer-based reader has an independent decoder and does not depend on any specific commercial reader interface. It makes our design adaptive to any ISM band commercial reader, which primarily serves as a power activator and multiple access handler (§4). Finally, RF-CHORD supports one-shot localization with 8 antennas and 16 frequencies across 200 MHz in ~5 ms.

RF-CHORD ensures *long range* (up to 6 m) with multi-sine waveform sniffer and sophisticated wideband channel information estimation. To follow the FCC regulation, the strength of the sniffer excitation signal needs to be *smaller than -13.3 dBm* (see §A for the calculation), which is 50 dB weaker than that of commercial readers. RF-CHORD features the following designs for signal-to-interference-plus-noise ratio (SINR) enhancement without modifying the tag chip: i) It exploits a multisine waveform, which constructs a whole 200 MHz band by taking samples with multiple narrow bands, to significantly reduce the noise bandwidth (§4.1); ii) It handles the high dynamic range requirements introduced by self-interference through high-resolution digital channelization and a low crest factor waveform design (§4.2); iii) It further exploits the integration gain of full packet matching (§4.3) and performs accurate tag clock offset mitigation (§4.4) and decoding with channel diversity (§4.5).

We deploy RF-CHORD and our results show that RF-CHORD presents the first RFID (localization) system meeting all the requirements (*i.e.*, reliability, throughput, and range) in the logistic network (Tab. 1). The key results are:

- **Reliability.** We evaluate RF-CHORD's performance at 384 locations and collect over 20k tag responses in the lab environments. Its 99% localization error is 0.786 m. We deploy RF-CHORD in the dock door of a warehouse and the scanning gate of a fresh food delivery store. We find that it could read 100% of the tags passing the checkpoint (0% miss-reading rate). Its cross-reading rate is only 0.0025%~0.0154%, which is up to 12x improvement compared to state-of-the-art [3, 4].
- **Throughput.** RF-CHORD can localize up to 180 tags per second, which is very close to pure inventory devices [16] and

Solutions	Requirements	Throughput (> 100 tags/s)	Range (> 3 m)	Reliability (Near Zero Miss-reading & Cross-reading)	Commercial Tag
Barcode (widely deployed)		No (~1 tag per second)	No (~1 m)	High (depend on the human labor)	Yes
xSpan [16] (Inventory based)		Yes (~185 tags/s with 142 mode)	Yes (~10 m)	Low (~6% miss reading and ~2% cross reading)	Yes
RFgo [3]		No (TDMA-based)	No (sub-meter)	High (99.8% recall)	Yes
NFC+ [4]		No data reported	Yes (~3 m)	High (0% miss reading and ~0.03% cross reading)	No
PinIt [6]		No data reported	Yes (> 5 m)	Median (a few decimeters)	Yes
RF-IDraw [17]		No data reported	Yes (> 5 m)	Low (sub-meter)	Yes
Tagoram [7]		No (0.2 second for one tag)	No (~2 m)	Median (a few decimeters)	Yes
MobiTagbot [8]		No data reported	No (~1.5 m)	High (a few centimeters)	Yes
NLTL tags [9]		No (depend on switching)	No (~1 m)	High (a few millimeters)	No
mmwave RFID [11]		No data reported	No data reported	Median (a few decimeters)	No
RFind [14]		No (6.4 second for one tag)	Yes (> 5 m)	High (a few centimeters)	Yes
TurboTrack [15]		No data reported	No (sub-meter)	High (a few centimeters)	Yes
RF-CHORD (Our system)		Yes (180 tags/s)	Yes (6 m)	High (0% miss reading and ~0.01% cross reading)	Yes

Table 1: Comparing RF-CHORD with state-of-the-art wireless systems for logistic network requirements.

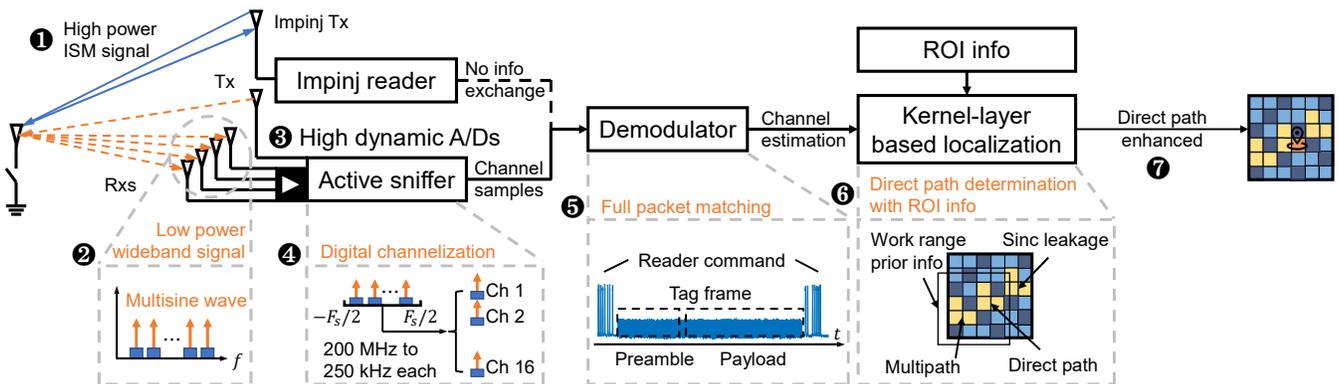

Figure 2: RF-CHORD system overview.

two to three orders of magnitude faster than state-of-the-art localization systems [7, 14].

- **Range.** RF-CHORD can localize tags 6 m away from the reader with transmit power below -15 dBm. There is no obvious throughput and reliability loss with distance increasing.

We open sourced the RF-CHORD’s hardware and software as well as the evaluation dataset in <https://soar.group/projects/rfid/rfchord>.

2 RF-CHORD’s System Overview

A high level operational flow of RF-CHORD is shown in Fig. 2. RF-CHORD embraces any ISM-band reader ① as the tag activator that is capable of charging, coordinating multiple access over EPC Gen II tags. Active sniffer reader observes tags by emitting a low power (-15 dBm) wideband multi-sine waveform to pick up tag responses over a wide frequency band. Specifically, we build the RF frontend and FPGA hardware ② as a scalable platform that can receive the tag response from 8 antennas and 16 frequencies of carriers simultaneously. Furthermore, despite the strict legal emission power limit, we still achieve a long range in sniffing the tag response in the wideband without exchanging any information (e.g., EPC ID) with the ISM-band reader. RF-CHORD achieve independent decoding and channel estimation by using dynamic range optimization ③, digital channelization ④ in hardware, and a real-time full packet matching ⑤ in soft-

ware. After one-shot tag inventory, RF-CHORD obtains adequate information from both frequency and spatial domains, which are important for robust localization in a multipath-rich environment. RF-CHORD also uses a kernel-layer-based near-field localization algorithm to suppress the multipath effect. This algorithm identifies the direct path with the time of flight profile and prior knowledge (region of interest or ROI information in our paper) ⑥. Then it enhances the direct path and estimates the location with a summation layer (a form of near-field AoA+ToF localization) ⑦.

3 One-shot Wideband with Multisine Wave

This section explains why we select multisine wave as the wideband signal and how RF-CHORD acquires fine-grained tag responses in one shot. We review the primer of the backscatter signal model and its fundamental narrowband constraint. Then we present our design of constructing a wideband backscatter signal with the multisine waveform on Tx and slicing it for real-time parallel processing on Rx.

3.1 Backscatter Signal Model Primer

The basic backscatter operation in RFID systems is shown in Fig. 3a. A device emits a high-power single-tone excitation signal $s(t)$ to power the tag and act as a carrier. This carrier will be modulated by the baseband signal $B_{tag}(t)$ of the tag.

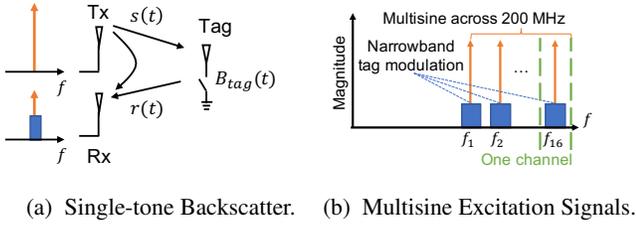

Figure 3: Model of Multisine Backscatter.

The resulting (mixed) backscattered signal is:

$$r(t) = s(t) \cdot B_{\text{tag}}(t)$$

Note that the bandwidth of $r(t)$ is the summation of that of $s(t)$ and $B_{\text{tag}}(t)$, and $B_{\text{tag}}(t)$ is typically a narrowband signal² for low power purpose according to the EPC Gen II standard. Therefore, the backscattered signal $r(t)$ will also be narrowband given that $s(t)$ is a single tone.

3.2 Backscattering with Wideband Multisine Wave

When applying a wideband signal $s(t)$, one can retrieve a wideband backscatter signal $r(t)$. Following this idea, RF-CHORD adopts a multisine signal as $s(t)$. The multisine signal is a combination of multiple single tones across wide band with the same amplitude $s(t) = \sum_i \sin(f_i t + \phi_i)$. The backscattered signal will be $r(t) = \sum_i B_{\text{tag}}(t) \cdot \sin(f_i t + \phi_i)$. RF-CHORD adopts 16 carriers with different frequencies across a 200 MHz band in the practical implementation. Fig. 3b shows the spectrum of multisine signal $s(t)$ with backscatter signal $r(t)$. Since the difference between each carrier frequency is much larger than the bandwidth of $B_{\text{tag}}(t)$, the received signal can be treated as multiple copies of $B_{\text{tag}}(t)$ modulated on different carrier f_i . Therefore, on Rx, $r(t)$ can be sliced to 16 individual narrowband channels without information loss, and then the channel information at each carrier frequency f_i can be extracted by using a well-explored RFID processing mechanism (e.g., mixing and demodulating) in parallel. In a nutshell, we sample the wideband with multiple narrowband signals, enabling RF-CHORD to construct the wideband channel information within one shot.

3.3 Why Multisine Wave

The multisine waveform has two advantages. First, the multisine waveform is adaptive to conventional narrowband decoding and channel estimation because the signal in each channel is still narrowband. Extracting these narrowband signals can achieve excellent data rate compression (§3.4). Second, the multisine waveform is amenable to noise and interference reduction because of the low noise bandwidth and low chances of being interfered with, resulting in SINR enhancement, which improves the work range (§4.1). Compared with the two alternative well-known wideband waveform choices, frequency hopping [14] and OFDM signal [15], the multisine waveform is more efficient because it avoids the time

²We take 250 kHz as the bandwidth $B_{\text{tag}}(t)$ for the whole paper according to the standard [18].

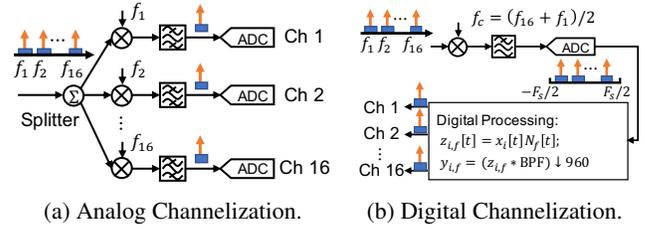

Figure 4: Two channelization approaches.

overhead in switching between carriers introduced by the former one, and uses the same bandwidth as the (tag) modulation bandwidth, which is 250 kHz out of the full 200MHz bandwidth used by the latter one. In fact, this wideband but narrow sample signal can introduce 29 dB gain on the SINR compared to the full wideband signal (see §4.1), which means around $5 \times$ range under the same transmit power. Furthermore, since the multisine wave captures all the backscatter signals in the time domain, the whole packet of tags can be fully utilized for integration gain to improve the SINR (see §4.4).

3.4 Digital Wideband Channelization

RF-CHORD utilizes channelization, which enables one-shot capturing of wideband signals across multiple antennas and reduces the amount of data to be processed during real-time operation. Channelization is a process of extracting effective narrowband signals from a received signal. When a wideband tag signal is received, the aggregated bandwidth of 8 antennas will be 1.6 GHz, resulting in a total of 64 Gbps data (16-bit IQ sample, $1.25 \times$ Nyquist). It is challenging to process such massive data in real time. However, recall that with a multisine excitation signal, the effective tag signal is only located around the carrier frequencies, as shown in Fig. 3b. Therefore, the effective bandwidth of the system should be $8 \times 16 \times 250 \text{ kHz} = 32 \text{ MHz}$, only 1/50 of the full 200 MHz bandwidth, so that channelization can compress the data validly without information loss.

There are two channelization schemes to extract these narrowband signals: analog channelization and digital channelization. As shown in Fig. 4a, the sniffer with analog channelization has multiple RF chains for the corresponding channels. Each RF chain uses one carrier frequency f_i as its local oscillator (LO) for down-conversion and a filter at the baseband to filter the signal from other channels out. Alternatively, digital channelization finishes all the aforementioned functions in the digital domain as shown in Fig. 4b.

RF-CHORD adopts digital channelization – the sniffer will generate and capture the whole multisine wave with one RF chain. On the Rx side, an ADC/DAC with a 245.76 MHz sampling rate captures all tag signals simultaneously. Further channel extraction can be achieved by digital down-conversion and digital filtering. Digital channelization offers two significant benefits over analog channelization: First, it has better scalability because it only needs one RF chain for each antenna, regardless of the number of channels (and sine

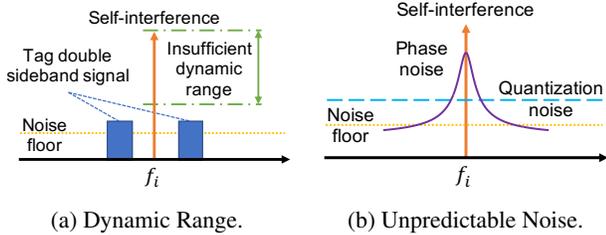

Figure 5: Two issues caused by self-interference.

tones) are required, while in analog channelization, each channel needs an exclusive RF chain with bulk components (*e.g.*, mixer, PLL, and VCO). Second, it is precisely synchronized among different tones in the multisine wave, while analog channelization needs extensive engineering efforts to synchronize among a large amount of ADCs/DACs and LOs. Nevertheless, analog channelization still has its own advantages, including the convenience of extending or switching bandwidth by changing the carrier frequency and the lower requirements of ADC bandwidth. RF-CHORD also embraces these advantages through the high-speed ADC and low crest factor multisine waveform, which will be introduced in §4.

4 SINR Improvement for Long Range

This section first presents how RF-CHORD improves SINR under long work range by reducing the external noise and canceling self-interference. It next explains how RF-CHORD exploits the full tag packet to incorporate the integration gain, which is based on the multiple channel decoder with clock offset mitigation.

4.1 External Noise Suppression

To follow the FCC regulation, the signal strength of each frequency component in the multisine is -15 dBm, which is 51 dB lower than the 36 dBm excitation signal in the ISM band (see details in §A). With the low signal strength limitation but the long range requirement, we need to reduce the external noise and interference as much as possible.

RF-CHORD adopts the tag signal with reduced bandwidth for lower chances of in-band interference and lower noise. The relationship between thermal noise P_{noise} and signal bandwidth B at room temperature can be expressed as $P_{\text{noise}} = -174 + 10\log_{10}(B)$ [19]. As described in §3.4, the digital channelization at the receiver separates a combined 200 MHz wideband signal into multiple 250 kHz narrowband signals. This means that the thermal noise can be reduced from -91 dBm to -120 dBm (29 dB gain). Furthermore, the reduced bandwidth also reduces the probability of being interfered with by other devices working in the same band.

4.2 Self-interference Canceling

Besides the external interference from other devices, the self-interference caused by the natural full-duplex operation of our active sniffer will also limit the SINR. RF-CHORD's multisine waveform and low power transmission reduce the complexity of self-interference cancellation. As shown in Fig. 5a, the

self-interference in one channel is just a single tone after channelization. A commercial tag uses double-sideband modulation with a subcarrier to differentiate the tag signal from the single-tone excitation signal. Therefore, RF-CHORD uses filters to cancel the self-interference caused by the single tone.

