Steering packets at the network layer (e.g., IP datagrams) comes with its own challenges, however. First, we do not have any application-level insight into the flow: we do not necessarily know how packet-level acceleration affects application-level acceleration, so we will need a careful steering heuristic. Second, even if we identify the packets to accelerate, sending packets within a flow across two different channels might result in the packets arriving out-of-order, confusing TCP. To address this issue, we will introduce a small *reordering buffer (ROB)* at the endpoints. The following subsections discuss these components of the design.

3.3 Packet Steering Intuition

Define a “message” as a sequence of one or more packets such that the receiving endpoint can take some useful action after receiving the full message. For example, an individual SYN or ACK is a message (because the transport layer can act on it), and an HTTP request or a full response spread across multiple packets is a message (because the application may be able to process the request, display an object to the user, etc.). In contrast, an individual data packet belonging to a large HTTP request/response is not a message on its own and would not be worth accelerating individually since we

¹If URLLC is assigned a capacity of 2 Mbps (≈ 250 bytes per ms) and its RTT is ≈ 15 ms less than that of eMBB, any object of size larger than 3.75 KB are likely to be delivered faster on eMBB.

need to accelerate the whole sequence of packets to finish the message.

Ideally, we would like to accelerate the delivery of messages, especially those that are most valuable to accelerate, within the bandwidth constraints of the LLC. This suggests a *cost-rewards calculation* weighing the benefit of accelerating a message against the cost of utilizing the meager bandwidth of the LLC which might be better spent on other messages.

A direct, exact cost-rewards calculation is infeasible since DChannel running at the network layer lacks full knowledge of message boundaries (in the application's data stream), as well as the relative value of messages to the receiver's transport layer or application. This leads us to begin with a permissive assumption: any packet *might* be a message boundary and we will optimistically consider accelerating it. Nevertheless, even operating transparently at the network layer, DChannel does have certain information about rewards and costs that will help it distinguish among packets.

First, the benefit of steering a packet to the LLC depends on how much its arrival time would improve, if at all, compared to using the HBC. This depends on packet size, current output queue lengths for both channels (which are locally observable), and latency of both channels (which can be estimated). In addition, the vast majority of applications utilize TCP or other transport that delivers messages in order.² This means that for a message inside packet P_i , *delivery of the message to the application* (as opposed to the delivery of P_i to the receiving host) will depend not only on the arrival time of P_i , but also on the arrival time of packets P_0, \dots, P_{i-1} (which can also be estimated). For example, suppose P_{i-1} was sent over the HBC, and P_i is ready to send immediately after. If P_i is also sent over HBC, the pair will arrive at about the same time. If P_i is sent over LLC, it will very likely arrive much sooner, but will end up waiting for P_{i-1} before it can be delivered to the application, meaning sending over the LLC is likely not useful in this case.

Second, the cost of utilizing LLC resources will depend on the packet length and how much the LLC will be in demand for other messages in the near future. The latter is not perfectly known, but current or recent outgoing LLC queue depths provide some signal.

The net effect of the above considerations is that packets should tend to get steered to the LLC when they are smaller, and when they are more isolated in time as individual packets or members of short packet sequences. This corresponds well with the intuition of prioritizing acceleration of control messages or small application-level messages. We now proceed to describe how we realize this cost-rewards approach.

3.4 Rewards and Cost

Problem statement. The packet steering algorithm is presented with a sequence of packets and needs to decide if each

²Some don't, of course, but our goal in this work is to develop generic packet steering, leaving application-specialized schemes for the future.

packet P_n should be sent via LLC or HBC. We let P_1, \dots, P_n denote the sequence of packets in a single end-to-end flow (by which we mean a unidirectional transport layer connection, which may contain multiple messages).

Rewards. At the packet level, the objective is to minimize the *packet completion time* C_n , defined as the time by which all packets P_0, \dots, P_n would arrive at the receiver. This captures the intuition (§3.3) that any P_n might be a useful message to accelerate on its own, but it wouldn't be delivered to the application until prior packets are also delivered. The benefit of sending a packet P_n via LLC is thus the reduction of C_n if P_n is sent via LLC (denoted $C_{n,LLC}$), compared to when it is sent via HBC (denoted $C_{n,HBC}$). Thus, we calculate the rewards for sending P_n via LLC as: $R(P_n) = C_{n,LLC} - C_{n,HBC}$.

To calculate the above, we first need to estimate the delivery time D for a packet that depends on the channel/link³ propagation delay $D_{prop,link}$ and bandwidth B_{link} , packet size, and the link's queue size Q_{link} at time t_n . The Q_{link} counts the number of bytes that have been enqueued for transmission through a *link* but have not yet been transmitted out the interface. Delivery time for P_n on a certain *link* is thus:

$$D_{link}(P_n) = D_{prop,link} + (size(P_n) + Q_{link}(t_n))/B_{link} \quad (1)$$

The packet completion time for P_n (C_n) should also account for completion times of P_0 through P_{n-1} (i.e., C_{n-1}) since P_n may arrive at the receiver before P_{n-1} , especially if P_n is sent over LLC and P_{n-1} was sent over HBC. Thus, we can calculate ($C_{n,link}$) as:

$$C_{n,link} = \max(C_{n-1}, (t_n + D_{link}(P_n))) \quad (2)$$

Note that $D_{prop,link}$ are nondeterministic, comprising dynamic channel delay and any congestion along the channel's path, and will thus have to be estimated. We return to this later.

Cost. The cost of sending a packet to the LLC comes from the increased utilization of LLC. Intuitively, the cost should increase with the added queueing delay that a packet arriving very soon after P_n would experience, i.e., $size(P_n)/B_{llc}$. The cost should also be higher if the LLC is currently more highly utilized so that its limited capacity is reserved for higher-reward packets. We use a heuristic that captures this by adding these two effects; specifically, we compute the cost (or fare F) of putting P_n on LLC as:

$$F(P_n) = (size(P_n) + Q_{llc}(t_n))/B_{llc} \quad (3)$$

Note that to be more precise, we should compute the difference in costs of putting the packet on LLC vs. HBC. But as the HBC bandwidth is dramatically higher, its cost is negligible and we omit it for simplicity.

³We use these terms interchangeably for convenience. Note, however, the LLC channel may involve acceleration in the WAN in addition to the RAN, so it actually may span multiple physical links.

Comparing rewards and cost. At a high level, we want to steer packets to LLC when the rewards outweigh the costs, but comparing them involves a tradeoff: the benefit is immediate to packet P_n , whereas the cost affects possible subsequent packets which may not appear. We introduce a parameter α to capture this, so that we will send a packet to LLC when: $R(P_n) > \alpha F(P_n)$.

Calibrating α . If we set α too low, a flow may aggressively send packets to LLC so that it will deny resources to another flow in a multi-flow application. If we set it too high, we can be too conservative in utilizing the fast LLC. To find a good α and determine how sensitive performance is to its value, we conduct experiments with web browsing across different alpha values. We load 40 web pages from our corpus over different α values and pick α with the best Page Load Time (PLT) result on average. We use our testbed (§5.1) and apply the packet steering over HBC and LLC. For LLC, we use 5G NR URLLC as a reference where the RTT and bandwidth is 5 ms and 2 Mbps. For HBC, we vary its RTT while fixing bandwidth at 200 Mbps.

The detailed results are in §A.2. In summary, the results confirm that setting α too low or high has suboptimal performance. The best value for HBC RTT of 20 ms to 60 ms is 0.75. This RTT range covers most cases of 5G eMBB. As the RTT increases to 80 ms and higher, $\alpha = 1$ is slightly better. The difference, however, is less than 1%. We use $\alpha = 0.75$ for all subsequent experiments.

Note on design. The steering approach described here is not an optimal choice derived from a model – it is a heuristic, particularly the calculation of cost and calibration of α , in part since some of the relevant information (like the application-level importance of a particular packet) is unavailable. However: (1) we find the heuristic does perform well in realistic environments, (2) even if poor decisions do occur, they lead only to suboptimal performance, rather than a correctness problem, and (3) performance is not very sensitive to the exact value of α . In particular, even with $\alpha = 0$ – which corresponds to the greedy strategy, where each packet uses LLC whenever it expects a reward for itself – there is still a very good PLT improvement, within 5% or less of the best α . That said, this problem could be interesting to formalize in the future, perhaps as an online algorithm that could provide worst-case guarantees, or using queueing-theoretic tools.

3.5 The Packet Steering Algorithm

Putting together the above pieces, the complete steering algorithm is shown in Algorithm 1 in Appendix A.1. To make a decision, the algorithm requires (1) packet size, (2) current LLC queue size, (3) LLC bandwidth, and (4) latency of both LLC and HBC. The LLC bandwidth is controlled (assigned by the operator) so it is known, and (1) is directly observable.

LLC queue size (2) may directly be observable at the client, assuming its NIC is limited to the LLC bandwidth. But the proxy may have a higher local NIC rate. The proxy, therefore,

tracks outgoing traffic per user and computes what the queue depth would be if the NIC had been limited. Depending on the service provider’s admission control policy, the rate could alternately be explicitly limited at the proxy. Client can also apply similar approach if (2) is not directly observable.

Latency (4) has to be estimated. To do this, we perform periodic handshakes (e.g., in every 500 ms in our use case). The handshakes consist of four steps, all with UDP packets: (1) the client agent sends a special packet we call a “D-SYN” to the proxy agent using both HBC and LLC. (2) The proxy agent upon seeing a D-SYN responds with “D-SYN/ACK” packets sent across both HBC and LLC. (3) The client agent receives the D-SYN/ACK packets, updates the base RTT value for both channels based on the difference between D-SYN/ACK receive time and D-SYN release time, and replies with “D-ACK” packets sent across both channels. (4) The proxy agent receives the D-ACK packets and updates the base RTT value for both channels. We use the minimum RTT value for the measurement. As we will see in the evaluation (§5), very rough latency estimates are sufficient.

The algorithm requires maintaining per-flow state, specifically to store C_{n-1} , the estimated completion time of the most recent previous packet. The proxy also stores per-user state for its queue depth calculation.

3.6 Reordering buffers at the endpoints

Splitting packets across asymmetric paths (particularly with a latency differential, as there is for LLC vs HBC) can cause out-of-order packet delivery, which can be harmful to application performance. In particular, TCP uses out-of-order packets as a signal of congestion, potentially causing retransmissions and a drop in sending rate. To solve this problem, we adopt a reordering buffer (ROB) in the receiving direction of each of our agents, to buffer packets arriving only from LLC. Note that we only buffer packets arrived from LLC as we only want to handle packet reordering caused by sending packets through the faster LLC and not to solve reordering caused by external factors such as wireless losses.

To avoid unbounded buffering delay if the previous packet was lost, the ROB also releases packets after a timeout. Ideally, the timeout should equal the latency of HBC, but because the latency of HBC can be variable and hard to track, we use a conservative 100 ms timeout. We evaluate the effectiveness of this timeout value under random packet loss in §5.

4 Prototype and Experimental Setup

Our experiments involve a client representing a mobile end-user application (e.g., a web browser) fetching content from a web or content server. Both the client and server endpoints have access to two interfaces, one representing the high-bandwidth channel (HBC) and the other the low-latency channel (LLC). In the case of 5G, HBC and LLC map to eMBB and URLLC, respectively. Depending on the experiment conditions, the interfaces may be real or emulated. We masked

the two interfaces at the endpoints, however, using a smart DChannel virtual interface implemented on top of a TUN device; the client and server use only this virtual interface to send and receive data. Our DChannel prototype then performs endpoint-transparent (and application-agnostic) steering of traffic.

We developed a DChannel prototype and packaged it as a UNIX shell, similar to the shells in Mahimahi [36]. The shell captures all outgoing traffic from any *unmodified* application running within it and tunnels them to our DChannel implementation; it processes incoming traffic in a similar application-transparent manner, so both the steering and buffering modules of DChannel are used. Our DChannel prototype attaches additional metadata (sequence number and flow ID) prior to transmission to assist the receiver in reordering packets and strips this before delivering to the application. We used our own metadata header as a convenience, but in a real implementation, this could be avoided by looking inside the layer 4 header.

We evaluated the performance of DChannel using this prototype under two settings. The first is a *live* setting where we used the actual 5G NR eMBB channel as HBC. The second setting, in contrast, is one where we emulated the eMBB channel based on traces that we gathered from an actual 5G eMBB channel. In both settings, since URLLC is not yet commercially available, we emulated its “expected” behavior (based on the 5G specification [6]) using a low-latency, bandwidth-limited wired Ethernet connection.

4.1 Live-eMBB Setting

In this setting, DChannel steers traffic over two real interfaces (Fig. 2): One interface is tethered with a 5G phone for providing access to a *live* eMBB channel, while another is connected to a low-latency bandwidth-limited Ethernet connection for emulating the URLLC channel. Packets transmitted over the 5G eMBB channel traverse the core network of the mobile provider before exiting via the packet gateway (i.e., *mobile path*) and then one or more ASes in the public Internet (i.e., *Internet path*) to reach our server. Data sent over the Ethernet interface, in contrast, traverse a traditional ISP and then one or more ASes to reach the server. On the server side, DChannel receives all the packets from both the interfaces, reorders them (if required), and then delivers them to the server-side application via the TUN device.

We used Ethernet and not WiFi for emulating URLLC, since the channel is expected to provide high reliability (≥ 0.9999) [8]. We capped the bandwidth of this link using `netem` to emulate the low bandwidth of URLLC. Since the client must remain physically plugged in to a wired network for emulating URLLC, this setting allows us to study performance only in stationary conditions.

4.2 Emulated-eMBB Setting

To evaluate DChannel under a wide variety of scenarios, specifically those including client mobility, we used *trace-*

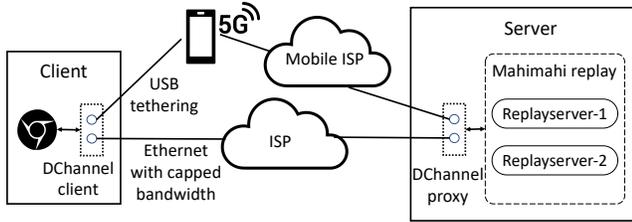

Figure 2: In our live 5G eMBB testbed, the client has two paths to the server: One path over a tethered connection to a 5G phone for utilizing the eMBB channel, and the other through a bandwidth-capped connection over Ethernet, for emulating the URLLC channel.

driven emulations. Below, we describe how we captured the network (latency and bandwidth) traces of the 5G eMBB channel under stationary and low-to-moderate mobility scenarios and used them in our emulations.

4.2.1 Collecting network traces

To capture the temporal variability of mobile networks, we measured both the latency and throughput of the eMBB channel over time.

Latency traces. We measured the latency of the eMBB channel by periodically sending probes (UDP packets) from the client to the server. We set the probing period to 15 ms to force the UE radio to remain always in “active” mode and generate only a small amount of probe traffic to avoid queuing. Our measurements capture the latency imposed by the base station and core network, since our server was always in close proximity to the client (i.e., less than 150 miles), minimizing the Internet-path latency. Our `tracert`s from the client to the server, although not shown in the paper, also confirmed that the latency between the client and the server was very close to the latency between the client and the packet gateway.

Bandwidth traces. We measured the throughput across time of both uplink and downlink channels by saturating them with MTU-sized UDP packets. Since TCP cannot reliably saturate the highly variable cellular uplink and downlink concurrently, we used an overestimated fixed sending rate to always fill the queue. First, we measured the maximum supported upload and download UDP throughput using existing tools such as `iperf`. Then, we sent traffic at this maximum rate from both endpoints. Finally, we used the actual packets received over time by the endpoints to estimate the uplink and downlink capacities.

Measuring both latency and bandwidth. A key challenge in measuring both latency and bandwidth simultaneously is avoiding interference: bandwidth-intensive operations can saturate the link and fill the queue, thereby inflating the latency. Since cellular networks use per-user queues, we addressed this challenge by measuring latency and bandwidth from separate devices. When using two separate devices, we did not see any perceivable interference for measurements on 5G low-band, although we observed them on 5G mmWave. Specifically, we

observed inflation in latency if a nearby device was uploading data at more than 5 Mbps using mmWave.⁴ For 5G mmWave, we measured, hence, only the downlink throughput over time; we set the uplink bandwidth to a single, fixed rate of 60 Mbps.

The accuracy of temporal variations in latency matters *most* for our trace-driven emulations, since the main applications that we use in our evaluations, web browsing and mobile apps, are latency-sensitive. The performance of such applications crucially depends on TCP-related configurations (e.g., initial congestion window) and network latency (or RTT) rather than on available bandwidth, particularly when the bandwidth is more than 16 Mbps [45]. Our approach to estimating bandwidths, therefore, is adequate for our evaluations.

4.2.2 Emulating the traces

In the emulated-eMBB setting, we run both the client and the server on the same machine. DChannel then steers traffic between them over two virtual interfaces, emulated using an extended version of Mahimahi [36]. Specifically, we extended Mahimahi’s delay shell to vary the eMBB channel latency over time, based on a trace generated from a real 5G deployment. The modified delay shell accepts a trace comprising a “timeline” of RTT values and halves each value to derive the individual uplink and downlink latency timelines. The shell then assigns per-packet latency by choosing an uplink or downlink latency by matching the time a packet arrives at the interface against the timelines. Since the trace-file granularity is one RTT sample per 15 ms, we use linear interpolation for assigning RTTs arriving between two samples. Similarly, we emulated URLLC with a propagation delay of 5 ms and bandwidth of 2 Mbps, unless noted otherwise.

Mobile applications’ traffic (especially web browsing) is typically bursty in nature and contains periods of inactivity. To preserve energy during *idle* periods, UEs switch to a low-power (or “sleep”) state, which supports discontinuous reception (DRX). The transition to the low-power state depends on an *inactivity timer* that we observed (through probing [35]) to be around 30 ms for 5G mmWave; once the device enters this state, it will “wake up” periodically (every 40 ms). When emulating the latency traces, we therefore also estimate the radio power states of the device (based on its activity) and take into account any additional latency the state transitions may impose. A packet that arrives 20 ms after the UE enters the sleep state, for instance, will experience an additional 20 ms delay before it is processed. This delay, however, is not incurred on the uplink. For 5G low-band, we set the inactivity timer to 100 ms and wake-up interval to 20 ms.

For the bandwidth emulation, we extended Mahimahi’s link shell to emulate a time-varying bandwidth that changes every second. To emulate a link of capacity 60 Mbps at time

⁴Low-band uses OFDMA so multiple devices can communicate at the same time and the latency is not inflated, while mmWave uses single carrier modulation, where multiple devices must take turns transmitting and the antenna must switch its beam pattern.

Table 1: Characteristics of network traces gathered from actual 5G deployments at different locations and under different conditions. ‘p50’ and ‘p98’ refer to the 50th and 98th percentiles, and ‘CV’ refers to the coefficient of variation.

Trace name	Span (mins.)	RTT (ms)					Mean bw. \uparrow/\downarrow (Mbps)	Description
		min.	p50	p98	mean	CV		
<i>mmWave-Stationary (MM-S)</i>	60	18	22	106	29.88	0.77	60/140	UE was in a building in the downtown Chicago, placed near a window with a base station in line of sight.
<i>mmWave-Walking (MM-W)</i>	56	16	22	120	30.32	0.98	60/110	UE was held by user walking in downtown area of Chicago.
<i>mmWave-Driving (MM-D)</i>	18	18	40	236	56.15	0.96	60/100	Phone was with a user driving through the downtown area of Chicago at low to moderate driving speeds.
<i>LowBand-Stationary (LB-S)</i>	60	34	40	132	45.20	0.50	26/93	Phone was located in a building in a university campus. It was placed near a window with full signal strength.
<i>LowBand-Walking (LB-W)</i>	53	32	52	156	58.94	0.50	21/63	Phone held by user walking in a university campus.
<i>LowBand-Driving (LB-D)</i>	23	34	54	202	68.84	0.62	15/57	Phone was with a user driving near a university campus.

n seconds, for instance, this extended link shell will release 7.5 KB per millisecond. In our emulation tests, we also used a FIFO (drop-tail) queue, and we set the buffer to 800 MTU-sized packets.

5 Evaluation

We evaluated DChannel using 5G eMBB and URLLC as HBC and LLC, respectively. We ran the client (e.g., a web browser) on a laptop, unless otherwise mentioned. The laptop had 16 GB RAM, 512 GB SSD, and an Intel Core i7 processor running Ubuntu 20.04 (Focal Fossa).

5.1 Testbed Configuration

In the live-eMBB setting, we tethered the laptop with a Google Pixel 5 phone using USB (refer Fig. 2). We ran the live experiments from two locations: UIUC campus with access to 5G low-band and the Chicago downtown area for 5G mmWave access. We emulated the URLLC link between the client and server using a wired (Ethernet) link and configured it based on URLLC end-to-end specification and use-cases [6]. The emulated link provides 5 ms RTT between the client and the network gateway and has 2 Mbps capacity. At the 5G mmWave test site, however, the wired link only provided a minimum latency of 8 ms for the URLLC emulation.

We also collected latency and bandwidth traces (summarized in Tab. 1) at the two test locations under three mobility conditions: stationary, walking, and driving. All traces were collected using Google Pixel 5 phones with Verizon 5G. Though mmWave offers lower latency (for eMBB) than low-band, it also experiences higher variance than low-band, even when the UE was stationary. This inconsistency in performance becomes even worse under mobility. Low-band offers a stable, albeit relatively higher, RTT than mmWave. We ran all the components, i.e., the client, DChannel’s modules, and the server, on the laptop in the emulated-eMBB setting, and used the traces (in Table 1) for emulating the eMBB channel.

5.2 Application use cases

We evaluated DChannel on 5G under a wide variety of network conditions to highlight its benefits for web browsing and web-based mobile (Android) applications. We supplemented these experiments with a bulk-download application for demonstrating DChannel’s merits for long (i.e., bandwidth-intensive) flows.

Web browsing. To measure the improvements brought about by DChannel for web browsing, we first fetched a set of 200 web pages of “popular” websites, selected uniformly at random from the Hispar corpus [16]. The sample comprised 40% of landing and 60% of internal pages from 200 websites. The median web page size and the number of objects are 3.7 MB and 60, while the 95th percentile are 11.8 MB and 168. When fetching these pages, we recorded all the HTTP requests and responses using mitmproxy [1]. Then we used a version of Mahimahi with HTTP/2 support [53] to serve the responses from our server. While recording the pages, we also estimated the server response time for each request by subtracting the *time-to-first-byte (TTFB)* from the client-to-server RTT. We used the server-response times to emulate server-side processing delays during the replays.

We used an unmodified Chromium browser spawned within a DChannel shell to fetch the pages from our server. We cleared the browser and DNS caches prior to each fetch and used the default Linux congestion control, TCP CUBIC, unless noted otherwise, for all web-browsing experiments. We measured the *page-load time (PLT)*, based on the `onLoad` event [37] in each experiment, on each fetch. In the live-eMBB setting, we first used the DCHANNEL scheme to fetch a page and repeated that page fetch in quick succession using a different scheme. We calculated the difference in PLT between the different schemes and repeat the fetch five times to compute the mean difference in PLTs. In the emulated-eMBB setting, we picked a random sub-sequence from a trace for each page fetch. Given a page, we used the same sub-sequence for measuring the PLT across different schemes

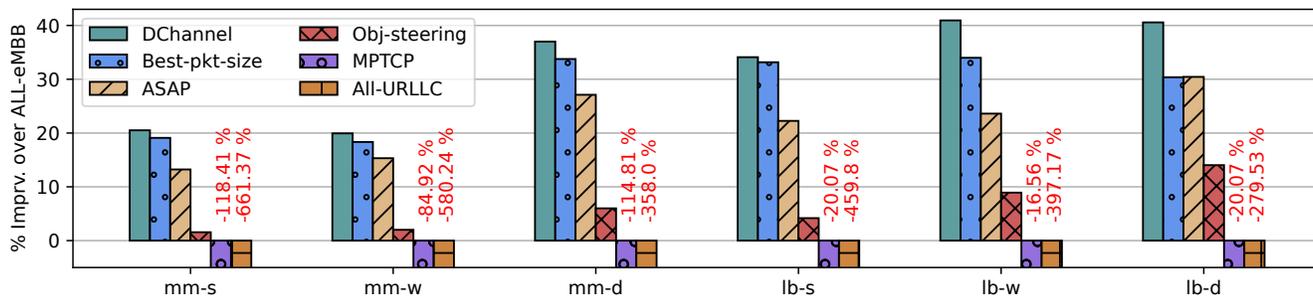

Figure 3: *DChannel* offers at least 20% lower PLT compared to that of *All-eMBB*, and it performs better than all other schemes. *MPTCP*'s PLTs are 17% to 118% worse than when using a single *eMBB* channel across all traces.

and computed the difference in PLTs. We used the mean of the PLT differences across five trials, with each using a random sub-sequence of the trace, for comparing and contrasting the different schemes.

Mobile application. We downloaded three popular Android applications from the Google play store, one each from three categories: social (Reddit), shopping (eBay), and news (CNN). We ran the applications on the phone (Google Pixel 5), but tunneled all network traffic to a *DChannel* shell running on our laptop. We then used the *DChannel* to steer the traffic over the appropriate channels. We evaluated the mobile applications only under the emulated-*eMBB* setting. Note that this setup may underestimate the performance improvements because of the additional overheads in tunneling the traffic from the phone to the laptop. We measured the RTT from our laptop to the application server to be 12 to 30 ms, which is significant given that our emulated *URLLC* and *eMBB* RTT can go as low as 5 ms and 16 ms.

To evaluate application performance, we calculated the *interaction response time (IRT)* [40]. *IRT* measures the time elapsed between when a user performs an interaction to when the end screen for that interaction is completely rendered. We automated user interactions with *AndroidViewClient* [13] and cleared application caches within each trial. We recorded the phone screen using *FFmpeg* [14] during each interaction and identified when the screen stopped changing visually using *scenecut-extractor* [12]. Since we do not control the servers used by the application, we repeated the interaction experiments with *DChannel* and other schemes, one after the other, in quick succession. We used the median *IRT* across ten trials to compare the performance of different schemes.

Bulk download. The setup for this use case is similar to that for web browsing. We simply used *curl* as the client to download a file hosted in our (Mahimahi) server and repeated the download five times.

5.3 Comparing steering schemes

We compared the PLT of *DChannel*'s *DCHANNEL* scheme with that of five other schemes across multiple scenarios (using the traces in Tab. 1) in the emulated-*eMBB* setting.

Table 2: Comparing the performance of *DChannel* with *All-eMBB* and *All-URLLC* when fetching the (182 KB) landing page of *amazon.com*.

Perf. metric	All-eMBB	All-URLLC	<i>DChannel</i>
<i>DNS lookup (ms)</i>	44	8	8
<i>TCP connect (ms)</i>	42	6	6
<i>TLS connect (ms)</i>	53	30	30
<i>Object transfer (ms)</i>	209	809	144
Total load time (ms)	349	853	189

The other schemes are as follows. **All-URLLC** steers all traffic over *URLLC*. **Obj-steering** requests web objects (requests and responses) on *URLLC* whenever its fetching time is smaller than *eMBB*. **Best-pkt-size** steers packets whose size is lower than the *best* predefined threshold to *URLLC*. **MPTCP** uses the two channels concurrently, by running the Linux kernel implementation of *MPTCP* [2] with the default configuration. **ASAP** [29] was designed for satellite networks. It diverts traffic from satellite links (or *eMBB* in our case) to 3G or 4G (or *URLLC*) since the latter has lower latency with a higher cost per byte than the former. *ASAP* code is not publicly available, so we used our in-house version.

Fig. 3 compares the relative difference in PLT of each scheme compared to that obtained when only using *eMBB* (i.e., *All-eMBB*). *DChannel* offers the best performance under all network conditions in our emulations. In stationary scenarios (*MM-S* and *LB-S*), it improves PLT by about 20% when using 5G *mmWave* and 35% with 5G *low-band*. These improvements in 5G *mmWave* and *low-band* correspond to absolute reductions in PLTs of about 290 ms and 642 ms, respectively, compared to the *All-eMBB* scheme. Per Fig. 3, *DChannel*'s performance increases in scenarios that involve UE mobility (*MM-W*, *MM-D*, *LB-W*, and *LB-D*). The PLT improvements are higher for *low-band* than *mmWave* since the former exhibits higher latency than *mmWave* (refer Tab. 1). We examined the relation between *DChannel*'s performance and *eMBB* latency in detail in §A.3.1.

Where do DChannel's gains come from? To illustrate the an-

swer to this question, we used `curl` to fetch the landing page (i.e., the root document, “/”) of `amazon.com` in the emulated-eMBB setting (40 ms RTT and 200 Mbps) without any server-side response delay. DChannel performs better than not only all-eMBB, but also all-URLLC (Tab. 2). While URLLC has lower latency than eMBB, it also has a significantly lower bandwidth than eMBB. We identified three key sources of performance gains by analyzing DChannel’s per-packet decisions. DChannel steers three types of packets over URLLC: (1) DNS packets; (2) *control* packets (e.g., SYN and client-to-server ACK packets); and (3) small *data* packets. Sending DNS and SYN packets over URLLC reduces DNS lookup and TCP connection-setup times, and accelerating ACK packets reduces the object transfer time. The last category includes small data transfers such as the TLS client-key exchange and HTTP requests.

Packet vs. web objects steering. Obj-steering performs HTTP request and response on URLLC when the web object size is small such that it will finish faster than eMBB. The scheme only offers slight improvement to PLT (2-14%). This is because not all small objects are critical. In fact, we found out that only 14% of small web objects have VeryHigh priority [25].

DChannel vs. static packet-size-based steering. Best-pkt-size steers individual IP packets whose size is smaller than the *best* static threshold to URLLC, and the reordering buffer will reorder any out-of-order packets. To find the best threshold, we performed web page load experiments for each trace with five different (size) thresholds: 250, 500, 750, 1000, 1250, and 1400 bytes. We found 750 bytes and 1000 bytes give the best-averaged result (across the stationary, walking, and driving scenarios) for mmWave and Low-Band traces, respectively.

DChannel shows an overall better improvement than best-pkt-size across different network conditions, albeit best-pkt-size offers similar improvements in stationary traces. In stationary traces, network latency is more predictable, and static decisions might suffice. When the network conditions are more variable, such as in the driving scenario, however, the static decisions do not suffice. DChannel observes network conditions, as they evolve, and estimates URLLC channel usage to make steering decisions dynamically. DChannel will not steer small packets to URLLC, for instance, if the channel is already congested. Note that these results are overly generous to best-pkt-size, for comparison purposes: the best size is selected in retrospect after running on the test scenarios. In reality, determining a single packet size threshold would be complicated: it depends on application traffic patterns as well as network conditions.

Is MPTCP not designed to exploit multiple channels? MPTCP works at the transport layer, and in general, it load-balances application traffic among the available paths and aggregates their throughput. In our evaluations, MPTCP performs worse (by inflating PLTs between 16% and 66% across

Table 3: The *p50* and (*p95*) of the avg. and max. buffer sizes (in bytes) when loading 200 web pages under MM-S and LB-D traces.

	MM-S		LB-D	
	Proxy	UE	Proxy	UE
Avg buffer size (b)	2 (15,7)	12 (63.5)	14 (96)	130 (2638)
Max buffer size (b)	392 (1122)	944 (2597)	757 (2375)	2848 (15521)

different conditions⁵) than simply using only the eMBB path. This poor performance stems from MPTCP’s default scheduler (*minRTT*), which prefers the path with the smallest estimated RTT. This scheduler thus infers that URLLC is better than eMBB and diverts traffic to URLLC until experiencing congestion. DChannel, unlike MPTCP, works at the network layer such that it allows steering data packets on eMBB and ACK packets on URLLC. MPTCP cannot perform such packet-level steering, since it results in each path having a separate data-ACK loop, which MPTCP cannot support.

DChannel vs ASAP. ASAP identifies the different phases of a web transaction (e.g., TLS handshake and HTTP request) and accelerates packets of latency-sensitive phases. It accelerates, for instance, TLS/SSL handshake as well as HTTP request traffic, but leaves HTTP responses to eMBB. ASAP performs better than all other schemes except DChannel. It falls behind DChannel, however, because of its static heuristics (e.g., accelerate all HTTP requests). HTTP requests are typically, but not always, small. A user uploading a photo, for instance, is one example where the assumption fails to hold. ASAP also encounters problems when the user browses complex internal pages that push some data to the server.

In the above experiments, we emulated URLLC based on the 5G standard. We found, however, that DChannel continues to offer significant PLT improvements even if URLLC latency is doubled or tripled or when URLLC latency changes over time (§A.3.2). DChannel offers good performance even in situations we cannot accurately estimate the eMBB RTT (§A.3.4), which is crucial for calculating rewards and cost (§3.4). We also examined DChannel’s performance under different URLLC bandwidths in §A.3.3. Finally, we evaluated DChannel’s rewards calculation accuracy in §A.4

5.4 Live 5G Experiments

We repeated the web-page fetches (similar to those in §5.3) over both the live-eMBB and emulated-eMBB settings. We then compared the relative improvements in PLTs brought about by DChannel across these settings, for both 5G mmWave and Low-Band (Fig. 4). In conclusion, the PLT improvements are quite similar between the live and

⁵We clipped the bottom of the Y-axis in Fig. 3 to focus on performance gains.

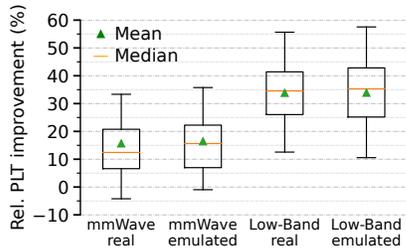

Figure 4: Comparison of relative PLT improvements in live-eMBB and emulated-eMBB settings⁶.

emulated-eMBB settings, albeit the mean PLTs in the former are higher than those in the latter. The mean PLT for the All-eMBB scheme in the live-eMBB setting for 5G Low-Band is 1718 ms, while that in the emulated-eMBB setting is 1522 ms. The high mean PLTs in the emulated-eMBB settings could be due in part to the limitations of the setup. The emulations do not capture all eMBB network characteristics such as out-of-order delivery. Moreover, the web server is hosted on dedicated hardware in the live-eMBB setting, whereas in the emulated-eMBB setting it runs on the same laptop as the client. These minor setup differences, however, do not affect our claims concerning the relative performance improvements (which are similar across the two settings).

5.5 Evaluating the reordering buffer

We evaluated the effectiveness of the reordering buffer (ROB) by comparing the web browsing performance of DChannel with and without the buffer. Along with the other experiments, this evaluation uses the default TCP CUBIC, which is sensitive to in-order packet delivery. Fig. 5 shows that without the buffer, the mean PLT improvement is decreased by up to 40% (in LB-D). Overall, DChannel without the buffer will be worse when the gap between eMBB and URLLC latency increases (implied in the figure as DChannel without the buffer is performing much worse in 5G Low-Band than mmWave) because DChannel will be more aggressive in offloading packets to URLLC, causing more out of order packets.

If ROB is implemented only on the UE (downlink), PLT improvement is only reduced by 2%. The decrease in PLT improvement is because DChannel tends to offload most web browsing uplink traffic to URLLC as the client requests are generally small such that minimal out-of-order persists. Our buffer analysis in Tab. 3 confirms that DChannel proxy does not use the buffer as frequently as the DChannel client (UE). Tab. 3 also shows that ROB requires only little memory as we do not have to buffer much URLLC traffic.

DChannel under random packet drop. Since ROB holds packets from URLLC for a fixed (100 ms) timeout when they are not in order, DChannel may suffer when packet loss happens as it may delay the packet loss signal, which can happen under certain conditions (§3.6). To evaluate this effect, we

⁶The mean PLT improvements of mmWave is lower than what we reported on MM-S in Fig.3 because we used 8 ms of URLLC RTT (rather than 5 ms).

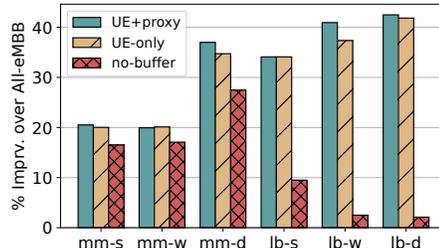

Figure 5: Adding reorder buffer to DChannel significantly improves web page load time.

Table 4: PLT under different random packet drop rates.

Loss	All-eMBB (ms)		DCHANNEL (ms)	
	MM-S	MM-D	MM-S	MM-D
0.0%	1108	1899	883 (20%)	1096 (42%)
0.1%	1203	1963	1011 (16%)	1311 (34%)
1.0%	2643	3421	2502 (5%)	3072 (10%)

investigated DChannel performance under stationary and driving traces in the case of random packet drops. We applied a stochastic packet drop in the uplink and downlink channels with packets being dropped in both eMBB and URLLC. This reflects the case where packet drops happen on the Internet path. Note that 5G eMBB generally exhibits low packet loss rates with the 99th percentile being 1.2% [34]. Per Tab. 4, DChannel is quite resilient to random packet loss, offering better performance than All-eMBB even under high loss rates. We also investigated the interplay between DChannel and latency-based congestion control algorithms in Appendix A.3.5.

5.6 Bulk download performance

Although our primary focus is latency-sensitive applications, we also evaluated how DChannel performed for a bandwidth-intensive use—bulk HTTP transfer of a file. Fig. 6 shows the download time for various file sizes using the mmWave driving (MM-D) trace. As expected, DChannel gets the largest improvement for small objects. But interestingly, DChannel also usefully improves large object download. This is because all control packets including TCP ACKs are accelerated in URLLC, which reduces the control loop delay, helping the transport layer adapt to bandwidth changes more quickly. Specifically, we found DChannel resulted in better utilization of the available eMBB throughput by $\approx 10\%$ when there are large throughput variations (e.g., in the driving scenario).

5.7 Mobile application performance

Fig. 7 shows the application response time improvement of DChannel across three common user interactions that require communication to the server. On average, DChannel improves the response times of application launch (15%), query searching (12%), and information (e.g., product or news) loading (21%). It is unsurprising that query searching gives lower improvement since it incurs higher server-side delay. The overall

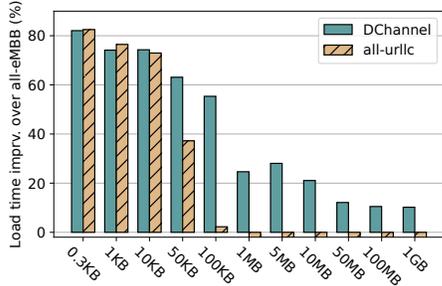

Figure 6: Download time improvement of variable-sized data under HTTP. The experiment used the MM-D trace with the buffer set to 800 packets ($\approx 2 \times$ trace BDP).

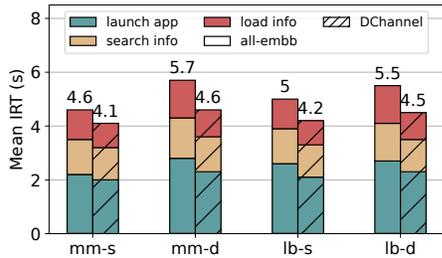

Figure 7: Android mobile application interaction response time (IRT) of All-eMBB and DChannel when performing three different tasks. We averaged the result from three applications.

mobile apps improvement is lower than the web browsing in part to our experimental setup (§5.2).

6 Discussions and Future Work

Deployment for 5G networks: DChannel requires cellular operator support, to allow URLLC for non-critical traffic and to perform stateful packet steering. However, operators may omit some of the DChannel implementations to make deployment easier, such as eliminating the reordering buffer (ROB) on the core gateway since DChannel shows only minor performance degradation without ROB in the proxy-side (§5.5). DChannel stateful packet steering may not be simple to implement especially when there are multiple gateways. We leave this to future work.

URLLC scalability: The number of users that can send general traffic to URLLC is an important matter which deserves to be evaluated quantitatively in the future. At the time of writing, URLLC is not yet deployed in public. However, based on the white paper [7], URLLC is targeted to support a relatively high connection density with modest per-user bandwidth. For instance, one of the URLLC use cases (discrete automation) requires a user-experienced data rate of 10Mbps, traffic density of 1 Tbps/km², connection density of 100,000/km², and max end-to-end latency of 10ms. Thus, the 2 Mbps maximum bandwidth per user for general application traffic used in our experiments is still reasonable based on others’ proposed use cases for URLLC, even in a dense urban area.

Disrupting URLLC native traffic: URLLC is primarily built

to serve latency-sensitive critical applications. To ensure we do not compromise the performance of these applications, the network operator can limit the per-user bandwidth and even choose to deprioritize non-critical packets as our approach does not require 99.999% reliability and is resilient to small increases in URLLC latency (§A.3.2).

Resource contention among applications: Multiple applications inside a user device may compete to use URLLC. We can regulate them using prioritization. One simple approach is to prioritize applications running in the foreground since mobile phone users are typically single-tasking.

Incentives for operators: While URLLC targets critical applications, it is up to the network providers to open URLLC for general mobile applications like web browsing. This is possible as 5G chipsets are typically designed to support multiple bands including the sub-6GHz bands for URLLC [6]. Expanding URLLC applications can encourage providers to foster a faster and broader deployment of URLLC as it brings a smoother experience to their major customers – mobile phone users; especially as the current market for URLLC applications like self-driving cars and remote surgery is still in its infancy.

Emulation uncertainty: The real URLLC performance might not match our emulated URLLC that follows the 5G NR white paper. However, we have performed several experiments to show the robustness of DChannel under variable URLLC conditions. Emulating the real behavior of a cellular network (eMBB) is also a known hard problem [51], and our approach of using two phones to capture both eMBB latency and bandwidth might not be perfect. We have compared DChannel performance with the emulated eMBB and live eMBB in stationary conditions and conclude that DChannel offers the same performance benefit (§5.4). However, we have not yet evaluated DChannel under non-stationary live eMBB due to the environment limitation (§4.1).

Other applications: LLC and HBC combination can also properly support applications from different domains that require high bandwidth and low latency, something that cannot be satisfied by utilizing a single channel. For instance, cloud gaming, which allows users to play games from remote servers, requires high bandwidth to stream content and low latency to remain responsive to user input. Since these applications can be vastly different than web browsing, a superior steering scheme may exist. We plan to analyze them further to determine an effective way of leveraging LLC and HBC.

Beyond mobile networks: Our insights may apply to other LLC and HBC combinations with analogous bandwidth and latency trade-offs. Examples include quality of service (QoS) differentiation providing separate latency- and bandwidth-optimized services [17, 39]; and routing traffic among multiple ISPs where one is more expensive but provides better latency, as may happen with very low Earth orbit satellite-based [24] or specialty [18] ISPs. To achieve the optimum cost-to-performance ratio, we can route only the latency-

sensitive traffic to the low-latency ISP.

Future wireless design: The 5G URLLC is only equipped with limited user bandwidth, and hence it is not suitable to serve general application traffic. The bandwidth is severely compromised because it needs to provide *both* low latency and very high reliability (99.999%). However, general applications do not need the almost-perfect reliability that URLLC guarantees. Future wireless networks (such as 6G) may reconsider this trade-off and provide a low-latency channel with somewhat greater bandwidth and somewhat lower reliability.

7 Related work

There have been multiple works that try to exploit the multi-access connectivity on the client.

Application layer multipath: Socket Intents [42] and Intentional networking [28] both expose custom APIs to applications and offer OS-level support for managing multiple interfaces. Both of them regulate application traffic based on application-specific information. Our work, in contrast, does not require application inputs or modifications, although in the future we might consider giving input to the steerer to support more specific applications.

Transport layer multipath: There are already numerous efforts to design multipath transport protocols such as R-MTP [33], pTCP [30], mTCP [52], SCTP multihoming [31], and MPTCP [49]. These protocols deliver application traffic through multiple paths to achieve better throughput and reliability. Due to the bandwidth aggregation focus, multipath transport protocols give notable benefits to long-flow dominated applications but not to short-flow dominated applications such as web browsing [20]. Our approach works transparently with single-path transport protocols (e.g., TCP and UDP).

Network layer multipath: Tsao and Sivakumar [46] proposed a super aggregation concept where TCP can achieve better WiFi throughput by selectively steering packets to 3G. ASAP [29] steers network packets over satellite ISP and lower-latency terrestrial networks to improve HTTPS. We compared DChannel against ASAP in our evaluation and found that DChannel is better for eMBB and URLLC pairs as it benefits from finer-grained decisions.

An early version of DChannel was presented in [43]. This work comes with a new and better-performing packet steering algorithm, a more robust evaluation with real-world traces and live 5G eMBB, and new use cases including mobile apps and bulk transfer.

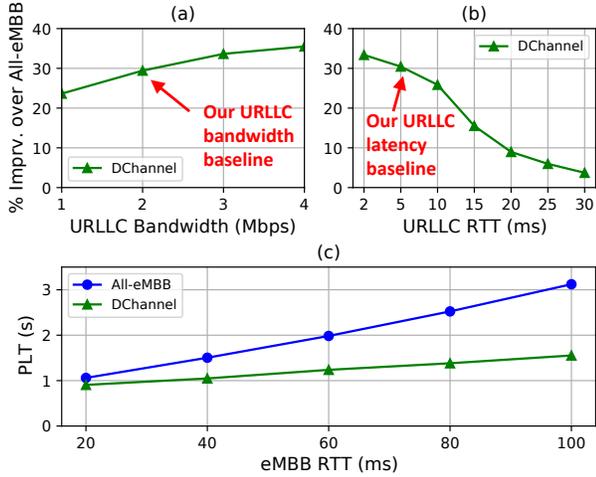

Figure 8: *DChannel* under varying *eMBB* and *URLLC* network conditions, conducted using the baseline (*RTT* (ms) / *bandwidth* (Mbps) for *eMBB* and *URLLC* are 40 / 200 and 5 / 2) with a single varying parameter.

A Appendix

A.1 Algorithm Listing

The packet steering algorithm is listed as Algorithm 1. Note that since HBC bandwidth (B_{hbc}) is typically large and relatively hard to measure, for simplicity, we omitted the queuing delay caused by $(size(P_n) + Q_{hbc}(t_n)) / B_{hbc}$.

Algorithm 1: *DChannel* steering algorithm

```

Result: Send a packet to either HBC or LLC
c_llc = t_now + llc_prop + (size(packet) + queue_llc) /
  band_llc;
c_hbc = t_now + hbc_prop;
rewards = c_hbc - max(prev_c, c_llc);
cost = (size(packet) + queue_llc) / band_llc;
if rewards > alpha * cost then
  send(pkt, LLC);
  prev_c = max(prev_c, c_llc);
else
  send(pkt, HBC);
  prev_c = max(prev_c, c_hbc);
end

```

A.2 Parameter Calibration

The results of our parameter sweep are shown in Table 5.

A.3 Understanding *DChannel* Performance

Below, we investigated how *DChannel* performs under tightly controlled network variables. We used a fixed network latency and bandwidth for the experiments below.

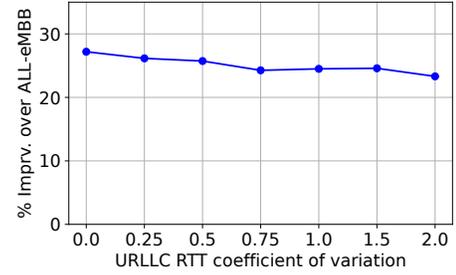

Figure 9: *DChannel* *PLT* improvement under time-varying *URLLC* *RTT* randomly generated according to a Gaussian distribution.

A.3.1 Performance under high *eMBB* *RTT*

We evaluated *DChannel* under *eMBB* *RTT* inflation and found it to be resilient towards the *RTT* increase (Fig. 8c). Specifically, *DChannel* is $2\times$ faster than the baseline when *eMBB* *RTT* is held at 100 ms, which is possible in device mobility as Tab. 1 shows. As *eMBB* *RTT* increases, *DChannel* web *PLT* degrades at a slower rate compared to All-*eMBB* because it uses *eMBB* primarily for bandwidth-sensitive (low rewards) traffic that is not affected as severely by the increased latency. Inline with our trace-based evaluation under mobility, the parallel channel setup can be extremely effective when the *eMBB* channel quality degrades.

A.3.2 Varying *URLLC* latency

Although *URLLC* is expected to deliver consistent low latency, we evaluated latency inflation on *URLLC* to reflect scenarios where web traffic is de-prioritized in favor of critical traffic. *DChannel* is still superior even when *URLLC* latency increases up to 30 ms and *eMBB* held at 40 ms (Fig. 8b). As expected, as *URLLC* latency increases and becomes closer to *eMBB*, the *PLT* improvement rapidly diminished because LLC no longer offers a competitive resource despite its higher cost.

To evaluate *DChannel* sensitivity to *URLLC* latency instability, we changed *URLLC* propagation latency over time to random values that follow Gaussian distribution. We kept the *URLLC* mean to 10 ms and ran experiments with an increasing amount of variation, controlled with the Gaussian distribution's coefficient of variation (CoV). We set the *URLLC* bandwidth to 2 Mbps while the *eMBB* *RTT* and bandwidth are 40 ms and 200 Mbps. We found that *DChannel* performance is relatively robust to the *URLLC* latency change (Figure 9); the *PLT* improvement only drops from 27.18% to 23.31% when the *URLLC* latency CoV changes from 0 to 2.

A.3.3 Varying *URLLC* bandwidth

The *URLLC* bandwidth is generally limited to ensure its reliable and low latency service. We tested *DChannel* under varying *URLLC* and summarize that its improvement flattens as *URLLC* bandwidth increases past 2 Mbps (Fig. 8a). As

Table 5: Percentage of improvement or ‘speedup’ in PLT (%ps.) along with the percentage of bytes (%sz.) sent via URLLC for various values of the eMBB channel RTT. The table also shows how the different values of α affect the performance benefits.

RTT (ms)	$\alpha = 0$		$\alpha = 0.25$		$\alpha = 0.5$		$\alpha = 0.75$		$\alpha = 1$		$\alpha = 2$		$\alpha = 3$	
	%ps.	%sz.	%ps.	%sz.	%ps.	%sz.	%ps.	%sz.	%ps.	%sz.	%ps.	%sz.	%ps.	%sz.
20	16.7	13.3	16.6	10.7	18.4	5.9	18.9	5.7	18.5	5.5	15.6	4.7	14.2	4.1
40	31.1	18.8	33.2	16.2	34.0	13.9	34.7	11.9	34.0	11.1	32.8	8.5	31.8	5.8
60	37.5	22.6	40.9	19.5	41.2	17.4	42.1	14.9	40.8	14.2	40.6	11.1	37.4	9.8
80	43.2	26.3	46.3	22.9	46.3	19.9	46.3	17.7	47.1	16.5	45.6	13.3	45.1	11.6
100	47.1	29.4	48.6	26.1	49.7	22.5	50.2	19.9	50.7	18.3	49.8	14.9	48.5	13.1

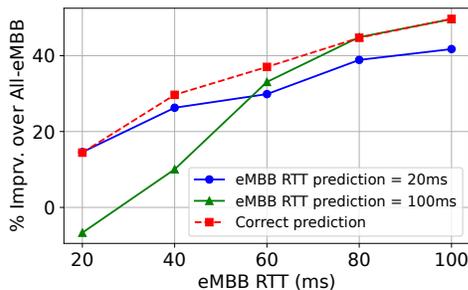

Figure 10: Effect of underestimating and overestimating eMBB latency on the mean PLT improvement.

URLLC bandwidth increases, DChannel aggressively offloads packets belonging to a larger transfer (e.g., HTTP response) to URLLC. It may not affect the completion time, however, as it still needs to wait for the remaining part to be transferred over the eMBB.

A.3.4 Working with Incorrect Latency Estimates

DChannel requires estimates of eMBB and URLLC latency to calculate rewards and cost (§3.4). While URLLC latency is predictable, it can be hard to get an accurate measurement of eMBB latency, especially under mobility. To better understand the sensitivity of DChannel to the latency estimates, we evaluated DChannel under underestimated and overestimated latency. Fig. 10 shows that underestimating eMBB latency is safer: When DChannel underestimates eMBB latency as 20 ms (from 100 ms, which is $5\times$ higher), the PLT improvement only decreases by 8%. Underestimating eMBB latency will underestimate the rewards, causing a more conservative use of URLLC and ensuring that the offloaded packets are high rewards packets. Overestimating the latency will, in contrast, overestimate the rewards, resulting in unnecessary packets being offloaded to URLLC, and slowing down the channel. Per Fig. 10, overestimating eMBB latency by $5\times$, DChannel gets worse performance than the baseline.

A.3.5 DChannel under TCP BBR

Since DChannel steers packets over two channels, the sender may notice an abrupt change in the flow RTT. We evaluated

Table 6: Mean PLT with TCP BBR under different eMBB RTTs. The URLLC RTT is set to 5 ms

	RTT=20ms	RTT=100ms
All-eMBB	915 ms	2661 ms
DChannel	716 ms (21%)	2713 ms (-2%)
pkt-uplink	860 ms (6%)	1628 ms (39%)

DChannel in TCP BBR, which uses RTT measurement to determine whether a path is congested. Tab. 6 shows the result when low (RTT=20 ms) and high (RTT=100 ms) eMBB latency are used. When the eMBB RTT is 20 ms, BBR works perfectly with DChannel because eMBB and URLLC latencies are not that different. As the latency gap widens, however, BBR starts to treat abrupt latency inflation as a congestion signal, reduces its windows rate, and increases PLT. We found that for 20% of the web page loads, DChannel performs worse than All-eMBB. These sites rely on a single TCP connection to deliver most web objects, and that flow suffers from a low sending rate. This can happen as DChannel accelerates the early packets (such as TCP SYN) to URLLC and suddenly switches back to eMBB once it sees large traffic. The abrupt RTT change gives a wrong congestion signal to the sender. One possible solution is to modify BBR to be aware of eMBB and URLLC use so that it can tolerate a change in RTT and maintain its sending rate. We leave this as future work. Alternatively, we can use different heuristics (pkt-uplink) that will send all uplink packets to URLLC and downlink packets to eMBB. This heuristic is based on the observation that client traffic is generally small and accelerating those packets will accelerate the flow RTT in a more consistent way. Table 6 shows we can get 39% improvement in PLT under BBR from this scheme.

A.4 DChannel rewards calculation accuracy

We evaluated DChannel packet rewards (R) calculation accuracy by comparing the calculated rewards and the *real* rewards. As we used a trace-based emulated network, we knew both network bandwidth, latency, and the link’s queue depth at any given time. Leveraging this information, we can calculate the

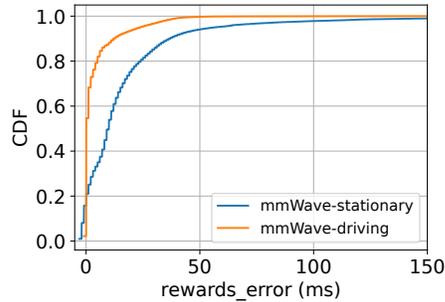

Figure 11: *DChannel* calculates rewards error distribution ($R_{real} - R_{est}$) across individual packets. A positive value denotes R underestimation. We limited the x-axis due to the high rewards error in the tail (155 ms and 604 ms at the 99th and 100th percentile).

real rewards before we commit a packet to a link. Figure 11 shows the rewards calculation error for the mmWave stationary (MM-S) and driving (MM-D) network traces. *DChannel* is able to accurately estimate R with just 12 ms of error in the 90th percentile in the stationary network traces due to the network latency being relatively stable and the bandwidth being large. In the driving traces, the error is noticeably higher with a long tail. However, 90% of the time the error is less than 37 ms. The R error mainly arises from the less accurate network eMBB latency estimation and the impact of ignoring the eMBB queueing delay (§A.1), since eMBB bandwidth may be low, and the delay becomes more significant).

The above is also why, as can be seen in the figure, R is rarely overestimated. Underestimation is the preferred direction of error, as we have shown that *DChannel* can tolerate some incorrect latency estimates and rewards underestimation (§A.3.4). However, better network measurement may improve *DChannel* performance; we leave this as future work.

SkyPilot: An Intercloud Broker for Sky Computing

Abstract

To comply with the increasing number of government regulations about data placement and processing, and to protect themselves against major cloud outages, many users want the ability to easily migrate their workloads between clouds. In this paper we propose doing so not by imposing uniform and comprehensive standards, but by creating a fine-grained two-sided market via an *intercloud broker*. These brokers will allow users to view the cloud ecosystem not just as a collection of individual and largely incompatible clouds but as a more integrated Sky of Computing. We describe the design and implementation of an intercloud broker, named SkyPilot, evaluate its benefits, and report on its real-world usage.

1 Introduction

The modern information infrastructure is built around three components. The Internet provides end-to-end network connectivity, cellular telephony provides nearly ubiquitous user access via increasingly powerful handsets, and cloud computing makes scalable computation available to all. These ecosystems obviously have many superficial differences, but perhaps their most fundamental difference lies in the degree of compatibility between providers in each of these ecosystems.

The Internet and the cellular infrastructure were designed with the goal of universal reachability. This required both uniform and comprehensive industry standards and broadly-adopted interconnection agreements (for Internet peering and cellular roaming) that led to a globally connected federation of competing providers. The cloud ecosystem has very different origins, emerging as a replacement for dedicated on-premise computing clusters rather than serving as an interconnected communication infrastructure. As a result, cloud providers began by emphasizing their differences rather than their similarities; though the clouds are all based on the same basic conceptual units (e.g., VMs, containers, and now FaaS), they initially differed greatly in their orchestration interfaces. These orchestration interfaces have become more similar over time,

but some clouds continue to differentiate themselves through numerous proprietary service interfaces, such as for storage or key-value stores. In addition, clouds typically impose much higher charges on data leaving than on data entering, resulting in “data gravity” (i.e., the difficulty of moving jobs to another cloud due to the expense of transferring the data). The combination of proprietary service interfaces and data gravity have led to significant customer lock-in: it is hard for companies who have established their computational workloads on one cloud to move them to another.

However, as cloud computing has become a critical part of our computational infrastructure, enterprises are increasingly worried about how difficult it is to migrate workloads between clouds. There are two compelling reasons for wanting more freedom in workload placement. First, no business wants any critical part of their infrastructure tied to a single provider because such lock-in reduces their negotiating leverage and also makes the business vulnerable to large-scale outages at the provider. Second, there are now strict regulations about data and operational sovereignty that dictate where data can be stored and computational jobs run. Not all cloud providers have datacenters in all countries, so the inability to migrate jobs between cloud providers could be a painful roadblock to satisfying these new regulations. These two reasons are not theoretical problems whose solutions would be “nice-to-have”; the recent occurrence of large-scale cloud outages and the increasing number of government regulations are quickly making such a solution a “must-have” for large-scale users of the cloud. This paper is about how we can ease the migration of workloads through the rise of Sky Computing, a concept first introduced in [81] but significantly extended and more deeply explored here. Sky Computing is when users, rather than directly interacting with the cloud, submit their jobs to what we call *intercloud brokers* who handle the placement and oversee the execution of their jobs.

To explain our approach in more depth, we first review related concepts and recent developments (§2). We then (§3) describe our vision of Sky Computing and its transformative possibilities. We present the requirements, architecture, and

*Equal contribution.

implementation of an intercloud broker, named SkyPilot, that focuses on computational batch jobs (§4). We then demonstrate its benefits on several applications (§5). Finally, we share our experiences with early deployments (§6), survey related work (§7), and conclude (§8). While the body of this paper is devoted to the technical characteristics of our system, in the appendix (§A.1) we speculate on how the cloud ecosystem might evolve once Sky Computing is more widely adopted.

SkyPilot is open source and available at <https://github.com/skypilot-org/skypilot>.

2 Related Concepts and Recent Developments

In this section we first review two concepts related to the ability to migrate workloads – standards and multicloud – and then discuss the recent progress towards compatibility.

2.1 Why Not Just Adopt Standards?

The first question one might ask is if seamless migration is the goal, why not adopt a set of uniform and comprehensive cloud standards, as was done for the Internet and cellular? In fact, a decade ago IEEE proposed a set of Intercloud standards for portability, interoperability, and federation among cloud providers [88] involving an Intercloud Service Catalog and an Intercloud federation layer. There are two fundamental problems with this and other proposals for such uniform and comprehensive cloud standards. First, there is no incentive for the dominant clouds (i.e., those with large market shares) to adopt such standards; it would decrease their competitive advantage and make it easier for customers to move their business to other clouds. Second, users interact with clouds at many levels, using high-level service interfaces such as PyTorch [76] or TensorFlow [53] in addition to low-level orchestration interfaces such as Kubernetes [36]. If the goal is to make workload migration seamless, then all of these interfaces would need to be standardized. Requiring every cloud to standardize every interface is both unrealistic (as noted in the first objection) and unwise (because these higher-level interfaces have changed significantly over time, and standardizing them would greatly hinder innovation).

2.2 Why Isn't This Just Multicloud?

Multicloud is now an industry buzzword, and there are reports [33, 52] that most enterprises have, or will soon have, multicloud deployments; this would seemingly imply that our goal of seamless workload migration has already been realized. However, the common use of the term multicloud only requires that an enterprise have workloads on two or more clouds (e.g., the finance team runs their backend functions on Amazon while the analytics team runs their ML jobs on Google), *not* that they can easily move those workloads between clouds. It is clear, from everyone we have talked to in the industry, that moving many workloads between clouds remains difficult. The exceptions to this are the recent third-party offerings (e.g., by Trifacta, Confluent, Snowflake, Databricks, and others) that run on multiple clouds; users can

indeed migrate their workloads that only use these services between clouds relatively easily (BigQuery, offered by Google, offers similar cross-cloud support). However, these are for specific workloads, and do not provide general support for workload migration.

In addition, there are several programming or management frameworks that support multiple clouds. JClouds [8] and Libcloud [10] offer portable abstractions over the compute, storage, and other services of many providers. However, the user still does the placement manually, whereas automatic placement is a key feature of Sky Computing. On the management front, Terraform [51] provisions and manages resources on different clouds, but requires the usage of provider-specific APIs, and also does not handle job placement. Kubernetes [36] orchestrates containerized workloads and can be run across multiple clouds (e.g., Anthos [5]). These frameworks, while quite valuable, focus on providing more compatibility in the lower-level infrastructure interfaces offered by the clouds (see §2.3), and as such are nicely complementary with Sky Computing but do not obviate the need for Sky Computing.

2.3 Growth In Interface Compatibility

Turning away from related concepts, we now discuss a recent development that Sky Computing will leverage. As noted before, users of cloud computing invoke a wide variety of computational and management interfaces. Many of these are open source systems that have become the *de facto* standards at different layers of the software stack, including operating systems (Linux), cluster resource managers (Kubernetes [36], Apache Mesos [63]), application packaging (Docker [27]), databases (MySQL [41], Postgres [43]), big data execution engines (Apache Spark [93], Apache Hadoop [89]), streaming engines (Apache Flink [57], Apache Spark [93], Apache Kafka [9]), distributed query engines and databases (Cassandra [7], MongoDB [39], Presto [44], SparkSQL [48], Redis [45]), machine learning libraries (PyTorch [76], TensorFlow [53], MXNet [58], MLflow [38], Horovod [79], Ray RLLib [66]), and general distributed frameworks (Ray [71], Erlang [55], Akka [1]). In addition, some of AWS's interfaces are increasingly being supported on other clouds: Azure and Google provide S3-like APIs for their blob stores to make it easier for customers to move from AWS to their own clouds. Similarly, APIs for managing machine images and private networks are converging.

These trends increase what we call *limited interface compatibility*, where both of these qualifiers are crucial. This compatibility applies only to individual interfaces and these interfaces are typically not supported by all clouds but by more than one. Our contention, based on what we see in the ecosystem, is that the number and the usage of these interfaces that have this limited compatibility – i.e., are supported on more than one cloud – is increasing, largely but not exclusively due to open-source efforts.

We are basing our approach on the belief that this trend will

continue, and that leveraging this trend is far preferable to pursuing uniform and comprehensive standards. To paraphrase a quote attributed to Lincoln, we know that all interfaces are supported by some clouds, and some interfaces may be supported by all clouds, but we cannot and should not require that all interfaces be supported by all clouds.¹

3 The Vision of Sky Computing

We first describe what Sky Computing is, and articulate why we see it as not just tactical but transformative.

3.1 What Is Sky Computing?

Given this increasing level of limited interface compatibility, how do we leverage it to ease workload migration? There are two key components. First, in order to reduce data gravity, clouds can enter into reciprocal free data peering; i.e., two clouds can agree to let users move data from one cloud to another without charge. With high-speed connections prevalent (many clouds have 100 Gbps connections to various interconnection points where they can peer with other clouds), we think such free peering can easily be supported, with its costs more than offset by the increase in computational revenue that it enables. One might worry about the delay that such transfers incur, but if the resulting computation times are superlinear in the data size (or linear with a reasonably high constant) then no matter how large datasets become, the networking delays will not be a major bottleneck.

The second component, and the one we focus on for the rest of this paper, is what we call *intercloud brokers*. In this paper we describe our intercloud broker, which is designed specifically for *computational batch jobs* (§4). While batch jobs (e.g., ML, scientific jobs, data analytics) represent only a fraction of today’s diverse cloud use cases, their computation demands are growing quickly [74] and are responsible for the recent surge of specialized hardware [15, 22, 23]. Thus, we have started with a broker designed for batch jobs as a tractable but common and rapidly growing workload. We expect future versions of the broker will address a wider range of workloads, and provide a broader set of features, but that is not our focus here. In addition, we expect that eventually there will be an open market in intercloud brokers that charge a small fee for their brokerage service; some of those brokers will be general purpose and others more tailored to specific workloads, as ours is.