However, given the wideband signals are too weak (*i.e.*, -15 dBm), there remain two practical challenges. First, the dynamic range of the receiver may not be large enough to detect the tag signal. Second, any unpredictable noise, such as phase noise and circuit noise from Tx, will be transmitted along with the $s(t)$ and may bury the wideband signal. Then we'll go over how to deal with these issues.

Dynamic Range. Dynamic range is the ratio between the largest and smallest values that the received signal can assume. Specifically, the largest value is the self-interference, and the smallest signal is the targeted wideband tag signal. As shown in the Fig. 5a, even though the tag signal strength is higher than the noise floor and interference, it can still be buried if the dynamic range is not large enough. RF-CHORD meets the requirement of dynamic range by adopting the following strategies: First, it adopts a high-resolution ADC because the dynamic range of the receiver will be bottlenecked by the dynamic range of the ADC. The theoretical dynamic range of the receiver is $6.02N + 1.76$ dB [20], where N is the resolution of the ADC. Therefore, a fundamental way to solve the issue is to increase the resolution of the ADC. RF-CHORD adopts 16-bit ADC, which has the largest resolution in 2022 when satisfying the 200 MHz bandwidth requirement. Secondly, it adopts a carefully designed low crest factor multisine wave on the transmission side to relax the dynamic range requirement of the Rx. The intuition behind this is that since the dynamic range requirement on the ADC is more related to the peak amplitude of the self-interference signal instead of the average signal power, it can be relaxed by using a lower peak signal while remaining the average power. The crest factor is the peak amplitude divided by the RMS value of the waveform, and for a multisine signal, it has been well studied that the crest factor can be reduced by tuning the phases ϕ_i in the multisine signal. Following the methods mentioned in [21], the crest factor of the multisine waveform adopted by RF-CHORD can be reduced from 4 to 1.24 (or peak-to-average power ratio from 12 dB to 1.87 dB).

Unpredictable Noise. The unpredictable noise is caused by the response of self-interference in the circuit. As illustrated in Fig. 5b, the noise floor may be dominated by the phase noise, DAC quantization noise, *etc.* along with the self-interference. Fortunately, RF-CHORD does not require a dedicated cancellation circuit like [22] because the power of RF-CHORD's self-interference is much lower than that of a commercial RFID reader. Moreover, RF-CHORD utilizes Analog Devices ADRV9009 transceiver of 16-bit ADC [23] and HMC7044 VCXO-based clock tree [24], ensuring an optimal quantization and clock phase noise below the noise floor. Therefore,

the RF frontend of RF-CHORD’s receiver is not saturated, and the noise will only go through the air instead of the feedback path of the receiver. The noise experienced by RF-CHORD is not dominated by unpredictable noise.

4.3 Full Packet Matching

RF-CHORD estimates each channel in parallel and then combines them into a wideband channel estimation. The standard channel estimation techniques for one channel can be expressed as follows:

$$h_i = \sum_t r(t) \hat{I}^*(t)$$

where $r(t)$ is received tag response and $\hat{I}(t)$ is a template. In most RFID systems, only the pilot signal part (RN16) is used for clock and phase estimation, and the main part of the tag signal (EPC ID) is left unused. RF-CHORD utilizes the full packet signal, including RN16 and EPC ID. The length of the signal will be extended from 0.31 ms to 2.31 ms when assuming the backscatter link frequency (BLE) of the tag is 250 kHz and the EPC ID length is 96 bits [25]. By doing the full packet matching, RF-CHORD can achieve $10\log_{10}\frac{2.31}{0.31} = 8.7$ dB integration gain.

We need to generate a noiseless template of the full packet for full packet channel estimation. However, unlike the predefined pilot signal, the template of the packet changes depending on the tag’s EPC ID. Collecting EPC ID and timestamp from a commercial reader device in real-time is unsupported due to the interface limitation: i) the available interface from a commercial reader is usually done by using asynchronous communication, which hinders real-time processing; ii) the timing information is usually not reported by commercial readers. Therefore, RF-CHORD needs to decode the wideband signal into EPC ID independently.

4.4 Clock Offset Mitigation

Accurate decoding needs to mitigate the clock offset of the RFID tag signal. Specifically, the protocol tolerates up to $\pm 10\%$ frequency offset and $\pm 2.5\%$ frequency fluctuation during backscattering (refer to Tab. 6.9 of [18]). For example, say we read a tag that is 2.5% faster than nominal BLF. For a typical randomized uplink packet of 128 bits with a perfect match at the start of the frame, the received signal will be ahead of the template by one bit at the 32nd bit, and the remaining 96 bits thereafter contribute useless fluctuations to channel estimation, as figured out in Fig. 6. RF-CHORD needs to analyze the clock and estimate the offset parameters for mitigation, which can be described by:

$$\tau(t) = \text{Square}((f_{\text{BLF}} - \alpha_0 - \alpha(t))(t - t_0))$$

Where t_0 is the actual start of frame (SOF), α_0 is the initial clock frequency offset (CFO) from prescribed BLF, and $\alpha(t)$ is the fluctuation of the clock. Next, we introduce RF-CHORD’s components which estimate these parameters.

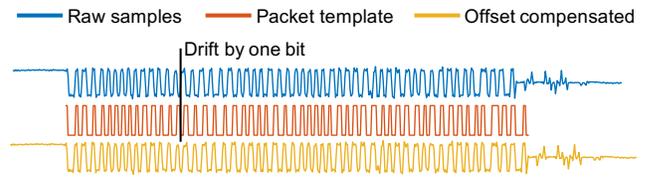

Figure 6: The waveforms of the tag signal with clock offset, the reference, and recovery signal from the offset.

Preamble Matching for t_0 and α_0 . RF-CHORD first estimates the t_0 and α_0 by adopting a standard sliding window correlator with a known preamble $p(t)$. Specifically, we derive the initial estimation of \hat{t}_0 and $\hat{\alpha}_0$ by this correlation calculation, where the $x(t)$ is the received samples, $p_\alpha(t)$ is the reference template tuned to a clock frequency of $f_{\text{BLF}} - \alpha_0$:

$$\{\hat{t}_0, \hat{\alpha}_0\} = \underset{t_0, \alpha_0}{\operatorname{argmax}} \left| \int_0^{T_p} p_{\alpha_0}^*(t) x(t + t_0) dt \right|$$

PLL to Track $\alpha(t)$ Variation. After eliminating α_0 , the clock still has residual offset $\alpha(t)$, which comes from the tag clock fluctuation during the communication and may be significant in the long packet. Because the Miller code of RFID [18] is a self-clocked and modulated bandpass signal, RF-CHORD can extract the subcarrier of the line code to track the clock frequency offset accurately. RF-CHORD adopts a feedback-based digital Costas PLL [26] to track the clock continuously.

After compensating estimated clock $\tau(t)$, the clock offset is mitigated (the last waveform shown in Fig. 6). We can see that the signal is well synchronized with the template.

4.5 Decoding with Channel Diversity

After clock offset mitigation, we can decode the full packet, extract the correct template $\hat{I}(t)$, and assemble the decoder. Because the tag baseband signals on all channels are the same, RF-CHORD can apply nulling and beamforming algorithms to utilize the diversity across frequencies and antennas to make a joint decoder. RF-CHORD combines the signals from all channels into one *steered* single-channel signal – it first performs an adaptive maximum signal-to-noise ratio (MSNR) beamforming over the array of each frequency to null the major jammer in the spatial domain and then performs maximum-ratio combining (MRC) beamforming across the frequency domain to improve the SINR further. With this cleaned steered single channel, RF-CHORD exploits a Viterbi decoder to decode the EPC ID. It then applies the EPC ID to make accurate channel estimations on all the channels. A series of efforts introduced in this section, including suppressing external noise, canceling self-interference, matching full packet, mitigating clock offset, and decoding with diverse channels, guarantees RF-CHORD to extract wideband channel estimations at a long distance even with the ultra-low power emission signal.

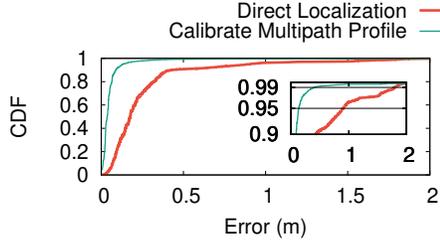

Figure 7: Eliminating the multipath effect reduces the 99th long-tail error.

5 Localization with Kernel-Layer Framework

In this section, we first conduct empirical experiments which show: i) multipath is the primary factor that confines the long-tail performance of the RFID localization system once the tag is successfully inventoried; ii) 200 MHz bandwidth is not sufficient to eliminate all the long-tail errors caused by multipath. To address these problems, we propose a kernel-layer framework for localizing RFID tags in the near field. It can suppress long tail errors from multipath by enhancing the direct path and incorporating prior knowledge from logistics.

5.1 Long-tail Errors Source Demystification

We conduct a validation experiment to confirm that multipath is the primary source of long-tail localization errors. In this experiment, we put five tags at a distance of 4 m from the reader. We use 16 carriers evenly spaced across 200 MHz bandwidth, 8 antennas, and a hologram-based localization algorithm (see details in §5.2). There is a metallic heater 1.5 m from the tag as the multipath source. Fig. 7 shows that the 99th localization error (red line) is 1.798 m, too large to ensure reliable usage in industry settings. The theoretical analysis explains this observation – the 200 MHz bandwidth is only able to differentiate paths that have a propagation distance difference larger than $c/(2B) \approx (3 \times 10^8 \text{ m/s})/(2 \times 200 \text{ MHz}) = 0.75 \text{ m}$. Once the propagation distance of two paths is smaller than 0.75 m, which is common for many indoor deployments, 200 MHz is insufficient for differentiating one from the other.

Then we evaluate the performance without the multipath effect to check our results double. We keep the experiment setup, conduct RF measurement of a reference tag close to target tags and extract its phase offset from the groundtruth. Considering that the multipath profiles of nearby tags are similar, we subtract each tag’s channel estimation with the offset from the reference tag. The 99th localization error of the same set of tags decreases to 0.400 m (green line in Fig. 7). It proves that multipath is the primary factor determining the long-tail performance of the RFID localization system, even with 200 MHz bandwidth.

5.2 Near-field Localization with Hologram Algorithm

Like most recent RFID localization systems, RF-CHORD locates a tag under the *near-field* condition, which differs from locating a distant target. Considering the Fraunhofer distance [27], a target is at near-field when its distance d from the antenna array meets:

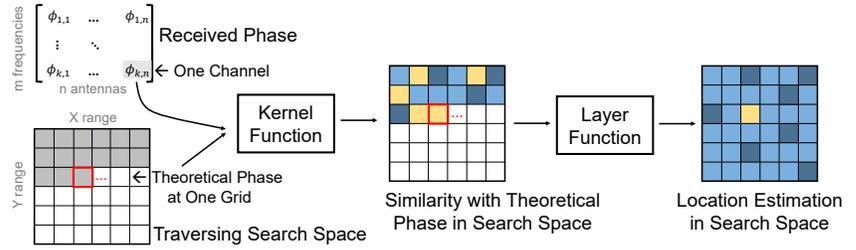

Figure 8: Kernel-Layer Framework.

$$d < \frac{2D^2}{\lambda}$$

where D is the aperture of the antenna array, and λ is the signal’s wavelength. The wavelength of the 915 MHz signal is around 30 cm. When using an antenna array or SAR, the aperture can easily span to 1 m for adequate spatial resolution. $(2D^2)/(\lambda) = (2 \times 1 \text{ m}^2)/(0.3 \text{ m}) = 6.7 \text{ m}$ and $d < 6.7 \text{ m}$ under most circumstances. Therefore, the response from a tag does not form a plane wave when reaching different elements in the antenna array.

We propose to develop our localization algorithm on top of hologram-based localization framework, which essentially identifies the most likely location as the location estimation, independent of plane wave incidence conditions. In the basic hologram algorithm, the theoretical phase $\theta(g(i,j), A_k, f_l)$ of a tag at location $g(i,j)$ received by an antenna A_k at frequency f_l can be written as:

$$\theta(g(i,j), k, l) = \frac{2\pi f_l}{c} (d_{Tx-Tag} + d_{Tag-Rx}) \pmod{2\pi}$$

where d_{Tx-Tag} and d_{Tag-Rx} are the distance between the tag and the transmitter and receiver, respectively. For location $g(i,j)$, its likelihood $P(g(i,j))$ of being the tag’s true location can be measured by the similarity between empirically received phase $\phi_{k,l}$ from l th carrier at k th antenna and the theoretically modeled phase $\theta(g(i,j), k, l)$. The hologram algorithm makes the similarity comparison across multiple antennas and frequencies. $P(g(i,j))$ can be written using the following equation:

$$P(g(i,j)) = \left| \sum_{l=1}^L \sum_{k=1}^K e^{-j(\phi_{k,l} - \theta(g(i,j), k, l))} \right| \quad (1)$$

Then we can estimation the location of the tag by choosing (i, j) with maximum P .

5.3 Kernel-layer Framework

Beyond the basic hologram algorithm [28], there are many hologram variants [7, 8, 29, 30]. We find that two key factors determine the performance of hologram-based localization algorithms, namely, kernel and layer:

Definition 1. Kernel is the function that measures the similarity between the received signal and the theoretical signal

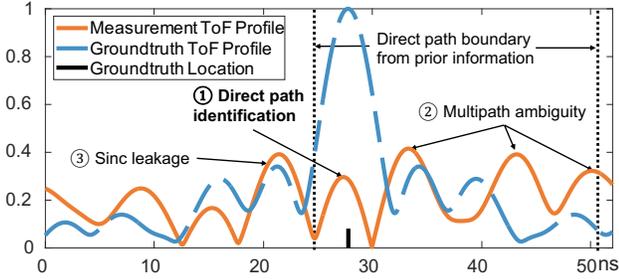

Figure 9: Direct Path Identification with ROI Information.

from one channel (*i.e.*, single carrier from a single antenna). For example, the $e^{j(\phi-\theta)}$ in Eqn. 1 is a kernel function that measures the phase similarity with an exponential function.

Definition 2. Layer is a function that determines how to combine kernels from multiple channels (*i.e.*, multiple carriers from multiple antennas) and obtain the location estimation. For example, the $\sum_{l=1}^L \sum_{k=1}^K$ in Eqn. 1 is a layer function.

We introduce a kernel-layer framework that tells us how kernel and layer affect the localization performance. Fig. 8 summarizes our kernel-layer framework, which describes the fundamentals of hologram-based algorithms. This framework can be used following these steps:

- *Model* calculates the theoretical channel information (*e.g.*, propagation phase) for each location.
- *Measurement* obtains the empirical channel information (*e.g.*, propagation phase and RSSI) by interrogating the tags.
- *Kernel* function profiles the similarity between the theoretical and empirical channel information.
- *Layer* function combines kernel function output from different antennas and frequencies.
- *Output* picks the location with the maximum likelihood as the estimated location.

Different kernels and layers can be combined into various near-field localization algorithms. See more examples in §B.

5.4 RF-CHORD's Kernel and Layer

We design our localization algorithm based the kernel-layer framework. When designing RF-CHORD's kernel and layer, we want to reduce the impact of multipath for low long-tail error, which can be achieved with the carefully designed kernel, layer, and prior information from the logistic scenario. RF-CHORD's kernel is similar to basic hologram algorithms:

$$\text{RF-CHORD's kernel: } e^{-j(\phi-\theta)}$$

RF-CHORD has 4 layer functions: ToF estimation layer, direct path identification layer, direct path enhancement layer, and summation layer. These layers work together to suppress the multipath and combat long-tail localization errors.