An intercloud broker takes as input a computational request that is specified as a directed acyclic graph (DAG) in which the nodes are *coarse-grained* computations (e.g., data processing, training).² For lack of a better term we call these computations “tasks”. The request also includes the user’s preferences about price and performance.

¹The following adage is widely but incorrectly attributed to Lincoln: “You can fool part of the people some of the time, you can fool some of the people all of the time, but you cannot fool all the people all of the time.”

²This is informed by workflow systems [6] that are now the de facto standard for orchestrating complex batch applications.

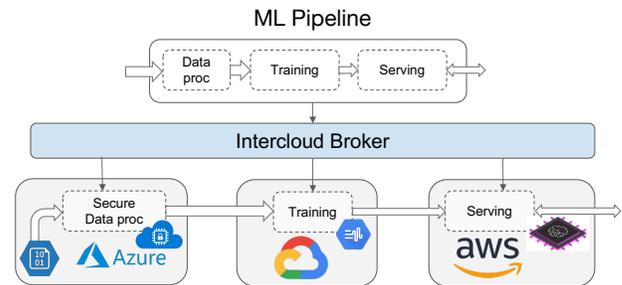

Figure 1: An ML pipeline running on top of Sky. The goal is to minimize cost while processing the input data securely.

The intercloud broker is then responsible for placing these tasks across clouds. Unlike existing multicloud applications which run an application instance per cloud, an intercloud broker can run a single application instance across several clouds. For example, Figure 1 shows a machine learning (ML) pipeline with three tasks: data processing, training, and serving. The user may wish to minimize the total cost while processing data securely. The intercloud broker might decide to run data processing on Azure Confidential Computing [16] to anonymize data and thus protect data confidentiality, training on GCP to take advantage of TPUs [23], and serving on AWS to take advantage of the Inferentia accelerator [15].

The ability to partition applications enables the emergence of specialized clouds. For example, a cloud provider can build a successful business by just focusing on a single task, such as ML training, and offering the best price-performance for that task; see §A.1 for a more detailed discussion of this.

In addition, the intercloud broker provides benefits even when the application (i) entirely runs on a single cloud, by automatically choosing the cloud that best matches the user’s preferences and choosing the best region and zone within that cloud, or (ii) uses services³ provided only by a single cloud, by placing a task on that cloud but still having the freedom to use other clouds for the other tasks.

3.2 Why Is This Transformational?

There are three reasons, each from a different perspective, why we see this as a transformational change in cloud computing, not as merely a tactical mechanism for workload migration.

User’s Perspective: When using an intercloud broker, users are no longer interacting with individual clouds, but with a more integrated “Sky” of computing. They merely specify their computation and their criteria, and the broker then places the job. This makes it significantly easier to use the cloud, and may lead to increased cloud adoption. Note that such an interface hides the heterogeneity between and within clouds. Users no longer need to research which clouds have the best prices, or offer a particular service. This also applies *within* individual clouds, because different regions within a cloud

³By “service” we mean the compute services or a hosted service provided by one or more clouds, such as hosted Apache Spark (e.g., EMR [4], HDInsight [17]) and hosted Kubernetes (e.g., EKS [3], GKE [32], or AKS [18]).

can offer different hardware options and different prices.

Competitive Perspective: Note that by serving as an intermediary between users and clouds, the intercloud broker is creating a fine-grained two-sided market for computation: users specify their tasks and requirements, and clouds offer their interfaces with their pricing and performance. Job placement is no longer driven mostly by measures to promote lock-in (e.g., proprietary interfaces and data gravity), but increasingly by the ability of each cloud to meet the user’s requirements through faster and/or more cost-efficient implementations. This means that the clouds, in order to increase their market, will likely start supporting interfaces that are commonly used in jobs, driving the market towards increased compatibility.

Ecosystem Perspective: Once there is a two-sided market established, the cloud ecosystem can transition from one in which all clouds offer a broad set of services and try their best to lock customers in, to one in which many clouds focus on becoming part of a computational Sky, where they can specialize in certain tasks because the intercloud broker will automatically direct computations to them if they best meet user needs for those particular tasks; the economic analysis in the appendix (§A.1.2) makes this case more precisely.

This vision should be tempered with several doses of reality. First, while we envision some clouds will embrace the vision of Sky Computing by focusing on compatible interfaces and adopting reciprocal free data peering, we expect others, particularly those with dominant market positions, to continue with lock-in as a market strategy. Nonetheless, the presence of a viable alternative cloud ecosystem will set the bar for innovation and meeting user requirements, so all users will benefit. Second, we assume that the creation of Sky Computing will be a lengthy process that will start slowly and gradually gather momentum. Our goal in this paper is to investigate how to start this transformation, not to define its ultimate form. As such, we start with an intercloud broker for batch jobs—a small but important set of workloads. Third, given our focus on the early stages of the Sky, we do not provide solutions to several problems that must eventually be addressed, such as how to troubleshoot failures that occur with applications running across multiple clouds.

4 Intercloud Broker

We now present an intercloud broker that targets *batch applications*. We first review the requirements of such a broker, and then propose an architecture. Finally, we describe our implementation of the resulting design, called *SkyPilot*.

4.1 Requirements

Cataloging cloud services and instances. There is a huge and growing number of services, instances, and locations⁴ across clouds. As shown in Table 1, the top three public clouds alone provide hundreds of compute VM types in dozens of

⁴We use “locations” to refer to regions and zones, collectively.

Cloud	Regions	Zones	VM types
AWS	20 (US: 4*)	64 (US: 15*)	≥ 558
Azure	51 (US: 8*)	124 (US: 23*)	≥ 714
GCP	35 (US: 9)	106 (US: 28)	≥ 155

Table 1: **Top public clouds with their myriad choices of locations and compute instance types.** Data is gathered from each cloud at the time of writing. *Not counting government cloud regions.

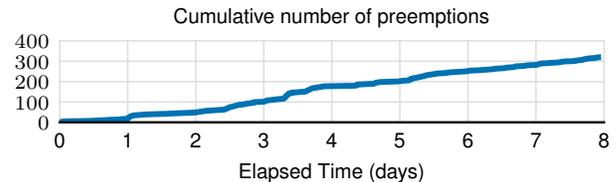

Figure 2: **Dynamic resource unavailability:** preemptions over time from a real-world bioinformatics workload trace. The workload ran for 8 days, using 24 large-CPU spot VMs on GCP, us-west1.

regions across the globe. Even for a simple request of a 4-vCPU VM in the “compute-optimized” family—advertised by all three clouds—there are at least 90 choices within the US in terms of region and VM type. Furthermore, each cloud has hundreds of software services (e.g., hosted Kubernetes/Spark, blob storage, SQL databases) to choose from. This is clearly beyond what can be navigated manually by ordinary users.

To provide the automatic placement of jobs, the broker must catalog the variety of instances and services, the APIs to invoke these services, and the subset of clouds and regions where these offerings are available.

Even after they have been cataloged, these many options are hard to navigate. Thus, the broker should expose filters on common attributes to applications so that they can easily narrow down the many options across clouds. For compute instances, filters may include the number of vCPUs, RAM, and accelerator types. For managed services (e.g., hosted analytics), filters may include the service or the package version (e.g., AWS EMR 6.5, or Apache Spark 3.1.2). Moreover, the broker should allow an application to choose specific services or instances supported only by one cloud.

Tracking pricing and dynamic availability. The price and availability of resources can vary dramatically across clouds and even regions or zones in the same cloud, often, but not always, following a diurnal pattern [73]. The variations are especially acute for *scarce resources* (§5.4), such as GPUs or preemptible spot instances that many applications use due to their lower costs, and change over time.

To illustrate the potential changes in resource availability, consider a real user’s application: a bioinformatics task running for 8 days on 24 spot VMs on GCP (see §5.2 for more detail). When a VM is preempted, it waits for another spot VM to become available. Figure 2 shows the cumulative number of preemptions over time. Note that preemptions happened every day and at *unpredictably* different rates (e.g.,

compare day 3–4 vs. day 4–5). The application experienced 319 preemptions, a preemption every 36 minutes on average.

Thus, the broker should track the availability and pricing to provide applications with the best choices at run time. One challenge is that clouds do not publish availability information explicitly. The broker may have to learn about availability implicitly by observing preemptions or allocation failures of both on-demand and spot resources in different locations.

Dynamic optimization. Recall that the goal of the broker is to meet the application’s cost and performance requirements under various constraints, such as data residency. This means the broker should choose the types of instances or services, clouds, and locations to run the tasks in the application DAG. This is a challenging optimization problem because of (1) the sheer number of choices (Table 1), (2) DAG topologies becoming complex (Figure 10), and (3) the unpredictable resource availability and price changes during the application’s provisioning or run time (Figure 2).

As a result, the broker should implement a dynamic optimizer that can reflect the current resource availability and prices, and quickly find an optimal execution plan out of the large search space. To use up-to-date prices, the broker needs to compute the execution plan whenever an application starts. In addition, when a task in an application DAG cannot run as the broker originally planned due to availability changes, the broker needs to generate a new execution plan by *re-optimization* during the application’s run time.

Managing resources and applications. Once the optimizer decides the placement of an application, the broker must provision the resources and free them when the application terminates. This involves starting and *reliably* shutting down instances on various clouds, or creating and terminating services (e.g., sending requests to a hosted service like AWS EMR). While these lifecycle operations may seem straightforward, bugs or failures can easily lead to inconsistencies between the broker state and the cloud provider state (e.g., leaking instances or intermediate data), which can be costly.

In addition, the broker must manage the execution of the application, i.e., start an application’s task when its inputs are available, possibly restart it in case of failures or preemptions, and move the task’s inputs across clouds/regions, if remote.

4.2 Architecture

Given these requirements, we propose an intercloud broker architecture consisting of the following components (Figure 3).

Catalog. The catalog records the instances and services available in each cloud, detailed locations that offer them, and the APIs to allocate, shut down, and access them. It also stores the long-term prices for on-demand VMs, data storage, egress, and services (typically these prices do not change for months). The catalog can provide filtering and searching functionalities. The catalog can be based on information published by the clouds, listed by a third party, or collected by the broker.

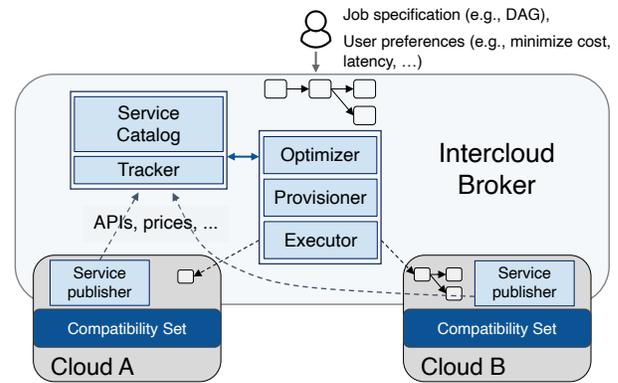

Figure 3: Architecture of the intercloud broker.

Tracker. This component tracks spot prices (which can change more frequently, e.g., hourly or daily) as well as resource availability across clouds and their locations.

Optimizer. The optimizer takes as inputs (1) the application’s DAG and its requirements, and (2) the instance and service availability as well as their prices provided by the catalog and tracker, and then computes an optimal placement of the tasks. Upon resource availability and price changes, the optimizer may perform re-optimization.

Provisioner. This component manages resources (§4.1) by allocating the resources required to run the execution plan provided by the optimizer, and freeing them when each task exits. To handle unpredictable capacity and user quota errors, the provisioner implements automatic failover, where it asks the optimizer for a new placement plan if the provision fails. Failures are also reported to the tracker.

Executor. The executor manages the application (§4.1) by packaging each application’s tasks and running them on the resources allocated by the provisioner.

In the future, we imagine intercloud brokers will offer more sophisticated services such as troubleshooting across clouds, providing more detailed performance measurements for specific applications on each cloud, the equivalent of spot-pricing but across clouds, reselling services at lower than listed prices (similar to the travel industry), and advanced configuration features for security and/or networking.

Furthermore, we expect a commercial broker to provide billing support to enable a user to have a single account with the provider of the intercloud broker, which then pays for the services rendered by each cloud on behalf of the user, and charges the user back. In our current deployment, our users have direct accounts with the three major clouds, so this functionality is not needed.

4.3 SkyPilot: An Implementation

We have implemented *SkyPilot*, which follows the architecture described in §4.2 with one difference: instead of implementing the tracker as a centralized component, *SkyPilot* distributes it between the catalog that refreshes prices daily, and the provisioner that tracks and caches provisioning failures.

SkyPilot is written in $\approx 21,000$ lines of Python code, and has involved several person-years so far. It currently supports AWS, Azure, and GCP. It is being used by users from 3 universities and 4 other organizations; we report our deployment experience in §6. Next, we first describe SkyPilot in detail, then discuss the services in the compatibility set it uses.

Application API. As mentioned earlier, an application is specified as a DAG of coarse-grained tasks. Example tasks include a Spark job to process data, a Horovod [79] job to train a model, or an MPI job for HPC computations. A task starts when all of the tasks that provide its inputs have finished. Each task is self-contained and includes its executable and all library dependencies (e.g., packaged as a Docker image).

A task specifies its *input and output locations* in the form of cloud object store URIs. Optionally, a task can provide the *size estimates* of its inputs and outputs to help the optimizer estimate the cost of data transfers across clouds.

Each task specifies the *resources* it requires. For flexibility, resources are encoded as labels, such as “cpu: 4” or “accelerator: nvidia-v100”, an idea we borrow from cluster managers such as Borg [85], Mesos [63], and Condor [82]. The optimizer uses these resource labels to search the service catalog for a set of feasible candidates for each task. If desired, the user can short-circuit the optimizer’s selection by explicitly specifying a cloud and an instance type.

The user optionally specifies the number of instances for each task by a “num_nodes: *n*” label, which defaults to 1. Since we target coarse-grained batch jobs, our users have not found this a burden. In the future, we plan to support autoscaling or intelligently picking the number of instances [54, 84].

Finally, the user supplies an optional *time estimator* for each task, which estimates how long it will run on each specified resource. These estimates are used by the optimizer for planning the DAG. The user could determine these estimates by benchmarking the task on different configurations. If a time estimator is unspecified for a task, currently the optimizer defaults to the heuristic of choosing the resource with the lowest hourly price.⁵

Example. Listing 1 shows an application consisting of two tasks. The `train` task trains a model. It reads the input data from S3 and writes the output (the trained model) to the object store of the cloud it is assigned to run on, which is determined by the optimizer. By using `Resources`, a dictionary of resource labels, the user specifies that this training task requires either an `nvidia-v100` accelerator or a `google-tpu-v3-8` accelerator with 4 host vCPUs. The user also provides a `train_time_estimator_fn` lambda that estimates the task’s run time on these two accelerators. For example, one can compute a rough estimate by dividing the total number of floating operations required for training the model by the accelerator’s performance in FLOPS (floating point operations per second),

⁵Prior work [83] have considered performance prediction for analytics [84] and machine learning [78] workloads, which can also be leveraged.

```
# A simple application: train -> infer.
with Dag() as dag:
    train = Task('train', run='train.py',
                 arg='--data=$INPUT[0] --model=$OUTPUT[0]')
        .set_input('s3://my-data', size=150 * GB)
        # '?': saves to the cloud this op ends up running on.
        .set_output('?:/my-model', size=0.1 * GB)
        # Required resources. A set ({} ) means pick any Resources.
        .set_resources({
            Resources(accelerator='nvidia-v100'),
            Resources(accelerator='google-tpu-v3-8', cpu=4)})
        # A partial function: Resources -> time.
        .set_time_estimator(train_time_estimator_fn)

    infer = Task('infer', run='infer.py',
                 arg='--model=$INPUT[0]')
        .set_input(train.output(0))
        .set_resources({
            Resources(accelerator='nvidia-t4'),
            Resources(accelerator='aws-inferentia', ram=16 * GB)})
        .set_time_estimator(infer_time_estimator_fn)
    # Connect the tasks.
train >> infer
```

Listing 1: API to express a simple application.

or use a more accurate benchmarking-based predictor.

The `infer` task performs model serving. It takes the trained model as input (`set_input(train.output(0))`). The Airflow-like statement, `train >> infer`, enforces this dependency. These two tasks are encapsulated in a `Dag` object. The DAG is passed to the optimizer to output an execution plan, which is then passed to the provisioner and the executor.

Figure 4a visualizes the DAG. (I/O data are task attributes and not nodes in the DAG; we show them for clarity.) While simple, this basic API already exposes many degrees of freedom. For example, while `train`’s input is on S3, the optimizer may choose to assign the task to a different cloud. In doing so, the optimizer must take into account the possible transfer costs, while satisfying the task’s requirements.

For convenience, SkyPilot also offers a YAML interface to specify an application in addition to the programmatic API.

Catalog. SkyPilot implements a simple catalog to support three services (IaaS, object stores, managed analytics) on AWS, Azure, and GCP. These offerings are sufficient for our target workloads. We use the clouds’ public APIs to obtain details about these offerings. Pricing is refreshed periodically.

Optimizer. The optimizer assigns each task to a cloud, location, and hardware configuration to best satisfy the user’s requirements, e.g., minimize the total cost or time. It achieves this by filtering the offerings in the service catalog and solving an integer linear program (ILP) to pick an optimal assignment.

Before the actual optimization takes place, the optimizer first translates the high-level resource requirements into a set of feasible configurations, i.e., tuples of (cloud, zone, instance type), that can be used to run each task.⁶ We call such a configuration a *cluster*. For example,

⁶This also applies to most hosted analytics offerings (e.g., EMR, Dataproc) as they allow users to specify the cluster size and instance types.

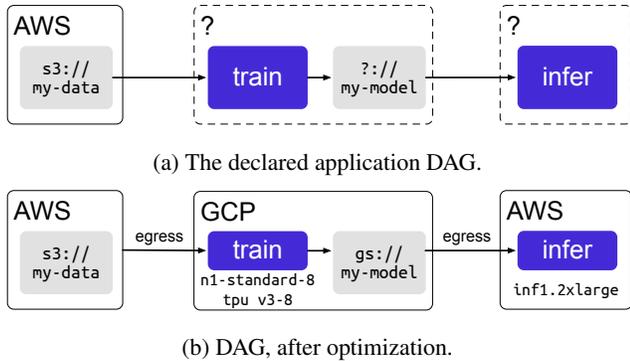

Figure 4: An application, before and after optimization.

Resources(accelerator='nvidia-v100') can be mapped to a cluster of AWS instances (AWS, us-west-2a, p3.2x) or Azure instances (Azure, westus2-1, NC6s_v3). To perform this translation, the optimizer filters the offerings in the service catalog to check if they satisfy the Resources required by each task. Each task is then annotated with the list of feasible clusters.

The optimizer computes execution plans at a zone level rather than a region level. This is because even in the same region, different zones can have different instance types and prices, and the data transfer between zones is not free.

ILP-based optimization. Consider a DAG with N tasks, each with C feasible clusters. Because C is typically in the 10s and can be up to 100s,⁷ naively enumerating all C^N possible assignments is infeasible even for modest values of N . To solve this, we formulate the assignment problem as a 0-1 ILP.

SkyPilot supports two types of optimization objectives: either total running cost or end-to-end run time. Our ILP formulation is inspired by Alpa [94], but we additionally consider the parallelism between tasks that do not have dependency on each other. This is critical for minimizing the DAG run time.

Given a DAG (V, E) where V is the set of the tasks and E is the set of the edges representing the data dependencies between the tasks, our goal is to find an optimal mapping from each task in V to one of its annotated feasible clusters. For each task $v \in V$, we denote the set of the feasible clusters by C_v . Then we use a task time estimator to obtain a time vector $t_v \in \mathbb{R}^{|C_v|}$, where each element is the time estimate for running task v on a cluster in C_v . The time estimator can be either provided by the user or set to a default value of 1 hour. In addition, we get a cost vector $c_v \in \mathbb{R}^{|C_v|}$ by multiplying t_v by the hourly price of each cluster. To account for the data transfer overhead between two tasks $(u, v) \in E$, we define a matrix $P_{uv} \in \mathbb{R}^{|C_u| \times |C_v|}$ whose (i, j) element is the data transfer time when the parent task u is mapped to the i -th cluster of C_u and the child task v is mapped to the j -th cluster of C_v . Similarly, we define $Q_{uv} \in \mathbb{R}^{|C_u| \times |C_v|}$ for the data transfer cost between u and v .

⁷For instance, the previous example that requires one V100 GPU maps to 79 feasible clusters globally across AWS, Azure, and GCP.

When minimizing the total cost, we have:

$$\min_s \underbrace{\sum_{v \in V} s_v^T c_v}_{\text{computation cost}} + \underbrace{\sum_{(u,v) \in E} s_u^T Q_{uv} s_v}_{\text{data transfer cost}} \quad (1)$$

where $s_v \in \{0, 1\}^{|C_v|}$ is a one-hot vector that selects a cluster from C_v . The objective explicitly considers the two types of cost: the first term represents the total cost spent in executing all tasks on the selected clusters, while the second term represents the total data transfer cost. After we linearize [61] the second term, we get a 0-1 ILP, which SkyPilot solves using an off-the-shelf solver, CBC [60].

Similarly, when minimizing the end-to-end time, we have:

$$\min_s f_{\text{sink}} \quad (2)$$

$$\text{s.t. } f_v \geq \underbrace{f_u}_{\text{parent finish time}} + \underbrace{s_u^T P_{uv} s_v}_{\text{data transfer time}} + \underbrace{s_v^T t_v}_{\text{computation time}} \quad \forall (u, v) \in E \quad (3)$$

where $s_v \in \{0, 1\}^{|C_v|}$ is the one-hot decision vector and $f_v \in \mathbb{R}$ is the *finish time* of the task v . The optimization constraint ensures that a task finishes no earlier than its parents, the input data arrive, and the task produces its outputs. Under these constraints, the running time of the DAG becomes the finish time of its sink.⁸ Again, as we can linearize the second term, this problem can be efficiently solved by 0-1 ILP solvers.

While we cover the two representative objectives above, our ILP formulation allows any combination of cost and time to be used for the optimization. For example, we can minimize the cost under a time budget (or vice versa), by augmenting Equation 1 with the constraint in Equation 3 and bounding f_{sink} by the time budget. Future work can incorporate carbon footprint of cloud regions [21] into placement decisions.

Provisioner. SkyPilot implements a *provisioner* that reads the optimized plan and allocates a cluster for the next task ready to execute. As discussed, allocations may fail due to either *insufficient capacity* in a cloud's location or *insufficient quota* of the user's account. On such failures, the provisioner kicks off *failover* as follows. First, the failed location is temporarily blocked for the current allocation request with a time-to-live. Then, the optimizer is asked to *re-optimize* the DAG with this new constraint added. The provisioner then retries in the newly optimized location (another location of the same cloud or a different cloud). If all available locations fail to provide the resource, either an error is returned to the user or the provisioner can be configured to wait and retry in a loop.

We found failover to be especially valuable for scarce resources (e.g., large CPU or GPU VMs). For example, depending on request timing, it took 3–5 and 2–7 location attempts to allocate 8 V100 and 8 T4 GPUs on AWS, respectively.

⁸ If the DAG has multiple sinks, we create a dummy sink that has a fake dependency on the real sinks.

Executor. After a cluster is provisioned, the *executor* orchestrates a task’s execution, e.g., setting up the task’s dependencies on the cluster, performing cross-cloud data transfers for the task’s inputs, and running the task (which can be a distributed program utilizing a multi-node cluster). We built an executor on top of Ray [71], a distributed framework that we use for intra-cluster task execution with fault tolerance support. Using Ray, rather than building a new execution engine, allowed us to focus on building the higher-level components new to the broker. For example, our executor implements a storage module that abstracts the object stores of AWS, Azure, and GCP and performs transfers. The executor also implements status tracking of task executions for resource management. On execution failures, the executor optionally exposes cluster handles to allow login and debugging.

The executor interface is modular. We envision other executors will be added in the future, e.g., for Kubernetes [36]. In addition, while our system formulation is generic enough to support arbitrary DAGs, our implementation of the executor has focused on supporting pipelines (sequential DAGs).

Compatibility set. One of the distinguishing features of Sky is leveraging the already existing services and APIs across clouds (i.e., compatibility set; §2.3), rather than building uniform services and APIs across all clouds. However, a broker still needs to develop some glue-code to handle similar but not identical services supported by different clouds. The natural question is what is the effort to implement such glue-code? The answer for our applications so far is “minimal”.

To manage clusters, SkyPilot uses Ray’s cluster launcher, which already supports AWS, GCP, and Azure. (Other frameworks could also be used, e.g., Terraform [51].) The main functionality we added is the control for automatic failover.

One of the most important components of any Sky application is storage. While the APIs provided by the object stores of the three major clouds are similar, they are not identical. Fortunately, all have libraries [20,30,46] exposing the POSIX interface, which allows us to mount different object stores as directories. Providing this functionality required only 400–500 lines of code (LoC) per object store.

Finally, for analytics applications we use high-level APIs, e.g., hosted analytics services provided by AWS (EMR) and GCP (Dataproc). Abstracting these services required us to implement just two methods: provisioning and termination. This involved only 200 LoC for EMR and Dataproc together.

5 Experiments

We conduct a series of experiments to evaluate the benefits of our intercloud broker. Overall, we found that:

- SkyPilot enables batch applications to take advantage of unique hardware, unique managed services, and improved availability across locations and clouds.
- On three applications (ML pipelines, scientific jobs, and data analytics), SkyPilot saves up to $2.7\times$ in time, 80%

Workload	Uses	Benefits from
ML	IaaS	unique hardware
Bioinformatics	IaaS (spot VMs)	improved availability
Analytics	managed analytics	unique software service & unique hardware

Table 2: Evaluated workloads, cloud services used, and benefits.

in cost, and $2\times$ in makespan, compared to using a single cloud or location.

- Even for single-cloud applications, the broker improves availability by migrating jobs across regions, a policy not supported by cloud providers’ own solutions (§5.2).

Table 2 shows all workload types and their respective benefits.

5.1 Machine Learning Pipelines

We start with running two ML pipelines on SkyPilot to leverage the strengths of different clouds. In both pipelines, the goal is to minimize the total cost. We consider two scenarios:

- Single-cloud: all tasks are constrained to a single cloud;
- Broker: each task runs according to the plan generated by SkyPilot’s optimizer, possibly on different clouds.

Overall, both pipelines benefit from SkyPilot’s flexibility to run compute-intensive tasks on clouds with unique hardware accelerators (e.g., Inferentia, TPUs) that can provide speedups which offset the cost and latency of moving the data.

Due to space limit, we show in appendix (§A.2) an additional experiment on SkyPilot leveraging spot instances across clouds to run ML training with improved availability and cost.

5.1.1 Vision Pipeline

The vision pipeline consists of two tasks: train and infer (see Listing 1). The train task trains a ResNet-50 model on the ImageNet dataset (150 GB, stored on AWS S3). The infer task runs offline inference on 10^8 images (e.g., nightly photo categorization for services like Instagram or Google Photos).

Since training deep learning models often requires iterative and heavy computations, we demonstrate a large reduction in cost and run time by moving the training data from AWS to GCP to leverage its TPU accelerators for training [23].

Setup. We specify resource candidates for each task as:

- train: `'nvidia-v100', 'google-tpu-v3-8'`
- infer: `'google-tpu-v3-8', 'nvidia-t4', 'aws-inferentia'`

For train, we use a V100 (common high-end GPU for training) or a TPU. For infer, we use a TPU, a T4 GPU (marketed as the most cost-effective GPU for model inference), or an Inferentia accelerator designed by AWS for cost-effective inference [15].

The best single-cloud plans are shown in Figure 5, termed {AWS, GCP, Azure}-only. The Broker plan is SkyPilot’s optimizer output that minimizes the total cost. In this experiment, we used a simple time estimator that divides the total FLOPs

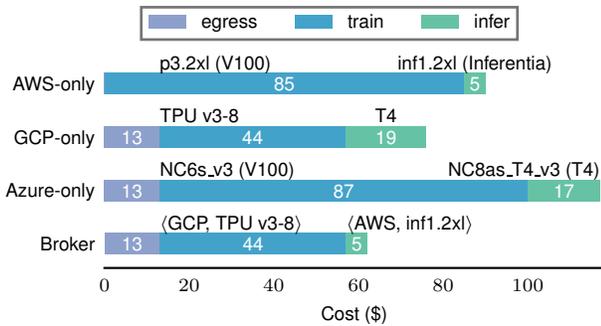

Figure 5: **Vision pipeline**: hardware and costs of each deployment. For simplicity, the zones chosen for the plans are omitted. For training we use mixed-precision and the XLA compiler [50] with TensorFlow Keras 2.5.0. For inference we use half-precision. On GCP, accelerators are attached to an n1-standard-8 VM.

required to train the model by the hardware FLOPs:⁹

```
def train_time_estimator_fn(resource):
    train_tflops = ... # Obtained from model analysis.
    if resource.accelerator == 'nvidia-v100':
        hardware_tflops = 120
    if resource.accelerator == 'google-tpu-v3-8':
        hardware_tflops = 420
    return train_tflops / hardware_tflops
```

We used a similar FLOPs-based time estimator for infer.

Results. We show the plan generated by SkyPilot’s optimizer in Figure 4b and the results in Figure 5.

While this pipeline is simple, *its search space is already large*, with a total of 2,170 possible assignments (details in §5.4), as we have multiple choices in hardware, cloud, and location. The optimizer successfully finds an optimal solution. Compared with the three single-cloud plans, the Broker plan lowers the total cost by 18%–47%, by taking advantage of the unique hardware capabilities across two clouds.

For train, the optimizer decides that, despite the input being stored on AWS, it is better to incur an egress cost and ship it to GCP to use the TPU. This choice leads to a cost of \$57 (\$44 compute, \$13 egress) which is less than training on AWS, at \$85.¹⁰ SkyPilot’s storage module uses GCP’s storage transfer service [31] to copy the data in about 3 minutes.

For infer, the optimizer estimates that AWS’s Inferentia is more cost-effective than the T4 GPU, after factoring in a small data egress cost (shipping the first task’s output, a 0.1 GB model, from GCP to AWS with a cost of \$0.01).

To understand the cost savings, we compare the detailed time and cost per task. For training (Figure 6a), SkyPilot’s choice of GCP TPU takes 5.4 hours and costs \$57 with egress included, which is 5.2× faster and 33% cheaper than the AWS V100 plan. (Azure V100 is similar but has \$13 for egress; hence omitted.) To make the hardware more comparable, we

⁹While crude, this estimate is a reasonable approximation for throughput-bound models with intensive matrix operations, such as ResNet.

¹⁰If we set the input 4× as large, at 600 GB, the optimizer decides against transferring the data as the egress cost will dominate.

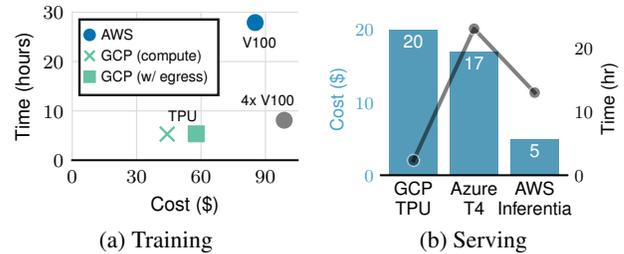

Figure 6: **Vision pipeline**: detailed breakdown per task.

submitted the task again requesting 4 V100s on AWS to match the FLOPS performance of a TPU v3-8: still, TPU is 1.5× faster and 42% cheaper than 4 V100s. For serving (Figure 6b), AWS’s custom Inferentia chip saves both cost (71%) and time (1.8× faster) compared to the widely available T4 GPU.

Thus, clouds offer *unique hardware incentives* to different tasks, even if the data is stored on a different cloud.

Optimizing for time vs. cost. To test SkyPilot’s ability to minimize the total time rather than cost (§4.3), we resubmit this pipeline to SkyPilot with the time-minimizing objective. The resource selection for train remains the same. For infer, SkyPilot now chooses GCP TPU (estimated to take 2.5 hours and cost \$21, per 10⁸ images) over AWS Inferentia (which was *cost-optimal*; estimated to take 8.2 hours and cost \$3). The estimates reflect the actual ranking in Figure 6b. Even though the TPU costs 4× more in total than Inferentia, it reduces inference time by 5.7×. This example shows that optimal placements can change based on user preferences.

5.1.2 NLP Pipeline

We next run a natural language processing (NLP) pipeline that emulates an increasingly prevalent workload: fine-tuning “foundation models” [56]. It consists of three tasks (Figure 1):

- **Confidential data processing:** remove sensitive information from raw data using Intel SGX hardware enclaves. We use the Amazon Customer Reviews Dataset [2] and treat it as if it contained personally identifiable information (PII) and thus must be processed securely. To remove sensitive data, we run Opaque [95] on an SGX-enabled instance to filter on a column (i.e., the filtered-out information is assumed sensitive), and output only the review texts and star ratings. The size of the output dataset is 1 GB.
- **Train:** fine-tune BERT-base [59], a popular natural language understanding model, on the preprocessed and now non-sensitive data. This model predicts a rating given a review text. We fine-tune the model for 10 epochs.
- **Infer:** use the model to classify 1M new reviews.

Setup. The first task requires `Resources(intel_sgx=True)`, which is currently only offered by Azure [16]. For training, we consider either 4 V100s, or a TPU v3-8. For serving, we consider either a T4 GPU, or AWS’s Inferentia.

Due to the confidential computing requirement, the only possible single-cloud plan is to run all three tasks on Azure:

		proc	train	infer	egress	Total
Time (hr.)	Azure	0.6	13.3	1.5	–	15.4
	Broker	0.6	3.8 <i>-71%</i>	1.4 <i>-7%</i>	0.03	5.8 <i>-62%</i>
Cost (\$)	Azure	0.8	163	1.2	–	165
	Broker	0.8	32 <i>-80%</i>	0.5 <i>-58%</i>	0.1	33.4 <i>-80%</i>

Table 3: **NLP pipeline**: run time and cost of each deployment plan.

a DC8 VM for SGX, an NC24s VM with 4 V100 GPUs for training, and an NC8as instance with a T4 GPU for serving.

Results. Table 3 shows the time and cost comparison between the single-cloud and Broker plans. Different from before, the Broker plan for this pipeline uses all three clouds. The search space is larger, *with over 16K possibilities* (§5.4).

As expected, the single-cloud plan restricts its choices of hardware to Azure and thus results in suboptimal cost and performance. While Azure’s Intel SGX offering is unique for secure processing, SkyPilot allows this pipeline to leverage different clouds for other tasks of the same application. SkyPilot’s optimizer picks the TPU (GCP) over 4 V100s for training, and the Inferentia (AWS) over the T4 GPU for serving. This considerably reduces both the total run time (by 62%) and cost (by 80%) compared with the Azure-only plan.

5.2 Bioinformatics

The intercloud broker should *dynamically* respond to the changing availability of resources (§4.1). We evaluate SkyPilot’s handling of availability changes by modeling a *real user’s workload*: A bioinformatic task of mapping DNA cells of sequencing data [67,92]. The jobs are independent, have variable-sized inputs and variable run times, with each using all CPUs within one machine. Jobs are not checkpointable and failures require recomputation from scratch. Finally, these jobs are *recurring*: there are 10s to 100s of jobs to run every week based on incoming data. Due to long run times, this user exclusively uses spot VMs on GCP to save costs, and has been continuously using SkyPilot to do so for several months.

We submit 40 jobs to SkyPilot, each running on an n1-highmem-96 spot VM on GCP for 8–12 hours. We implement and compare two policies in SkyPilot: (1) *SingleRegion*, which retries each preempted job in other zones of the same region—this models providers’ managed instances solutions [35]; (2) *Broker*, which retries each preempted job in the next cheapest region chosen by the optimizer. We start two sets of 40 jobs together (to minimize variance due to time) in the region with the cheapest price for this VM (us-west1). We ensure the jobs are within quotas so all job migrations are due to preemptions.

Overall, the Broker policy finishes significantly faster than the SingleRegion baseline, due to experiencing fewer preemptions. Figure 7 (top) shows that Broker completed 75% of the jobs 1.6× or 7 hours faster than SingleRegion. At around $T = 16$ hours, all Broker jobs finished, while 30% (12) of SingleRegion jobs were still running. The last SingleRegion

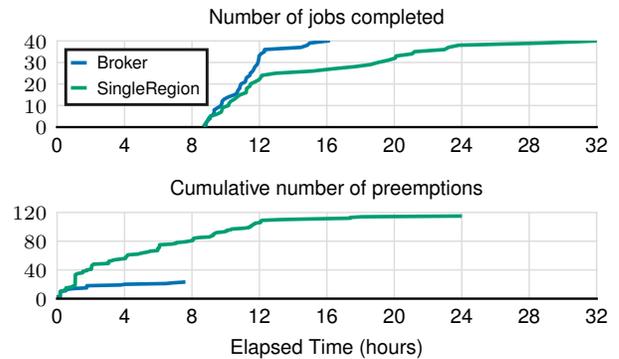

Figure 7: **Dynamically adjusting to availability** on a bioinformatics workload of 40 jobs on spot CPU VMs. *Broker* moves preempted jobs to a new region, while *SingleRegion* moves preempted jobs to other zones in the same region. Note the shared x-axis. Cloud: GCP.

job finished at $T = 32$ hours, yielding a 2× longer makespan.

Figure 7 (bottom) shows the speedup comes from Broker incurring 5× fewer preemptions. Since both policies started in the same region, the preemption curves initially overlapped. Broker swiftly moved the 22 preempted jobs to another region, which remained non-preemptive for the entire duration (e.g., last preemption occurred before $T = 8$ hours). The original region continued to experience a high preemption rate in all zones, causing SingleRegion to have far more stragglers.

While this example represents a good case (moving from a region with a high preemption rate to a region with a low preemption rate), it shows that SkyPilot can dynamically use multiple regions to improve availability *when needed*. Managed solutions from cloud providers, e.g., spot fleets [49] or managed instances [35], are *confined within a region* and thus cannot support such a cross-region (or cross-cloud) policy.

Finally, note that this policy is not always better than SingleRegion. For example, if the jobs started in a region with a low preemption rate, some unlucky jobs could be preempted and moved to a region with a higher preemption rate, which could be worse than SingleRegion. Importantly, SkyPilot allows new policies (cross-cloud/region) to be implemented easily, and we expect this to be an area of future research.

5.3 Managed Data Analytics

So far, we demonstrated SkyPilot’s ability to use IaaS (VMs) on different clouds. We now use the broker to run an analytics workload on the *managed analytics services* of two clouds: AWS EMR [4] and GCP Dataproc [29]. While VMs with the same hardware on different clouds should have mostly the same performance, we expect hosted services to exhibit more performance variations due to differences in software. We run TPC-DS [72] on the following (scale factor 100, or 33 GB of data in Parquet, generated locally on each cloud):

- GCP Dataproc: which runs vanilla Spark 3.1.2, on a 3-node n2-standard-16 cluster. Version 2.0.29-debian10.
- AWS EMR: which runs an *optimized runtime* [42] for

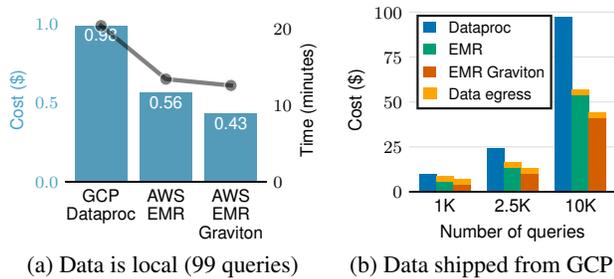

Figure 8: **Using managed analytics services with SkyPilot.** TPC-DS. (a) Cost (left y) and time (right y) of two hosted services in three configurations, where data is generated locally. Benefits of software and hardware offerings can combine. Mean of 3 runs. (b) Assuming data is stored in GCP, running more queries offsets the egress cost.

Spark 3.1.2, on a 3-node m5.4xlarge cluster. Version 6.5.0.

- AWS EMR Graviton: like above, but on a 3-node m6g.4xlarge cluster, which uses the Graviton2 ARM-based processors custom-designed by AWS [14]. Due to its cost-performance benefits, several large companies such as Netflix and Snap have moved some of their workloads to Graviton2 from traditional x86 instances [13].

Figure 8a shows AWS EMR finishes 34% faster and 43% cheaper than GCP Dataproc. We ensured that GCP’s n2 cluster has the same or better hardware than AWS’s m5.4x cluster. Thus, the speedup is due to EMR’s optimized software runtime [42] for Spark, representing a *unique software incentive* for users with similar analytics workloads.

In addition, AWS EMR Graviton *improves* both the cost and run time over AWS EMR by 23% and 6%, respectively. Thus, this is a case of combining the *unique software* and *hardware* advantages to attract such workloads even more.

To understand the tradeoff between better services vs. data gravity, Figure 8b shows the cost of running more queries from the benchmark, assuming the data is not generated locally but initially resides in GCP and has to be copied. (Here, we simply execute the TPC-DS benchmark’s 99 queries multiple times to increase the number of queries we ran.) With 1K queries, EMR’s speed advantage already offsets the data transfer cost (\$2.8). Running 2.5K queries yields a cost saving of 32% for EMR and 46% for EMR Graviton, while running 10K queries yields 42% and 55% savings, respectively.

To request a managed service for a task, we specify

```
task.set_managed_service(
    AnalyticsService(
        dependencies={'Spark': '3.1.2', 'Hadoop': '3.2.1', ...},
        resources=Resources(cpu=16, ram=64 * GB, num_nodes=3)))
```

where `AnalyticsService` is backed by concrete implementations such as EMR or Dataproc. The `dependencies` field specifies the desired package versions for the hosted service; such version lists are published by the cloud providers [11,26] and recorded in SkyPilot’s service catalog.

Type	Hardware	Zones	On-demand \$		Spot \$	
			Max/Min	CV	Max/Min	CV
CPU	AMD (8 cores)	146	2.5×	16%	7.3×	59%
	Arm (8 cores)	88	2.1×	12%	2.5×	17%
	Intel (8 cores)	248	1.6×	12%	9.4×	39%
GPU	K80 (1 chip)	56	9.5×	48%	5.9×	60%

Table 4: **Capturing the large heterogeneity of locations and pricing in the catalog.** We show for a subset of offerings, the number of zones that provide them (out of 294 zones globally across the top 3 clouds), the pricing ratios of the most costly to the cheapest zone, and the coefficients of variation (CV) of prices across zones. CPUs are the latest generation in the “general-purpose” family.

5.4 Analyzing the Broker

Location and pricing heterogeneity in the catalog. We analyze SkyPilot’s service catalog (over 76K entries) to see how well it captures the heterogeneity in locations and prices for all three clouds. Table 4 shows the results. We see that not all offerings (VMs, accelerators) are present in all zones, and there can be large price differences across zones.

Among the 294 zones across the three clouds, the latest Intel CPUs are widely offered, but AMD is only offered in 50% of the zones, while ARM is in only 30%. CPU workloads, e.g., bioinformatics (§5.2) and analytics (§5.3), can suffer from up to 2.5× price premiums if run in the most expensive zone, which increase to 9.4× if spot instances are used. These differences are even larger for NVIDIA GPUs, which are present in just 16–50% of all zones, and their prices vary by up to 9.5× for on-demand and 10.8× for spot. Finally, despite TPUs being offered only in 4–5 (or 5%) GCP zones, there is still a 10%–20% price difference across those zones.

This significant heterogeneity in *locations* and *pricing* makes it hard for users to manually find the best placement. By capturing this heterogeneity, SkyPilot’s catalog enables the optimizer to automatically exploit these differences.

Optimizer overhead. We evaluate SkyPilot’s optimizer overhead on a variety of DAGs. Figure 9 shows the search space sizes and the optimization time for the two ML pipelines in §5.1 and 3 other DAGs (see below). Despite the pipelines’ simple structures (Vision, NLP), *their search spaces already have 2K–16K possible assignments*, making them non-trivial or infeasible to optimize by hand. Using the ILP, however, our optimizer can find an optimal solution in under 1.4 seconds.

Additionally, we test on three larger and more complex DAGs, found in Airflow’s repository [6]: the first two (Figure 10a, Figure 10b) are commonly used in the real world [68], while the third (Figure 10c) has a more complex structure.

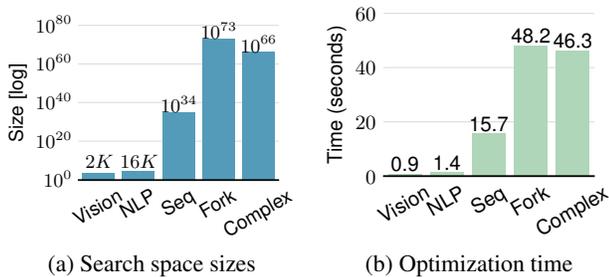

Figure 9: **Search spaces and optimization times.** Timing is measured on an M1 MacBook Pro; mean of 3 runs. Objective is cost. Locations of feasible clusters are limited to all US zones on 3 clouds.

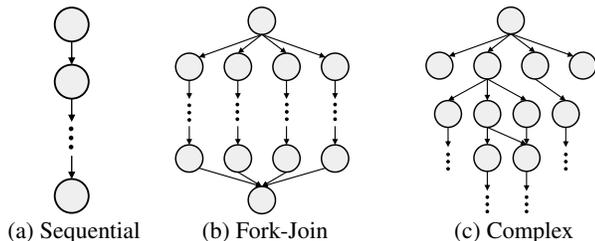

Figure 10: **Larger DAGs found in Airflow's repository.** (a) Sequential: $|V| = 20, |E| = 19$. (b) Fork-Join: $|V| = 42, |E| = 44$. (c) Complex: $|V| = 38, |E| = 53$.

We assume each task requires an 8-vCPU Intel VM in US zones, which leads to 55 feasible clusters for each task. We assign random time estimates (sampled from $U(0, 1)$ hours) to each task and a random data transfer size (sampled from $U(0, 100)$ GB) to each edge. While the search spaces for the DAGs are combinatorially large (10^{34} – 10^{73} possible assignments), optimization takes at most 48.2 seconds. Since each task in a DAG is coarse-grained (e.g., can take hours), this optimization time is a negligible portion of the DAG run time.

If resource availability changes during run time, the DAG may need to be re-optimized to generate a revised execution plan. As the process of re-optimization involves updating the list of feasible clusters and restarting the ILP optimization, its overhead is comparable to that of the initial optimization.

6 Deployment Experience

We have deployed SkyPilot to dozens of users from 3 universities and 4 other organizations, who have been using the broker to run both adhoc and recurring batch jobs in the clouds for many months. These users have switched to the intercloud broker from their prior solutions of manually interacting with specific clouds, either via web consoles or low-level APIs. Below, we discuss our experiences with the system so far based on user feedback.

Benefits of an intercloud broker. By surveying our users, we found that users value the broker not only for cost reduction, but also for improved availability (see §5.2) and in general for *improving their productivity*. For example, users like the broker's ability to automatically provision scarce

resources across clouds or regions, the easy access to best-of-breed hardware (e.g., TPUs), and the simple packaging of existing programs. Moreover, by interacting with the broker rather than the clouds, they value the ability to run the same jobs on different clouds with no change to their code or workflow.

Cluster reuse for faster development and debugging.

Users have reported that the typical provisioning time of several minutes for a new cluster is too long, especially during the iterative code development phase. To alleviate this, we added the ability to reuse existing clusters for running a new application. This also helps the debugging of Sky applications as the users can log into a cluster to inspect and troubleshoot.

Moving data is acceptable for many workloads.

Data gravity can prevent workloads from being moved across clouds. However, we found that for many batch workloads, cross-cloud data transfers are not as slow or costly as we expected. In fact, moving data can be profitable even after factoring in the egress (Figure 5; Figure 8).

There are several reasons for this. First, the computation complexity of many batch jobs, such as ML training, is typically *super-linear* in the input size. Second, many datasets are not excessively large. For example, a study from Microsoft reports that most production ML datasets are between 1 GB to 1 TB [75]. Our results (§5.1.1) suggest that a 1 TB dataset can likely be moved in ~ 20 minutes with a cost of $\sim \$90$. Depending on the job, this delay and cost can be easily offset by the destination offering better hardware, software, or pricing.

On-premise clusters as part of the Sky.

Users have requested the support for running jobs on on-premise clusters through the broker. There are several benefits. First, this would enable users to take advantage of idle local clusters and burst to the cloud when they are overloaded. Second, the broker would offer the same interface that hides the heterogeneity (to the extent possible), so the same Sky applications could run both in the cloud and locally. Challenges include designing spillover policies and handling compatibility and storage.

7 Related Work

Sky Computing. We are not the first to use the name “Sky Computing” as several papers, dating back to 2009, also used this term [62, 69, 70]. However, these papers focus on particular technical solutions, such as running middleware (e.g., Nimbus) on a cross-cloud Infrastructure-as-a-Service platform, and target specific workloads such as high-performance computing (HPC). This paper takes a broader view of Sky Computing, seeing it as a change in the overall ecosystem and considering how technical trends and the market forces can play a critical role in the emergence of Sky Computing.

The work most closely related to this paper is [81], but here we significantly extend that work by refining the vision, designing and building a broker, demonstrating its benefits in several applications, and reporting on early adoption.

Cross-cloud compute, storage, and egress. Supercloud [65] is a virtual cloud that can span multiple zones and clouds, using nested virtualization and live VM migration to move stateful workloads across locations. Our proposal shares the goal of easing workload migration, but supports migrating higher-level jobs (not VMs), considers a broader set of cloud services in addition to IaaS, and focuses on batch jobs by optimizing for price, performance, and availability.

There have been several proposals for cross-cloud storage solutions. CosTLO [91] and SPANStore [90] use request redundancy and replication to minimize storage access latencies. Perhaps the most comprehensive is Gaia-X, a European effort to create a federated open data infrastructure that enables data sharing with strong governance properties and respecting data and cloud sovereignty [28]. These efforts are largely orthogonal to our focus on computational tasks.

Several industry efforts have been started to reduce cross-cloud data egress fees. The Bandwidth Alliance [19] is one such effort, consisting of several cloud providers who agree to reduce or even eliminate egress fees from their clouds to Cloudflare or other members. Closely related is Cloudflare R2 [24], an object store that promises to charge zero egress fees. Naturally, Sky Computing benefits from these efforts to combat data gravity, and the intercloud broker can be extended to support zero-egress storage systems.

Middleware. Middleware solutions (e.g., CORBA [25], Microsoft BizTalk [37], IBM WebSphere [34], etc.) bear some resemblance to our work. While these solutions allow systems from different vendors to communicate and interoperate, our proposal allows an application to utilize cloud services offered by different cloud providers.

There are several differences between these efforts and the intercloud broker. First, we consider satisfying requirements such as minimizing costs which have not been a concern of these systems. Second, the intercloud broker focuses on placing the components of the same application rather than on how systems from different vendors interoperate. Finally, we are operating in a cloud setting rather than a traditional distributed system setting.

Differences aside, middleware solutions that allow cloud services to interoperate (e.g., connect an AWS S3 bucket with GCP Dataproc) could be considered as being part of the compatibility set, which the intercloud broker can leverage.

Integration Platform-as-a-Service (iPaaS). Like the middleware systems discussed above, iPaaS solutions [40, 47] also integrate distinct systems but are often run as managed services on the cloud. iPaaS solutions provide adaptors to connect APIs from different services and systems (e.g., APIs for Snowflake, Jira, or Stripe). Developers can build workflows on top (e.g., on receiving a new case in Salesforce, call Jira's API to open a ticket) and deploy them through the iPaaS.

While iPaaS can run integration workflows on the cloud, our proposal places and runs compute-intensive jobs on the

most suitable cloud based on price, performance, and availability. Similar to middleware, iPaaS is complementary as we can leverage these adaptors to expound the compatibility set.

Optimization for geo-distributed analytics. A line of work has optimized the performance of geo-distributed analytics [64, 77, 86]. This setting is similar in spirit to ours: it considers running a MapReduce-style job (an analytics query) across many sites, while we consider running a DAG of coarse-grained computations potentially across several clouds.

There are three main differences. First, these techniques are system-specific optimizations, and we in general do not assume as much knowledge about the application. Second, these techniques mostly assume different sites to differ only in their WAN bandwidths and otherwise have identical hardware, while we exploit the inherent differences in hardware, software, pricing, and resource availability of several clouds or regions/zones within a cloud. Third, these solutions optimize for faster completion times, while we also consider minimizing costs and improving resource availability.

That said, we note that the intercloud broker could potentially leverage system-specific optimizations if it is told that the application is of a certain type (e.g., MapReduce).

8 Conclusion

This paper describes the design, implementation, applications, and early deployment of an intercloud broker, SkyPilot. SkyPilot enables users to seamlessly run their batch jobs across clouds to minimize cost and/or delay. We see this as the first step towards a paradigm we call Sky Computing, which we hope will transform the cloud computing ecosystem to better meet user needs.

A Appendix

A.1 Implications and Economics of the Sky

While the body of this paper was firmly rooted in what an intercloud broker could offer now, we turn our attention to the future and ask: what are the implications of the Sky for the future cloud ecosystem? This section is inherently more speculative, so we have included it as an appendix to provide some context for where we think this approach could take us.

A.1.1 Embracing Diversity

While there is an increase in limited interface compatibility, in the overall ecosystem there is an increasing diversity in terms of location and hardware. The aforementioned regulatory concerns require greater flexibility in location; Sky Computing provides an easy way to specify the necessary location constraints. However, there are two other important location considerations. First, some tasks should be run on nearby edge clouds to lower latencies between client and cloud. Second, some tasks should be on on-premise clusters, rather than public clouds, to lower costs (see [87] for an argument as to why this is crucial). These concerns can be met by bringing edge and on-premise clouds into the Sky. The intercloud broker could then automatically send jobs to the closest edge cloud (if lowering latency is important) or to the on-premise cloud (if lowering costs is important and there is enough capacity).

In addition, by allowing users to specify specific hardware requirements in their request, one can automatically seek out clouds that have the appropriate hardware support. Or one can merely ask for high performance, and the intercloud broker will find the highest-performing cloud for that task, regardless of how they achieve it. Thus, Sky Computing turns the diversity of the current clouds from an impediment to an advantage: as long as one cloud meets a user’s needs in terms of location or hardware or other constraints, the intercloud broker will find it.

A.1.2 Economic Analysis

For analytical convenience here we assume that in the future clouds will fall into two categories. Some clouds will remain *proprietary*, offering their own APIs for some tasks and charging for data egress in an attempt to keep customers tied to their cloud. However, others will join the Sky and become a *commodity* cloud in that they fully embrace the open source interfaces and do reciprocal data peering with other clouds that have joined the Sky. The economic choice facing clouds is which of these alternatives they choose. Note that even proprietary clouds can be used by the intercloud broker, but doing so may entail data egress charges.

The choice facing consumers is which of these two types of clouds they choose to use: do they send their workloads to a single proprietary cloud, or do they let the intercloud broker find which clouds to run on? In what follows, we assume that users attempt to optimize some measure of price and

performance of each task; we will denote this metric by P2, and define it so that smaller values are better. The relative importance of price and performance will differ between users, but we do not address that here as it overcomplicates the analysis without adding much insight; instead, we assume all users attempt to minimize the same measure P2. We now analyze, in a vastly oversimplified model, how the ecosystem of clouds might evolve given this consumer behavior.

Denote by R the set of proprietary clouds and denote by S the set of commodity clouds (i.e., the Sky). Assume that the workload from user α consists of a set of tasks j , with a weight or frequency w_j^α that represents the fraction of their workload that consist of task j . Note that this analysis can either apply to individual applications (which involve a DAG of tasks), or an overall workload.

The P2 of task j on cloud c is denoted by P_j^c . If a cloud does not support that task, P_j^c is set to be infinite. Let \tilde{P}_j^c be the P2 taking into account the delays (and perhaps egress charges, if a proprietary cloud is used) in sending data between different clouds. We then define P_j and \tilde{P}_j as the minimal P2's achievable (the latter taking into account the extra inter-cloud delays and cost, and the former not): $P_j = \min_{c \in SUR} [P_j^c]$ and $\tilde{P}_j = \min_{c \in SUR} [\tilde{P}_j^c]$.

Assume for simplicity that these workloads are either sent to the Sky (i.e., placement determined by the intercloud broker), or to a single proprietary cloud. Given these assumptions, if the workload is sent to a proprietary cloud, the user α will choose the cloud $c \in R$ that minimizes $\sum_j w_j^\alpha P_j^c$; call this cloud $c(\alpha)$. If sent to the Sky, then the overall P2 is $\sum_j w_j^\alpha \tilde{P}_j$. Given our assumptions, a user will pick between $c(\alpha)$ and the Sky, depending on whether the sum $\sum_j w_j^\alpha [P_j^{c(\alpha)} - \tilde{P}_j]$ is positive (Sky) or negative (proprietary cloud $c(\alpha)$). Note that since by definition $P_j \leq P_j^{c(\alpha)}$ this can only be negative if the inter-cloud delays or costs are significant.

The question a cloud faces is whether to join the Sky or not. If it remains a proprietary cloud, the only customers it gains are those for whom its overall average P2 is best: i.e., for those users for whom it is $c(\alpha)$. If it joins the Sky, it gains revenue for each task j where its performance is best among the clouds (taking into account the inter-cloud delays).

Assuming most users have a broad workload including many tasks, this analysis suggests that a cloud should only remain proprietary if it can compete across a broad collection of tasks. Joining the Sky becomes the rational choice for clouds who realize they cannot compete broadly, but can find narrower market niches (i.e., sets of tasks) where they excel.

Note that two proprietary clouds compete in a zero-sum manner: for users sending their workloads to proprietary clouds, either one gets the business or the other. Sky clouds compete in a much different way. Of course, they all compete to provide the best P2 implementations for each task. However, a cloud providing a superior solution for one type of task *helps* a cloud focusing on other types of tasks, because

users will only use the Sky if the overall service they get is better than that on proprietary clouds. Thus, the ecosystem of Sky clouds combines *competition* on each task type with *collaboration* to provide high-quality support across a broad spectrum of tasks. This is the interdependence in the Sky.

This analysis is obviously oversimplified in many dimensions. For instance, users make different tradeoffs between cost and delay, and workloads are more complicated than just a linear combination of tasks. However, none of these considerations undercut the general observation above that proprietary clouds must be prepared to compete across a wider range of tasks (since their egress charges and proprietary interfaces *purposely* reduce the likelihood of users offloading to other clouds).

For a fledging cloud provider, it seems clear that joining the Sky is the preferable choice. These new clouds can concentrate on narrow sets of tasks where they can compete favorably with existing commodity and proprietary clouds, and they need not worry about marketing as the intercloud brokers will seek out the best P2 available.

None of these results are surprising, as the intercloud broker effectively sets up a two-sided market. Two-sided markets are common, and they are typically opposed by market actors who have high margins and want to preserve them, but are welcomed by those struggling to get a foothold in the market and who cannot otherwise overcome the inherent advantages of the dominant market players (such as much better name recognition, much larger sales forces, etc.). In the current cloud market only Amazon and perhaps Azure can be seen as having dominant market positions; all other cloud providers have less than 10% of the market [80]. For all of these other cloud providers, which comprise roughly half of the current cloud market, the Sky may be the preferable choice.

A.1.3 Speculation

In many ways, the intercloud broker is merely a mechanism that turns cloud computing into a more competitive market. However, efforts to create the Sky will be for naught if the currently dominant clouds remain dominant and proprietary even after the intercloud broker is put in place. Here we speculate briefly on the factors that will play a critical role in how the competition plays out. We start with four basic assumptions:

Sky-based clouds may innovate faster: Sky clouds need not market their technologies; they merely need to post faster speeds and/or lower prices for various workloads. Thus, the intercloud broker itself speeds innovation because workloads will automatically follow the better P2s, no matter how they arose. In addition, Sky clouds can focus their innovative energies on narrow classes of tasks where they might have special expertise (e.g., Oracle for databases) or special hardware (e.g., Samsung for storage, Google for TPUs, NVIDIA for GPUs). In fact, this is already happening; see the recent announcements by Nvidia, Equinix, and Cirrascale [12].

Large clouds have economies of scale: There are undeni-

able advantages to operating a cloud at scale, such as greater leverage with suppliers and the ability to amortize various infrastructure costs over larger deployments. These advantages may be the single biggest barrier to the success of Sky.

Infrastructure providers might provide smaller clouds with better economies of scale: Infrastructure providers, such as Equinix, who have experience in building out clouds and who can amortize infrastructure costs, can help smaller clouds with deployment. This will not match the economies of scale of the largest clouds, but will allow small clouds to be deployed with reasonable efficiency.

Small clouds are not necessarily small companies: One worry is that the proprietary clouds would engage in predatory pricing to prevent the Sky from emerging. However, many companies that will deploy Sky-based clouds will be using them as showcases for their technology (Samsung for storage, Oracle for database workloads, etc.), and they have very deep pockets. So predatory pricing will actually hurt the large clouds more than the smaller ones (because they have smaller market share, their losses are smaller).

Based on these assumptions, the crucial question is whether the rate of innovation of the smaller clouds (which can be more narrowly targeted) is sufficient to compensate for their disadvantage in economies of scale (which is mitigated by infrastructure providers). We have no wisdom to offer on this central but speculative question. However, with innovative companies like Google, IBM, and Alibaba counted as “small clouds” likely to join the Sky rather than remain proprietary, we believe that there is a significant chance that the Sky could emerge as an economically viable alternative to the current cloud ecosystem.

A.2 ML Training on Spot Instances Across Clouds

In §5.1 we evaluated SkyPilot’s benefits for ML pipelines; here, we show an additional experiment to demonstrate that SkyPilot can run a single ML training job on spot instances across clouds, improving resource availability and reducing costs. In the event of spot instance preemptions, SkyPilot supports migrating a job to another zone, region, or cloud where spot instances are available. We consider training a BERT model with a V100 GPU on a subset of Wikipedia, WikiText-103 (0.5 GB), for 30 epochs. For failure recovery, we save the current model checkpoint (1.5 GB) periodically to a persistent storage. Each epoch runs for around 40 minutes and each checkpointing incurs an overhead of 0.5 minutes.

We evaluate three different strategies to run the job:

- *On-Demand*: runs on an on-demand instance on AWS.
- *SingleRegion*: runs on a spot instance in a single AWS region, us-east-1.¹¹
- *Broker*: runs on a spot instance, with SkyPilot having the freedom to choose among all US regions of AWS or GCP.

¹¹We chose it as it had the lowest preemption rate at the time of experiment among all US regions. Spot hourly price was \$0.91, vs. on-demand’s \$3.06.

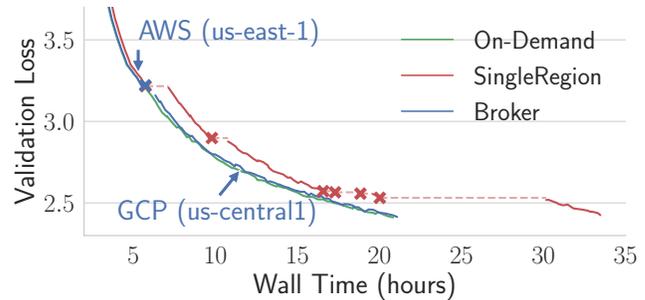

Figure 11: Loss curves of training BERT on V100 for 30 epochs. Each x marker is a preemption event; gaps between segments are the time periods when spot instances are not available. After the first preemption event, Broker migrates the job from AWS us-east-1 to GCP us-central1, while SingleRegion waits in the same region.

	Cost	Makespan
On-Demand	\$61.2	20 hrs
SingleRegion	\$21.8	34 hrs
Broker	\$18.4	21 hrs

Table 5: Costs and makespan for the three strategies to finish BERT training. Data transfer and checkpointing overheads are included.

For a fair comparison, we launch all strategies at the same time and in the same starting region. With SingleRegion, if no spot instances are available in the region when a preemption happens, it waits until they become available again and then resumes the job from the latest checkpoint. With Broker, if no spot instances are available it immediately triggers re-optimization and searches for availability in other regions and clouds; if found, SkyPilot transfers the data/model checkpoint to the new location and resumes the job there. The cost of each data and checkpoint egress across clouds is \$0.2.

Figure 11 plots the validation loss curve for each strategy. Around hour 6, the spot instances used by both the SingleRegion and Broker strategies get preempted. SingleRegion sticks with the same region (us-east-1), but needs to wait for 3 hours (dashed line) to get a new spot instance. In contrast, Broker searches for spot instances in other AWS regions, which fail to provide capacity, before finding availability in GCP’s us-central1 region. After hour 6, the SingleRegion job experiences several more preemptions which cause further delays. Overall, the delays from using a single region adds more than 10 hours to the completion time.

Table 5 shows the total cost and makespan for the three strategies. Broker finishes ~40% faster than SingleRegion because it can leverage spot instance availability across regions and clouds. Moreover, Broker is 10% cheaper than SingleRegion: despite the cross-cloud data egress costs incurred by Broker, the faster recovery time and fewer preemptions (thus, less lost progress) reduce the overall cost compared to SingleRegion. Compared to On-Demand, Broker saves 70% cost due to lower spot prices, while incurring a minimal overhead in makespan (~5%) due to job recovery and checkpointing.