ToF Profile Layer. By using the wideband bandwidth captured, this layer computes the time-of-flight profile of the received signal. The computation follows Eqn. 2 where ϕ is

the empirically measured phase value, f_l is the frequency, and τ is the propagation delay of each path.

$$\text{ToF estimation layer: } S(\tau) = \sum_{l=0}^L e^{-j(\phi_l - 2\pi f_l \tau)} \quad (2)$$

Direct Path Identification Layer. It is still challenging to identify the direct path in the ToF profile layer in Fig. 9 because there are three interfering factors: ① If the difference is smaller than 0.75 m, we can only observe one mixed peak in the time-of-flight profile of the received signal. ② If the difference is larger than 0.75 m, there will be ambiguity from multipath at the locations farther from the groundtruth. ③ The sample on the frequency domain, which is a sinc function on the time domain, may leak its side lobe and form fake peaks at a nearer location than the groundtruth. To address these problems, RF-CHORD leverages a key observation: prior information. In practical logistic deployment, we can employ the size of the scanning area, the track of tags, *etc.* to help localization. RF-CHORD constructs a layer that leverages this prior information for direct path identification. Fig. 9 shows an example of this layer with scanning range [a,b] in meters as prior information, which is common in warehouse deployment. The corresponding algorithm is shown in Alg. 1. In this example, we first compute the bound of the theoretical propagation time in this range $\tau_a = a/(3 \times 10^8)$ and $\tau_b = b/(3 \times 10^8)$. The prior information, τ_a and τ_b , acts as a filter that eliminates any multipath with a propagation time smaller than τ_a or larger than τ_b , which helps us identify the right direct path (right peak) rather than nearer one from sinc leakage or farther one from multipath.

Algorithm 1 Direct path identification layer

- Input:** 1. ToF profile: $[S(\tau_1), S(\tau_2), \dots, S(\tau_s)]_{1 \times s}$
 2. Prior info: scanning area in meters [a,b]
 3. Peak threshold: p

Output: Direct path distance rough estimation \tilde{d}_0

1. $\tilde{d}_0 = 0$, $\tau_a = \frac{a}{3 \times 10^8}$, $\tau_b = \frac{b}{3 \times 10^8}$;
2. $L = \text{find } \tau_i \text{ closest to } \tau_a \text{ in } [\tau_1, \tau_2, \dots, \tau_s]$, return index;
3. $R = \text{find } \tau_i \text{ closest to } \tau_b \text{ in } [\tau_1, \tau_2, \dots, \tau_s]$, return index;
4. $S(\tau) \leftarrow S(\tau)[L : R]$;
5. $path \leftarrow S(\tau)[0 : \text{end} - 1] - S(\tau)[1 : \text{end}]$

for $i \leftarrow 1$ to $s - 1$ **do**

if $path[i] > 0$ & $path[i - 1] < 0$ & $S(i) > p$ **then**
 $\tilde{d}_0 = \tau_i \times 3 \times 10^8$;
break;

end if

end for

Direct Path Enhancement Layer. RF-CHORD uses a across-frequency phase redress algorithm to further enhance the signal quality of the direct path signal. RF-CHORD first identifies potential multipath – if there are multiple peaks (identified by

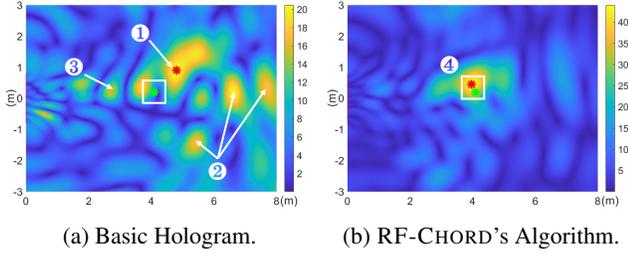

Figure 10: RF-CHORD can suppress sinc leakage, multipath ambiguity, and enhance direct path for finer resolution compared to basic hologram algorithms in Eqn. 1.

2D peak find algorithm [31]) in the basic hologram results, the location estimation is likely affected by the multipath effect. Instead of using the empirically measured phase ϕ , RF-CHORD combines the direct path signal from all frequencies and constructs an enhanced phase $\tilde{\phi}_l$. This process is done by the layer function of Eqn. 3. See §C for detailed mathematical derivation.

$$\text{Direct path enhancement layer: } \tilde{\phi}_l = \angle \sum_{i=1}^L e^{j\phi_i} e^{j\frac{2\pi}{c}(f_i - f_l)\tilde{d}_0} \quad (3)$$

Summation Layer. The last layer in RF-CHORD is the summation layer, which combines information from all L frequencies and K antennas and computes the likelihood of the tag position. For every location $g_{(i,j)}$, RF-CHORD computes the likelihood $P(g_{(i,j)})$ and choose the position with the highest likelihood as the estimated result.

$$\text{Summation layer: } P(g_{(i,j)}) = \left| \sum_{l=0}^L \sum_{k=0}^K e^{-j(\phi_{l,k} - \theta(g_{(i,j),l,k}))} \right| \quad (4)$$

Putting Everything Together. All above layers and kernel work together as our multipath suppression algorithm. Fig. 10 shows an visual example. The heatmaps are the location likelihood with the basic summation layer in Eqn. 1 (Fig. 10a) and with our direct path enhancement algorithm (Fig. 10b). The green cross is groundtruth and the red cross is location estimation. If we only use the simple summation layer, there are three factors disturbing the localization accuracy. RF-CHORD handles them with customized kernel-layer algorithm design. The peak of location estimation ① is the superimposed responses from all the paths within distance resolution nearer the direct path. RF-CHORD utilizes coherent summation layer with full 200 MHz bandwidth to increase distance resolution to 0.75 m. The paths with large distance differences from the direct path will generate ambiguity at farther arrival distances as multipath ambiguities ② or even at nearer distance as sinc leakage ③. By using prior information of work range (tags are in different check-in passage with different ranges) to clarify the direct path identification and using direct path enhancement to suppress multipath, we obtain the accurate location estimation ④.

6 Implementation

6.1 Active Sniffer

Antenna. We chose a recent variant [32] of the Foursquare patch antenna [33], which is metal-backed and of concentric dual-polarization, as our wideband Tx and Rx antennas for its advantages of small-size, low-cost, and high adaptability to surroundings. The original antenna design is for 1.7~2.7 GHz LTE and we scaled it with HFSS [34] to fit the UHF band 700~1100 MHz. We also attached each Rx antenna to a 915 MHz bandstop filter [35] to suppress the high-power ISM-band leakage from the commercial reader.

Array. We built the Rx array through a laser-cutting sheet of aluminum. The mounting holes and SMA clearances on the sheet define a 1×8 linear array with element spacing of 21 cm. We set a notable 31.5 cm gap in the middle for a 2:3 co-prime array configuration [36] to suppress the grating lobe. We hang two Tx's 0.4 m lower than the receiver's horizontal array along its geometric bisection. The right one was wideband Tx and the left one was ISM-band Tx.

Baseband Processor. One of the key implementation challenges towards one-shot inventory is to convert the 31 Gbps I/Q samples from the A/D to the application processor. We developed high throughput baseband with 2 ADRV9009 [23, 37] RF chips and an XCKU060 FPGA SoM [38, 39] in charge of 4 receivers over 200 MHz bandwidth for PCIe streaming.

Application Processor. The host is equipped with a Core-i9 9900 CPU and an RTX 3090 GPU for real-time decoding and CSI acquisition. GPU was used to handle the template matching during the decoding with FFT convolution acceleration and parallelism. We used Process Explorer [40] to measure resource utilization and report the results in Tab. 2. The decoder is developed with C++/Eigen except that the most compute-intensive part, *i.e.*, the full packet matching algorithm, is implemented on GPU with CUFFT [41].

CPU (Utilization)	GPU (Utilization)	I/O Bandwidth	Memory
Core-i9 9900 (16.1%)	RTX 3090 (38.0%)	520.1 MBps	4.1 GB

Table 2: Hardware Resource Utilization.

6.2 RFID Tags

In order to ensure compatibility and low-cost, we used a commercial RFID IC Impinj Monza-M4A [42] and implemented a bandwidth extension technique [43] to redesign the metal inlay (antenna) on 80×80 mm single-sided PCB. The CAD of the RFID antenna is shown at the top left of Fig. 11 and its direction gain (similar to dipole antenna) is shown in Fig. 15a. It works on 700~1000 MHz, whose copper geometry can be transferred to flexible inlay for massive production.

7 Evaluation

7.1 Experimental Setup

Testing Environment. We evaluate RF-CHORD in an office with multiple reflectors (*e.g.*, metal furniture, low ceilings,

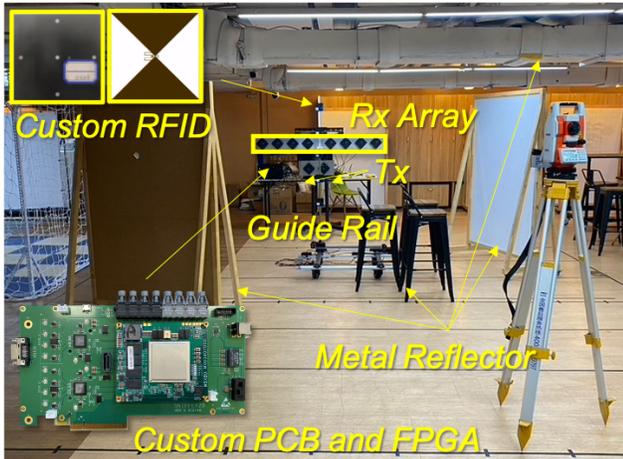

Figure 11: Experimental setup for evaluating performance. Five tags are mounted on the rail and ~20k tag responses are collected in 384 locations.

and walls). The evaluation range is the area of 6×3.2 m ahead of the antenna. We divide the evaluation space into 20 cm grids and use guide rails to move the tags. All the tags are facing the array. The dataset containing about 20k wideband RFID channel information measurements at 384 locations is open-sourced at [44]. The setup is shown in Fig. 11.

Location Groundtruth. Groundtruth is measured from a total station theodolite (TST) [45] with a 2 mm/2" accuracy.

Frequency Band Configuration of Active Sniffer. We use the band of 787~987 MHz and avoid selecting carriers in ISM band 902~928 MHz. The carriers are almost evenly selected with spacing of 11.1 MHz³. The spectrum analyzer shows the inter-modulation distortion of carriers is very little.

ISM-band Reader. We use an Impinj R700 [46] as the ISM-band reader, which is configured on "Radio Mode 142" (Miller-4 coding and BLF of 256 kHz) and a single linear-polarized antenna aligned with the wideband Tx. We empirically pick this mode since it balances throughput and range. Other coding methods and BLF can also be adopted with few modifications to our system.

7.2 Throughput in One-shot Localization

Fig. 12 shows RF-CHORD's throughput at different distance. RF-CHORD can read and localize ~180 tags per second (97% of the tags read by an Impinj reader) at up to 6 m. RF-CHORD is 1000× faster compared to previous sniffer-based wideband systems with frequency-hopping. For instance, RFind [14] needs 6.4 seconds to localize one tag. We also evaluate RF-CHORD's throughput across emission power. Fig. 13 shows that RF-CHORD's throughput decreases when we reduce its emission peak power from -15 dBm to -35 dBm. It works fine with an emission power above -25 dBm.

³The frequency set of carriers is {787.1, 798.2, 809.3, 820.4, 831.5, 842.6, 853.7, 864.8, 875.9, 887.0, 898.1, 942.5, 953.6, 964.7, 975.8, 986.9 MHz}.

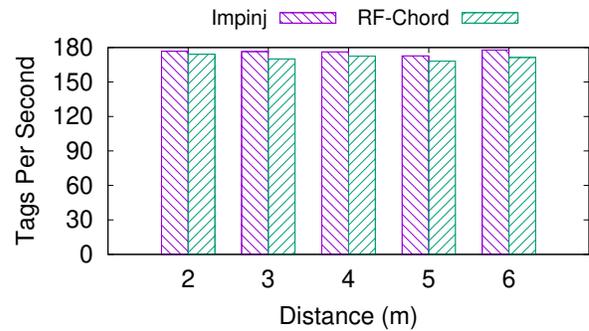

Figure 12: Throughput across distances. RF-CHORD can localize around 180 tags/s with -15 dBm emission power.

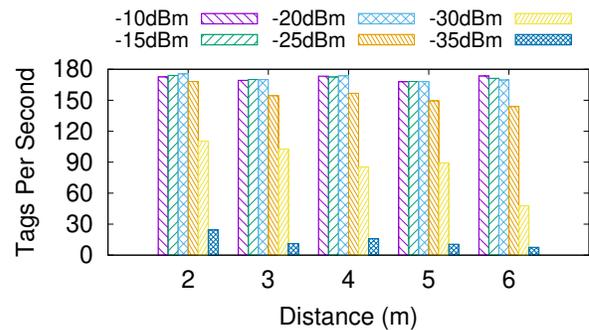

Figure 13: Throughput across distances with different emission power. The performance of RF-CHORD is stable with above -25 dBm emission power.

7.3 Localization Performance

RF-CHORD utilizes large bandwidth, multiple antennas, and the multipath-suppression algorithm to realize one-shot and high-reliability localization. We conduct microbenchmarks to evaluate how physical resources (frequency and spatial domain), algorithms, and orientation influence the localization.

Bandwidth. We evaluate the localization performance with 8 antennas and different bandwidths. Fig. 14a shows 99th localization errors are 2.398 m, 1.646 m, 1.203 m and 0.786 m with 50 MHz, 100 MHz, 150 MHz and 200 MHz bandwidths. The median errors are 0.325 m, 0.227 m, 0.155 m, and 0.144 m, separately. The results show increasing bandwidth, thus increasing the time resolution, can not only improve the median performance but also reduce the long-tail error. Even when the median performance is close to the upper limit (150 MHz v.s. 200 MHz), the long-tail errors can still be reduced by increasing bandwidth.

Number of Antennas. We evaluate RF-CHORD's localization performance with 200 MHz bandwidth and different numbers of antennas (thus different array apertures). Fig. 14b shows RF-CHORD's 99th localization errors are 4.513 m, 1.467 m, 1.081 m and 0.786 m when 2, 4, 6 and 8 antennas are used. The performance of the 4, 6, and 8 antennas is very similar on median errors (about 0.14 m). However, their long-tail errors are significantly different. The results

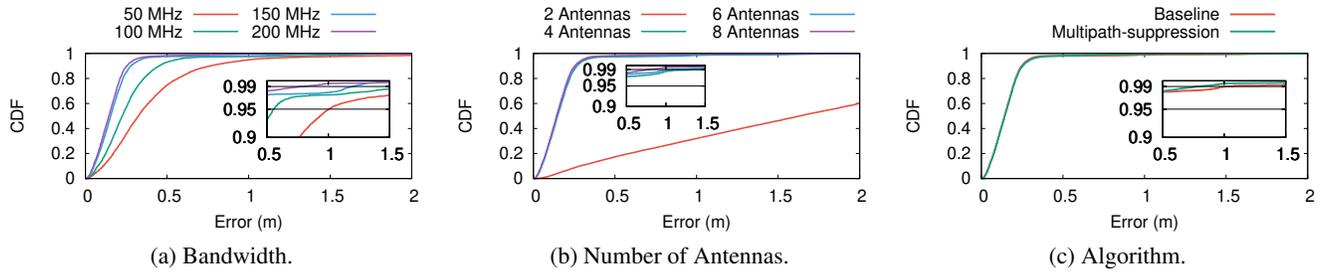

Figure 14: RF-CHORD's localization errors with different bandwidths, antenna numbers, and algorithms.

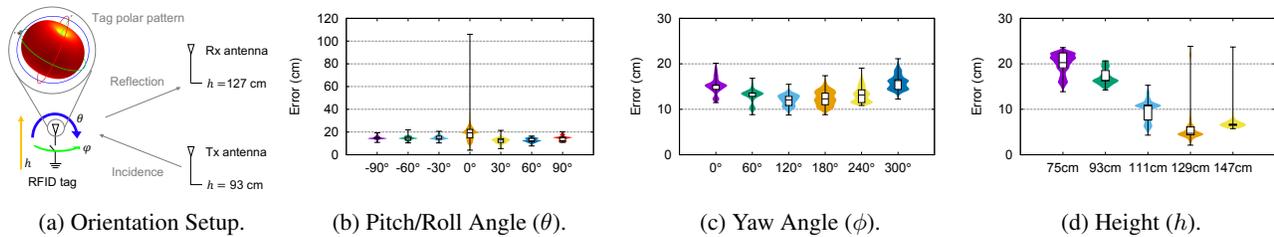

Figure 15: Microbenchmarks with different tag orientations and heights related to the antennas.

show increasing the number of antennas (from 2 to 8) can always improve long-tail performance. Increasing the number of antennas/apertures strengthens the system's immunity to interference in specific directions and improves the angular resolution for localization.

Algorithms. We take basic hologram (Eqn. 1) as the baseline algorithm and evaluate our multipath-suppression algorithm with 8 antennas and 200 MHz bandwidth. Fig. 14c shows that 99th localization errors of baseline and RF-CHORD are 1.018 m and 0.786 m respectively. The median errors of baseline and RF-CHORD are 0.143 m and 0.144 m, respectively. The algorithm effort can improve long-tail performance by handling more corner cases, but hard to improve median performance. Physical resources (*i.e.*, the bandwidth and the antenna array aperture) fundamentally limit the algorithm's performance, and the long-tail improvement from the algorithm is primarily attributed to the introduction of prior information – it provides an appropriate carrier for making use of prior information.

Orientation. In practice, the orientation of tags will influence the link angle and polarization, thus introducing SINR and phase changes. We evaluate how orientation influences the localization error. We set the target tag at a 1-m fixed distance to the antenna array to eliminate the influence of the multipath effect. Then, we change the pitch angle θ (as same as the roll angle due to the symmetry), yaw angle ϕ , and height of the tags as shown in Fig. 15a for orientation microbenchmark:

- **Pitch/Roll Angle.** In Fig. 15b, we keep $\phi = 0^\circ$ and $h = 111$ cm (at the center between Tx and Rx). The worst performance occurs when the pole of the antenna points to the rx, which rarely happens in practical deployments (to be discussed in §8.1). It is difficult to read tags due to the low SINR, and even if successful, the long-tail error will be more than 1 m.
- **Yaw Angle.** In Fig. 15c, we keep $\theta = 0^\circ$, $h = 111$ cm and

change ϕ from 0° to 300° . The errors at different yaw angles are similar because the directional gain across ϕ is symmetrical. The results show that the yaw angle does not affect long-tail localization error (bounded within 30 cm).

- **Height.** In Fig. 15d, we keep $\theta = 0^\circ$, $\phi = 0^\circ$ and move the tag from 75 cm to 147 cm. The long-tail errors do not change much across different heights, which shows that height is not the key factor affecting long-tail errors.

8 Practical Deployment

8.1 Deployment Constraints

We summarize the practical factors that influence SINR in Fig. 16 and introduce the constraints in real-world logistic scenarios. We also explain how we avoid or utilize them for high-reliability localization.

Orientation. The localization error may be significant if the pitch angle of the tag is closed to 90° according to §7.3. In the deployment shown as Fig. 17, the orientation of tags may not be uniform but unlikely to be completely disordered. All the tags are attached to the sides of boxes or crates and then stacked on the pallet. The chaos of stacking and the movement of the pallet may cause yaw angle (ϕ) change but not cause much pitch/roll angle (θ) change, which only introduces negligible localization errors according to Fig. 15c.

Polarization. We set the tags and sniffer antennas all vertically polarized, so horizontal tags can not be read. Similar to orientation, no tag will be misplaced in our scene because the pallet stack constraints the crate direction.

NLOS and Tag Coupling. We also stipulate that all the tags should be in the line of sight from one side dock door, which means stacking at most two-column crates on the pallet. It is because the performance of UHF RFID will decrease rapidly with nearby water [47]. This rule excludes severe NLOS occlusion/reflection and severe tag coupling. Most of the pallets

	Miss Reading Rate	Cross Reading Rate
Warehouse	0	0.0025%
Food delivery	0	0.0154%

Table 3: Reliability performance in practical deployments.

in our scenes naturally meet this requirement, and in rare cases, we need to waste some space.

8.2 Real World Deployment

We deployed the full-fledged RF-CHORD (*i.e.*, 200 MHz bandwidth and 8 antennas) in the warehouse dock door and lightweight RF-CHORD (*i.e.*, 200 MHz bandwidth and 4 antennas) in the fresh food delivery store according to cost and scene conditions for operational evaluation.

Warehouse Deployment. We deploy RF-CHORD in a warehouse to understand its performance in logistic check in and out. RF-CHORD is installed in the dock door of the warehouse as shown in Fig. 17. This warehouse’s goal is to distribute a large amount of food and daily necessities supplied by the upstream warehouse to city delivery stations. The crates are various and packaged without unified standards. Ideally, RF-CHORD should report all the tags inside of the scanning area and not report any tags outside of the scanning area. Our previous deployment experiments in the same scenario show that commercial read-or-not solution Impinj xSpan [16] has ~6% miss-reading rate and ~2% cross-reading rate in the similar scene. We attached over 10,000 tags to various items, mainly plastic crates, also including water bottles, cans, milk boxes, rice, *etc.* The scanning area is 2×1 m between the two poles of the dock door (as ROI) and the user walks through the aisle with about 50~100 tags on a trailer in 1 to 4 seconds. According to Tab. 3, RF-CHORD is able to identify tags inside of scanning area with a 100% accuracy (perfectly no miss reading) and 0.0025% cross reading. Therefore, RF-CHORD can provide sufficient localization accuracy in the warehouse deployment, which significantly outperforms the state-of-the-art commercial solutions.

Fresh Food Deliver Store Deployment. As shown in Fig. 18, we also deploy lightweight RF-CHORD in a fresh food delivery store where fresh food is packaged into a container and transported via a moving belt. Once the RFID tag on the

container is scanned, the delivery personnel will be allocated to pick it up. RF-CHORD needs to ensure all the containers on the moving belt are scanned and do not scan any tag outside of the moving belt. Tab. 3 shows that the miss-reading rate of RF-CHORD is 0%, and cross-reading rate is 0.0154%. Therefore, RF-CHORD can achieve sufficient accuracy in the fresh food delivery store deployment.

9 Discussion

Polarization Mismatch. In our scenarios, the work pipeline guarantees the polarization match. However, in more general scenarios, the polarization may be mismatched when the orientation of tags is disordered. The conventional solution is to use circular polarization antenna [48] or dual-polarization switching [16]. RF-CHORD can be adapted to them conveniently because its wideband four point antenna is inherently dual-polarized. We can plug a polarization switch into each sniffer antenna, which acts synchronously and does not influence throughput and range performance.

Blind Spots. RF-CHORD is free of cross reading, and therefore it can use high transmission power and sensitivity ISM-band reader for achieving nearly zero miss-reading rate. However, miss reading still threatens reliability in certain complex environments. It can be mitigated by switching between antennas or beam patterns [3, 49]. As our Tx is synthesizing multiple tones, it is feasible to add a Tx beamforming array for blind spot suppression.

Integration with Robots. In recent years, logistics robots (*e.g.*, automated guided vehicle (AGV) [50], automated storage and retrieval systems (ASRS) [51], and autonomous mobile robots (AMR) [52]) have been developed rapidly to reduce the movements and operations of sorters and improve efficiency. These robots still need to cooperate with a label identification system (*e.g.*, barcode or QR code). RF-Chord has the potential to replace such system and cooperate with logistics robots to achieve more efficient automation.

Cost. The ultimate goal of deploying RFID is to reduce manual labor and error while improving efficiency, which requires careful cost accounting. We emphasize that although baseband chips and RF circuits will increase the cost of readers to thousands of dollars, the main cost of RFID-based logistics

still comes from RFID tags. Considering a medium warehouse with 10k packages delivered every day, the annual cost of tags is approximately $\$0.1 \times 10,000 \times 365 = \$365,000$. Our strategy is not modifying the tag chip because most of the manufacturing cost comes from the chip and the assembly process [53]. Therefore, the wideband tag we designed maintains almost the exact cost as current commercial tags when in massive manufacturing.

10 Related Work

Narrowband Localization. There are three main localization approaches to boost accuracy even with the limited time resolution of narrow ISM bandwidth: The first approach is to improve spatial resolution by SAR. Tagoram [7] uses the motion of tags to build multiple virtual antennas, while Mobitagbot [8] exploits antenna motion. The hologram algorithms in these two systems inspired the kernel-layer framework in our paper. Other hologram algorithm variants [29,30,54] can also be viewed as different combinations of kernels and layers. However, the assumption of free antennas or tags mobility and lengthy startup time for tracking do not fit the logistic network. The second approach is to acquire prior information by reference tag. PinIt [6] exploits a dense grid of reference tags and determines the nearest reference tag for NLOS localization by dynamic time wrapping. However, reference tags share time slots, which influences the throughput and scalability. The third approach is to increase the number of links by tag array. Attaching more tags to the target can increase the number of links and improve localization performance. Tagyro [55], and RF-Dial [56] utilize the phase difference of the tag array to solve orientation ambiguity and improve localization performance. Trio [57] models the equivalent circuits of coupled tag and uses the tag interference for refined localization. Liu et al. [58] uses spatial-temporal phase profiling for relative RFID localization. These tag array based localization approaches are accurate but may be error-prone in a complex environment. Unlike these proposals, RF-CHORD is a sniffer-based wideband localization system that improves time resolution for fundamental performance enhancement.

Wideband Localization. Wideband RFID localization has been proposed to overcome the time resolution limitation. RFind [14] uses a low-power sniffer antenna by frequency hopping to collect the narrow sample channel state information across 220 MHz. TurboTrack [15] develops an OFDM-based one-shot wideband channel estimation approach and a Bayesian space-time super-resolution algorithm to achieve fine-grained localization. However, these systems need multiple shots in the channel estimation or the algorithm to converge for fine location estimation, thus very slow startup for localization or tracking. Modifying tags to work on other frequencies (*e.g.*, Wi-Fi [59], millimeter-wave [11], UWB [12,13]) or cross-frequency based approaches (*e.g.*, communicate with Wi-Fi [10], communicate at 1.4~2.4 GHz [60]) are also expected as the solutions for both finer localization

and higher throughput, but their tags are not ready for massive manufacturing at low cost due to the complicated RF frontend and control circuits. Inspired by these works, RF-CHORD develops a multisine waveform to realize one-shot localization without modifying the commercial tag chips, resulting in high accuracy with no throughput loss or cost increase.

RFID Reader. Commercial RFID readers [46,61,62] have heavily optimized RF analog frontend, decoder, and protocol stack but do not support real-time tag critical information (*i.e.*, EPC ID, timestamp) retrieval. There are a series of open-source RFID reader systems. Buettner et al. implemented EPC Gen II downlink stack [63] and the full functional reader [64], respectively. Kimionis et al. implemented a GNU radio-based reader, which supported OOK and noncoherent FSK [65]. However, their energy and edge detection algorithms are too simple to decode applicable code (*e.g.*, miller-4 coding). A recent reader designed by Kragas et al. [66] is featured by coherent detection and initial duration deviation search but only supports simple FM0 encoding. There are other research projects featured by multisine waveform [67], parallel sensing support [68], and active transmit leakage cancellation [69]. However, they only focus on specific optimization and do not provide source code. In a nutshell, no out-of-box reader design meets our requirements of high throughput and low decoding threshold, so we develop a wideband reader with a customized RF frontend and decoder while reusing the MAC layer of the commercial reader for slot arrangement and collision handling. It supports our wideband localization with high efficiency, sensitivity, and compatibility.

11 Conclusion

We illustrate the three key requirements in reliability, throughput, and range to meet the industry-grade standard of the logistic network, and present RF-CHORD, the first RFID system that considers all these factors from wideband signal and baseband processing to localization algorithm framework development. We believe our real-world empirical results demonstrate that RF-CHORD paves the way for the practical hardware-software methodological solution of RFID localization-based logistic network and makes an important step towards large-scale operational deployment.

Acknowledgments

We are grateful to the reviewers for their constructive critique, and our shepherd, Vikram Iyer in particular, for his valuable comments, all of which have helped us greatly improve this paper. We also thank Xieyang Xu and Weicheng Wang for providing an early implementation version of the work. We are grateful to Yunfei Ma for the thoughtful suggestions based on the early version of the work. A FCC Compliance

RF-CHORD adopts a 200 MHz bandwidth in the UHF band, much wider than the 902~928 MHz ISM band. We need to reduce the power of the signal emitted in the licensed band to follow the FCC regulation [70]. Similar operations exist in other systems, such as RFind [14]. RFind adopts a duty-cycled single-tone signal with a peak power of -3 dBm and average power of -13.3 dBm. However, due to the throughput requirement of the localization, RF-CHORD's sniffer should always be ready to localize a tag, which means duty cycling is unacceptable. Therefore, RF-CHORD adopts a hard limit of -15 dBm per tone and can be even lower with similar performance. One may concern that the multiple carrier operation will not be the same as RFind [14] since the total bandwidth is larger than the 0.25% bandwidth limitation in FCC 15.231 (c) [71]. However, RF-CHORD can adopt the alternative method mentioned in [72], which calculates the total bandwidth by summing the individual occupied bandwidths of each carrier frequency. Since we did not apply any modulation to the carriers, the sum of respective bandwidths will be extremely small, which can comply with the FCC regulation. Other modulated waveforms (e.g., OFDM) cannot follow this alternative method and may potentially violate the regulation.

B Kernel-layer Combinations for Different Localization Algorithms

Kernel-Layer near-field localization framework supports various localization algorithms because of the flexibility of measuring the similarity between receiving signal and theoretical

signal and combining information across channels. For example, traditional ToF and AoA estimation algorithms can be implemented under the near-field condition with different kernels and layers.

Kernel and Layers for ToF Estimation. ToF estimation can be done by choosing the following kernel and layer, where ϕ_l and θ_l are the empirical and theoretical phases at frequency f_l respectively, and d is the distance between tag and reader.

$$\begin{aligned} \text{Kernel: } & e^{-j(\phi_l - \theta_l)} = e^{-j(\phi_l - 2\pi f_l d/c)} = e^{-j\phi_l} e^{2\pi f_l \tau} \\ \text{Layer: } & \sum_{l=0}^n S(\tau) = \sum_{l=0}^n e^{-j\phi_l} e^{2\pi f_l \tau} \end{aligned} \quad (5)$$

When using the above kernel and layer functions, $S(\tau)$ is the inverse Fourier transformation of the empirically measured phase value $\phi_1, \phi_2, \dots, \phi_n$. Therefore, $S(\tau)$ is the time-of-flight expression of the empirically measured phases.

Kernel and Layers for AoA Estimation. Similar to the ToF estimation, we can also design kernel and layer functions to extract angle-of-arrive (AoA) estimation. For the AoA estimation, we can use the following kernel and layer functions, where ϕ_k and θ_k are the empirical and theoretical phases at antenna k , respectively. Δd is the distance between two neighboring antennas.

$$\begin{aligned} \text{Kernel: } & e^{-j(\phi_k - \theta_k)} = e^{-j(\phi_k - 2\pi f_k \Delta d \sin(\psi)/c)} \\ \text{Layer: } & \sum_{k=1}^m S(\psi) = \sum_{k=0}^m e^{-j\phi_k} e^{2\pi f_k \Delta d \sin(\psi)/c} \end{aligned} \quad (6)$$

$S(\psi)$ measures the similarity of the theoretical signal coming from angle ψ and the empirically measured phase value $\phi_1, \phi_2, \dots, \phi_m$ received by m antennas. Therefore, correct AoA ψ is identified when $S(\psi)$ is maximized.