Unlocking unallocated cloud capacity for long, uninterruptible workloads

Anup Agarwal[†], Shadi Noghabi[‡], Íñigo Goiri[§], Srinivasan Seshan[†], Anirudh Badam[‡]
[†]Carnegie Mellon University, [§]Azure Systems Research, [‡]Microsoft Research

Abstract

Cloud providers auction off unallocated resources at a low cost to avoid keeping hardware idle. One such mechanism is Harvest VMs (HVMs). These VMs grow and shrink as the unallocated resources in a server change. While HVMs are larger in size and less prone to eviction compared to other low-cost VMs, their resource variations severely slow down long-running, uninterruptible (hard to checkpoint/migrate) workloads. We characterize HVMs from a major cloud provider and discover large spatial variations in their stability and resources. We leverage this diversity by predicting which HVMs will be stable enough to run tasks without preemptions. We use the predictions to inform scheduling and resource acquisition decisions. Our evaluation with real workloads shows that we can reduce mean and tail (90th percentile) job completion times by 27% and 44% respectively, at 75% lower cost than regular VMs.

1 Introduction

Motivation. Failure to monetize idle hardware in cloud deployments is a huge opportunity cost for cloud providers. Providers typically provision hardware for peak demand, with little over-subscription, to deliver an illusion of elastic resources with strong isolation and performance guarantees. Due to variations in demand, 25–30% hardware sits idle [3]. Many proposals try to address this problem, including better resource packing using abstractions like FaaS (Function-as-a Service), and auctioning unallocated capacity (unreliably) using Spot or Burstable VMs [2, 18, 49, 74]. A latest advancement towards isolating and exposing unallocated resources is Harvest Virtual Machines [3].

Harvest VMs (HVMs) are variable-sized VMs co-located with other regular (on-demand, high-priority) VMs. When a new regular VM is allocated to a server, the HVM shrinks in capacity, and when a regular VM finishes, it grows. This agility allows HVMs to gather 2.5–7.5× more resources compared to other low-priority low-cost fixed-sized VMs (e.g., Spot VMs) at lower eviction rates (§2.1, [3]). This creates a new opportunity and a new challenge.

Large harvested capacity overcomes a major capacity bottleneck [21, 60] allowing many large-scale applications [15, 16, 34, 47, 67, 68, 81, 89] in the financial, scientific, genomics, energy and meteorology sectors to run economically in the cloud. However, HVM’s resource variations can signif-

icantly slow down these long, uninterruptible (hard to checkpoint/migrate) applications due to preemptions (§2.3).

Prior efforts try to mask such overheads using scheduling, resource acquisition, and load-balancing techniques (§5). Unfortunately, these efforts do not fit well for the combination of HVMs and long, uninterruptible workloads. They either address only VM evictions (not resource variations exhibited by HVMs), or rely on the unique properties of Spot markets. On the workload side, they often use a combination of checkpointing, migration, replication, or application level changes. These are prohibitive or impractical as uninterruptible workloads have large working sets, run at large scale, and rely on many domain-specific libraries and frameworks with complex state stored in memory (§2.2).

Our work. We seek to answer: “How can we best use HVMs to run long, uninterruptible workloads?” We begin by characterizing HVMs and a collection of long, uninterruptible production workloads from a major cloud provider. We find large spatial diversity in the stability and resources of HVMs, i.e., some HVMs are more stable (change less often) or get more resources than others. Simultaneously, we observe large diversity in the runtimes of tasks in our workloads.

We leverage our observations in two ways to build SLACKSCHED. First, we build a scheduling component that avoids preemptions by better matching tasks to HVMs, i.e., runs longer tasks on more stable HVMs and vice versa. Second, we build a resource acquisition component that improves overall stability of the HVM pool by retaining relatively stable HVMs and continuously de-allocating unstable HVMs.

In building SLACKSCHED, a key technical challenge is identifying which HVMs are going to remain stable in the future. Resource variations in HVMs can depend on a number of factors which are hard to predict or control (e.g., the arrivals, lifetimes, and placement of regular VMs). We work around this using our insight that the distribution of time between HVM resource changes is relatively stationary over time. We use this to estimate when new resource changes are likely to occur and match tasks to HVMs that are likely to not change during task lifetimes.

We implement our scheduler as a pluggable component of YARN [5], a popular cluster orchestrator, and the acquisition component as a module that manages resource negotiation between the cloud provider and YARN. We evaluate SLACKSCHED under a variety of production workloads, operating conditions, and HVM environments considering

HVM traces collected from multiple regions and time periods. We find that SLACKSCHED reduces mean and tail (90th percentile) job completion times by 27% and 44%, respectively.

We note that our system does not make any assumptions about, nor is reliant on, the cloud provider’s allocation policy. The diversity of unallocated resources is fundamentally tied to the diversity in regular VM workloads. As evidence, we consider future sources of resource variability, e.g., if unallocated resources change in capacity based on variations in power supply to the data center due to renewable energy sources [13, 23], in addition to variations due to regular VM arrival/departure. We find SLACKSCHED has similar performance in this new environment.

Summary. We make the following contributions:

- We characterize the behavior of real-world production HVMs and long, uninterruptible cloud workloads (§2).
- We build a practical method to estimate future variations in HVMs (§3.1.1, §3.1.2).
- We design and implement SLACKSCHED, a system that enables the use of HVMs for large-scale, long-running, uninterruptible workloads (§3, §3.3).
- We show that our scheduling and resource acquisition decisions are effective in mitigating the overheads of HVMs for varied workloads and environments (§4).

2 Characterization & Motivation

We first characterize HVMs (§2.1) and long-running uninterruptible workloads (§2.2). Then, we focus on the overheads of running these workloads on HVMs (§2.3). Our characterization reveals two opportunities that motivate our design (§2.4). We detail in §5 and Appendix B.1 why past efforts at managing resource variability and building reliable infrastructure out of unreliable services are ineffective for the combination of uninterruptible workloads and Harvest VMs.

2.1 Harvest VMs

Background. HVMs dynamically expand and contract to leverage the unallocated resources left by regular VMs. As more (or fewer) on-demand VMs are placed on a server, an HVM will shrink (or grow) its core count. We focus on HVMs that harvest CPU cores but our work can be leveraged when harvesting other resources (e.g., memory [32] and storage). For Spot VMs to expose the same capacity as HVMs, one needs to provision more and/or larger size Spot VMs. This significantly increases the number of evictions to handle and the management overheads (e.g., more copies of the OS).

HVMs are configured with a minimum size (e.g., {2,4,8} CPU cores and {16GB, 32GB, 64GB} of memory). If an HVM needs to shrink below its minimum size (e.g., because of on-demand VMs), it will be evicted. HVMs are overall cheaper in price than both Spot and on-demand VMs. Today, HVM’s minimum size is charged at the Spot VM discount (e.g., 48% to 88% cheaper than regular VMs [87]), and each harvested core has a further discounted price.

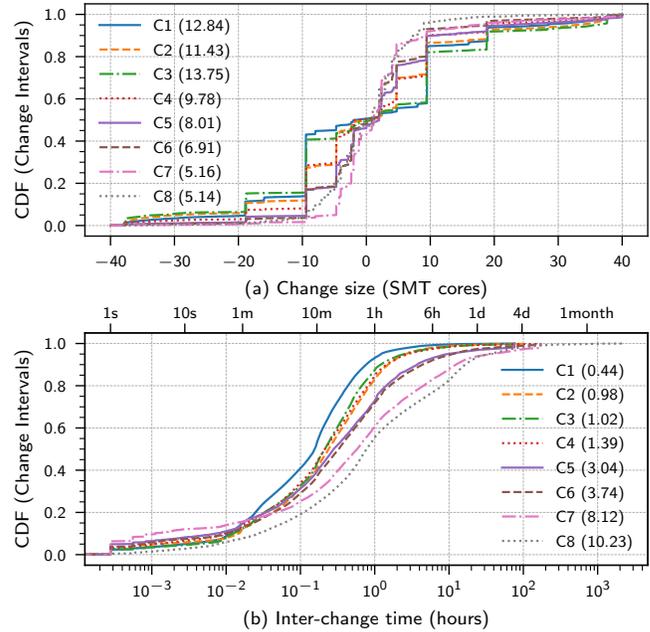

Figure 1: Resource variation in HVMs across clusters. The parenthesis in the legend lists (a) the mean magnitude of change size and (b) mean inter-change time (hrs). The clusters are sorted in increasing order of the mean inter-change time (C1–C8).

Overview. Prior work has studied properties of HVMs at an aggregate level [3, 87]. However, to understand how broader workloads might be impacted, we analyse HVMs at an individual level and answer: (1) *stability of HVMs*: how often and by how much do HVMs change? (2) *spatial and temporal diversity of HVMs*: how do different HVMs compare and how do they change over time? (3) *impact of workloads*: how do the runtimes of long, uninterruptible workloads compare to the resource variations of HVMs? With this goal, we study HVM traces (from March 2019 and August 2021) for 8 clusters across 5 regions of a major cloud provider.

Stability. We measure the resource changes in terms of *size*: number of added/removed cores, and *frequency*: time between two consecutive changes (inter-change time or change interval). We count HVM evictions as a resource change to size 0.² We observe that different clusters witness different amounts of activity from regular VMs, so we order the clusters, with lower activity clusters on the bottom (C7–C8 in Figure 1).

Size of changes. Figure 1(a) shows the size of changes in HVM resources across clusters. Positive changes signify resource growths and negative changes signify shrink events. The mean magnitude of change is between ≈ 5 and 13 SMT cores (simultaneous multi-threaded cores or hardware threads) for different clusters. These are large variations, given the typ-

¹While this aspect has been considered in [87], it was in the context of short-running FaaS workloads and considered only a single cluster. Hence, we revisit it in the context of our target workloads for more clusters.

²We do not separately study HVM evictions as these occur rarely relative to task durations in our workloads ([3], §2.2).

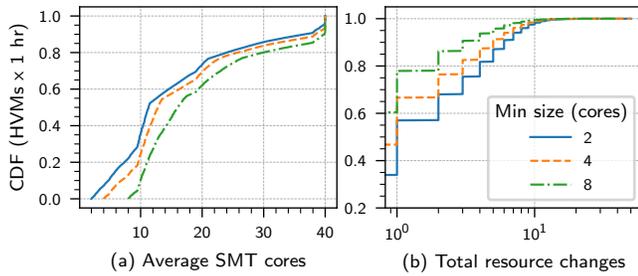

Figure 2: Spatial Variation — HVMs on different servers differ in amount of resources harvested and stability.

ical minimum size of 2–8 SMT cores for an HVM and given that 1–2 cores is a popular regular VM size [25, 41].³ Such large variations can have significant performance implications on applications (both positive and negative).

Frequency of changes. Figure 1(b) shows that the inter-change times have high variance and long tails. For higher activity clusters (C1–C6), we see 93–72% of changes within an hour, a mean inter-change time of 26–224 minutes, and a 95th percentile of 1.2–11.2 hours. For the lower activity clusters (C7–C8), we see 61–55% changes within one hour, a mean of 8–10 hours, and 95th percentile of a few days.

There are long time intervals without any resource changes (e.g., multiple days) as well as short intervals (e.g., 84% within one hour, 40% within 10 minutes, 16% within 1 minute for cluster C2). Ideally, we want to get the most out of long intervals without resource changes while coping with short change intervals. To this end, we analyse how the change intervals are distributed across space (HVMs) and time. This helps understand if there are periods of high activity or if changes are spread spatially. We show this analysis for a high activity cluster (C2). Other clusters exhibit similar trends but differ in the frequency and magnitude of variations.

Spatial diversity. The behavior of Spot and on-demand VMs is determined by the VM configuration and the region. However, HVMs with the same configuration (e.g., minimum size) can behave differently depending on the server they land on (even within the same region). This diversity is directly tied to competing VMs on the server as an HVM shrinks when new competing VMs are allocated and grows when competing VMs are deallocated.

For each HVM, for each 1-hour time window, we measure the harvested cores (time-averaged over the 1 hour) and stability (number of changes), shown in Figure 2. HVMs with a minimum size of 2, 4, and 8 get an average of 15, 17, and 20 cores respectively, which is 2.5–7.5× more resources than the minimum size. At the same time, the top 10% HVMs get a minimum of 36, 38, and 39 total cores while the bottom 10% get at most 3, 3, and 2 additional cores beyond the minimum size. Given that the additional harvested cores have an

³A VM advertised with 2 cores may be mapped to a fractional amount of SMT cores, e.g., 1.5 or 2.5 SMT cores, depending on the VM’s over-subscription or headroom.

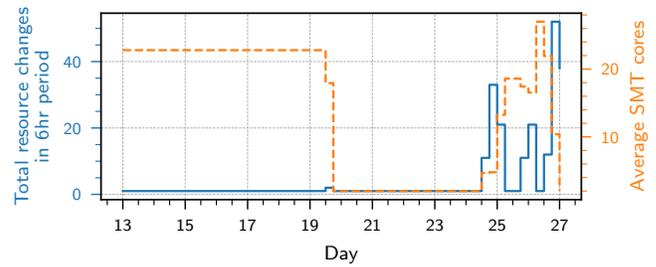

Figure 3: Temporal Variation in a single HVM.

additional cost, HVMs will also exhibit a wide cost diversity.

All HVM minimum sizes show similar trends in terms of stability. Figure 2(b) shows that larger minimum size HVMs tend to be slightly more stable than smaller ones on average. However, a specific larger minimum size instance is not guaranteed to be stable. The worst 10% HVMs can witness tens of changes in an hour while the relatively stable 50% HVMs witness up to one change in an hour.

Temporal variation. The stability and resources of a particular HVM can also change over time (e.g., a stable HVM can start changing resources frequently). Figure 3 shows an example HVM over a 15 day period (aggregated over 6h windows to gauge longer term stability). For the first ≈ 4 days the HVM is very stable with over 40 harvested cores. However, towards the end, the HVM witnesses large number of resource variations.

2.2 Target Workloads

We focus on long-running and uninterruptible (hard to checkpoint or migrate) workloads. Many applications fall into this category, such as workloads in genomics, oil and gas, weather & financial simulations, geo-spatial workloads, and many scientific computing tasks [15, 16, 34, 47, 67, 68, 81, 89]. The market for these workloads is worth tens of billions of dollars with all major cloud providers pushing towards bringing them to cloud environments [35, 45–47, 59, 67, 68].

These workloads are often run at large scale. Thus, currently they are predominantly run in on-premise clusters that are perceived to be cheaper (compared to regular VMs) and more reliable (compared to Spot VMs, due to evictions). HVMs with their high resource availability and lower eviction rates pave the way for *economically* and *reliably* running these workloads in cloud environments. However, tasks in these workloads tend to be long relative to the typical change intervals of HVMs, hence a single task may see multiple resource variations leading to thrashing/preemptions. These workloads often use domain-specific libraries in containerized environments with large working sets [19, 34], making checkpointing entire containers prohibitive and making tailored checkpoints impractical due to the domain-specific nature of the code coupled with a rich ecosystem where new libraries are continuously added. Further, users of these applications are typically reluctant to modify applications [30, 61].

For concreteness, we study two large-scale production ap-

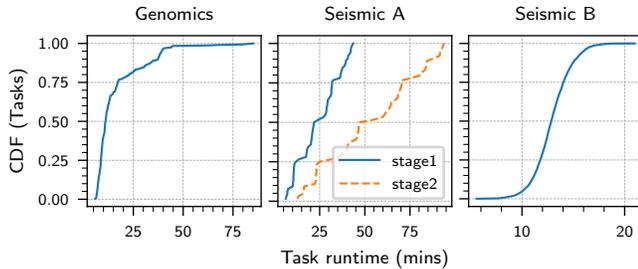

Figure 4: Analysis of task runtimes for two workloads (Genomics analysis and Seismic simulations).

plications from a major cloud provider: (1) an application in the oil and gas domain that performs seismic imaging simulations [15, 81, 89], and (2) a genomics application that analyses genetic material to identify various properties (e.g., disease susceptibility for humans and physical traits of plants) [34].

To understand the impact of HVMs on these workloads, we contrast the HVM resource change intervals (representing supply variability) with the task execution times of these workloads (representing demand requirements). Figure 4 shows that tasks in both example applications are long, with a median of tens of minutes, and tails of over 75 minutes. Task distributions for different applications have various shapes (e.g., Uniform and Gaussian for Seismic A & B, and Bounded Pareto for Genomics). Task runtimes range from a few minutes to an hour either within a single job or across different jobs (for Seismic B, not shown). In other words, there is a sizable overlap in the range of the task runtimes and the range of HVM inter-change times. This means that tasks in these workloads are likely to witness a few resource change events during their execution on typical Harvest VMs.

While Gaussian-distributed runtimes are common in typical cloud workloads, Pareto and Uniform distributions show up because of concurrent tasks being heterogeneous. In the genomics applications, some tasks do the actual analysis while others do verification or data transformation. In the seismic simulations, different tasks perform imaging at different resolution or area/volume depending on the analysis requirements.

2.3 Running Workloads on HVMs

The unpredictable and arbitrary resource changes, especially shrink events, can cause tasks to slow down, thrash (for memory harvesting VMs [32]), or get preempted altogether. This leads to execution time overheads and resource wastage since preempted tasks need to be restarted from scratch (under uninterruptible workloads) wasting any previous progress. We measure these overheads comparing HVMs to on-demand VMs running a mix of our target workloads. We use trace-driven simulation for this analysis (methodology in §4).

Figure 5(a) shows the *slowdown* of jobs running on HVMs. We define job slowdown as:

$$\text{Slowdown}(\text{Job}) = \frac{\text{ExecutionTime}(\text{Job}) \text{ on HVMs}}{\text{ExecutionTime}(\text{Job}) \text{ on regular VMs}}$$

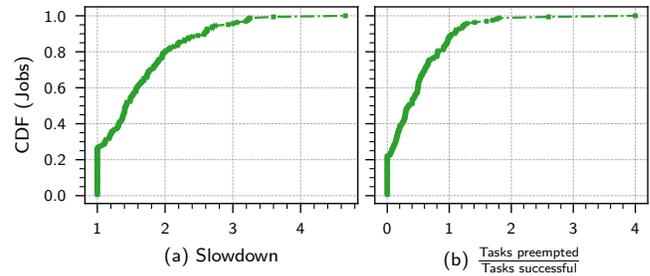

Figure 5: Impact of HVM resource variations on workloads. (a) HVM resource variations slow down jobs. Geometric mean slowdown is $1.5\times$ with some jobs even slowing down by more than $4\times$. (b) HVM resource shrinks cause the preemption of a third of all launched tasks, i.e., for each successful task, there are 0.5 failed tasks on average. The same task might be preempted multiple times causing preemptions per successful task to grow beyond 1.

When running on out-of-the-box HVMs, the geometric mean job slowdown is $1.5\times$ while some jobs are delayed by more than $4\times$. Such high slowdowns make HVMs impractical for many scenarios. This slowdown is caused by tasks being preempted when the HVM shrinks. For instance a task that needs 4 cores is preempted when the HVM shrinks to 2 cores (or when the HVM evicts, i.e., shrink to size 0). Figure 5(b) shows the distribution of tasks preempted across jobs. Around a third of all tasks fail which leads to an additional resource consumption of $\approx 20\%$. This directly translates into 20% more cost. SLACKSCHED’s goal is to *make the execution of long uninterruptible workloads on HVMs similar to their execution on regular VMs*.

2.4 Opportunities for Improvement

To improve the efficiency of our target workload on HVMs, we build on the following observations:

- There is a large diversity in both task runtimes (within a job or across jobs) and HVM inter-change times and they have significant overlap in their ranges. This provides an opportunity to match long tasks to more stable HVMs and short tasks to unstable HVMs, thus allowing efficient use of HVMs by minimizing preemptions and reducing costs.
 - Some HVMs are more stable than others and the stability of a HVM can change over time. There is an opportunity to improve workload execution times by acquiring and retaining a higher fraction of instantaneously stable HVMs.
- These two implications motivate our design for two HVM-tailored components: (1) *Scheduler* that matches tasks to HVMs and (2) *Acquirer* that continuously maintains a relatively stable mix of HVMs. Leveraging these insights is not straightforward as the behavior of HVMs depends on multiple unknown factors (e.g., regular VM arrivals and departures).

3 SLACKSCHED Design

SLACKSCHED manages application execution on HVM clusters rented by a cloud user. Many applications running in the cloud run on top of cluster orchestrators like YARN, SLURM,

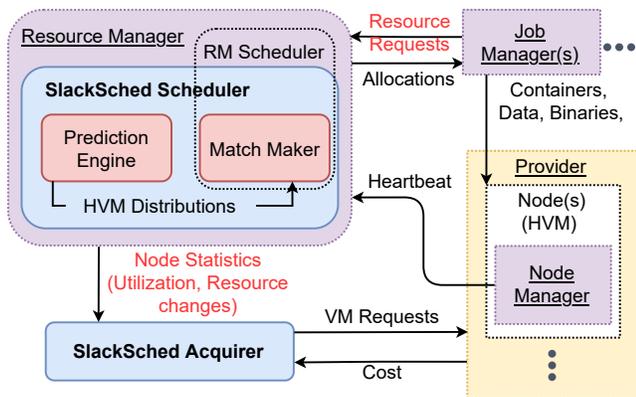

Figure 6: SLACKSCHED architecture with new components in blue and modifications shown in red and red.

Mesos, and others [5, 48, 53, 73], or their managed variants (e.g., Azure Batch [14], AWS Batch [9], GCP Batch [36], AKS [11], AWS EKS [55], and GKE [54]). SLACKSCHED works within such orchestrators, replacing key components to support more efficient use of HVMs. Cloud users can install modified version of orchestrator and/or providers can incorporate SLACKSCHED within managed variants of the orchestrators. Since SLACKSCHED mostly improves execution of individual jobs (§4) (in addition to improving aggregate job execution), providers can use SLACKSCHED to even manage workloads from different cloud users.

Figure 6 shows the architecture of SLACKSCHED and the coordination of three main entities (shown in purple). (1) A per-node *Node Manager*, running on each node in the cluster, that is responsible for reporting the health of the node and running tasks on the node. In the case of HVMs, this is also responsible for conveying instantaneous resource availability on the HVM.⁴ (2) A per-job *Job Manager* (or “Application Master” in YARN terminology) that is responsible for managing the progress of the tasks in a single job. (3) A cluster-wide *Resource Manager* (RM) that receives requests for resources from the Job Managers, schedules and maps these requests to nodes, and conveys resource allocations to the job managers. Then, the Job Managers launch containerized programs on nodes based on the allocations. Additionally, we assume that Job Managers annotate their requests with resource requirements and task runtimes. These can be estimated based on input parameters and the type of computation (similar to [25, 50]). The Genomics and Seismic workloads that we consider already have resource requirement annotations. We measure sensitivity to errors in runtime estimates in §4.2.1.

SLACKSCHED consists of two key components (shown in blue): the *Scheduler* (§3.1) and the *Acquirer* (§3.2). The *Scheduler* extends the default orchestrator scheduler and exploits the diversity in task runtimes and HVM resource varia-

⁴The hypervisor exposes the same number of logical cores to HVMs and only changes their mapping to physical cores at runtime. User programs can query the hypervisor for the core assignment anytime.

tions to match tasks to HVMs. The *Acquirer* interacts with the Provider and the Resource Manager to acquire and maintain a set of HVMs that are low cost, harvest more resources, and are stable enough for the workload.

3.1 SLACKSCHED Scheduler

Typically, cluster schedulers decide on (1) the order of jobs, (2) the order of tasks within a job, and (3) the placement of tasks onto nodes. SLACKSCHED only affects the third decision and uses the default orchestrator mechanisms for the first two. The SLACKSCHED Scheduler tries to minimize preemptions and improve completion times by intelligently matching tasks to HVMs. Based on the task duration and the stability of HVMs, the Scheduler assigns longer tasks to more stable HVMs (predicted to maintain their resources for a longer time) and shorter tasks to less stable HVMs. Our design splits the operation into: (1) the *Prediction Engine* (§3.1.1) that predicts the stability of each HVM in the future, and (2) the *Match Maker* (§3.1.2) that matches tasks to HVMs based on task duration and HVM stability.

3.1.1 Prediction Engine

Challenges. For match making, we need fine granularity models that predict the resource availability of an individual HVM, e.g., “when will an HVM change its resources?” or “how many resources will it harvest?”. This is very challenging since the resource availability of individual HVMs depends on several unknown and uncontrollable factors such as: (1) the arrivals and lifetimes of on-demand VMs, (2) the placement/VM allocation policy of the provider, and (3) the requested configuration of the HVM (e.g., minimum size). Even the cloud provider does not have full future knowledge, especially about when the on-demand VMs will come and go.

Prior efforts at modeling HVM resource availability [3] are not sufficient since they only make predictions at an aggregate level, rather than an individual level. For instance, they provide estimates such as “X% of HVMs will survive in the next hour”, or “HVMs will expose on average Y number of cores in a specified time window”. In addition, point prediction approaches similar to [25, 43, 78, 88], which use various machine learning models including SVMs, CNNs, and LSTMs [62, 75] to model resource availability, are not a good fit for HVM environments for two main reasons: (1) similar historic resource variations may provide widely different behaviors in the future, which makes point estimates inaccurate; (2) HVMs depict large skews in their behavior (§2.1) which makes the use of computational methods such as machine learning hard.

Key insights. Instead of making point estimations, we take an alternate approach of distribution-based predictions and conditional probabilities. This was inspired by prior work on task scheduling with unknown runtimes [63, 69, 83]. These make probabilistic estimates instead of exact predictions, leveraging the fact that the distribution of task runtimes is known

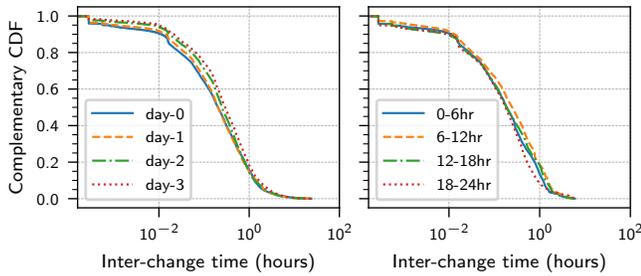

Figure 7: The inter-change-time distribution varies only slightly at different time scales. The legend lists the time period within the trace for which the CDF was computed. The historical inter-change time distribution is a good estimate of the future distribution.

even though the exact runtime is unknown. They proceed by computing the expected remaining runtime by conditioning on the task’s progress or age. For instance, given a task has been running for 1 hour, what is the probability that it will run for 30 more minutes.

Similar to prior work, we condition on the inter-change time distribution to estimate the remaining time until the next change for a specific HVM. *We find that the inter-change time distribution is relatively stationary over time. Thus, even though the exact times when resource changes will occur is unknown, the distribution of time between changes is known.* Figure 7 shows the inter-change time distribution at multiple time scales. There are little changes in the distribution over multiple hours/days. As validated in Section 4.5, this approach generalizes to other future sources of variability in unallocated capacity, such as using renewable energy to power a data center, an emerging approach for sustainable cloud computing [12, 76, 77].

Workflow. The *Prediction Engine* maintains a rolling snapshot of the inter-change time distribution in the past D days ($D = 1$ in our implementation) for estimating the *completion probability*, i.e., the probability that a task will complete successfully on an HVM without getting preempted. We use completion probability as a proxy for HVM stability as it allows us to rank if an HVM is stable enough for a task.

We approximate the completion probability for a task and HVM as the probability that the HVM will not shrink during the lifetime of the given task. In reality, tasks can complete successfully despite witnessing resource shrinks, e.g., if the node is underutilized and has enough resources even after shrinking. However, since we only use the completion probability to obtain a relative ranking of nodes, its absolute value is of little consequence. This approximation also allows robustness to inaccuracies in task runtime estimates. Future work can consider predicting shrink size for more accurate estimation of completion probability and potentially better job execution on HVMs.

We compute completion probability in two steps. First, we estimate the likelihood that there will be a resource change event during the lifetime of a task on a particular HVM. Sec-

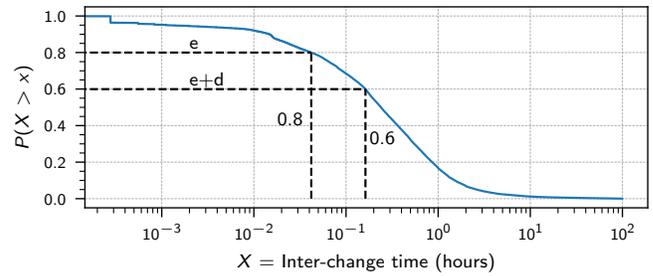

Figure 8: We use the inter-change time distribution for computing the probability that a resource change will occur during a task’s lifetime. Say e time has elapsed since the HVM has seen a resource change, and d is the duration of the task. Then, from the complementary CDF, we get: $P(X \leq e+d | X > e) = 1 - P(X > e+d | X > e) = 1 - \frac{P(X > e+d)}{P(X > e)} = 1 - \frac{0.6}{0.8}$

ond, we estimate the likelihood that this resource change event will be a shrink event. Finally, the *Match Maker* combines these likelihoods (§3.1.2). Note, there are other ways to compute completion probability (Appendix B.2).

Likelihood of resource change. To estimate the probability of a change during the lifetime of a task, we condition on the inter-change time distribution (Figure 8). Given that e time has elapsed since the last resource change event, we compute the probability that the next change event will occur within d time from now, where d is the duration of the task.

Likelihood of shrink. To compute the probability for the next event to be a shrink, we perform an n-gram (bigram) analysis [17] on the sequence of resource changes. Specifically, we look at a historical sequence of resource changes and calculate how often a shrink occurs after a growth and how often a shrink occurs after another shrink. We use this to compute the probability that the next event will be a shrink given that the last one was a growth (or shrink) event. *We find that such shrink probabilities are also relatively stationary over time.*

3.1.2 Match Maker

To minimize task preemption likelihood, the *Match Maker* places tasks on HVMs with a high completion probability for the task. When no HVMs with available resources yield a high completion probability, the *Match Maker* may wait for occupied HVMs to free up resources (“delayed scheduling”). We now describe how we calculate the completion probability, perform delay scheduling, and our matching logic.

Completion probability. The *Prediction Engine* maintains the inter-change-time and shrinking probability distributions (§3.1.1). The *Match Maker* uses these distributions to compute the completion probability as follows:

$$\begin{aligned}
 P_c(x, e, d) &= 1 - P \left[\begin{array}{c} \text{shrink occurs during} \\ \text{task lifetime} \end{array} \right] \\
 &= 1 - P \left[\begin{array}{c} \text{resource change} \\ \text{is shrink} \end{array} \wedge \begin{array}{c} \text{change occurs} \\ \text{during task lifetime} \end{array} \right] \\
 &= 1 - P_s(x) \cdot (1 - P(X > e+d | X > e)) \quad (1)
 \end{aligned}$$

Table 1 shows the definition for each symbol. Recall that tasks are annotated with their estimated runtimes (§3).

Delayed scheduling. In certain situations, waiting for a more stable node (i.e., with better completion probability) might be a better choice than picking from the currently available resources. For example, rather than launching a task on a node with low completion probability, it might be better to wait for old tasks to complete on a node that is relatively stable but may be fully occupied with previous tasks. This implies a non-work-conserving schedule where the scheduling of tasks may be delayed even when resources are available.

It is challenging to decide whether to wait or run with current the best resource without future knowledge. A strawman approach is to launch tasks on an HVM only when it provides a threshold completion probability. However, this may cause the scheduler to delay indefinitely. To tackle this, we formulate the cost and benefit of waiting by estimating the expected completion time obtained from various decision choices. We derive expected completion time as follows:

$$\begin{aligned}
 E_{wc}(x, a, e, d) &= E \left[\begin{array}{l} \text{time spent waiting} \\ \text{for node to free up} \end{array} \right] + E \left[\begin{array}{l} \text{time for completion} \\ \text{and preemptions} \end{array} \right] \\
 &= a + p \cdot d \\
 &\quad + (1 - p) \cdot \left(E \left[\begin{array}{l} \text{time wasted} \\ \text{to preemption} \end{array} \right] + E \left[\begin{array}{l} \text{time after} \\ \text{restart} \end{array} \right] \right) \\
 &= a + p \cdot d + (1 - p) \cdot (w + E_{wc}(g, 0, 0, d)) \quad (2) \\
 e' &= e + a \\
 p &= P_c(x, e', d) \\
 w &= E(X - e' | (X > e') \wedge (X < e' + d))
 \end{aligned}$$

This equation incorporates when will the node free up resources (a), the duration of the task (d) if it completes successfully (with probability p), time potentially wasted (w) in case the task fails (with probability $1 - p$), and the cost of rescheduling the task ($E_{wc}(g, 0, 0, d)$). Note that this is the worst-case expected completion time since we reschedule a task on the worst-case node that has just started (has not remained stable at all, i.e., $e = 0$). In reality, after preemption, the task may be started on a stable node. Since we know the estimated duration of tasks, their resource requirements, and how long they have been running, we can deterministically compute when the node will have enough resources to run a given task (a). The time wasted (w) is the expected time between when the task starts and when the node shrinks, given that the node does shrink during the lifetime of the task.