The summation layer, which sums up all the channels first by row and then by column, combines all the information for the final result. In this case, it combines near-field ToF and AoA estimations. We can develop more complex algorithms with the kernel-layer framework, such as the multipath-suppression algorithm in our paper.

C Direct Path Enhancement

We enhance the direct path and suppress the influence from multipath with a frequency domain algorithm [14]. Assume there are N paths with distances of $d_0, d_1, d_2, \dots, d_N$, and d_0 is the direct path. The channel h_l of l th carrier can be expressed as:

$$h_l = a_0 e^{-j\frac{2\pi}{c} f_l d_0} + \sum_{i=1}^N a_i e^{-j\frac{2\pi}{c} f_l d_i}$$

a_i is the propagation attenuation of the i th path. To simplify the derivation without loss of generality, we assume $a_0 =$

$a_i = 1$, ($i = 1, 2, 3, \dots$), and what we measure is the phase of channel response:

$$\phi_l = \angle h_l = \angle \left\{ e^{-j\frac{2\pi}{c} f_l d_0} + \sum_{i=1}^N e^{-j\frac{2\pi}{c} f_l d_i} \right\}$$

If we have a rough estimation of d_0 , called \tilde{d}_0 , we can use this algorithm to enhance the part of $a_0 e^{-j\frac{2\pi}{c} f_l d_0}$ (direct path) and suppress the part of $\sum_{i=1}^N a_i e^{-j\frac{2\pi}{c} f_l d_i}$ (multipaths) for a better location estimation. In more detail, we use the prior knowledge of ROI to help determine the rough estimation of direct path \tilde{d}_0 with Alg. 1. Then we enhance the direct path profile and suppress profiles of other paths by Eqn. 3 because the enhanced phase $\tilde{\phi}_l$ can be written as:

$$\begin{aligned} \tilde{\phi}_l &= \angle \sum_{i=1}^n e^{j\phi_i} e^{j\frac{2\pi}{c} (f_i - f_l) \tilde{d}_0} \\ &= \angle \left\{ e^{-j\frac{2\pi}{c} f_l d_0} \sum_{i=1}^N e^{j\frac{2\pi}{c} (f_i - f_l) (\tilde{d}_0 - d_0)} \right. \\ &\quad \left. + \sum_{i=1}^N [e^{-j\frac{2\pi}{c} f_l d_i} \sum_{i=1}^N e^{j\frac{2\pi}{c} (f_i - f_l) (\tilde{d}_0 - d_i)}] \right\} \end{aligned}$$

$\tilde{d}_0 \approx d_0$ so $(\tilde{d}_0 - d_0) \Delta f / c \ll 1$, and it leads to:

$$\sum_{i=1}^N e^{j\frac{2\pi}{c} (i-1) \Delta f (\tilde{d}_0 - d_0)} \approx \sum_{i=1}^N 1 = N$$

For multipath whose d_i is different from \tilde{d}_0 , $\tilde{d}_0 - d_i$ is large so

$$\left| \frac{\sum_{i=1}^N e^{j\frac{2\pi}{c} (f_i - f_l) (\tilde{d}_0 - d_i)}}{N} \right| \approx |\text{sinc}[B(\tilde{d}_0 - d_i)/c]| \ll 1$$

The part of the direct path is much larger than the part of other paths, so the direct path is reinforced. \tilde{d}_0 helps to get rid of the leakage interference from multipath, and the following summation layer can make a better estimation of d_0 as the final output. Besides using the prior knowledge, other methods (e.g., fingerprinting-based algorithm, Bayesian-based algorithm) can also be used to determine the rough estimation \tilde{d}_0 , which is beyond the scope of this paper.

Exploring Practical Vulnerabilities of Machine Learning-based Wireless Systems

Zikun Liu[†], Changming Xu[†], Emerson Sie[†], Gagandeep Singh^{†‡}, Deepak Vasisht[†]

[†]University of Illinois Urbana-Champaign, [‡]VMware Research

Abstract

Machine Learning (ML) is an increasingly popular tool for designing wireless systems, both for communication and sensing applications. We design and evaluate the impact of practically feasible adversarial attacks against such ML-based wireless systems. In doing so, we solve challenges that are unique to the wireless domain: lack of synchronization between a benign device and the adversarial device, and the effects of the wireless channel on adversarial noise. We build, RAFA (Radio Frequency Attack), the first hardware-implemented adversarial attack platform against ML-based wireless systems and evaluate it against two state-of-the-art communication and sensing approaches at the physical layer. Our results show that both these systems experience a significant performance drop in response to the adversarial attack.

1 Introduction

Next-generation networks, 5G and beyond, promise to be unprecedented in their scale and the diversity of applications, ranging from virtual reality to low power Internet of Things applications. Machine Learning (ML) has emerged as a key component of such future networks to deliver application-specific performance goals by optimally managing the diverse capabilities of these networks – multiple antennas, different spectrum bands, and smart surfaces. In academia, researchers have efficaciously applied ML for both communication [45, 55, 60, 79, 85] and sensing [6, 51, 59, 74, 94] applications. ML-based techniques are increasingly making their way to the industry, in both RAN (radio access network) and the network core. This trend has been accelerated by the recent shift of telcos to cloud-based execution models.

Our goal: We investigate the vulnerabilities of using ML in wireless systems. Our investigation is motivated by two reasons. First, wireless networks play a crucial role in many human-critical applications like autonomous driving, smart healthcare, factory control, etc. Any failure to meet network performance goals can have severe consequences in such settings. Second, in popular domains such as computer vision and natural language processing, past work has shown that an adversary can add small imperceptible noise to the inputs of a neural network making it predict completely different results [27, 76] (e.g., a turtle is classified as a gun). Several of these attacks have been reproduced in the real-world on state-of-the-art ML models in these domains [5, 48, 49, 71], showing that despite their impressive performance, the ML models are not robust. These practical attacks have promoted

the development of new techniques for formal verification [40, 72, 73] and robust training [11, 34, 81, 84, 87, 90] in the vision and NLP domains.

Our goal is to explore the *practical* vulnerabilities of state-of-the-art ML-based wireless systems using adversarial attacks. To mount practical real-world adversarial attacks, an adversary must meet three requirements. First, it must not need access to the infrastructure in real-time, i.e., it cannot coordinate its transmissions with a benign sender, or access the signal sensed by a benign receiver. Second, it must be low complexity, i.e., it must not require large antenna arrays. Finally, it must be low power. It is relatively straightforward to jam the spectrum with blind high-power transmissions. However, jamming causes large-scale disruption to the spectrum and causes spectrum owners (e.g., telecom operators) to react. We are interested in small changes of the signal that specifically target the ML models in wireless systems, and expose their vulnerabilities.

Past work [2, 7, 9, 17, 18, 23, 43, 68] has studied adversarial attacks against ML-based wireless systems in simulation. These attacks do not meet the requirements above. Specifically, these attacks make unrealistic assumptions about the attacker capabilities. For example, they assume that an adversary can perfectly transmit adversarial signal or the attacker can directly manipulate the input matrix to the neural network. In practice, these assumptions do not hold. Adversarial signal undergoes wireless transformations described below before it arrives at a receiver. Similarly, directly altering the input matrix to the neural network requires access to the receiver.

Challenges: Consider the scenario shown in Fig. 1, where a (multi-antenna) base station communicates with a client device and uses ML-based models to deliver communication or sensing services. The adversary introduces small amounts of noise in the environment. Generating real-world adversarial attacks in such scenarios is challenging because of the underlying physics of wireless signal propagation. A typical adversarial attack takes an input to the ML model and crafts a noise vector specific to this input. This structured noise, when added to the input, causes the model to predict an incorrect output. In the wireless systems context, an attacker does not know the wireless channel between the client and the base station, and therefore does not know the signal being fed to the ML model. Secondly, the noise vector transmitted by the attacker is vastly different from what gets observed at the base station because: (a) Propagation effects: As the noise travels from the attacker to the end device, the noise vector undergoes the wireless channel experiencing reflection, attenuation, and phase shifts in the environment. (b) Clock offsets: the clock of

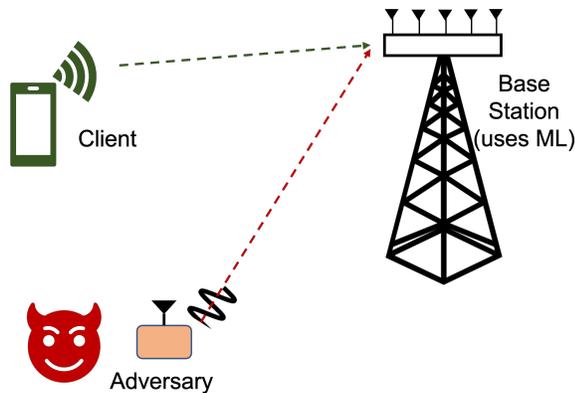

Figure 1: A multi-antenna base station uses ML-based methods to deliver communication or sensing services to the client. The adversary transmits small amounts of noise and disrupts these services.

the adversary is not synchronized with the end device, leading to random time and frequency offsets.

RAFA: We build the first real-world hardware-implemented adversarial attack platform, RAFA, that solves these challenges and targets ML-based wireless systems. Our system operates using a single antenna software defined radio and does not need real time access to the client or the base station in the attack setup. RAFA senses an ongoing communication on the wireless medium and introduces small amounts of noise (perturbation) to the medium that disrupts state-of-the-art ML-models. We demonstrate this attack on two state-of-the-art systems at the physical layer: one communication system (FIRE [55]) and one localization system (DLoc [6]). We show the effectiveness of RAFA in both white-box and black-box settings. The design of RAFA solves the following challenges:

Unknown Inputs: Adversarial algorithms [16, 27, 57] typically identify a perturbation that changes the output of a neural network *for a given input*. However, in practice, a wireless adversary, like RAFA, does not know the input to the ML model because: (a) the wireless channel from the client to the base station is unknown to the adversary, and (b) once the signal is received at the base station, the signal undergoes transformations (e.g., correcting for carrier frequency offsets) before it is fed to the ML model. Therefore, to model practical attacks, we require generating input-agnostic adversarial perturbations. We, first, design a universal adversarial perturbation (UAP), that focuses on changing the output on a distribution of inputs, rather than a single input. This allows us to be robust to the distribution of wireless signals, implying that we do not need to know the channel from the client to the base station. Furthermore, we develop differential versions of the pre-processing steps so that the adversary can generate perturbation vectors that remain adversarial even on pre-processed data points.

Lack of Synchronization: The adversary is not synchronized

with the client or the base station. Therefore, its transmission is *not* aligned with the client in time or frequency. The lack of time synchronization creates temporal misalignment between the benign signal and the adversarial perturbation. Similarly, the lack of frequency synchronization creates a time-varying phase shift between them. Furthermore, such clock offsets are random and hard to predict beforehand. To counter such offsets, we create a robustness mechanism in our UAP design, that tests the perturbation vector for arbitrary phase offsets, and picks perturbation vectors that are robust to such offsets. By doing so, we shift the burden of dealing with the clock offsets from hardware to software, therefore simplifying our hardware design for the attack.

Channel-induced Transformation: Finally, the perturbation vector crafted by RAFA undergoes a channel transformation as it travels to the base station. The channel transformation changes both the amplitude and phase of the perturbation vector. Therefore, there are no guarantees on the value of the perturbation vector after the channel transformation. This means we cannot design a perturbation vector that is robust to these transforms. RAFA leverages reciprocity to counter this challenge. Specifically, the base station occasionally transmits beacons or responses to its legitimate clients. Our adversary overhears these transmissions and uses it to estimate the channel from the base station to itself. Due to the reciprocity principle, this channel is equal to the channel from the adversary to the base station. Once we know this channel, we use our robust UAP method to construct a perturbation vector that is effective even after the channel transform.

While these factors serve as natural protectors for wireless systems against adversarial attacks, RAFA demonstrates the ability to mount effective adversarial attacks despite these challenges. We have implemented RAFA using the USRP software defined radio against two state-of-the-art ML-based wireless systems: FIRE [55] (for MIMO communication), and DLoc [6] (for ML-based localization). For FIRE, RAFA's adversarial attack can reduce the median SNR (from original SNR of 17.8 dB) of the predicted channel by 4.1 dB on average compared to just 2.1 dB drop for Gaussian baseline. Similarly, for DLoc, RAFA increases the median localization error (from original error of 1.04 m) by 71 cm on average compared to just 2 cm increase for Gaussian baseline. Our results also present a preliminary version of potential defense strategies.

Contributions: Our main contributions are:

- We design a new robust adversarial attack against ML-based wireless systems that is input-agnostic and models real-world effects such as lack of synchronization.
- We leverage channel reciprocity to model the effect of wireless channel on adversarial perturbations.
- We demonstrate the first hardware-implemented adversarial attacks against ML-based wireless systems.

ML-based wireless systems are increasingly being pro-

posed in academia [6, 10, 35, 55, 94], and actively being explored in the industry [39, 64, 65]. Therefore, it is timely and important to explore the challenges posed by adversarial attacks in this context. To the best of our knowledge, our work is the first to demonstrate realistic hardware-implemented attacks against ML-based wireless systems. We believe RAFA will allow researchers and practitioners to test the practical robustness of ML systems before they get deployed widely in the real-world and have severe consequences for any failures when exposed to such attacks. We also envision that adversarial examples exposed by RAFA will lead to development of robust ML models. An early attempt at developing such robust models is demonstrated in Sec. 6.6.

2 Adversary Model

Objective: Our goal is to promote the development of robust ML-models by identifying the attack surface of ML-based wireless systems in the real world. We focus on the existence and performance of *practically feasible* wireless attacks. We identify *practically feasible* as attacks that can be implemented using real hardware and without requiring coordination with the base station or client. Furthermore, we are interested in vulnerabilities specific to ML-models in the wireless setting. Therefore, we do not consider jamming, which is a brute-force solution that blocks all communication in the medium. We consider the scenario in Fig. 1. A client communicates with a base station on the wireless medium. The base station can have multiple antennas. The base station relies on a machine learning based approach to deliver communication or localization services to the client. Some examples for ML-based communication systems are shown in Tab. 1.

Application	Examples
Communication	FIRE [55], OptML [10], NeuMac [35]
Localization	DLoc [6], IPS [93], LAFA [38]

Table 1: Examples of ML-based Wireless Systems

Adversary Goal: The adversary wants to degrade the quality of ML-based location or communication service offered by the base station. The adversary aims to target specific ML-based services, and not jam the entire spectrum. To achieve this objective, the adversary transmits a carefully designed perturbation signal over the wireless channel. This perturbation gets superimposed at the receiver (which could be a cellular base station, access point, etc) with the benign signal transmitted from the client such as a cell phone. The receiver will later feed this seemingly intact but actually compromised signal into the ML-pipeline, negatively affecting its output prediction. Consistent with recent trends, we focus on neural networks as target ML models for this paper.

We describe the attacker properties in our threat model:

Coordination-free: We do not assume any coordination between the base station and the adversary (or between the

client and adversary). This implies that the adversary is unsynchronized, i.e. has time and frequency shifts with respect to the other (benign) devices. The adversary also does not know when the transmission from the client begins or ends.

Base Station Information: The adversary does not know the location of the client or the base station. The adversary knows only public information about base station hardware, such as information which can be gleaned from FCC filings or standards documents.

Low-complexity: The adversary uses low complexity hardware. Even though the base station and the client may have multiple antennas, the adversary uses a single antenna transmitter. This reduces the cost and complexity of the attack, making it more universal, and generalizable.

Knowledge about the ML model: We assume that the adversary can sample data from the training distribution of the ML model running on the base station and knows the model family (e.g., variational autoencoder) but not necessarily the architecture (e.g., fully-connected, convolutional), and the operations involved in the pre-processing pipeline. We believe that these assumptions are feasible for the real-world ML-based wireless systems because: (1) details about the model family are disclosed and accessible, (2) the attacker can access sample data simply by overhearing the client transmission, and measuring the corresponding wireless signals, (3) pre-processing pipelines (e.g., correcting for channel frequency offsets) are fairly standardized. We consider both white-box (access to model architecture and parameters) and black-box adversaries (no access to model architecture and parameters). Our results show that black-box adversaries are almost as effective as white-box ones.

Noise Budget: To avoid large-scale disruption to the wireless spectrum, we require that the L_∞ -norm of the noise vector crafted by the adversary is bounded by a small constant $\epsilon \in \mathbb{R}$. This prevents the noise being concentrated in individual sub-frequencies. We show the effect of the noise crafted with different values of ϵ on the model performance in Sec. 6.

Test Time Attack: We do not consider attacks that interfere with model training, the model is trained and fixed for our attacks. The adversary transmits a noise signal at test time.

3 System Overview

3.1 Target Systems

We consider two state-of-the-art ML-based wireless systems – one each for communication and sensing. In this paper, we focus solely on physical layer systems, while delegating investigation of attacks on higher layers to future work.

A. FIRE: Reciprocity for FDD MIMO systems – In order to achieve MIMO capabilities in 5G, base stations need to know the downlink wireless channel from their antennas to every client device. In FDD (Frequency Domain Duplexing)

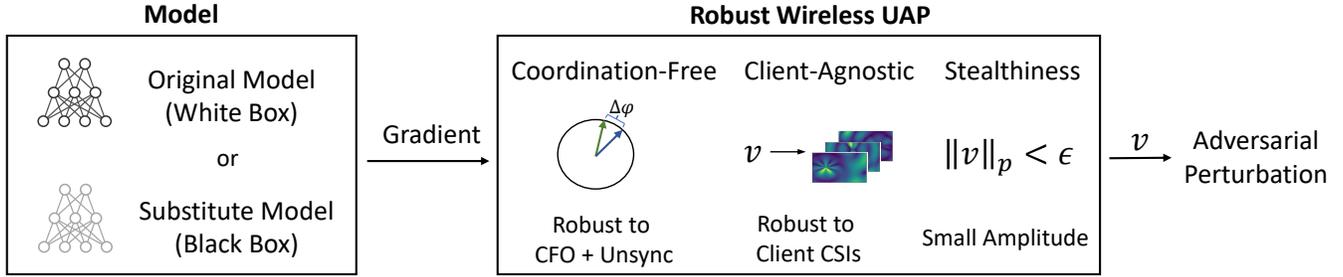

Figure 2: *RAFA Pipeline: RAFA works in both modes – white-box and black-box (with a substitute model). RAFA is robust to multiple wireless transformations such as clock offsets and channel transformations.*

systems, dominant in the United States, the client devices measure the wireless channel using extra preamble symbols transmitted by the base station and send it as feedback to the base station. However, this feedback is unsustainable and causes huge spectrum waste. Leveraging the intuition that both uplink and downlink channels are generated by the same underlying physical environment, recent work [55] proposed FIRE which uses an end-to-end ML based approach to predict the downlink channels without any feedback from the client. FIRE’s ML model uses a variant of the variational autoencoders (VAE). FIRE takes uplink channels measured at the base station as input and predicts the downlink channel. The accuracy of the downlink channel prediction determines the performance of multi-antenna techniques like MIMO, MU-MIMO. Our goal is to induce errors in this model and make it predict erroneous downlink channels. Errors in downlink channel estimates reduce the communication efficiency of multi-antenna systems (e.g., MIMO).

B. DLoc: Deep Learning based Wireless Localization – DLoc [6] is a deep learning based wireless localization algorithm that overcomes traditional limitations of RF-based localization approaches such as multipath and occlusions. DLoc acquires wireless channels from four fixed access points to the user device that it wants to localize. The wireless channels are then sent into an autoencoder neural network as input. The network predicts the user location in 2D-Cartesian coordinates. DLoc achieves state-of-the-art localization accuracy in indoor localization. Therefore, we choose DLoc as the representative sensing application. Our goal is to increase the localization error of DLoc, and hence, increase failures in location-based applications (such as robotic navigation).

3.2 Operation Overview

Both the systems defined above rely on the wireless channel estimated at the base station. Our goal is to alter this wireless channel by transmitting a perturbation vector during the channel estimation process. During the channel estimation process, the client transmits a preamble. The preamble is by the standard and is, therefore, public knowledge. The base station receives the preamble and uses it to identify the wireless channel. Due to the broadcast characteristic of the wireless

channel, we can pollute the channel estimation process by transmitting a noise signal. RAFA transmits the adversarial perturbation using our custom hardware platform. Thus, the signal received at the base station is a function of both the preamble transmitted by the client and the noise transmitted by our platform.

Fig. 2 shown an overview of RAFA’s operation. RAFA’s algorithm (discussed in Sec. 4) computes an adversarial perturbation which will be transmitted by the RAFA hardware, described in Sec. 5. The base station receives a sum of the signal transmitted by the client and the adversary, with channel and clock distortions. This combined signal then passes through the pre-processing steps and the ML-models defined above. We evaluate the performance of the ML-models with and without the adversarial perturbation in Sec. 6.

Notation: For the rest of this paper, we use capital-bold to denote matrices ($\mathbf{M}, \mathbf{N}, \dots$), small-bold to denote vectors ($\mathbf{u}, \mathbf{v}, \dots$), and mathematical font to denote functions or ML-models ($\mathcal{A}, \mathcal{L}, \dots$).

4 Radio Frequency Attack (RAFA)

In this section, we present our formulation of RAFA. We start with a brief background on adversarial attacks then discuss our attack formulation and modeling of wireless properties. Finally, we discuss our algorithmic implementation of RAFA.

4.1 Background on Adversarial Perturbations

For a given trained ML-model \mathcal{M} mapping inputs \mathbf{x}_i to outputs \mathbf{y}_i , an adversarial attack algorithm aims to find a perturbation vector, \mathbf{v}_i , whose magnitude is bounded by a small constant $\epsilon \in \mathbb{R}$ in some norm, such that the loss function $\mathcal{L}(\mathcal{M}(\mathbf{x}_i + \mathbf{v}_i), \mathbf{y}_i)$ is maximized, i.e., the output of the model for the perturbed input $\mathbf{x}_i + \mathbf{v}_i$ is far away from the target \mathbf{y}_i . Formally, the attack algorithm solves the following optimization problem:

$$\arg \max_{\mathbf{v}_i} \mathcal{L}(\mathcal{M}(\mathbf{x}_i + \mathbf{v}_i)) \text{ s.t. } \|\mathbf{v}_i\| < \epsilon \quad (1)$$

This attack problem formulation is well studied and many approaches [16, 27, 57] have been proposed to approximate this optimization problem. We utilize the state-of-the-art Projected Gradient Descent (PGD) [57] method. PGD iteratively

takes steps in the direction of the gradient while restricting the total perturbation to be within ϵ . The constraint on the norm of the noise vector ensures that the perturbed vector is not significantly different from the original input \mathbf{x}_i . We note that PGD requires access to the model parameters for computing gradients. One way to handle the black-box setting where the attacker does not have this access is to train a surrogate model on the training distribution of the original model (to which the attacker has access) and transfer the attacks computed on the surrogate model to the original model.

As discussed before, our model does not know the input to the model, therefore we rely on universal adversarial perturbations (UAPs) [58]. Instead of computing a different additive noise for each input, UAPs compute a single additive noise that is effective for all inputs, $X = \{\mathbf{x}_i\}_{i=1}^N$ in the training distribution of the ML model. One way to encode this is by maximizing the expected value of the loss.

$$\arg \max_{\mathbf{v}} \mathbb{E}_{\mathbf{x}_i \in X} \mathcal{L}(\mathcal{M}(\mathbf{x}_i + \mathbf{v}), \mathbf{y}_i) \text{ s.t. } \|\mathbf{v}\| < \epsilon \quad (2)$$

Typically, this optimization problem is approximated by iteratively computing input-aware gradient updates (obtained from the original or a surrogate model) to a perturbation vector over the training set [58]. We use a variant of the UAP, called robust UAP [83], which designs a universal adversarial perturbation such that it is robust to transformations (such as image rotations, and translations etc for vision models).

4.2 Our Attack Formulation

For simplicity, we start with a single input case, i.e., we wish to design a perturbation vector that is specific to wireless channel matrix, \mathbf{H} , observed at the base station. \mathbf{H} is a $N_{ant} \times N_{subc}$ matrix, where N_{ant} is the number of antennas on the base station and N_{subc} is the number of OFDM subcarriers. Our goal is to search for a perturbation vector, \mathbf{v} , of length N_{subc} that can disrupt a machine learning model \mathcal{M}_θ , where θ is the set of weights for the model. Specifically, we aim to optimize:

$$\arg \max_{\mathbf{v}} \mathbb{E}_{T_\tau \in \mathcal{T}_\tau} \mathcal{L}(\mathcal{M}_\theta(\mathcal{P}(\mathbf{H} + T_\tau(\mathbf{v}))), \mathbf{y}), \text{ s.t. } \|\mathbf{v}\|_p < \epsilon \quad (3)$$

where $\mathcal{L}(\cdot, \cdot)$ is a chosen loss function to measure the difference between the model's prediction and the ground truth, ϵ restricts the l_p norm of the perturbation vector. We also define two new abstractions in the equation above: $\mathcal{P}(\cdot)$ is the pre-processing pipeline used by the base station, before it is fed to the ML-model, \mathcal{M}_θ . Similarly, \mathcal{T}_τ represents the transformations T_τ the perturbation vector goes through before it arrives at the base station. These transformations are parameterized by τ . Next, we discuss how these abstractions model the real-world effects for wireless systems.

4.3 Modeling Pre-Processing

Both our target systems perform pre-processing on the estimated channel and feed the processed channel to the neural network for prediction. We model these pre-processing steps as \mathcal{P} . FIRE involves two pre-processing steps: it standardizes the Carrier Frequency Offset (CFO) and hardware detection delay across different measurements of the same channel. DLoc transforms the channel into the 2D-cartesian heatmap representing the probability of a signal originating from a given location (using signal-processing approaches like Fourier Transforms).

We need to represent \mathcal{P} as a differential operation, to enable optimization in Eqn. 3. In both pre-processing methods, there are non-differentiable functions such as $\text{argmax}()$, $\text{ceil}()$, $\text{sign}()$ that hinder gradient propagation for our optimization problem. Therefore, we use a differentiable approximation of these functions which is supplied by common ML frameworks such as Pytorch [61].

4.4 Modeling Lack of Synchronization

Since the adversary is not synchronized with the client or the base station, the noise transmitted by it experiences two kinds of distortions that must be modelled by $\mathcal{T}_\tau(\cdot)$ defined above:

Carrier Frequency Offset: The oscillators at the adversary and the base station are not synchronized. This leads to a CFO between them. This frequency offset, denoted by Δf , will continuously add a phase shift in the received signal $\hat{s}(t)$ with respect to the true signal $s(t)$ over time: $\hat{s}(t) = s(t)e^{j2\pi\Delta f t}$.

Since the client and attacker have different transmission chains, their CFO with respect to the base station is also different. Assume the CFO between the client and the base station is Δf_1 , the CFO between the attacker and the base station is Δf_2 , thus the CFO discrepancy will add phase offset $e^{j2\pi(\Delta f_1 - \Delta f_2)t}$ to the transmitted adversarial signal with respect to the client signal. This is a time-varying effect, implying that the sum of the client signal and the adversary signal changes over time. Since t , Δf_1 and Δf_2 are random, we can simplify this effect as a multiplication of $e^{j\phi}$, $\phi \in [0, 2\pi]$ to the adversary signal.

Unsynchronized Transmissions: Ideally, the adversary should start transmitting the perturbation signal at the same time when the client starts transmitting the preamble so that the perturbation can be superimposed at the base station precisely. In the real-world setting, this is hard to achieve since the attacker cannot coordinate with the client preemptively or synchronize its clocks. There are two possible approaches to solve this problem: (a) A part of the signal preamble is used for packet detection before the channel estimation phase. One can design an attacker that detects the start of the packet, and starts transmitting a perturbation in response. This can achieve coarse-grained synchronization, but requires fast processing (e.g., FPGAs). (b) An alternative approach is to let the

adversary transmit multiple copies of the perturbation signal, and deal with the resulting large mis-alignment.

For simplicity, we go with the latter approach, which requires much lower overhead. This causes a random time delay Δt between the benign client signal and the adversary signal in the time domain. Due to the properties of OFDM, this is equal to a phase offset $e^{-j2\pi\Delta t f_i}$, where f_i is the frequency of the i th OFDM subcarrier. Note that, this is similar to timing misalignment in typical OFDM receivers [24, 77], wherein a portion of the OFDM symbol is repeated (in the cyclic prefix). Any sample misalignment adds a phase that is linearly dependent on the amount of misalignment and the frequency of the subcarrier. We model this phase shift in $\mathcal{T}_\tau(\cdot)$.

4.5 Modeling Channel Transformations on the Perturbation Vector

Like any other wireless signal, the perturbation vector transmitted by the adversary goes through the wireless channel. Let us say that the wireless channel matrix for the adversary is, \mathbf{H}_a , with dimensions $N_{ant} \times N_{subc}$ (same dimensions as \mathbf{H} for the client). Then, if the adversary transmits the perturbation vector, \mathbf{v} , it is received at the base station as $\mathbf{H}_a \mathbf{v} + \mathbf{g}$, where \mathbf{g} is additive white Gaussian noise.

Each element in \mathbf{H}_a has an amplitude and a phase. Therefore, the final outcome of the added perturbation can be unbounded, if we do not know \mathbf{H}_a . However, \mathbf{H}_a can only be measured at the base station, that too in the absence of the client signal. Clearly, measurement by this method is not possible for the attacker because it does not have any coordination with the client or the base station. Therefore, it is pertinent to find an alternative method to measure \mathbf{H}_a .

To estimate \mathbf{H}_a , we leverage channel reciprocity. Channel reciprocity is a fundamental physical principle that states that wireless signals take the same path in either direction between any two devices. Therefore, the wireless channel from the adversary to the base station is equal to the wireless channel from the base station to the adversary (modulo some hardware differences). RAFA listens to the wireless medium and captures signals transmitted by the base station (either periodic beacons or communication with legitimate clients). This allows the adversary to estimate an approximation to \mathbf{H}_a . We discuss in Sec. 5 how this step is implemented in practice.

4.6 Generating Practical Adversarial Attacks

The above factors will jointly modify the adversarial perturbation signal v^i transmitted in the i th subcarrier by the following transformation function:

$$\mathcal{T}_{\phi, \Delta t, \mathbf{h}_a, \mathbf{g}_i}(v^i) = v^i e^{j\phi} e^{-j2\pi f_i \Delta t} \mathbf{h}_a^i + \mathbf{g}_i \quad (4)$$

Note that the CFO term ϕ is invariant to the frequency, so it's the same across all the subcarriers.