Workflow. The *Match Maker* uses the above formulation (Equation 2) to schedule the task on the node which gives the best expected completion time. If this node does not have resources at the moment, then it waits and reconsiders the decision at the next scheduling iteration. This automatically includes both preferring nodes with higher completion probability and considering to wait for nodes to free up. For

Symbol	Interpretation
P_c	Probability of completion
X	Inter-change time distribution
$x \in \{g, s\}$	Denotes whether last change event was growth or shrink. Default is growth for a newly started node
e	Time elapsed since last resource change event
d	Remaining duration of the task under consideration
P_s	Probability that the next resource change event is a shrink
E_{wc}	Expected worst case completion time of the task
a	Time between now and when the node will have enough resources to run the task under consideration. If the node currently has enough resources, then $a = 0$
w	Expected time wasted due to a shrink occurring before task completion

Table 1: Symbol definitions.

completeness, we list the pseudo-code for the *Match Maker* in Algorithm 1 in the Appendix.

3.2 SLACKSCHED Acquirer

Challenges. Ideally, we want to maintain a set of HVMs whose stability matches the runtime of the tasks. However, in addition to task runtime information, this requires full knowledge on: (1) how unallocated resources are distributed across servers in a data center, and (2) how stable these resources are at any point in time. As a user (or cluster orchestrator), this information is not available or possible to model. Even as the provider, these metrics are only instantaneously available while HVM patterns may change over time (Figure 3).

Approach. We use a simple “exploration-exploitation” strategy to navigate the set of potential HVMs that the provider can offer to maintain a stable pool of HVMs. The Acquirer starts with a random mix of HVMs and periodically identifies the *worst* HVMs and decommissions them, gradually converging to a more stable pool of HVMs. The Acquirer defines “worst” as the most recently changed HVMs. This simple strategy works when there the HVM pool is unstable relative to the HVMs that can be returned by the provider (4.3).

In our implementation, the Acquirer runs hourly and deallocates 10% of allocated HVMs. Concurrently, it requests an equal number of new HVMs from the provider to maintain the same amount of cluster resources.⁵ To avoid getting a HVM on the same server as the one just deallocated, the Acquirer first requests new HVMs and then deallocates the unwanted ones. To avoid task preemptions, it *gracefully decommissions* HVMs before deallocating them. The scheduler stops sending new tasks to the decommissioning HVMs and once all running tasks complete, the Acquirer deallocates them.

To maintain a target set of resources in the midst of load variations, the Acquirer works with a scaling policy that maintains the cluster utilization between a lower and upper bound (i.e., 60 to 80%). It requests or deallocates VMs whenever the utilization falls outside of this target range. When scaling-in, we decommission and deallocate the worst HVM first. The

⁵Currently, we consider mixes with only HVMs. One can consider a mix of both HVMs and regular VMs.

Acquirer can work with different scaling policies [8, 10], and the scaling can be decoupled from the intentional deallocations/allocations. In our implementation, scaling is triggered every hour coupled with the Acquirer. Scaling also allows maintaining resources as HVMs grow/shrink.⁶ Algorithm 2 in the Appendix shows the pseudo-code for the Acquirer.

We studied different choices for the Acquirer’s trigger period. We found that trigger periods in half to two hours range yield similar performance as 1 hour. Longer periods can lead to a stale cluster (with unstable HVMs) and shorter periods can operate on limited historical information (especially for HVMs allocated in the previous trigger) leading to erroneously deallocating potentially stable HVMs. In general, the trigger period should be chosen based on the range of HVM inter-change times and task runtimes.

3.3 Implementation

We implement SLACKSCHED within YARN [5] version 3.3.0. This includes the changes by [3] that make YARN aware of HVM resource variations. We added an Acquirer module that interfaces with the provider’s VM request API and monitors statistics about allocated nodes. We updated Job Managers to convey task runtime estimates as part of Resource Requests and updated the matching logic to use our design (§3.1). These changes (highlighted in Figure 6) preserve compatibility with other scheduling features, e.g., reservations [27], delay scheduling [86], affinity [4], etc. Specifically for multi-dimensional packing [38], the affinity between tasks and nodes can be defined as a combination of resource match and stability match. We believe that our implementation can be easily ported to other cluster managers.

4 Evaluation

We evaluate SLACKSCHED to answer the following questions:

1. How much benefit do we gain solely from scheduling under different HVM resource profiles? (§4.2)
2. How robust is our design to various workload characteristics, operating conditions and estimation errors? (§4.2.1)
3. How much do we benefit from resource acquisition? (§4.3)
4. How does SLACKSCHED handle time varying arrival rate and compare with other VM types? (§4.4)
5. How does SLACKSCHED compare to prior techniques for addressing VM evictions? (Appendix B.1 and §5).
6. What happens under future and more extreme sources of resource variability (e.g., as a result of using renewable energy)? (§4.5)

4.1 Methodology

Setup. Since HVMs are highly variable and our method is probabilistic, to reach any conclusive results, we needed to run each experiment at a large scale: ≈ 50 jobs, where each job lasts hours and requires 100s of regular VMs. However,

⁶Due to growth/shrinks/evictions, instantaneous cluster utilization can fall outside our target range in the time between two scaling triggers.

running such long and large-scale experiments was impractical on a real testbed. Thus, we evaluated our system using Hadoop’s discrete time simulator [1, 6]. This simulator accurately mimics real-world setups, with only $\approx 1.3\%$ error on completion times and $\approx 1.5\%$ error on resource utilization [24]. The simulator runs actual YARN Resource Manager [5] code and only simulates the Node Managers, Job Managers, and clock and communication layers. Using a simulator also allows us to maintain the exact same trace of HVM availability, ensuring fair A/B testing across experiments.

Resource traces. We use two sets of production resource traces from Microsoft Azure: (1) *HVM traces*: time series of HVM resource availability that includes the time and sizes of growth/shrink events for each HVM; (2) *On-demand VM traces*: VM arrival times, lifetimes, and placement decisions made by the provider’s production allocator. Our dataset includes traces from 8 clusters (700 – 2000 servers each) across 5 regions from two time periods (March 2019 and August 2021). For our experiments, we randomly select 64 HVMs for each cluster. This translates to 160–480 regular VMs in terms of resources as each HVM gets 2.5–7.5 \times more resources than their minimum size (§2.1).

Extensions to the simulator. To ensure different scheduling schemes witness the same HVM changes, we extend the simulator to replay HVM traces. When an HVM shrinks, containers are killed (in increasing order of their start time) until the available resources on the node exceed or equal the used resources on the node. When an HVM grows, new containers may be allocated to the node. These are the default Resource Manager behaviors. In other words, a task does not benefit from cores beyond what it asked for and is killed as soon as it gets fewer than its requested cores.

In addition, for resource acquisition experiments (that continually request new HVMs), we want every experiment to receive the same HVMs when requesting the same configuration at the same time. To ensure this, we replay the on-demand VM allocation traces to reconstruct the state of the unallocated resources. Alongside, we add a simulated HVM allocator to place HVMs on servers with unallocated resources. We study different allocation policies including random, load-balancing, and packing. Note that we use the simulated HVM allocator only for the resource acquisition experiments (§4.3, §4.4).

Workloads. Our traces are based on a collection of two workload categories running in a production environment: Seismic and Genomics [16, 22, 34, 58, 59]. We log their execution to build distributions of task runtimes, number of tasks, and resource requirements. We sample from these distributions to build traces of jobs/tasks. We model job arrival as a Poisson process (similar to [38–40, 56]) and study a variety of mean inter-arrival times.

Schemes. For scheduling, we compare SLACKSCHED (4) against the three schemes (1-3 below):

1. *CapacityScheduler* (or *CapS*): The default scheduler in

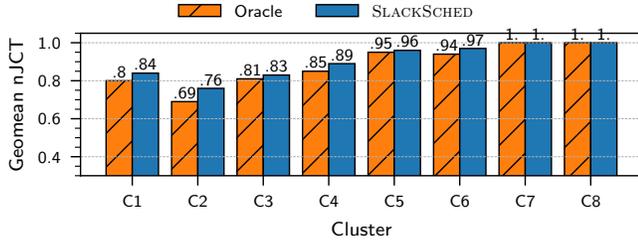

Figure 9: Normalized job completion time (nJCT) relative to *CapacityScheduler* across HVM traces from different clusters. SLACKSCHED improves JCT across different clusters.

YARN. Considers resource requirements (cores and memory) of tasks to select nodes [7].

2. *Oracle*: Uses future knowledge to schedule a task on an HVM only if it is guaranteed to complete before any future resource shrinks, and skips allocation otherwise. Skipping implicitly delegates scheduling to other nodes or later times. This provides an upper-bound for SLACKSCHED.
3. SLACKSCHEDNODELAY (or SSNODELAY): Only uses current resources to make decisions and does not wait for nodes to free up resources. It places tasks on nodes with the highest completion probability.
4. SLACKSCHED (or SLACKS): Uses expected completion time to match tasks to nodes and can wait for nodes to free up resources (§3).

Oracle is a good proxy for job completion time on a regular VM cluster that has same total resources as the HVM cluster. This is because *Oracle* does not cause any task preemptions and the clusters are sized to ensure little to no task queuing.

Metrics. We study job completion time (JCT), normalized job completion time (nJCT), and dollar cost, where,

$$\text{nJCT}(\text{Job}) = \frac{\text{JCT}(\text{Job}) \text{ with scheme}}{\text{JCT}(\text{Job}) \text{ with baseline}}$$

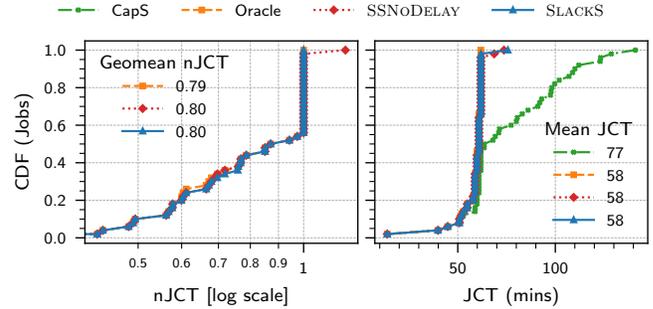

JCT distributions show absolute and tail completion times, while the normalization allows us to study the impact on jobs with different runtimes. A smaller nJCT i.e., $\text{nJCT} \in (0, 1)$ is better, while $\text{nJCT} \in (1, \infty)$ is worse. nJCT of 0.7 translates to $(1 - 0.7) * 100 = 30\%$ reduction in JCT (cf. [40]), and $1/0.7 = 1.43\times$ factor of improvement or speedup (cf. [39]). For computing nJCT, we use baseline as *CapacityScheduler* unless mentioned otherwise.

For aggregating across jobs, we study (a) mean reduction in JCT ($1 - \text{GeometricMean}(\text{nJCT})$), (b) reduction in mean JCT ($1 - \frac{\text{mean JCT with scheme}}{\text{mean JCT with baseline}}$), (c) reduction in tail (90th percentile or p90) JCT.

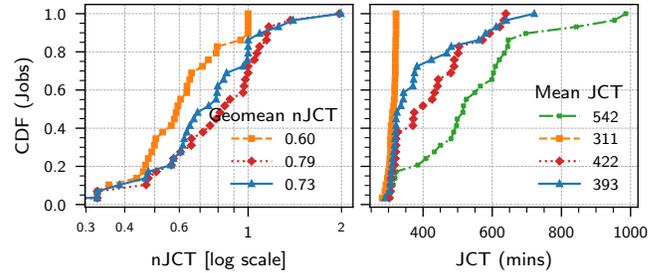

We delegate a subset of these metrics to Appendix B.5.

4.2 Scheduler Evaluation

We evaluate SLACKSCHED on the production clusters from our dataset under the same workload trace. Figure 9 shows the geomean nJCT relative to *CapacityScheduler*. Mean reduction from SLACKSCHED ranges from 0 to 24% (i.e., geomean nJCT from 1 to 0.76). Improvements from SLACKSCHED are

(a) High-activity cluster (C2, frequent resource changes) with shorter tasks.

(b) Low-activity cluster (C8, infrequent resource changes) with longer tasks.

Figure 10: SLACKSCHED’s mean reduction in JCT is 20–27%. Waiting for more stable nodes provides a further 0–7.5% reduction. SLACKSCHED reduces mean JCT by 25–27% and p90 JCT by 20–44%. We use Seismic A workload (§2.2) for this experiment which has uniformly distributed task runtimes.

close (within 13%) to the *Oracle*.

The frequency of resource changes relative to the task durations govern how much overhead HVMs impose and in turn govern how much benefit we can get from SLACKSCHED. We observe that benefits are greater in clusters that witness more activity from regular VMs (i.e., more HVM resource changes). Specifically, for the last two clusters (C7 and C8) which have the least amount of activity from regular VMs (§2.1), HVMs cause little slowdown for the particular workload.

We zoom into the JCT and nJCT distributions for a high-activity cluster (C2). We also study a low-activity cluster (C8) with longer tasks. These represent cases when HVMs impose non-trivial overhead. Figure 10 shows that SLACKSCHED’s mean reduction in JCT is 20–27%. 40% of the jobs see more than 30% reduction in their completion times. 0–15% jobs have $\text{nJCT} > 1$, implying their JCT increases. Since our method is probabilistic, SLACKSCHED can make poor decisions for some individual tasks compared to a random matching decision (taken by *CapacityScheduler*). However, *on average*, SLACKSCHED’s matching decisions are better than random. SLACKSCHED reduces mean JCT by 25–27% and p90 JCT by 20–44%. In §4.2.1, we vary various aspects of the workload.

Impact of “waiting” for stable nodes. Figure 10 also quantifies the impact of waiting for stable, but currently busy nodes (§3.1.2). As shown, SLACKSCHED provides an additional

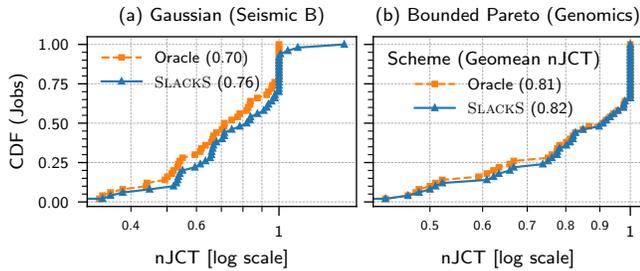

Figure 11: nJCT for workloads with different task runtime distributions. SLACKSCHED consistently improves JCT.

0–6% mean reduction in JCT compared to when this feature is disabled (SLACKSCHEDNODELAY). Specifically, for the high-activity cluster (C2), SLACKSCHEDNODELAY is already close to *Oracle* and there is little scope of further improvement from waiting.

Resource waste reduction. We compare the fraction of resource waste (i.e., work wasted due to preemptions divided by total work done). We find that *CapacityScheduler*, SLACKSCHED, and *Oracle* waste 20–40%, 3–20%, and 0% work respectively, i.e., SLACKSCHED reduces resource waste by $\approx 20\%$ compared to *CapacityScheduler*. This saving comes from the better task-to-HVM matching that avoids preemptions and reduces wasted work or resources.

4.2.1 Improvement Conditions and Robustness

SLACKSCHED’s gains depend on the range and distribution of task runtimes relative to the inter-change times of HVMs. We find that SLACKSCHED provides benefits in JCT when:

- There is spatial variation in stability of HVMs and spatial variation in runtime of concurrently running tasks. Otherwise, different mappings from tasks to nodes are equivalent.
- The range of HVM inter-change times is similar to the range of task runtimes. If tasks are too short, there is not much room for improvement as there are few preemptions. If tasks are too long, preemptions cannot be avoided.

Both conditions hold for a large set of workloads and HVM resource profiles (regions/clusters) (§2). We now describe our robustness experiments that led to these findings.

Task runtime distribution. We change the task runtime distribution in accordance with different workloads (§2.2) under the same HVM resource variations (high activity cluster, C2). This is shown in Figures 10a (Uniform), 11a (Gaussian), and Figure 11b (Bounded Pareto). Workloads with higher variance (Uniform and Pareto) see more improvements from SLACKSCHED since they benefit more from matching of tasks to resource variability.

Task duration. We analyzed the impact of varying the range of task runtimes. We use uniformly distributed task runtimes between 1 and X minutes (max task time) and vary X . Figure 12 shows that the improvements in both SLACKSCHED and *Oracle* diminish with short tasks (< 20 min) as they are rarely preempted (no scope for improvement).

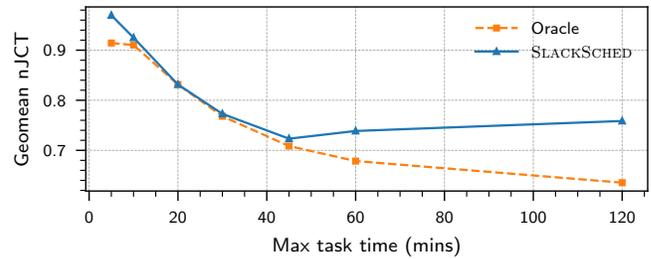

Figure 12: nJCT with varying task runtimes. SLACKSCHED is effective for a wide range of task runtimes.

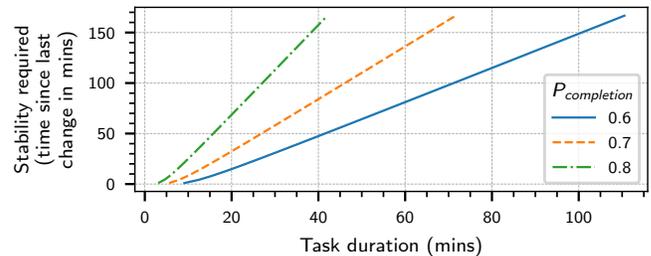

Figure 13: HVM stability required for different task durations at different confidence levels. To obtain 70% confidence in completion without preemption for a task with duration d , we roughly need a node to have been stable for $2.6 \times d$ time. We compute “stability required” using inverse CDF of inter-change-time distribution.

SLACKSCHED’s improvements also diminish when tasks become too long as it becomes harder to find stable nodes. This is because SLACKSCHED relies on past history to predict the future, e.g., to schedule a task of duration d with 70% confidence, it needs a node which has remained stable for roughly $2.6d$ time (Figure 13). On the other hand, *Oracle* can identify future stable nodes even if they have been unstable in the past, allowing it to find matching nodes for long tasks.

Cluster load. We increase the load by reducing the mean inter-arrival time of jobs while keeping the same set of HVMs, task runtime distributions, and task resource requirements. Figure 14 shows that when load becomes very high ($\approx 100\%$ at 3 mins mean inter-arrival, as shown in the first data point), the benefits of SLACKSCHED diminish, since the relative number of stable nodes decrease and SLACKSCHED has a harder time finding nodes for longer tasks (same reason as shown before with Figure 13). *Oracle* still provides improvement since it has full future knowledge and can still find stable nodes.

Task runtime misestimates. SLACKSCHED uses estimates of task runtimes to compute completion probabilities and expected completion times. We evaluate SLACKSCHED’s sensitivity to misestimates by injecting errors into the runtimes reported while still running tasks with their original runtimes. To inject errors, for each task, we deviate its duration estimate by a number sampled uniformly between 0 and some max percentage error. Negative error implies underestimates and positive error implies overestimates. Figure 15 shows there is little impact of misestimates on SLACKSCHED. Completion times inflate when runtimes are underestimated. This is be-

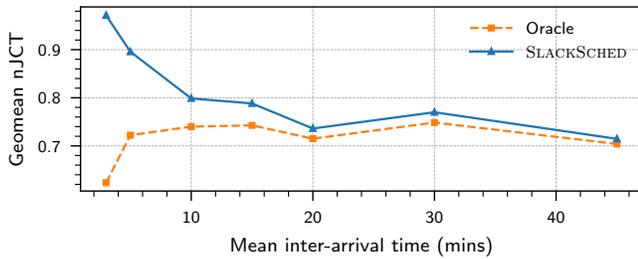

Figure 14: nJCT with varying job inter-arrival rates. SLACKSCHED improves JCT at different cluster loads.

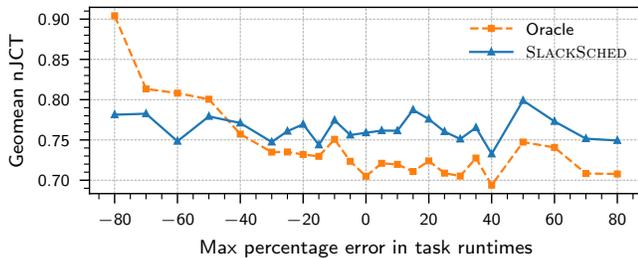

Figure 15: nJCT with varying errors in task runtimes estimates. SLACKSCHED improves JCT even under modest errors.

cause runtime underestimation results in overestimating the completion probabilities and matching tasks to nodes which may not remain stable through the lifetime of the task. We see more impact on *Oracle*, as it makes many close calls which are rendered incorrect due to inaccurate duration estimates.

4.3 Acquirer Evaluation

We study benefits from SLACKSCHED-Acquirer considering settings where there is room for improvement in job completion time between *Oracle* and SLACKSCHED-Scheduler.

Methodology. Different experiments differ in their scheduling and acquisition logic. In all cases, HVMs are continuously (minimum size chosen uniformly randomly) requested to maintain ≈ 64 HVMs worth of resources. For these experiments, we do not use the scaling policy (§3.2) and consider a constant job arrival rate. Our baseline uses the *CapacityScheduler* with no intentional HVM deallocations.

These experiments require a simulated HVM allocator and we test our system with three policies to decide which server to place an HVM on: (1) *Balancing*, picks the server with the most amount of unallocated resources, (2) *Packing*, picks the server with the least amount of unallocated resources, (3) *Random*, picks a random server. All policies only consider servers which have enough resources to support the minimum size of the HVM at the time of allocation.

Results. Figure 16 shows qualitatively similar improvements across different HVM allocation policies solely from the SLACKSCHED-Scheduler (16–24% mean reduction). We also obtain 8–23% mean reduction solely from the SLACKSCHED-Acquirer. The Scheduler and the Acquirer complement each other to provide a mean reduction of 27–32%.

Improvement conditions. In addition to the improvement

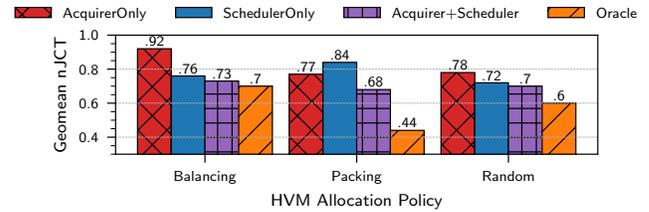

Figure 16: nJCT relative to baseline. SLACKSCHED’s scheduling and resource acquisition complement each other to reduce JCT.

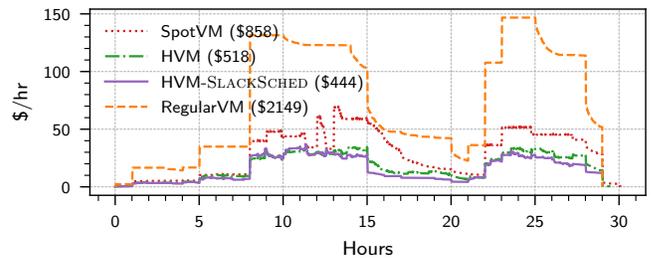

Figure 17: Cluster size over time in terms of cost (\$) per hour. Acquisition logic adapts to time-varying job arrival rate. HVMs are cheaper than Spot and Regular VMs due to the discounted harvested cores. Legend lists the total cost (\$) in parentheses.

conditions in §4.2.1, resource acquisition is useful when there is room for improving the stability of HVMs in the cluster. This happens if (1) there are not enough stable HVMs in the cluster and (2) there are better HVMs that can be returned by the allocation policy. For instance, when most HVMs are allocated on *buffer servers*, there is little scope to improve the HVM mix. Providers typically reserve buffer servers to satisfy sudden demand for regular VMs. In the absence of sudden demand changes for regular VMs, HVMs on buffer servers witness few resource variations and cause little to no job slowdown. In our implementation, we disallow the *Balancing* policy from placing HVMs on buffer servers ($\approx 5\%$ of all servers). This is because, in practice, multiple users will request HVMs from the cloud provider and a single user will only get a small portion of HVMs allocated on buffer servers. In general, we expect individual users to see HVMs that behave closer to those allocated by the *Random* policy.

4.4 Scaling and Cost Comparison

We study how SLACKSCHED adapts to a workload that varies over time. For such a workload, we compare the performance (JCT) and cost of maintaining homogeneous pools of HVMs, Spot VMs, and regular (on-demand) VMs.

Methodology. To generate the time-varying workload, we vary the mean job arrival rate between $1\times$ and $4\times$ the base rate every 6 hours. For the environment, the Acquirer maintains a homogeneous cluster of Spot VMs, HVMs or regular VMs in separate runs. Runs without SLACKSCHED (i.e., SpotVM, HVM, RegularVM in Figures 17 and 18) use *CapacityScheduler*. For these cases, the Acquirer does not intentionally deallocate servers and only uses the scaling policy to

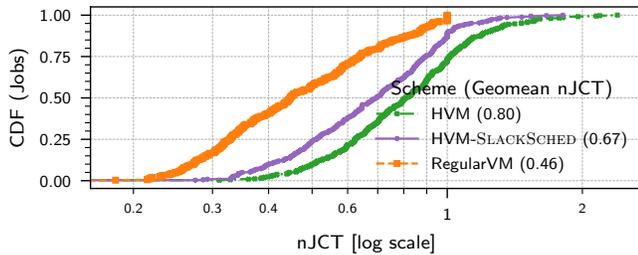

Figure 18: nJCT relative to Spot VM. SLACKSCHED improves JCT over out-of-the-box HVMs under a time-varying job arrival rate. Vanilla HVMs yield better JCT than Spot VMs.

tune the cluster size in response to changing job arrival rate, randomly choosing which VMs to deallocate.

We use the Random allocation policy (from §4.3) to determine the placement of HVMs and Spot VMs. Spot VMs are fully evicted if resources are needed for competing regular VMs allocations (i.e., they do not shrink like HVMs). We obtain the cost of regular and Spot VMs from [74]. For HVMs, we follow the same pricing scheme as [3, 87] and charge their minimum size at the same price as Spot VMs of the same size and charge additional harvested cores at a 50% discount.⁷

Scaling results. Figure 17 shows that the SLACKSCHED-Acquirer scales the cluster in and out in response to the changing job arrival rate for all VM types. It maintains a relatively constant core utilization over time (not shown). Across schemes, the Acquirer maintains similar core utilization and amount of resources. Different schemes have different number of preemptions and resource waste.

Cost results. Figure 17 also shows that HVMs are 40% ($1.67\times$) and 75% ($4\times$) cheaper than Spot and regular VMs respectively. The $\approx 14.2\%$ difference in cost with and without SLACKSCHED (\$444 vs. \$518) mainly comes from (1) less resource waste, and (2) intentional deallocations that move utilization closer to the upper bound (80% threshold §3.2).

JCT results. Figure 18 shows that HVMs without SLACKSCHED already provide mean reduction of 20% compared to Spot VMs as HVMs shrink instead of getting evicted. The Scheduler+Acquirer in SLACKSCHED provide a mean reduction of 33% over Spot VMs even under a time-varying arrival rate and without incurring extra cost.

4.5 Case Study: Renewable Energy Sources

To further test the generality of our approach, we consider a future source of resource variability: renewable energy sources (e.g., wind and solar power). Power generated from renewable energy sources typically fluctuates over time as these sources are driven by weather conditions that are in

⁷We are only interested in price variations across space but not across time. Temporal variations in price would affect all HVMs (at least within the same region) symmetrically and would not significantly affect our acquisition decisions. Thus, we pick costs from [74] at a single point in time. In reality, Spot VM prices, and in turn HVM prices, are volatile over time and can range between 48% and 88% of the regular VM price.

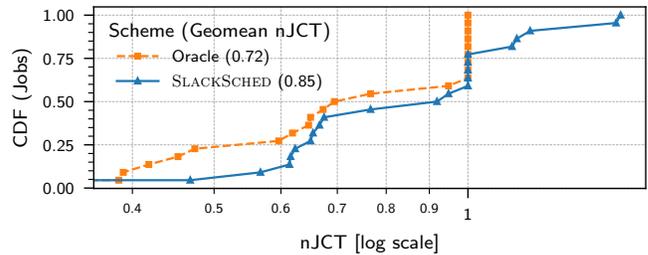

Figure 19: SLACKSCHED improves completion times even under power variations due to renewable energy sources.

turn variable over time. We study the case of HVMs that vary in resources due to a changing power supply in addition to on-demand VM arrivals/departures. In these scenarios, leveraging an unreliable resource supply is a necessity rather than an optimization.

Methodology. We use the same simulation environment and workloads as before. For generating HVM traces under renewable energy variations, we use wind power generation traces from the ELIA dataset [66]. We scale the power trace such that the cluster is fully powered at the max power in the trace. For simplicity, we also assume that cores powered on a server are proportional to the power supplied to the server. We replay the on-demand VM allocation traces and the power generation traces. Whenever power drops, we reduce the power supply to servers that have unallocated resources, effectively reducing the size of the HVMs. When no such servers exist, we evict on-demand VMs (assuming they are migrated out). When power rises, we increase the power supply to servers that have a lower supply than the max power, effectively increasing the size of the HVMs. Additionally, we relaunch previously-evicted on-demand VMs to maintain the cluster load (assuming they are migrated in).

Results. We observe that the inter-change time and shrink distributions are still relatively stationary when taken for a day. However there are more variations at smaller time scales (e.g. when taken for a window of 6 hours). Since SLACKSCHED maintains a large enough snapshot (i.e., 1 day) of the HVM distributions, it still prevents preemptions and improves completion times. Figure 19 shows that SLACKSCHED provides a mean reduction in JCT of 15%. Similar to Figure 10, $\approx 25\%$ jobs degrade ($nJCT > 1$) relative to their execution with *CapacityScheduler*.

5 Related Work

Related work not covered in §3.1 can be classified into:

Checkpointing, migration, and replication. Work like [71, 80] use a combination of these techniques to mitigate the impact of preemptions caused by Spot VM evictions. These are prohibitive for long uninterruptible workloads. In Appendix B.1, we empirically show that SLACKSCHED outperforms these techniques for our target workloads by profiling their checkpointing overheads.

Multiple markets. [20, 43, 70, 71, 80, 84] mitigate the impact of VM evictions by picking Spot VMs from different VM types/sizes and regions (i.e., markets). Different markets can have different prices and eviction rates. These efforts estimate Spot VM eviction likelihoods based on spot prices and bids. However, pricing-based prediction techniques may not necessarily predict resource changes (e.g., HVMs shrinking) which cause workload preemptions. Further, SLACKSCHED yields improvements even for a cluster of HVMs taken from a single market (i.e., the same minimum size and region) as shown in Figure 10b. For such setting, we expect multi-market techniques will perform similar to the *CapacityScheduler* as they will not distinguish between VMs taken from a single market.

[44, 70, 80, 84] use an ensemble of on-demand and Spot VMs. SLACKSCHED provides improvements without requiring on-demand VMs that cost 2–10× more than HVMs.

Bidding, pricing, and admission control. [57, 85] use bidding strategies to control VM eviction likelihoods. These may not control HVM resource variations which can preempt workloads. Further, pricing-based techniques only work when evictions and pricing are related. These methods do not generalize to flat pricing models [51, 74]. Many of these efforts are also scoped to different workloads (e.g., machine learning training [44], database queries [84]) and do not generalize to long uninterruptible workloads.

In a setting where jobs have different levels of importance, admission control [65] techniques may be useful. This is orthogonal to SLACKSCHED.

Scheduling and task placement. Most prior work assumes fixed resources over time [33, 37–40, 52, 64, 79, 86]. They leverage multi-dimensional packing, locality, fairness, and workload properties (e.g., dependencies). These ideas are orthogonal to our work and SLACKSCHED can leverage them to further improve scheduling objectives including efficiency, fairness, and completion times. However, HVMs incur large resource variations which are not addressed by this prior work.

Other proposals [3, 56, 87] adapt cluster scheduling frameworks to address resource variability. However, they are scoped to specific workloads that are less challenging than long-running uninterruptible workloads. [56] only considers elastic query processing workloads, [87] considers serverless functions with short tasks, and [3] just reacts to resource variations rather than avoiding preemptions. The closest to our work is SciSpot [51] that schedules tasks using a time-to-eviction distribution for Spot VMs. It does not consider waiting for VMs to free up resources. Waiting (delayed scheduling) provides better performance (§4.2). SciSpot also does not provide any empirical evaluation and only estimates potential for improvement using theoretical analysis. It does not consider resource acquisition and only works with bathtub-shaped time-to-eviction distributions.