Algorithm 1: Robust Wireless UAP (RW-UAP)

Input : Dataset $\mathbf{x}_i, \mathbf{y}_i \in \mathcal{H}$, network model $\mathcal{M}_\theta, l_\infty$ norm threshold ϵ , desired network loss value δ , attacker channel \mathbf{H}_a , number of epochs ep

Output : Robust universal perturbation \mathbf{v}_g for dataset X

- 1 Initialize $\mathbf{v}_g \leftarrow \text{Uniform}(-\epsilon, \epsilon)$
- 2 **for** $n \leftarrow 0$ **to** $ep - 1$ **do**
- 3 **for each batch** $\mathbf{B}_i \subset \mathcal{H}$ **do**
- 4 $\Delta \mathbf{v}_i \leftarrow \text{RW-PGD}(\mathbf{B}_i, \mathbf{v}_g, \mathcal{M}_\theta, \epsilon, \delta, \mathbf{H}_a)$
- 5 $\mathbf{v}_g \leftarrow (\mathbf{v}_g + \Delta \mathbf{v}_i). \text{clamp}(-\epsilon, \epsilon)$
- 6 **end for**
- 7 **end for**

Now that we have characterized both \mathcal{P} and \mathcal{T}_τ , we try to find a perturbation that is robust to these wireless factors. We build on the algorithm presented in [83] which works in the vision domain to work with \mathcal{P} and \mathcal{T}_τ , Algorithm 1 shows the pseudocode for generating Robust Universal Adversarial Perturbations in the wireless setting. It contains two loops to iterate multiple times on the training dataset and on every batch of data points respectively. We first initialize the perturbation vector \mathbf{v}_g randomly. Because of random initialization, we can generate several different UAPs by running the algorithm multiple times. The algorithm iteratively updates the initial perturbation with the goal of being adversarial for all elements in the training set. Given a set of training data points \mathcal{H} sampled from the training distribution of the ML model, the algorithm iterates over batches $\mathbf{B} \subset \mathcal{H}$. During each epoch, it iterates over every batch, \mathbf{B}_i , finding an adversarial direction vector $\Delta \mathbf{v}_i$ that is robust to wireless factors for that batch using the Robust Wireless PGD (RW-PGD) algorithm shown in Algorithm 2. $\Delta \mathbf{v}_i$ is then added to \mathbf{v}_g and the result is projected back so that the updated \mathbf{v}_g does not violate the constraint on its norm.

Next, we describe the RW-PGD algorithm shown in Algorithm 2. It contains two loops to iterate multiple times on the input data points and on different transformations respectively. The algorithm takes a batch of inputs, \mathbf{B} . It then first randomly samples N tuples of wireless factors including CFO, resynchronization, and gaussian noise as described in the previous section. Increasing the value of N increases both the robustness of the output perturbation and the runtime of the RW-PGD algorithm. We chose a value of N that balances the tradeoff between cost and robustness. At each iteration, we transform our current perturbation by each of the N transformations. We then compute the mean loss over all data points in the batch added to each of our N transformed perturbations and conduct gradient ascent on it aiming to increase the mean loss. Unlike traditional PGD [57], we compute a single vector per batch of data points. We further found that using the raw gradient

Algorithm 2: Robust Wireless PGD (RW-PGD)

Input : Batch of data points $\mathbf{x}_i, \mathbf{y}_i \in \mathbf{B}$, current perturbation \mathbf{v}_g , network model \mathcal{M}_θ , l_∞ norm threshold ϵ , desired network loss value δ , attacker channel \mathbf{H}_a , maximum number of epochs ep , learning rate α , number of transformations N

Output : Robust perturbation \mathbf{v}

```
1 Initialize  $\mathbf{v} \leftarrow 0$ 
2 Sample  $N$  sets of wireless factors,
    $\tau_j \leftarrow \{\phi_j, \Delta t_j, g_j, \mathbf{H}_a\}$ , uniformly at random

```

to update was more effective than the $sign(\cdot)$ of the gradient in our case. Note that, \mathbf{H}_a , i.e., the wireless channel between the attacker and the base station, is fixed and obtained by the attacker without sending any preambles.

\mathbf{H}_a is continuously sampled by the attacker, so we need to recompute the attack on the fly. This is inevitable as different \mathbf{H}_a have essentially unbounded effect on the perturbation. Thus, we further speed up our algorithm by computing multiple UAPs at the same time. We have chosen algorithm parameters that maximize the speed for our required performance.

By using the above algorithm, we are able to find robust universal perturbations that work effectively against a variety of wireless factors. In order to truly expose the vulnerabilities of wireless system models, we show in a real-world hardware setting that our attack is effective.

5 Hardware Design

After identifying the adversarial noise to inject, we ask if this noise is feasible in practice, i.e., can we design hardware that can introduce such noise? In this section, we design a generic physical hardware platform as an attacker to inject such perturbation into wireless channels. We believe that this step is novel and unique to the wireless domain because no past work has demonstrated hardware-driven attacks on wireless systems. We describe the design principles of RAFA's hardware platform and its implementation.

5.1 Design Principle

We design our platform with following design principles:

No Synchronization Needed: We design RAFA's platform to have minimum assumptions, no requirement to access the client and the base station. Our attack belongs to the realm of pilot contamination but previous literatures [28, 36, 37] all assume that the attacker know the exact timing to synchronize with the client so that it can transmit the noise signal at the same time when client transmits the preamble. In our design, we get rid of this assumption and instead, transmit the attacker's perturbation in an unsynchronized manner. According to Sec. 6.2, our perturbation is robust to such unsynchronization on the sample level, as a result, we don't need the timing of the client to conduct effective attack.

Leveraging Reciprocity: Recall that we leverage reciprocity to estimate \mathbf{H}_a , the channel from the attacker to the base station. However, reciprocity requires correcting for the hardware effects caused by each respective transmitter. These effects comprise of phase and signal strength variations. The phase variations are captured in the transformations caused due to CFO and timing offsets for our perturbations. Therefore, in our attack, we just need to calibrate for the difference in transmit power between the attacker and the base station.

Specifically, the transmit power is different at the attacker and the base station (the base station transmits a much higher power). Although transmit powers don't affect the applications enabled by reciprocity such as beamforming, signal nulling, etc. [41, 47, 53], we need to know the true channel value including the power in order to control the received perturbation power at the base station, as shown in Algorithm 2. The adversary can obtain the transmit power of the base station using public documents like FCC filings. We can estimate the transmit power of the adversary hardware using specification sheets. Then, the adversary computes the difference between the two and uses it to correct for the transmit power difference.

Single Antenna: We design RAFA's hardware platform with a single antenna. This limits our hardware complexity and making it easy to implement (single transmit-receive chain). One class of adversarial attacks on traditional systems [42, 44] is only effective when the attacker has same or more number of antennas as the base station. In our case, we show that even with one antenna, it is possible to mount reasonable attacks.

However, this choice limits the capability of the attack. While the input channel matrix, \mathbf{H} , has dimension $N_{ant} \times N_{subc}$, the perturbation is a vector \mathbf{v} with length N_{subc} . Inherently, this implies that the perturbation has less control over the final output. Mathematically, \mathbf{v} operates in a 1-dimensional subspace of a N_{ant} dimensional antenna space. The larger the N_{ant} , the less powerful our adversary. We expect multi-antenna adversaries to be more effective, but we chose single antenna adversaries for their low complexity.

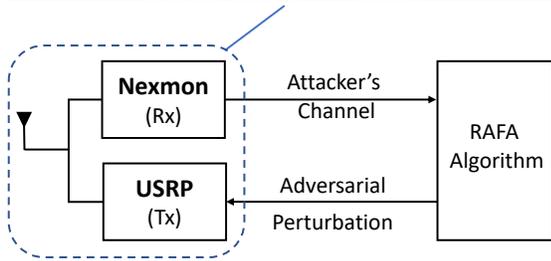

Figure 3: (Top) The top-down view of the attacker hardware platform. (Bottom) The platform consists of a Nexmon-receiver and a USRP transmitter – both share a single antenna connected through a splitter.

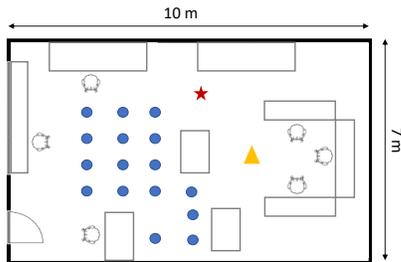

Figure 4: Layout of the experimental environment: We conduct our experiments in a lab setup measuring 10m by 7m. (Blue: Client Locations, Yellow: Base station, Red: Attacker)

5.2 System Implementation

We use the Nexmon [29] tool to measure wireless channels. We build a 4-antenna base station using a commercial Asus RT-AC86U router with bcm4366c0 WIFI Chip. This router reports channel state information (CSI) and signal strength (RSSI) for each received packet. We configure a client to connect to this router and send Wi-Fi packets. The router periodically sends broadcast beacons, as is standard for the Wi-Fi protocol and is set to work in the 5GHz frequency band.

For the attacker, we use a Nexmon receiver and a USRP (X310 [21], a software-defined radio) as the transmitter. The Nexmon receiver and the USRP transmitter share a single antenna through a splitter. The Nexmon receiver measures the wireless channel from the base station to itself and feeds it into the RAFA system. RAFA applies the reciprocity correction to estimate, \mathbf{H}_a , and computes an adversarial perturbation, \mathbf{v} , and transmits it using the USRP software-defined radio. The setup is shown in Fig. 3

We implement the client using a USRP software-defined radio (X310) equipped with one antenna and we configure it to transmit the 802.11ac packets generated from MATLAB wireless toolbox. This signal is received by the base station

and used to measure the wireless channels as the input to the neural networks in the wireless applications mentioned in Section 3.1. Note that, the client and attacker do not have any time or frequency synchronization between them.

During our experiment, we deploy RAFA on a local machine with RTX3070 GPU, a low-end GPU. Our implementation is written in PyTorch. For attacking FIRE, it takes 13 seconds on average to generate a single perturbation. We believe that further speedup can be achieved using more advanced computing resources.

6 Results

In this section, we show the effectiveness of the RAFA attack against FIRE and DLoc. We further show that our attack can be performed in a black-box setting. Finally, we show that adversarial training can be used in order to harden our models and defend against these attacks.

Baselines: We compare RAFA against two baselines: (a) Gaussian noise, and (b) vanilla UAP. Gaussian noise transmits randomly sampled noise into the air. Vanilla UAP designs and injects perturbations attacks that do not include robustness to wireless transformations implemented by RAFA. For fairness, we evaluate each method with the same budget ϵ on the magnitude of the perturbation vector measured in L_∞ -norm.

6.1 Wireless Systems Re-implementation

We do a best-effort re-implementation of our target systems: FIRE [55] and DLoc [6] using details provided in the respective papers and by email exchanges with the authors.

We re-implement the Variational Autoencoder for FIRE. We adopt 7 linear layers in both the encoder and decoder networks, which is 3 layers more than the original design to optimize FIRE’s performance. We train FIRE using dataset collected in our environment. We collect 10000 data points by moving the antenna randomly in a lab space shown in Fig. 4. The size of the lab is 10m by 7m, and is composed of many reflectors (like metal cupboards, white-boards, etc.) and obstacles. We split the dataset in the ratio of 8:2 for training and testing, and the training takes roughly 20 minutes. Note that the training only needs to be done once before the attack is initiated. Our trained model achieves a channel SNR of 17.8dB on the test dataset and confirm the SNR of 15.8dB on validation dataset, which is consistent with the performance of FIRE reported in [55].

Training DLoc requires dataset collected using a robot (which performs joint mapping and localization). We do not have access to the robot, thus cannot recreate the original experiments. However, the datasets and code for DLoc are in the public domain. Therefore, we train DLoc model using the datasets collected by its authors with the name ‘jacobs_Jul28’ and keep the original neural network architecture and training setting. The dataset contains channel estimation matrices collected from 4 routers and each router has 4 antennas (so 16

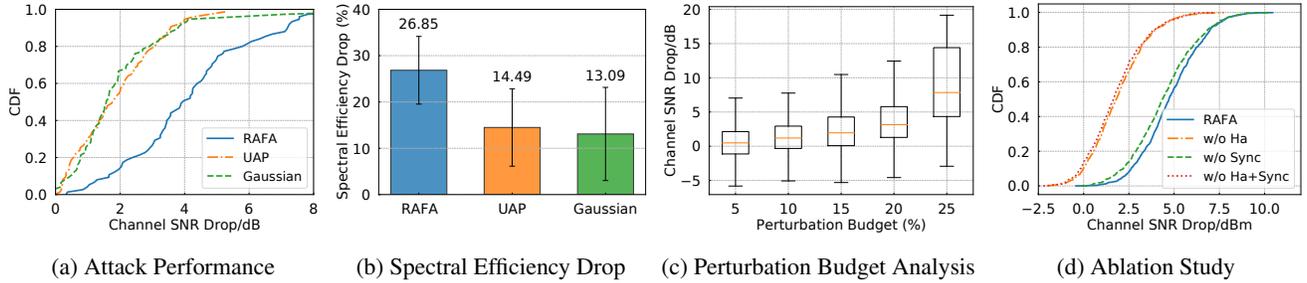

Figure 5: Attacking FIRE: (a) RAFA causes a median drop of 4.06 dB on FIRE’s channel prediction accuracy, over 2X better than baselines. (b) This corresponds to a 26.85% drop in spectral efficiency. (c) Increasing the perturbation budget increases the effectiveness of the RAFA adversary. (d) Modelling channel reciprocity is the dominant reason for RAFA’s improved performance.

antennas in total), and the training takes roughly 40 minutes. We achieve the localization accuracy of 1.04m on the test dataset which is randomly split with the ratio of 3:7 to the training dataset. This is consistent with the results reported by the authors in [6]. To create the adversarial perturbation for RAFA, we sample channels from the same distribution as the data used for training.

6.2 Adversarial Attacks against FIRE

To mimic a real-world setup, we deploy the base station at a fixed location, while the client moves across the 16 positions shown in Fig. 4. The attacker is also deployed at a fixed location shown in the figure. The attacker and the client can be in line-of-sight or non-line-of-sight.

Attack Effectiveness: We first compare RAFA with other two baselines in the real world attack scenario. FIRE predicts downlink channels, given uplink channels. Our goal is to reduce the SNR of the predicted channels, so as to disrupt multi-antenna communication between the base station and the client. To perform this experiment, we perform five attack rounds for every method at each client location. In each round, the adversary transmits the RAFA adversarial perturbation for 10 seconds. Then, we transmit the UAP adversarial perturbation and Gaussian perturbation each for 10 seconds at the same perturbation budget as RAFA which is set to be maximum of 20%. The budget is the ratio of the maximum value that’s allowed for any element of the perturbation vector compared to the average amplitude of the benign channel estimates and is ϵ in Algorithm 1. Overall, we get 8000 channel estimates at each client location for every baseline. We set the learning rate of RW-UAP to start from 10 and decay by 0.6 for every epoch. We set the number of total epochs in RW-UAP to be 3 and we only use a random 10% of the training dataset for each epochs to accelerate the training which leads to a running time of roughly 30 seconds with the setup in Sec. 5. We set the RW-PGD iterations to be 10, and 10 transformations in each iterations are used to get the robust perturbations. We use the same parameters (e.g., number of epochs, % of training dataset) for training Vanilla UAP.

We show the effect of different attack methods on FIRE prediction in Fig. 5a. Each of these methods causes the SNR

of the predicted channel to drop. We plot the CDF of this drop in channel SNR across all of our attacks, e.g., a CDF value of 0.3 with a corresponding drop of X dB indicates that 30% of the inputs had a drop of X dB or less in performance. It shows that when being attacked by RAFA, the SNR of the channel predicted by FIRE drops by 4.06dB on average (7.15 dB drop on the 90-th percentile). Traditional UAP attacks and Gaussian baseline are not as effective. RAFA outperforms the baselines by $2.21\times$ and $2.14\times$ respectively on this metric. Our benefits over Gaussian noise stem from the directed nature of our attack, i.e., we specifically target the ML model and find its vulnerability. On the other hand, the UAP-based model finds perturbations that are directed at the ML model, but undergo transformations in-air which render it ineffective when implemented in the real world. This result highlights that: (a) FIRE is vulnerable to practical adversarial attacks, even when the adversary uses low-complexity hardware, and (b) modelling the wireless transformations on the adversarial noise (as done in RAFA) are essential for practical adversarial attacks.