Addressing underutilization. Prior work has also looked at underutilization in cloud environments [78, 88]. These try

to co-locate latency critical services and batch workloads to reduce resource fragmentation and improve cluster utilization. These techniques often also leverage the fact that jobs do not use their peak resources all the time and thus oversubscribe resources. However, such oversubscription is typically only done for first party workloads and not customer facing services [3, 42, 72, 88]. Hence, providers still deal with unallocated resources [3, 88].

Serverless computing or FaaS (Function-as-a-Service) give up on the VM abstraction and allow providers more flexibility to dynamically spread computation and reduce resource fragmentation. HVMs try to preserve the VM abstraction allowing use of harvested capacity for workloads that are not suited for serverless computing, e.g., workloads that maintain state, need the abstraction of a machine, shared libraries, or operating system, or require significant software engineering effort for porting to FaaS abstractions.

While HVMs expose unallocated resources, SmartHarvest [82] also opportunistically exposes allocated but unused resources. It uses machine-learning techniques to decide when and how many resources can be harvested without harm. SmartHarvest resource variations are fine-grained (millisecond level) and would require additional scheduling solutions.

6 Conclusion

Cloud providers have started using new mechanisms like Spot VMs and Harvest VMs (HVMs) to monetize their unallocated resources. After a characterization of HVMs and workloads, we identified that prior work falls short at running long, uninterruptible workloads in such variable environments. To enable these workloads, we propose SLACKSCHED, which leverages distribution-based predictions to maintain a stable pool of HVMs and intelligently match tasks to their ideal resources. SLACKSCHED successfully enables running workloads on HVMs as if they were run on regular VMs.

We experimentally demonstrated that our proposal reduces resource waste by 20% and improves mean and tail (90th percentile) completion time by 27% and 44% respectively, at 75% lower cost than regular VMs. We also show that our system generalizes to cases where resource variations are caused by a variable power supply. We plan to contribute our code to the Apache YARN project [5].

Acknowledgments

We would like to thank anonymous reviewers, our shepherd John Wilkes, and Srikanth Kandula for feedback that helped us improve this work. We would also like to thank Peeyush Kumar for useful discussions, Philipp Witte and Roberto Lleras for help with workloads, and Shivkumar Kalyanaraman and Srinivasan Iyengar for help with the renewable energy case study.

A Pseudocode

For completeness, we list the pseudocode for the algorithms used by the SLACKSCHED Scheduler and SLACKSCHED Acquirer. Algorithm 1 is used by the scheduler to match tasks to nodes, and Algorithm 2 is used by the acquirer to select nodes to deallocate.

Note, in our implementation we ensure that the allocations and deallocations by the Acquirer do not nullify those done by the scaling policy by considering the net change in number of nodes that needs to be there. We also let the scaling policy scale out the cluster after intentional deallocations instead of Acquirer directly requesting VMs after decommissioning VMs (i.e., lines 6, 7, 8 of Algorithm 2 are coupled in our implementation). The implementation can be done in a way that avoids this coupling. Decoupling would actually be needed for cases when scaling and acquisition are triggered independently.

SLACKSCHED for heartbeat-based scheduling. In some cluster managers (e.g., Apache YARN [5]) scheduling is triggered on heartbeats [7]. In these cases, the node to schedule on is implicitly decided based on the node which sent the heartbeat. However, SLACKSCHED needs to explicitly decide which node a task should be mapped to. Thus, we adapt the scheduling logic so that the scheduler can wait for heartbeats from other nodes rather than necessarily assigning tasks to the random node that sent a heartbeat. Specifically, for the node that sent the heartbeat, if the task meets a threshold completion probability, we directly schedule the task on that node, otherwise, we look at the expected completion times offered by all the other nodes and wait for more heartbeats if there are better nodes. The pseudocode for this logic is listed in Algorithm 3. This adds negligible overhead to the time complexity of the scheduler.

Algorithm 1: SLACKSCHED Scheduler

```

1 Function MatchMaker (Task t, Nodes N)
2    $W \leftarrow []$ 
3    $d \leftarrow \text{duration}(t)$ 
4   for  $n \in N$  do
5      $x \leftarrow \text{lastChangeDirection}(n)$ 
6      $a \leftarrow \text{nextAvailTime}(n, t)$ 
7      $e \leftarrow \text{timeSinceLastChange}(n)$ 
8     // Using formulation in §3.1
9      $c \leftarrow \text{expectedCompletionTime}(x, a, e, d)$ 
10     $W.append((c, n))$ 
11  end
12   $(c^*, n^*) \leftarrow \text{min}(W)$ 
13  if  $\text{feasible}(t, n^*)$  then
14     $\text{schedule}(t, n^*)$ 
15  end
16  // Otherwise re-visit decision
17  // at the next scheduling event
18 end

```

Algorithm 2: SLACKSCHED Acquirer

```

1  $\text{deallocateFraction} = 0.1$ 
2 Function OnEpochEnd (Nodes N)
3    $N.sort()$ 
4   // increasing order of timeSinceLastChange
5    $\text{toDeallocate} \leftarrow N[:N.size() * \text{deallocateFraction}]$ 
6    $\text{requestNVMS}(\text{toDeallocate.size}())$ 
7    $\text{gracefullyDecommission}(\text{toDeallocate})$ 
8   // trigger scaling
9 end
10

```

Algorithm 3: SLACKSCHED Scheduler

```

1 Function ScheduleOnNodeUpdate (Tasks T, Machine m)
2    $w \leftarrow []$ 
3    $x \leftarrow \text{lastChangeDirection}(m)$ 
4    $e \leftarrow \text{timeSinceLastChange}(m)$ 
5   for  $t \in T$  do
6     if  $\neg \text{feasible}(t, m)$  then
7       continue
8     end
9      $d \leftarrow \text{duration}(t)$ 
10     $p \leftarrow \text{completionProbability}(x, e, d)$ 
11    if  $p > \text{threshold}$  then
12       $w.append((p, t))$ 
13    end
14  end
15  if  $w$  is not empty then
16     $(p^*, t^*) \leftarrow \text{max}(w)$ 
17     $\text{schedule}(t^*, m)$ 
18  end
19  else
20     $N \leftarrow \text{getAllNodes}()$ 
21     $t \leftarrow \text{shortestTask}(T)$ 
22     $\text{MatchMaker}(t, N)$  // (Algorithm 1)
23  end
24 end

```

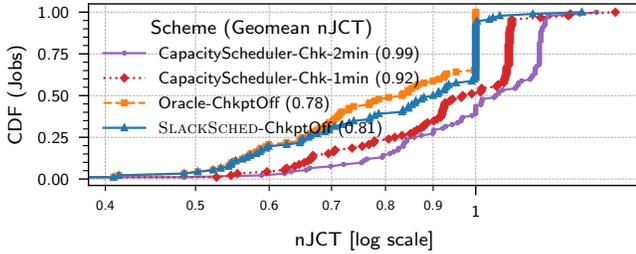

Figure 20: nJCT relative to *CapacityScheduler* without checkpointing. SLACKSCHED outperforms the checkpoint-migrate technique. We set the time-per-checkpoint as 1 min and 2 min in the two schemes with checkpointing.

B Additional Evaluation

B.1 Comparison to prior work for Spot VMs

Prior work [28, 29, 71, 80] employs checkpointing, migration, and replication techniques to mitigate the impact of preemptions. We empirically show that these techniques are insufficient to curb the overheads imposed by HVMs on our target workloads.

Checkpointing and migration. A common approach to handle Spot VM preemptions is to periodically checkpoint tasks [28] and when they get evicted, restore them in other servers. Universal checkpointing techniques like the one docker uses based on CRIU [26, 31] only handle effects inside the container and ignores any external ones (e.g., external storage for intermediate outputs). The workloads we study do not perform checkpointing. On preemptions, tasks are simply restarted inside a new container with reinitialized external storage for intermediate results and outputs. Implementing efficient and complete checkpointing would require application specific insights and expensive engineering.

For the sake of evaluation, we measure overhead for checkpointing memory and processor state using the docker mechanism [31]⁸. This checkpointing delays tasks by ≈ 1 –2 minutes per checkpoint even for containers with less than 1 GB of memory⁹. This relatively large delay is because our applications rely on stateful shared libraries, open multiple TCP connections, and open a number of files in memory. These findings are consistent with [19].

To study the end-to-end impact of checkpointing, we extend our simulation framework to stall tasks being checkpointed. We delay each task by $X=1,2$ minute(s) per checkpoint (independent of container memory size) and run checkpoints every 10 minutes. On preemptions, tasks are restarted from the latest checkpoint and assume no overhead to migrate checkpoints. Figure 20 shows the normalized job completion time. We find that even with such optimistic checkpoint-migrate overheads, SLACKSCHED outperforms checkpoint-migrate

⁸These checkpoints are not restorable, a complete checkpoint would include local files and external storage/effects.

⁹The checkpointing latency (i.e., time when the checkpoint is available for restoration) is typically larger than the delay added to the task.

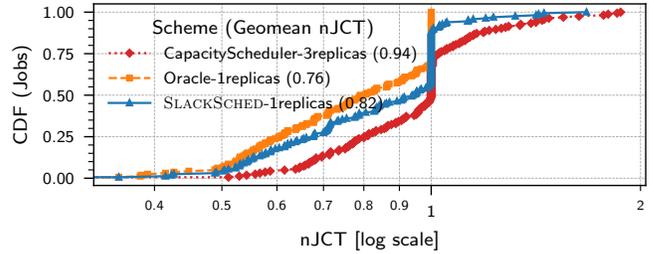

Figure 21: nJCT relative to *CapacityScheduler* without replication. Replication only slightly improves job completion time.

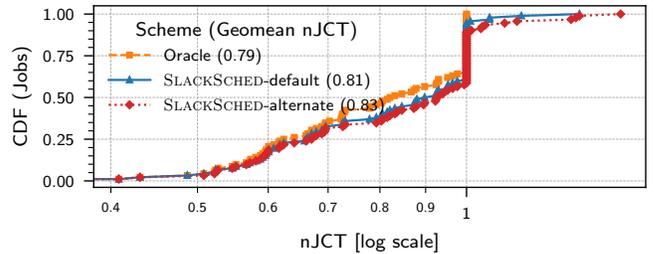

Figure 22: nJCT relative to *CapacityScheduler*. There may be multiple ways to define affinity between a task and an HVM and/or compute completion probability.

techniques.

Replication. Another alternative to handle preemptions is to launch multiple tasks replicas and once one completes, kill the rest. This technique is common in MapReduce systems [29]. In our implementation, we launch 3 replicas for each task and kill other replicas as soon as any replica completes. Figure 21 shows that while replication reduces JCT for the *CapacityScheduler*, SLACKSCHED outperforms both *CapacityScheduler* with and without replication. In addition, replicas lead to a higher number of total preemptions and a much higher load.

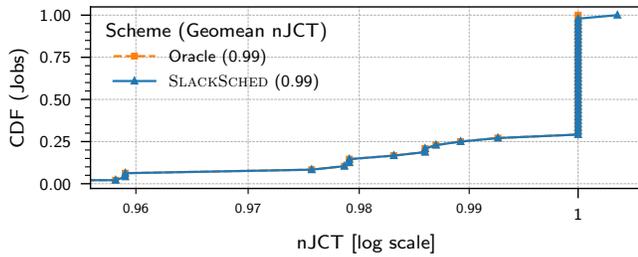

B.2 Alternate method for computing the completion probability

There are other ways of computing completion probability beyond the method presented in §3.1.1. One notable way is to construct the distribution of time between consecutive resource change and resource shrink events¹⁰ and then compute completion probability as:

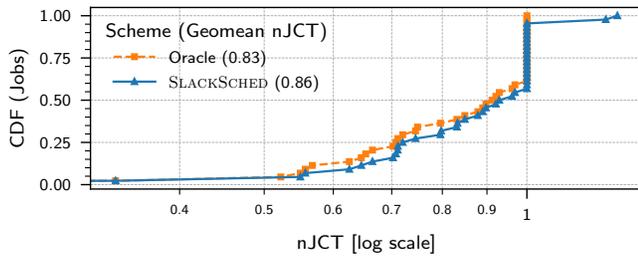

$$\begin{aligned}
 P_c(e, d) &= P \left[\begin{array}{l} \text{shrink does not occur} \\ \text{during task lifetime} \end{array} \right] \\
 &= P \left[\begin{array}{l} \text{shrink occurs} \\ \text{after task lifetime} \end{array} \right] \\
 &= P(Y > e + d | Y > e)
 \end{aligned} \tag{3}$$

where Y is the distribution of time between resource change and resource shrink events, e is the time elapsed since the

¹⁰Note, the inter-change time distribution also captures the time between two consecutive resource growth events.

(a) Interruptible jobs.

(b) Uninterruptible jobs.

Figure 23: SLACKSCHED improves JCT in a cluster serving a mix of interruptible and uninterruptible workloads.

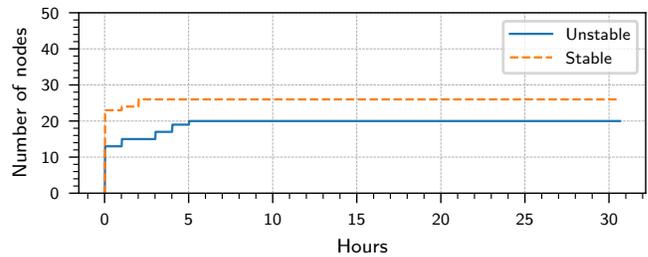

last resource change event, and d is the (remaining) duration of the task being considered for scheduling. We observe that using this alternate method provides similar benefits as SLACKSCHED as shown in Figure 22. The default method of SLACKSCHED provides mean reduction of 19% compared to *CapacityScheduler*, while the alternate method provides mean reduction of 17% compared to *CapacityScheduler*. The main difference is that SLACKSCHED also conditions on whether the previous resource change event was growth or shrink to compute completion probability, which gives slightly better completion probability estimates.

B.3 Mixing interruptible and uninterruptible

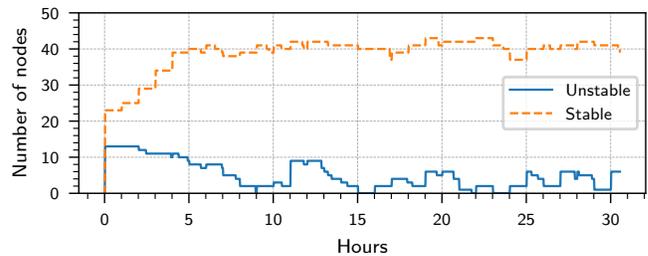

We study how SLACKSCHED performs in a cluster serving a mix of interruptible and uninterruptible jobs. Interruptible jobs are those that have negligible checkpointing and migration overhead.

Methodology. We simulate interruptible workloads by running checkpoints every minute and add zero overhead for checkpointing and migration. On preemption, the tasks restart from the latest checkpoint. No checkpointing or migration is done for uninterruptible jobs. The cluster serves a 50-50 mix of uninterruptible and interruptible jobs that arrive according to a Poisson process. We use the same distribution to generate task runtime and resource requirements for uninterruptible and interruptible jobs. Recall, these distributions were based on genomics and seismic workloads, which are hard to checkpoint and migrate. As such the interruptible jobs are synthetic — they do not necessarily resemble a real workload — unlike the uninterruptible jobs.

Results. Figure 23 shows the distribution of nJCT relative

(a) Without SLACKSCHED-Acquirer

(b) With SLACKSCHED-Acquirer

Figure 24: SLACKSCHED-Acquirer converges to a set of relatively more stable HVMs.

to *CapacityScheduler* separately for the uninterruptible and interruptible jobs. SLACKSCHED shows qualitatively similar improvement as before for uninterruptible workloads. For interruptible workloads, there is no significant difference in completion times across schemes.

B.4 Acquirer with known ground truth

To verify the operation of SLACKSCHED-Acquirer and to study its convergence properties, we study its operation on HVMs with known ground truth stability. To establish the ground truth, we generate a synthetic regular VM arrival and placement trace such that HVMs on half the servers are unstable (i.e., witness frequent regular VM arrivals and departures); while HVMs on other half are stable (i.e., witness infrequent regular VM arrivals and departures). We use the scaling policy that maintains a fixed resource budget and use the random policy for HVM allocation. We measure and compare the number of stable and unstable HVMs with and without using SLACKSCHED-Acquirer. Figure 24 shows that the Acquirer converges to a mix with a larger portion of stable HVMs.

B.5 Absolute JCT metrics

Due to space constraints we show normalized JCT for most experiments in the main text. Here we show graphs for absolute JCT. In all our experiments, we observe that mean reduction in JCT follows similar trends as reduction in mean JCT. We compute reduction in mean and p90 JCT relative to *CapacityScheduler* unless mentioned otherwise.

Abstract

Cloud tenant networks are complex to provision, configure, and manage. Tenants must figure out how to assemble, configure, test, *etc.* a large set of low-level building blocks in order to achieve their high-level goals. As these networks are increasingly spanning multiple clouds and on-premises infrastructure, the complexity scales poorly. We argue that the current cloud abstractions place an unnecessary burden on the tenant to become a seasoned network operator. We thus propose an alternative interface to the cloud provider’s network resources in which a tenant’s connectivity needs are reduced to a set of parameters associated with compute endpoints. Our API removes the tenant networking layer of cloud deployments altogether, placing its former duties primarily upon the cloud provider. We demonstrate that this API reduces the complexity experienced by tenants by 80-90% while maintaining a scalable and secure architecture. We provide a prototype of the underlying infrastructure changes necessary to support new functionality introduced by our interface and implement our API on top of current cloud APIs.

1 Introduction

Almost all large cloud customers use multiple cloud providers to improve reliability and avoid provider lock-in [57]. Unfortunately, splitting a workload among large cloud providers is not as seamless as it should be. One major problem is that today’s tenant networking abstractions are essentially virtualized versions of the low-level building blocks used to build physical networks and hence customers are required to craft complex topologies using subnets, virtual links, gateways, a myriad of virtual appliances, *etc.*

While an individual virtual network or simple deployment may not be overly complex, for larger tenants, reasoning about the scalability, availability, security, *etc.* of their virtual networks requires detailed knowledge and configuration of a range of networking technologies, and the problem is particularly acute when considering transit between clouds.

In response to this underlying complexity, our goal is to make multicloud architectures simple by making this inter-virtual-network transit trivial. We achieve this primarily through leveraging existing “publicly-routable but default-off” addresses for all endpoints. These addresses are publicly-routable, but the cloud provider will deny all traffic not specifically permitted by the tenant. With this choice, connectivity becomes trivial with only minor infrastructure changes.

With this connectivity assumption, we develop a new API for cloud tenants to reserve networking resources based on high-level abstractions. Ultimately, this results in a declarative approach that allows tenants to essentially associate SLOs to endpoints, without concern for *how* to achieve their networking goals. In other words, *we believe that the best way for tenants to think about networking is to not think about networking at all.*

Today’s tenant networking abstractions are largely relics of the early cloud era, with a 1:1 mapping between datacenter physical network devices and cloud networking abstractions. This appealed to early cloud customers who wanted the same management experience as they shifted infrastructure from private datacenters to the cloud, but these abstractions are not fundamentally necessary nor especially accurate to what occurs in the cloud provider’s network underneath. A key contribution of our paper is to show that even a modest refactoring of the existing functionality and modification of the underlying network virtualization platform can result in a far simpler higher-level API.

Such an API is beneficial to cloud providers as well as it allows them to offer their customers a seamless multicloud experience, and yet retain the ability to differentiate (*e.g.*, through performance, options, *etc.*). Furthermore, and perhaps more importantly, the API is far less complex than the low-level APIs offered today. A simpler API means fewer mistakes and thus fewer resources dedicated to customer support.

We recognize that our proposed cloud interface may not be immediately appropriate for all cloud tenants. Fortunately, the abstractions we propose can coexist with those available today so that tenants may choose the tradeoff they desire.

This paper presents the rationale (§2), design (§3-5), implementation (§6), and evaluation (§7) of a new API – which we refer to as *Invisinets* – for tenant networking. This work builds on our earlier workshop paper [41], refining and expanding the API as well as adding a complete implementation and evaluation. Our evaluation applies this API to several deployment case studies and measures several metrics to capture complexity. Accordingly, we show that *Invisinets* can reduce the number of network components that a tenant must interact with by ~80%-90% in these scenarios.

2 Motivation

In this section, we discuss the status quo to motivate the need for a simpler tenant networking API. Throughout this paper, we default to Azure terminology for cloud network

components, though equivalent ones are typically available in other clouds.

2.1 Deployment Walkthrough

Consider an enterprise tenant whose workloads span multiple regions within a cloud, multiple clouds, and an on-prem deployment. To highlight the complexity that enterprise network engineers encounter, we will walk through the steps to construct such a virtual network today. At a high level, tenants must complete the following 5 steps to create a deployment.

(1) Create virtual networks. The basic construct in a tenant's network is a *virtual network* (or VPC in the terminology of AWS and GCP) which builds on the traditional concept of a subnet – a portion of the network whose hosts share a common IP address prefix. The tenant's first step, creating their virtual networks (or vnets), involves assigning IP prefixes to each vnet based on the anticipated number of instances, whether they should be IPv4 or IPv6, public or private, *etc.* These are important decisions as a particular choice (*e.g.*, IPv4 vs. IPv6) leads to a separate path down the decision tree of subsequent connectivity options. As a tenant's deployment scales, managing non-overlapping subnets across 100s of vnets becomes challenging, prompting special address planner tools [9]. Beyond address management, defining a vnet involves configuring a range of additional parameters such as security groups, ACLs, route tables, and individual VM interfaces. For simple deployments, this complexity can be hidden via default configurations but this approach rapidly breaks down with larger deployments.

(2) Connectivity in/out of the virtual network. Next, the tenant must define how instances within a vnet access resources outside the vnet. Options include setting up a "NAT Gateway" (for address translation), a "VPN Gateway" (for private VPN connectivity), or a "Virtual Network Gateway" (which can be configured for VPN or to terminate a direct link). AWS has even more gateway options, some simply to allow the virtual network to access the Internet [8]. Each gateway must be configured with the appropriate routing and access policies.

(3) Networking multiple virtual networks. Next, the tenant must interconnect these virtual network. Within a cloud, this generally requires a virtual network peering and installing the necessary routes, though these links often have some regional limitations. To connect virtual networks across clouds, VPN gateways or Internet access (via necessary gateways or security rules) will be necessary. Each of these connections come with their own specific configuration parameters.

(4) Specialized Connections. An increasingly common component in large tenant networks are dedicated connections that promise higher bandwidth, lower latency, and/or more consistent performance than seen on the public Internet (*e.g.*, ExpressRoute [44], Dedicated Interconnect [28], or Direct Connect [7]). These allow tenants to reserve a physical, dedicated link between their virtual network and a colocation facility. From there, the enterprise may complete the circuit to

their on-prem resources or stitch the connection together with one from another cloud. Provisioning and managing these links requires low-level networking knowledge such as BGP configuration and coordination between the enterprise, cloud provider, and the colocation point. Since these dedicated connections are expensive, tenants might configure their routers to schedule higher priority or sensitive traffic over these links, while routing other traffic over the public Internet.

(5) Appliances. The above steps establish a basic topology and connectivity between the tenant's instances, but tenants also deploy a range of virtual appliances such as load balancers and firewalls. Each cloud offers both first-party and third-party appliances for many of these purposes. Even within the first-party selection, there are often multiple options for a single appliance. The tenant must select appliances, place them in their virtual topology, configure routing to steer traffic through the right appliances, and finally configure each appliance (*e.g.*, DPI rules, load-balancing rules, *etc.*).

Once the tenant has completed all of these steps, the job is not done. The tenant must continue to respond to changing requirements, application and network migrations, inevitable configuration mistakes, and outages caused by any other issue. When determining their procedure for confronting these issues, tenant network operators must keep all details from the above steps in mind, acting as a seasoned network expert.

2.2 Problems

We briefly highlight the main sources of complexity that we observe from the above walkthrough.

(1) Abstractions are too low-level. Provisioning and managing a virtual network involves many of the same steps as in a physical datacenter. Tenants are essentially given virtual versions of the low-level abstractions found in a physical network (*e.g.*, links, gateways, subnets) and must assemble these (which involves topology planning, routing policies, *etc.*) to achieve their higher-level intents for the overall deployment. Many of these abstractions require addressing configuration in particular to achieve basic connectivity between tenant applications/endpoints.

(2) Complex planning. Beyond determining the topology of the deployment, cloud marketplace options can make it difficult to determine the correct virtual appliance. For example, Azure offers four load balancing options and the flow chart to guide the decision is five layers deep [43] and this does not consider other third-party (*i.e.*, non-Microsoft) options. Cloud appliance marketplaces also feature third-party options (*e.g.*, firewalls from Palo Alto Networks) that vary in features and price points. A cottage industry of businesses offering answers on how to minimize cloud costs has appeared to help tenants with this problem in recent years [10, 17–19, 66].

(3) Fragmentation across clouds. As each cloud has its own similar yet different abstractions and appliances, tenants with multicloud deployments end up with siloed stacks for each cloud. This often results in teams dedicated to each cloud

with their own expertise, scripts, and approaches.

(4) Complex to maintain and evolve. As the requirements for their applications change, tenants will evolve their own deployments. Likewise, tenants must adapt as cloud providers evolve their offerings. This adds complexity and management overhead to the existing challenge of keeping applications modern and performant for tenants. Misconfigurations are common causes of network incidents [36] and outages ([35, 62] provide recent high-profile examples). With 1:1 abstractions, virtual networks suffer many of the same issues. The cloud providers also suffer from this as well, as they are obligated to provide support to a wide array of clients with unique deployments. Further, management complexity increases as the deployment size increases, so large enterprise tenants suffer significant management burdens.

In summary, tenant networks today are constructed from low-level building blocks that are unique to a given cloud. With the growing popularity of large, multicloud deployments, this complexity can compound and become even more difficult.

2.3 Current Solutions

In our experience, many enterprises undertake this complexity themselves using an array of per-vendor controllers and DIY scripts. This often requires a team that understands networking in all its gore: BGP, address management, VPN config, *etc.* These teams must understand multiple cloud environments, which change frequently and outside of their control.

Other tenants are turning to a new generation of 3rd-party multi-cloud management solutions [5, 12, 67, 68]. Some of these solutions are essentially a shim on top of the various cloud networking abstractions. They provide a unified “pane of glass” via which the tenant manages individual devices across clouds [12, 67] but do not fundamentally change the level of abstraction; *e.g.*, a key component in Aviatrix deployments is a transit router abstraction that interconnects virtual networks. Yet other 3rd-party solutions essentially run a virtual network as a service for tenants [5, 68], which allows tenants to completely outsource the problem. This shifts the burden but does not fundamentally solve it.

Anthos [22] integrates k8s and service meshes in a manner that frees app developers from having to reimplement common networking related tasks on a per-app basis. With Anthos, every service container is integrated with a “sidecar” container that implements common network-related tasks such as TLS termination, HTTP load balancing, tracing, and so forth. This clean separation between app and networking concerns gives app developers a cloud-agnostic (and hence multicloud friendly) approach to implementing network-related features. However, it is important to note that Anthos does not address the problem of network virtualization that we address here: in Anthos, sidecars are L7 proxies and (like all k8s services) they assume L3 addressing and connectivity has already been established. Implementing that L3 connectivity still requires

a network engineer to set up the virtual networks, links, VPN gateways, *etc.* that we have been discussing [30, 33]. Thus we view the goals of Anthos and Invisinets as complementary: Anthos simplifies the construction of multicloud deployments for app developers, while Invisinets does the same for infrastructure operators.

2.4 It’s Time for Simplification

Network virtualization technologies were originally designed to allow cloud providers to virtualize their *physical* network infrastructure [34, 53]. In this context, providing the user (in this case, the datacenter operator) with virtualized equivalents of their physical network is appropriate, and we do not question the approach.

Extending the same approach to cloud *tenants* also made sense in the early days of cloud adoption when enterprises with well-established on-prem datacenters often used the so-called “lift-and-shift” strategy: creating a networking structure that mimics the on-premises network that previously served the workload. This strategy was justifiably appealing as it allowed tenants to use familiar tools and tested configurations in their new cloud deployments. However, we see this approach as neither desirable nor necessary as tenants embrace the cloud more fully in both the scope of their deployments and in (re)designing applications for cloud environments.

Nonetheless, we recognize that certain enterprises may choose to continue with building virtual networks for reasons that range from satisfying compliance requirements (*e.g.*, with data protection laws [55, 65]), to familiarity with existing tools, and the perception of greater security. Fortunately, this need not be an either-or decision: the architecture we propose can be deployed alongside existing solutions allowing tenants to choose whether and when to migrate their workloads.

Our approach requires new support from cloud providers, but we believe this is reasonable since the current situation is non-ideal even for cloud providers. The current complexity imposes a steep learning curve for onboarding new customers, and plenty of room for configuration errors that will, regardless of fault, result in unhappy customers. Simplification can decrease the number of tenant errors and therefore decreases the support burden on the cloud provider. Further, the cloud provider could likely achieve higher resource efficiency by taking control of networking and orchestration from tenants.

3 Approach

Our guiding philosophy in designing a simplified networking API is that *the right way for a tenant to think about the network is to not think about it at all*. *I.e.*, ideally, the network should be invisible. When diagnosing the root cause of today’s complexity, we arrive at the observation that the problem starts with the fact that tenant endpoints live in a private IP address space. Given private addresses, tenants must then establish (virtual) connectivity between them which necessarily implies managing subnets, constructing a virtual topology

with links, routers, and appliances, running routing protocols that must be configured, and so on.

Seeking to avoid this leads us to an alternate proposal: *can we give every endpoint a public IP address?* This makes connectivity trivial, notably even across clouds. Essentially, this allows virtual networks to reuse the connectivity of the underlying (physical) network rather than recreating it. Importantly, we must assume IPv6 so that address scarcity is not an issue.

At first glance, our proposal might seem concerning from the viewpoint of security: if any host on the Internet can reach any tenant endpoint, then surely we’re exposing a tenant’s endpoints to attack, including DDoS. Yet, our intuition was that security should not be a concern for public endpoints *that are hosted in the cloud*. This is because cloud providers (or CPs for brevity) have already addressed this problem with their own address management architectures. As we elaborate on in the next section, within a CP’s infrastructure, when an endpoint is assigned a public IP address P^1 , this address is not actually routable *within* the CP’s regional datacenters. I.e., the endpoint associated with P is not actually hosted on a server with the address P . Instead, the server at which the endpoint runs has an internal/private address D and the CP uses solutions to translate P to D with appropriate security and access control checks at the point of translation.

Thus, instead of the typical public *vs.* private address trade-off, P represents a new form of address that is publicly routable but default off (PRDO), with the important property that a packet destined to a PRDO address is delivered to the CP’s domain but will not be delivered to an endpoint until the CP has *explicitly taken action to associate P to a physical endpoint’s D* . Thus our intuition was that we can leverage the PRDO addressing architecture to spare tenants from having to solve the connectivity problem in their virtual networks.

Given this, our next step was to verify our intuition and understand whether CP address management infrastructure could indeed be leveraged and extended to serve all tenant endpoints. To answer these questions, we engaged with two major CPs (Azure and GCP) and found that, perhaps surprisingly, our proposal could be supported with little modification to their existing infrastructure and raises no new scaling or security challenges. We elaborate on existing CP address management infrastructure and the implications of PRDO addressing in §4. Thus our contribution lies not in devising novel techniques or radical clean-slate designs but rather in proposing a radically simplified tenant abstraction and showing how we can repurpose existing infrastructure to implement this abstraction.