We also show how these adversarial attacks affect the application quality in the real world. We plot the spectral efficiency (bits per Hz) results with the budget of 20% in Fig. 5b. Spectral efficiency is the data rate that can be transmitted over a given bandwidth and can be computed through channel SNR [62]. With small amount of budget, RAFA is able to shrink the user data rate by 26.85% which is two times as effective as the UAP attack. This will affect the user experience severely, especially in latency critical applications such as online meetings.

Finally, we note that, we focus on reducing SNR for FIRE, because FIRE is trained to optimize for SNR. SNR is also a key metric for any communication techniques. Independent mechanisms like coding and CRC checks do not prevent against attacks like RAFA. For example, if a coding scheme is chosen to optimize for SNR X dB, it won’t be sufficient if the actual SNR is X-5 dB (when under attack).

Effect of Adversarial Budget: In the same setup as above, we study the effect of budget on the effectiveness of the attack. We experiment with 5 different budget parameters and plot the SNR drop for these parameters in Fig. 5c. As expected, as

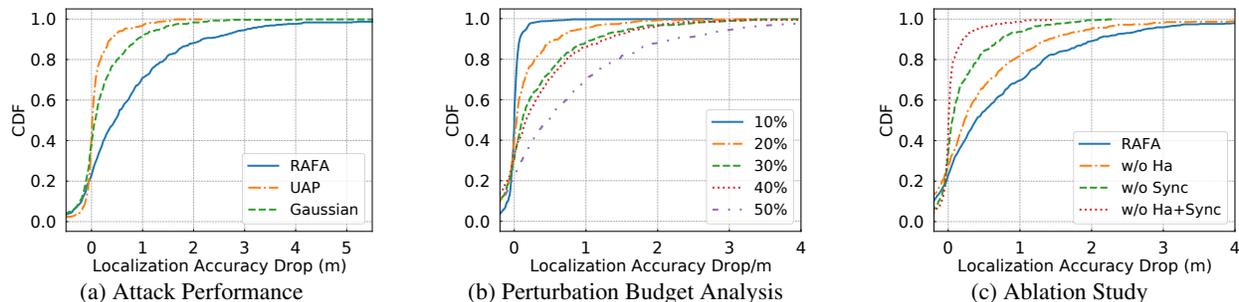

Figure 6: Attacking DLoc: (a) DLoc’s original localization error (median) is 1.04 m. RAFA increases this by 0.71m. (b) The attack performance improves with increasing perturbation budget. (c) Synchronization robustness is the most important factor in attacks on DLoc.

Budget (%)	10	20	30	40	50
Power Ratio-FIRE (%)	1.5	4.7	8.6	14.7	12.0
Power Ratio-DLoc (%)	1.3	8.6	20.2	34.6	51.8

Table 2: Power Ratio vs Budget

the budget parameter increases, RAFA’s attack becomes more effective. With the budget parameter set to 25%, the SNR of the predicted channel drops by 7.4 dB on average, with lower drops at lower budget values (e.g., 2.14 dB at 15%).

Note that, the budget defines what’s the maximum absolute value of any perturbation subcarrier, and not the average value. Therefore, the average power of the perturbation is expected to be lower than the budget. We compare the average power of the adversarial signal to the average power of the user signal at the base station. We show this ratio as a function of the budget parameter in Table. 2. As shown, for 20% budget, RAFA’s perturbations utilize <5% power on average compared to the user signal. Even with a 50% budget parameter, this value is only 12%. This shows that RAFA’s attacks are surreptitious. Note that, counter-intuitively, the power ratio at 50% is lower than 40% budget parameters. This is possible because bigger budget parameters allow some subcarriers to have larger peaks, and enable more flexibility for RAFA to choose "peakier" more effective perturbation vectors.

Ablation Study: Next, we analyze the contribution of different components of RAFA. We conduct an ablation study on attacking FIRE using the same dataset that we used for real-world attack experiment. We compare the original RAFA effectiveness with the following cases: removing the attacker channel (\mathbf{H}_a), removing the synchronization robustness term (Sync), and removing both of them. The results are shown in Fig. 5d. For FIRE application, removing the knowledge of the attacker’s channel has the most significant impact on the effectiveness of the attack, the channel SNR drop decreases by 59.5% compared to the optimal performance achieved by RAFA. This is because our RW-UAP algorithm derives an adversarial perturbation specifically for a given attacker’s channel. When removing the synchronization robustness term, the SNR drop decreases by 7.5%. We believe that this effect is milder because FIRE’s design includes some pre-processing to normalize CFO, hardware detection delays, etc.

6.3 Adversarial Attacks against DLoc

Next, we study the effect of RAFA on DLoc. DLoc conducts user localization using the channels estimated from 4 routers with a total of 16 antennas as the input to a neural network, consisting of 12 Resnet blocks [32]. Compared to FIRE, which uses a single router, four antennas, and a simpler network structure, the attack scenario is harder.

Experiment Setup: As noted before, getting ground truth location estimates for DLoc in new environments requires a robot for data collection. We perform our attack in a trace-driven simulation using the data collected by the authors as we do not have access to their robot. We randomly sample, \mathbf{H}_a , the attacker’s channel to each access point from the set of channels in the original DLoc dataset. Then, RAFA’s perturbation undergoes the attacker channel in addition to random time and frequency offsets. We repeat this experiment with different values of \mathbf{H}_a to remove any bias. Our attacker is still a single antenna attack. We limit to a set of 128 datapoints, out of 8008, randomly sampled from the original training set and use only 4 transformations during RW-PGD. We train the perturbation for 3 epochs. The learning rate is set to 0.006 and decays by 0.99 per iteration. We evaluate on randomly sampled ~ 500 datapoints from the test set and average the performance of the attack over 8 randomly sampled transformations to generate different wireless transmissions. The same parameters are used for training Vanilla UAP.

Attack Effectiveness: The adversary aim is to reduce DLoc’s localization accuracy. We plot the accuracy degradation caused by RAFA, traditional UAP, and Gaussian noise in Fig. 6a. The attacker has a single antenna simultaneously attacking 16 infrastructure antennas, so we set a budget of 50%. The original DLoc median localization accuracy is 1.04 meters, RAFA is able to increase this error by 0.71 meters. Furthermore, RAFA increases the error by more than 1 meter in 30 % of cases. This is significant as some safety-critical applications such as autonomous driving [66,67] are sensitive to even 0.1 meters of localization accuracy drop. Our two baselines, UAP and Gaussian are only able to drop the accuracy by 0.02 m, and 0.08 m respectively. Similar to our discussion before, this shows the benefit of our directed, robust attack.

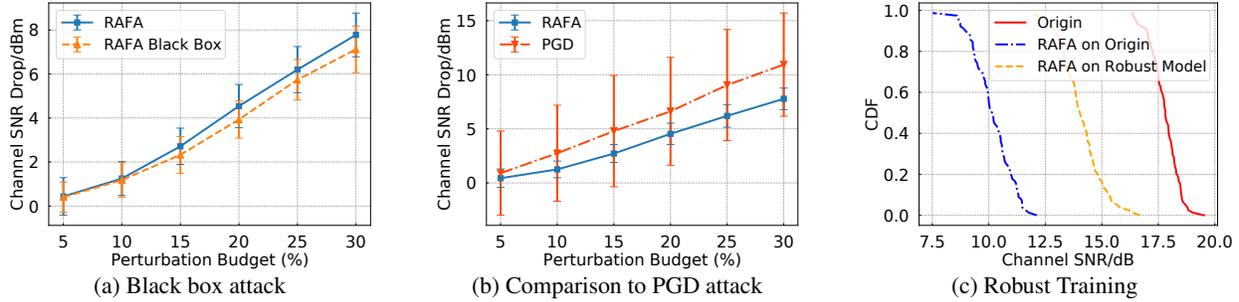

Figure 7: *Other Attack Models and Defense on FIRE: (a) A black-box attack, where RAFA does not know about the model running on the base station is feasible and has similar attack performance to the white-box attack. (b) An unrealistic attack, where adversary has access to model inputs, performs better than RAFA, but is not practically feasible. (c) Our adversarial training approach can improve model robustness on FIRE.*

Next, we study how choosing different budgets will affect RAFA’s potency on DLoc. We increase the budget from 10% to 50% and plot the DLoc accuracy on Fig. 6b. We also calculated the power ratio of the perturbation generated on DLoc in the second row of the Table. 2. As expected, as the perturbation budget increases, the power used by RAFA increases. Similarly, the attack efficacy increases. We highlight that the power used by RAFA for attacking DLoc is higher than that for FIRE. This is because we have a single-antenna attacker attacking a sixteen-antenna system spread out in space (one-dimensional control in a 16-dimensional space). RAFA adapts to this large space by increasing the power of its transmitted noise, achieving an error increase of 0.71 m at 50% budget.

Ablation Study on attacking DLoc: We conduct an ablation study on DLoc to understand the contribution of RAFA’s different components, using the same 50% budget from above. Similar to ablation study settings on FIRE, we compare the original RAFA effectiveness with the cases when removing Ha, removing Sync and removing both, and the results are shown in Fig. 6c. Different from FIRE’s ablation study results, it shows that removing Sync term will bring down the effectiveness the most, the median localization accuracy drop decreases by 73.4% compared to the original RAFA. This is because DLoc localizes the user by receiving the signal at four routers instead of one in FIRE case. Thus misalignment becomes much more significant when the attack signal reaches multiple routers and modeling this effect is necessary. Compared to the ablation study on FIRE, we confirm that different components in RAFA modeling have different impact on different applications. So, to expose vulnerabilities on generic wireless algorithms, we should leverage the end-to-end model with all the components of RAFA.

6.4 Comparison to Input-Aware Attacks

RAFA is an adversarial attack that aims to work in the real-world. Therefore, it does not assume access to the input. What is the impact of this assumption on RAFA’s performance? What if we give RAFA access to the input. We evaluate this

hypothetical case next. We compare RAFA’s adversarial performance with input-aware attack, e.g, PGD. Since this attack is not realistic, we evaluate this in a simulator. We plot the result in Fig. 7b. Note that we implement the PGD by using Algorithm. 2, for each data point in the test dataset, we get a PGD perturbation that is robust to wireless properties, but this perturbation is not universal across data point.

The results show that an input-aware attack is more effective. At 30% budget on FIRE, the input-aware attack achieves an SNR drop of 10.97 dB, compared to the 7.77 dB drop of RAFA. This result highlights that the properties of the wireless medium (e.g., the adversary not knowing the channel from client to base station) provide some natural protection against adversarial attacks. However, even with this protection, real-world adversarial attacks are possible and effective.

6.5 Black Box RAFA

In this section, we evaluate RAFA under a preliminary black box setting to show its feasibility, where the attacker knows the model family but not the specific architecture or weights. In order to conduct the black box attack, the attacker can train a substitute model on a dataset with a similar distribution to attack. The attacker can later use the obtained perturbation from the substitute model to attack the true model.

In order to conduct the black box attack, we use a substitute model with a different architecture (4 less layers, different number of neurons, and batchnorm). Using the same pipeline for RAFA we attack on a different dataset collected in the same lab. We then use that perturbation to attack the original model in a trace-driven simulation. Fig. 7a compares the performance of RAFA in white box and black box scenarios under different perturbation budgets. As shown, the performance of the black-box adversary closely matches that of the white-box adversary, with only a minor drop. At 25% perturbation budget, the black-box adversary causes a 5.7dB of channel SNR drop for FIRE which is only 0.5dB less than the white box setting. This result shows that while access to the model helps, we can still get good performance without it.

6.6 Defense: Adversarial Training

RAFA's attacks demonstrate effectiveness across different systems and settings. To initiate a discussion on potential defense strategies, we show that FIRE can enhance its robustness to adversarial attacks with robust training. Adversarial training involves adding adversarial examples while training [57]. In our case, since we are defending against a UAP based attack, we use our RW -PGD algorithm in order to compute batch-wise perturbations. We choose the RW -PGD algorithm since it is similar but stronger than RW -UAP as it assumes that the attacker has access to the inputs processed by the ML model.

During training, we compute 5 random attacks on each batch with a budget of 10%. We then apply each attack to the entire batch before learning. While this method adds overhead during training, it significantly reduces the ability of RAFA to find successful attacks. With our initial study and parameters we find that training time goes from ~ 5 mins to ~ 125 mins; however, we expect that further tuning could significantly reduce this training time. Fig. 7c shows the effect of RAFA at the budget of 30% on FIRE. When applying RAFA on the original model, the average channel SNR provided by FIRE drops from 17.79dB to 10.16dB. Promisingly, the robust model maintains an SNR of 14.09dB, which is 38.6% higher than original model improving the model robustness by 57%. This result highlights the potential for building robust training approaches. We delegate a detailed study of such methods to future work.

7 Related Work

Adversarial Attacks in Other Domains: Adversarial attacks have been widely studied for measuring model robustness in computer vision for tasks including object detection [80, 82], image classification [19, 20, 33], and semantic segmentation [4, 12]. Beyond vision, adversarial attacks exist for natural language processing [14, 88, 91], reinforcement learning [25, 52, 63], and graph classification [92, 96]. While most of these works only expose theoretical vulnerabilities as the generated attacks are not physically realizable, recent studies show that real-world adversarial attacks are possible. The works of [5, 22, 46, 49, 56, 71, 82] generate real-world adversarial examples for the models in the vision domain. Compared to the wireless setting, there is less signal distortion and hardware imperfections in the vision domain. The authors in [50] attack voice assistant systems such as Alexa, but their attack generates loud guitar music which is easy to detect and defend against. [83] proposes the basic structure of robust adversarial attacks in vision domain, we extend this into wireless domain by modeling the effect of wireless transformations and further test them out in real-world rather than purely simulation. To the best of our knowledge, we are the first to consider real-world attacks in wireless systems.

ML-based Wireless Systems: Machine learning has been extensively used in different tasks in wireless systems in-

cluding both sensing and communication. In sensing, ML has been leveraged for human motion sensing [3, 95], sleep monitoring [30, 51, 89], emotion detection [94], indoor positioning [1, 6, 15, 75], etc. In communication, ML is also widely used in MIMO systems [31, 45, 60], modulation and signal classification [54, 78], resource allocation and management, and MAC protocol design [13, 35, 86]. In this paper, we limit our analysis to physical layer ML-models.

Adversarial Attacks against Wireless Systems: Recent work has shown theoretical attacks [2, 7, 9, 17, 18, 23, 43, 68–70] on ML-based wireless systems. However, none of these are feasible in the real world as they consider unrealistic threat models such as no distortion exists during transmission or the availability of coordination between the base station and the attacker. The closest work to ours is [8], where the authors use generative models [26] to obtain universal perturbations. They demonstrate the attack on simulated data and are not feasible in the real-world because the attack model does not account for: (a) the effect of the wireless channel on adversarial noise, (b) the lack of time-synchronization between a client's and adversary's transmissions. Our work is the first to demonstrate real-world hardware-implemented adversarial attacks by explicitly incorporating robustness to real-world channel transformations and un-synchronized transmissions.

8 Concluding Discussion

We present RAFA, the first real-world adversarial attack design on machine learning-based wireless systems. Our results show that adversarial attacks are feasible in the real-world, in spite of channel distortions, hardware noise, and black-box assumptions. We conclude with some directions that future work may consider for expanding on our paper:

- **More Capable Adversary:** We consider a single antenna adversary and show its feasibility in conducting real world attack. A multi-antenna adversary has more degrees of freedom and can cause more damage. It also opens up new questions on synchronization between different antennas, the tradeoffs between antenna count, efficiency, etc.
- **Higher Layer Attacks:** We focus on physical layer ML systems. We envision future work will consider attacks at higher layers (e.g., MAC), which can explore new modalities such as frame injection attacks.
- **Robust Training and Other Defenses:** How do we train models that are not prone to adversarial attacks? We show it is feasible to defend, but can this be made faster and more robust? Adversarial training provides empirical robustness, can we provide formal guarantees on when a model does or does not work? Finally, can we design cross-layer defense mechanisms that are robust to attacks in the physical layer?