With PRDO addressing as our starting point, what API can we offer tenants? We observe that, for the vast majority of cloud tenants, the network is a means to an end: *i.e.*, tenants care that their application endpoints (*i.e.*, VMs or containers)

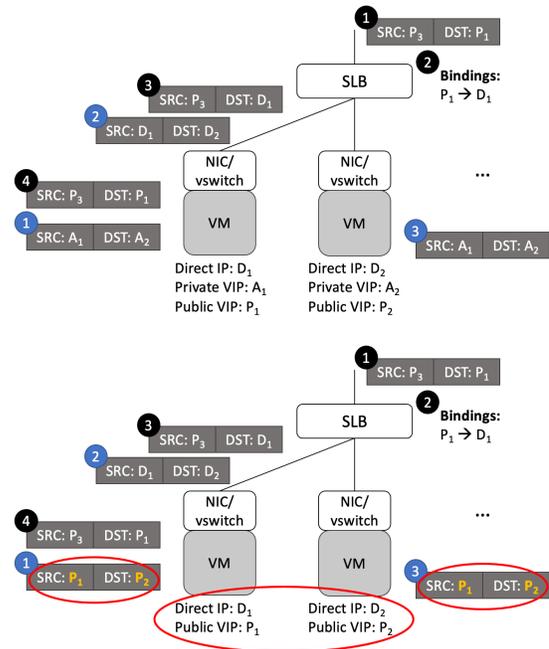

Figure 1: Cloud addressing as it is done today (top) and our proposed changes (circled, bottom). Black packets show the translation and path of packets between VMs in the same virtual network while the blue path shows an external connection using the VM’s public IP.

can communicate with each other with high availability, a certain level of performance (*e.g.*, latency, throughput), security against unwanted access, and scalable mechanisms for management. These are the goals that a tenant is trying to achieve when they set up and manage a virtual network topology with firewalls, links, and routers. Hence, we design an API that allows tenants to express *what* they want the network to accomplish, rather than *how* it does so. Moreover, we note that the parameters that specify a tenant’s goals are associated with how *endpoints* – VMs/containers – experience the network. Hence, our general approach is to assign PRDO addresses to all tenant endpoints and then provide tenants a high-level API that associates SLOs (for availability, security, and performance intents) with these endpoints (or groups of endpoints), thus completely eliminating today’s low-level “links and boxes” abstractions.

We do not require that CPs cooperate to implement the API, nor even that all CPs adopt the API. Likewise, CPs don’t have to implement identical versions of the API. Converging on a single API across all CPs would certainly be ideal but, even if each CP adopts their own flavor of the API we propose, tenants will benefit from the simplification in configuring that CP, and the high-level nature of the API will make it easier to port deployments across clouds.

4 PRDO Addressing

In this section, we first review the addressing architecture commonly implemented by CPs today (§4.1). This discussion reiterates information published before [20, 21, 54] but distills

¹By which we mean an address from the address space the CP advertises into the Internet’s routing infrastructure - *e.g.*, [27] for GCP

the aspects relevant to Invisinets. We then discuss how this addressing infrastructure can be used to support Invisinets (§4.2) and the security implications of the same (§4.3).

4.1 Addressing in Today’s Clouds

A cloud provider’s infrastructure involves a few different address spaces. Public IP addresses (PIPs) are drawn from public prefixes that the CP advertises into the Internet at large. CPs vary in the details but, generally speaking, a packet destined to a PIP will be delivered to a specific datacenter or region in the CP’s global infrastructure.

In addition, each cloud datacenter has a private address space of “direct” IP addresses (DIP) – a DIP is the actual IP address of the physical server and the basis for routing within a datacenter fabric. It is used internally to the CP and is never exposed to the tenant, providing a layer of indirection and allowing the CP to place/move VMs as needed.

Finally, at the virtualization layer, tenants see a virtual IP (VIP) for their VM or endpoint. A VIP may be public or private (a VM may have both) but crucially is not actually assigned to the server and therefore is not routable in the datacenter fabric. Instead, it is used at the tenant-layer for virtual network-level routing, *etc.* For packets sent between two VMs with private VIPs in the same virtual subnet (A_i addresses), the source and destination fields are translated in the vswitch/NIC at the VMs; the vswitch/NIC translates from the private VIP address space to the corresponding DIPs ($A_i \leftrightarrow D_i$) [25, 54] as shown in Figure 1 with the blue series of packets. The fabric only understands how to forward traffic with DIPs and is unaware of the tenant address space (giving the virtualized layer full flexibility in assigning addresses).

Endpoints with public VIPs are assigned an IP address drawn from the CP’s public address space (P_i). However, this address is not directly assigned to the VM. Instead, any incoming traffic destined to P_i is first routed through a software load balancer (SLB) in the datacenter (see Figure 1 black series of packets) that maintains a binding from P_i to D_i .² The mapping between public VIPs and DIPs are installed when the public IP is provisioned and associated with an endpoint. Thus the SLB advertises all public VIPs under its control and translates incoming traffic to the endpoints DIP to route to the endpoint. For traffic exiting the VM, no translation is necessary as the source is the public VIP and default routes are used to exit the datacenter.

Thus in the terminology introduced earlier, all PIP addresses (including ones assigned as public VIPs) act as PRDO addresses, requiring explicit SLB and vswitch/NIC configuration before packets can be delivered to an actual endpoint.

4.2 Applied to Invisinets

The core proposal in Invisinets is that we will no longer use private VIPs at all and instead give all endpoints a public VIP

²The SLB is often implemented as a distributed scale-out software system capable of high-speed address translation [21, 54].

(Figure 1). Thus, tenant addresses will be drawn from a CP’s public IP address space and we will leverage the CP’s PRDO addressing infrastructure to ensure that a tenant’s endpoints are not exposed to unwanted access.

To leverage existing CP solutions, we propose a division of labor in which tenants specify *permit lists*: for each endpoint P_i , this is the list of other endpoints that are allowed to communicate with P_i (with the possibility for extension parameters for more specificity).³ The CP is responsible for enforcing this permit list: ensuring that only traffic explicitly permitted to access the endpoint may do so. Any packet not cleared by the permit list should be dropped.

Ensuring these semantics to the tenant requires minimal changes to the CP’s infrastructure. The CP simply programs SLB bindings for external connections only as necessary based on the tenant’s permit list. We use “external” to mean outside any boundary necessary to meet the CP’s addressing constraints; *e.g.*, DIPs may only be unique within a region, therefore “external” connections are those spanning beyond the region. We call the boundary within which a DIP is unique the *DIP scope*. The DIP scope determines when an address must be added to the SLB bindings as any connections to endpoints outside the DIP scope may be in overlapping address space and will not be reachable without address translation.

To support this in the datacenter fabric, we first modify the address translation for traffic which typically uses private VIPs (the blue process in Figure 1). Now, packets are translated from the public VIP space to the corresponding DIPs in the vswitch/NIC. Second, the SLB translation process for packets incoming from external endpoints must be slightly modified. The translation between public VIPs and DIPs in the SLB remains the same, but the time at which the SLB binding is installed is changed. Instead of installing when the IP is associated with the VM, the binding is only instantiated when the VM’s permit list allows traffic external to the datacenter. When no mapping exists for an incoming packet, the SLB simply drops the traffic (as it does today). This provides an initial coarse layer of protection for PRDO endpoints. Importantly, each endpoint’s permit list is enforced at the host as well, so dropping at the SLB is not strictly necessary but offers some defense-in-depth for endpoints.

We assume that in order to support this model, the CP can allocate addresses arbitrarily as is convenient (*e.g.*, the CP isn’t required to assign addresses from predetermined prefixes of the address space). The tenant should not expect any particular addressing scheme for the IPs they are assigned. Thus, our API takes reachability (L3) between endpoints as a given from the CP and builds directly on the underlay routing and address translation rather than requiring every tenant to reconstruct their own L3 network.

³For convenience, we will introduce the ability to specify *groups* of endpoints in §5.

4.3 Security Implications

We argue that Invisinets does not fundamentally alter the security posture of either the tenant or CP.

Consider first the public exposure of a tenant’s endpoints. Today, the tenant has 3 types of endpoints: (1) public (*e.g.*, a VM associated with a public IP), (2) “semi-private” (*e.g.*, a VM with only a private VIP, but behind a VPN/NAT that restricts access to the VM), and (3) private (*e.g.*, a VM with a private VIP). Under our proposal, nothing changes for endpoints in (1). For endpoints in (3), they are equally unavailable to outside connections in Invisinets (since no SLB bindings will be programmed for them).⁴ For endpoints in (2), access is still limited however Invisinets does change *how* this access control is implemented. In Invisinets, access to a semi-private endpoint is restricted by the permit list and SLB bindings; effectively, we’re replacing the tenant’s VPN/NAT with the CP’s SLB/NAT infrastructure.⁵

This change does however, modify the trust boundary between the tenant and the CP. Today, the tenant trusts the cloud provider to implement the network architecture they specify faithfully. In Invisinets, the tenant trusts the cloud provider to construct the necessary network architecture to achieve their connectivity requirements and accordingly trusts that any connectivity not explicitly permitted will not be enabled.

From a CP viewpoint, a potential concern is that the larger number of allocated public IP addresses increases the risk or impact of a DDoS attack on their infrastructure. We found that this was not a concern for CPs because they currently advertise entire IP prefixes, independent of what subset of those addresses are actually allocated: *e.g.*, Azure advertises $>1.4 \cdot 10^{20}$ [46] while GCP advertises $> 7.1 \cdot 10^{26}$ IPv6 addresses [27]. Any of these addresses can be used as the target of a DDoS attack and this remains unchanged with Invisinets.

Furthermore, CPs today deploy cloud DDoS mitigation systems [45] to thwart high-volume traffic attacks targeting a specific endpoint (since these might overwhelm specific links in their WAN). Notably, only one public IP is sufficient for an attacker to attempt such an attack and hence Invisinets does not materially increase the likelihood of such attacks. A final concern might be attacks that spread traffic over multiple endpoints. However, such attacks are already possible today (given the large advertised address space) and handled through filtering at the destination datacenter where SLB mappings reveal what traffic is valid. In such cases, attack traffic is carried over the CP’s wide-area links, however the extensive use of load-balancing in these networks is effective in this case (since the attack comprises many smaller flows) and hence the increase in backbone traffic volume is not problematic, akin to a general increase in valid traffic volume.

⁴However, if a private endpoint today is in a virtual network which spans across more than one DIP scope, it would be installed in the SLB.

⁵In some cloud SLB implementations [21], tenant-level NATs are implemented in the SLB. In this case, the only change is that each endpoint has its own binding in the cloud SLB.

API	Description
<code>request_eip(vm_id)</code>	Grants endpoint IP
<code>request_sip()</code>	Grants service IP
<code>bind(eip, sip)</code>	Binds EIP to SIP
<code>set_permit_list(eip, permit_list)</code>	Sets access list for EIP
<code>annotate(eip, middlebox)</code>	Adds middlebox to EIP’s traffic
<code>set_qos(region, dest, bandwidth)</code>	Sets (region, dst) BW allowance
<code>set_qos_class(class, five_tuple)</code>	Defines tenant QoS class
<code>tag(eip, tag)</code>	Associates endpoint with tag

Table 1: Proposed cloud tenant network API.

5 API Design

In this section, we outline the Invisinets API and describe how it achieves each of its goals. The design implications for each piece of the API are discussed as necessary. We expect the listed arguments to be the minimum required parameters and deliberately leave room for cloud providers to differentiate their services with additional extension parameters. A complete list of our proposed API is shown in Table 1.

5.1 Connectivity

Rationale. As explained in §3, we modify the CP infrastructure to support PRDO addressing for all endpoints and enable trivial connectivity. By giving all endpoints publicly-routable IP addresses, we can abandon the virtual network altogether. Accordingly, tenants are not obligated to construct the networks to facilitate communication outside of a given virtual network, as is required by the inherent isolation of the virtual network abstraction.

API. Connectivity between the tenant’s VMs/storage endpoints/*etc.* in the same cloud, across clouds, and to their on-prem network (provided they expose public endpoints) is trivially achieved given that tenant instances have public IP addresses. Thus our basic `request_eip` API allows the tenant to request and receive an *endpoint IP address (EIP)* for each of its instances. A tenant must be prepared to treat its EIP as a flat address with no assumptions about whether its addresses can be aggregated, drawn from certain prefixes, *etc.* This gives providers flexibility in assigning addresses from their overall pool (*e.g.*, to maximize the ability to aggregate for routing, *etc.*) and with effective tagging mechanisms should not affect tenants in any way (since tenants are no longer configuring routing with mechanisms such as BGP).

Design. As discussed in §3, the infrastructure necessary to support PRDO addresses requires only minor modifications to the SLB in the datacenter fabric and otherwise the existing vswitch/NIC functionality is sufficient. When an external endpoint is added to a permit list, only then is the EIP of the local endpoint installed in the SLB.

IPv6 will be necessary to support PRDO-only addressing as the IPv4 address space is too small to feasibly give all cloud endpoints an address. Since these addresses will be allocated arbitrarily from the tenant’s perspective, grouping mechanisms will be critical to managing a flat address space. We address this need directly in §5.5.

5.2 Availability

Rationale. Tenants often build highly-available services using multiple backend instances. The service is associated with a service IP address (SIP) and an in-network load balancer maps traffic destined for SIP to an available backend instance. We'd like to support this use-case without requiring that tenants engage with the lower-level details of load balancers.

API. We allow tenants to request a SIP and introduce a `bind` API that allows tenants to associate EIPs with a SIP (Table 1). This SIP address is globally routable, however, traffic destined for the SIP is routed / load-balanced across the EIPs bound to it and we place the responsibility of load balancing on the cloud provider. Hence, the `bind` call allows the tenant to inform the cloud provider of how load-balancing should be implemented, with optional parameters that guide load-balancing policy (e.g., associating a weight with each EIP, akin to weighted fair queuing policies).

Design. Requesting SIPs can be supported today and is in fact somewhat similar to service mesh integrations with cloud load balancers today [29]. The `bind` call only requires changes to the interface tenants use request load balancing services.

5.3 Security

Rationale. In §4.3, we addressed the security implications for the network fabric. We now discuss how tenant-level security concerns are addressed in the Invisinets API. We assume the tenant is primarily concerned about service-level attacks and targeted resource exhaustion. To address potential attacks, our architecture will implement tenant-level security in two main pieces: middlebox annotations on endpoints and network-level permit lists. Both of these are specified by the tenant but implemented/enforced by the CP.

Today, tenants protect their services through a combination of per-VM/virtual network permit lists and by deploying various security appliances such as first-party firewalls and third-party DPI systems (e.g., [52]). Network permit lists are specified by the tenant but implemented by the cloud provider (typically through filtering in the vswitch/NIC at each endpoint) while security appliances may be deployed and managed by the tenant. Together, these mechanisms protect the tenant from both service-level attacks (e.g., intrusion or exfiltration attacks caught by DPI firewalls or proxies) as well as resource exhaustion attacks that specifically target the tenant (e.g., overwhelming the tenant's service).

Ideally, we would remove middleboxes from the cloud offerings altogether and instead implement security measures in an API gateway in the service itself [6, 63]. However, we acknowledge that some applications may have strict security requirements that demand middleboxes and therefore we expand our API to include those available today.

API. The per-host tenant-level permit lists can be naively implemented at the endpoint with the access lists used today such as Network Security Groups in Azure. To the tenant, our API

will look similar to these access lists. To permit from another host, the tenant simply uses the `set_permit_list` function to update the given endpoint's allowed hosts.

The tenant may use the `annotate` API to apply the desired middlebox to an endpoint's traffic. The cloud provider is responsible for the instantiation and placement of the middlebox and the routing necessary to direct the relevant traffic. The tenant will provide the type of middlebox (could be their own VM as seen with some third-party network appliances today) and configure it as done today. Additional parameters to the `annotate` API could specify a subset of the traffic to be sent through the middlebox (i.e., by destination) or specify the ordering of a series of middleboxes.

Design. We propose a two-pronged approach to protect tenants from attacks. First, we allow tenants to continue their use of cloud middlebox offerings by annotating endpoints. Therefore, they may continue to use their DPI firewalls, IDS/IPS appliances, etc. as they do today. However, the tenant does not have to manage the placement of these appliances in their networks and route relevant traffic. The cloud provider will install the necessary routing in the vswitch/NIC. By including security-focused middlebox functionality in our API, tenants can continue their defense-in-depth best practices as they do today. Secondly, we propose that the cloud provider protect the tenant from network-level resource exhaustion attacks by reusing the same infrastructure it already implements to protect itself. In addition to the above, we assume the cloud provider will continue to enforce the tenant's permit list through filtering at the endpoint's vswitch/NIC. These permit lists are essentially available today as NSGs (Azure) and Security Groups (AWS), so we adopt the underlying architecture unchanged.

5.4 Performance

Rationale. Today, cloud providers offer rather limited network performance/QoS guarantees. Tenants are generally not promised any minimum bandwidth and are instead throttled above a certain threshold. However, some tenants seeking high availability and reliability may reserve a dedicated link [7, 28, 44] which the tenant must then provision, configure and operate as discussed in §2.

The abstraction of a dedicated link is fundamentally at odds with our goal of a high-level endpoint-centric API since a link implies a topology that incorporates it and routing that steers select traffic over the link. Our goal is to avoid this complexity and hence we instead ask: *can we approximate the benefits of these dedicated links without obligating the tenant to worry about the many details they do today?*⁶

The point-to-point link abstraction offered today requires coordination between the entities on either end of the link and

⁶One might ask whether the performance of dedicated links justify their cost and complexity in the first place. In Appendix 11, we present early results showing that these links may not always offer a performance benefit but leave a full evaluation to future work.

is not offered directly between clouds. To avoid the coordination and low-level configuration of direct links, our proposal is to approximate the *effect* of dedicated links by guaranteeing some amount of dedicated egress bandwidth to another domain to tenants who purchase it at a predefined granularity (in this paper, we will assume regional granularity). We hope that since clouds already have an incentive to be highly connected with one another, this guaranteed bandwidth when leaving a region is enough to roughly estimate the effect of dedicated links stitched together at a colocation facility. With this overall goal, we then ask how to provide such an abstraction to the tenant as a service.

The service model we assume is in terms of bandwidth reservations, rather than point-to-point links with a specified bandwidth as is available today. Tenants will specify to the cloud provider their desired amount of dedicated egress bandwidth to another domain (*e.g.*, another cloud) for some region. Then, we seek to make the traffic management necessary to use this link as simple as possible by allowing tenants to define traffic classes and map them to strictly ordered priorities. These priorities will define which traffic gets to use the dedicated bandwidth if/when the aggregate traffic for the tenant in that region is greater than the allowed dedicated bandwidth.

API. Ultimately, the tenant will define their own traffic classes (in terms of five-tuples). The CP will then label traffic as necessary and map these classes to their own high (“dedicated”) and low (“best-effort”) priority classes in the fabric of the datacenter. To the tenant, reserving the regional aggregate egress bandwidth will simply require calling `set_qos` and setting the priority of traffic via `set_qos_class`.

Design. Our `set_qos` API is based on the assumption that clouds are reasonably well-connected with one another so that dedicated egress bandwidth between a cloud region and another domain can approximate a direct link between the two clouds. If not, congestion between the clouds could impact the available bandwidth beyond the control of either CP. Further, we require that the CP can classify egress traffic into reserved bandwidth packets and best effort-packets. Reserved-class packets are guaranteed to not experience congestion on egress (up to their reserved bandwidth) while best-effort may.

In offering the `set_qos` API, the CP has two primary goals: (1) enforce that the tenant does not consume more than its aggregate egress guarantee and (2) make it easy for the tenant to use all of their promised bandwidth without requiring low-level traffic engineering (as is required today to utilize dedicated links). Since the bandwidths are offered at a per-tenant, per-destination-domain, per-region level, the CP must monitor usage across multiple endpoints in a region and enforce the cumulative bandwidth limit at each endpoint. In doing so, there will be a tradeoff between reactivity and cost as enforcing the limit strictly will impose higher overheads. Scalability is also a challenge as performing distributed rate limiting across all tenant endpoints (in the 10s of millions) must be done with minimal resource consumption.

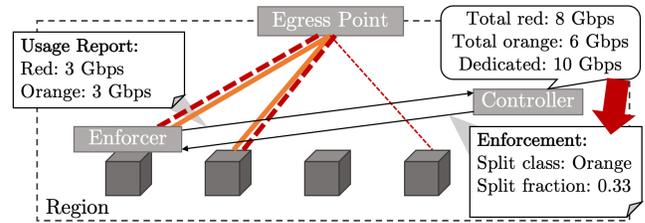

Figure 2: QoS enforcer example. The tenant sends traffic in two classes: red (dashed) and orange (solid), prioritized in that order. The reserved egress bandwidth is 10Gbps.

Our approach to enforce the `set_qos` API is as follows: we assume that tenants define traffic classes each with a different priority level and the cloud provider marks their traffic accordingly. The cloud provider then determines whether a particular traffic class (or what fraction of it) should be assigned reserved vs. best-effort bandwidth based on the tenant’s current traffic demand aggregated across all its endpoints (collected at the host and reported to the controller). This mapping between tenant traffic classes and reserved vs. best-effort bandwidth is computed by a per-tenant *QoS controller*. The QoS controller communicates the appropriate mappings to a *QoS enforcer module* at each endpoint (implemented in the NIC or vswitch) which accordingly marks egress packets and rate limits reserved priority flows according to their current bandwidth allocation. Finally, the egress router classifies packets based on these markings and (priority) schedules them accordingly. Hence, the additional infrastructure that our API imposes on the cloud provider is the per-tenant QoS controllers and the QoS enforcer modules (Figure 2).

Using per-tenant controllers mitigates potential scaling issues since each controller need only scale to the number of endpoints per tenant (*vs.* all endpoints) per region, thus dividing the regional rate limiting into reasonably-sized problems.

Figure 2 shows an example of this design for a single tenant. The tenant has two traffic classes, red and orange, which are prioritized in that order. The communication between only one enforcer and the controller is shown for clarity, though each VM would participate. The controller determines that the red class does not use the full egress reservation and allows 1/3 of the orange traffic into the dedicated class. For a more formal discussion of the QoS controller, see Appendix 12.

This model requires cloud providers to engage with an underlying capacity provisioning problem (*i.e.*, how does one ensure that the total reserved bandwidth across all customers is actually there?). For the purpose of this API, we assume that the CP has some policy for installing and allocating bandwidth, but we do not address the specifics of the policy.

5.5 Grouping

Rationale. One noticeable advantage of today’s abstractions over a purely endpoint-centric view is that virtual networks can serve as a helpful and simplifying grouping mechanism (*e.g.*, to apply an identical policy or configuration to all VMs

running a Spark job). Without a method to group hosts, reasoning at an endpoint-level may be difficult, especially since tenants are not given EIPs from a continuous address space.

We support the convenience of grouping via tags that can be associated with EIPs such that tenants may use tags in place of a list of EIPs in permit lists. This ensures cleaner semantics for the tenant while the cloud provider can “compile” these to IP addresses for filtering on packets at the end host associated with the permit list. Similar features, called service tags, are available today for Network Security Groups [48] while AWS offers general purpose tagging across resources [59]. Our use of tags is limited to EIPs as they are known across clouds while specific resources are not.

API. To provide the benefits of grouping, we adopt a method for tagging as a means of convenience for tenants in our API with `tag`. Here, tenants may associate an EIP with a given tag as shown in Table 1. Tags can be used in other APIs such as `set_permit_list` in place of addresses.

6 Implementation

To demonstrate the feasibility of our proposed API itself, we have developed an implementation using existing APIs for AWS and Azure to expose our simplified API; *i.e.*, it effectively builds a shim layer on top of existing APIs. As discussed in earlier sections, most of our API requirements map onto existing abstractions and hence can be implemented in a straightforward manner. The key new addition is the QoS API for which we provide a partial implementation as described below. This approach – *i.e.*, building on top of existing APIs – is unfortunately deeply tied to specific cloud implementations. In the long term, we hope/expect the shim layer to thin over time as clouds provide the Invisinets API as a first-party implementation.

Implementing the QoS API requires three infrastructure components: (i) per-host enforcement modules, (ii) QoS controllers, and (iii) modifications to egress routers to appropriately classify and prioritize traffic. We built a prototype of the first two components but lack the access to realize (iii); in this sense, our implementation of the QoS API is only a partial one. At the same time, such classification and priority scheduling is standard on high-end routers and hence we anticipate no problem in realizing the API more fully in production.

For the enforcer module, the rate limiting is done through Linux `tc` operations and a `bpf` filter implemented as a `bcc` program [3]. This approach was chosen to fit easily into any host-based approach, though in a production deployment we expect this logic would reside in the hypervisor or virtual switch [25]. The `bcc` programs monitor outgoing traffic volumes on a per-traffic-class basis and reports to a reporting process on the host. The host sends usage to a per-tenant controller via RPCs [31]. The controller calculates per-host mappings to each traffic class and reports back to all hosts which reported in the last time interval. The host process then inserts this data into `bpf` tables for the rate limiter to observe.

The rate limiter classifies traffic based on the tenant to cloud provider class mapping. The cloud provider classes correspond to classes in a `tc` hierarchical token bucket which rate limits the egress traffic from the node.

7 Evaluation

In our evaluation, we focus on answering two questions: (i) to what degree does Invisinets simplify a tenant’s experience when networking their workloads? and, (ii) is implementing the Invisinets API technically feasible for cloud providers?

We evaluate simplicity using a two-pronged approach. First, we consider three sample tenant deployments and compare the complexity of implementing each deployment using Invisinets versus doing so with existing solutions (§7.1). This approach allows us to do a deep-dive evaluation for specific deployment scenarios and solutions. For a broader view on tenant deployments, we also analyzed 677 publicly available deployment scenarios as captured by their Terraform files on GitHub and quantify the extent to which existing network abstractions contribute to the overall setup and configuration complexity that a tenant faces, and the extent to which Invisinets can remedy this complexity (§7.2).

When considering the feasibility of implementing Invisinets, we focus primarily on scalability. This is because, as discussed earlier, cloud providers already implement (close approximations for) the individual building blocks needed to implement our Invisinets API – *e.g.*, address translators, load balancers, rate limiters. Hence, the main question is whether extending their use of these components to a larger fraction of their tenant pool will create new and problematic scaling bottlenecks. Thus, in §7.3, we evaluate scalability using a combination of system microbenchmarks and deployment statistics from cloud providers.

7.1 Evaluating Simplicity via Case Studies

Methodology. We compare the complexity of tenant networking using Invisinets versus existing solutions. For the latter we consider: (i) a DIY tenant that writes scripts directly atop existing “first-party” cloud APIs, and (ii) Aviatrix [12] as representative of third-party multi-cloud solutions.⁷

Given that there is no best practice for measuring simplicity, we propose a metric which we believe is reasonable, though we do not claim that it perfectly captures all notions of complexity. We measure simplicity in terms of the number of network components that the tenant must consider within three main categories: network boxes, links, and configuration points. Network *boxes* refers to device abstractions such as transit gateways, VPN devices, firewalls, and so forth. *Links* refers to various forms of virtual link abstractions including dedicated egress links (*e.g.*, Azure ExpressRoute [44]), `vnet`

⁷As mentioned earlier, Aviatrix offers tenants a management layer built atop per-cloud abstractions and optimized cloud appliances. Tenants view their multicloud deployments through a “single pane of glass”, but must still be fluent in per-cloud building blocks as well as Aviatrix-specific constructs.

peerings [42], and private internal links [47]. Finally, *configuration points* counts any abstraction that exposes network configuration parameters for the tenant to consider. We count the number of configuration points (e.g., a firewall) rather than lines of code or configuration (e.g., number of firewall rules) since the latter can often be arbitrarily scaled in our scenarios and hence may be misleading.

We further clarify certain aspects of how we account for configuration points. First, every box is also counted as a configuration point: e.g., a gateway is both a box (must be placed in a topology) and a configuration point (must be configured with routes, tunnels, etc.). Second, while boxes are always configuration points, the inverse is not true: e.g., abstractions such as virtual networks or subnets are not boxes but do require configuration and hence are counted as configuration points. Invisinets in particular has multiple configuration points but few boxes so both measures are needed for a fair comparison. Finally, we ignore security groups/permit lists and endpoint IP addresses when counting configuration points as these are present in all solutions and depend on the number of endpoints which can be scaled arbitrarily.

We compare solutions using three case studies: one is a validated design published by Aviatrix [11] and the other two were defined by us to represent extremes of simple vs. sophisticated deployments.

Case Study 1: A Simple Tenant Network. We start with a rather contrived, simple deployment in which a single VM in one cloud (Cloud A) must communicate with a service in another cloud (Cloud B) in a shared address space as shown in Figure 3a. The service in Cloud B uses two VMs which are load balanced. Table 2 shows the complexity of implementing this scenario with each of the three solutions we consider.

Metric	First-Party	Aviatrix	Invisinets
Boxes	3 (VPN, LB)	3 (GW, LB)	0
Config. Point	7 (vnet, subnet, VPN)	7 (vnet, subnet, VPN)	1 (SIP)

Table 2: Complexity analysis for a Simple Tenant Network. In parentheses, we list the "top three" abstractions in terms of their contribution to complexity (see Fig. 3 for abbreviations).

We see that even this simple scenario incurs non-trivial complexity with existing solutions. With the DIY approach, tenants must still consider virtual network gateways, a load balancer, backend pools, local network gateways, route propagation parameters, and more, leading to a total complexity of 10 network components. Aviatrix is similar, though it uses 2 Aviatrix gateways in lieu of the first-party VPN gateways.

Invisinets, however, completely eliminates the virtual network layer and instead requires just one configuration point (the SIP in Cloud B), allowing the deployment to be expressed in just 9 lines of code as shown below:

```
eip1 = cloud_a.request_eip(vm1_id, name="vm1")
eip2 = cloud_b.request_eip(vm2_id, name="vm2")
eip3 = cloud_b.request_eip(vm3_id, name="vm3")
sip = cloud_b.request_sip(name="service")
bind(eip2, sip)
bind(eip3, sip)
```

```
set_permit_list(eip1, [eip2, eip3])
set_permit_list(eip2, [eip1])
set_permit_list(eip3, [eip1])
```

By contrast, our DIY script using the AWS and Azure Python APIs requires over 45 lines of code (snippets shown in Appendix 13) even assuming IPs and the underlying virtual network have already been provisioned.

Case Study 2: (Aviatrix) Multi-Region Design. We consider a design from Aviatrix [11], as seen in Figure 3b. This deployment involves 3 virtual networks running different services in two different cloud regions. They are connected to one another via a transit virtual network which contains firewalls for security. These transit virtual networks also contain direct links to on-prem datacenters. Table 3 summarizes the complexity costs in implementing this design.

Metric	First-Party	Aviatrix	Invisinets
Boxes	4 (GW, FW)	18 (GW, FW)	2 (FW)
Links	9 (peering, DL)	2 (DL)	0
Config. Point	29 (peering, subnet, vnet)	36 (GW)	2 (egress BW)

Table 3: Complexity analysis for the Aviatrix design. See Fig. 3 for abbreviations.

We see that, compared to our first case study, complexity rises significantly with both the DIY and Aviatrix solutions. The majority of this complexity comes from the gateway and virtual network peering abstractions. Interestingly, Aviatrix incurs greater complexity than a DIY implementation due to its recommended redundant gateways, though first-party peerings cannot be redundant. In contrast, Invisinets requires only 4 network components (egress reservations to approximate the direct links and middlebox annotations for firewalls), which represents a more than 90% reduction in complexity relative to the DIY and Aviatrix solutions. Creating this deployment with the available first-party APIs would take over 45 lines of code even assuming all instances and their IPs have been provisioned and the out-of-band coordination to set up the direct links has been performed. In addition, we do not count lines only defining configuration, otherwise the script is well over 200 lines. A significant portion of this code sets up the necessary routes to get traffic from each virtual network to the appropriate firewall and/or gateway.

Case Study 3: A Heterogeneous Tenant Network. Our third scenario showcases a network deployment that involves a range of connectivity requirements, as shown in Figure 3c. This scenario is representative of virtual networks constructed by larger cloud tenants, though we chose to scale it down for understandability. For the sake of demonstration, in Figure 3c, the Azure network is depicted in some detail while the GCP deployment is unrealistically simple. In this scenario, the tenant's cloud deployments in GCP and Azure are each connected to the tenant's on-prem datacenter via direct links to an Internet exchange point where the tenant has reserved a virtual router and an MPLS link to their datacenter. In the Azure deployment, the ExpressRoute terminates at a VPN gateway which must reside in its own subnet [49]. From there, user-defined routes send traffic to the appropriate subnet or

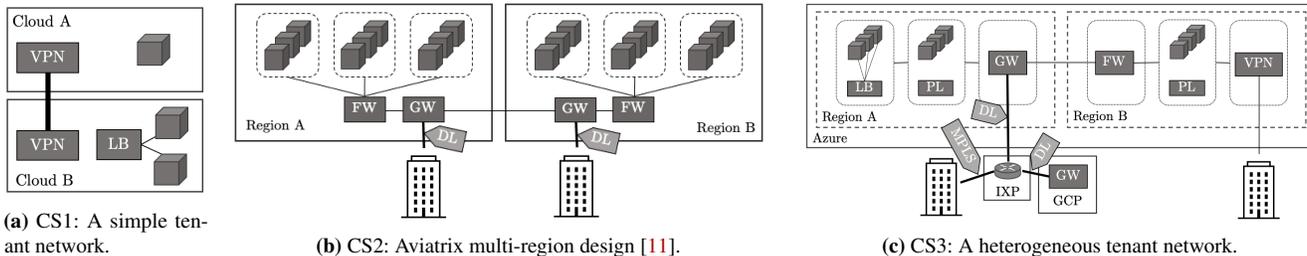

Figure 3: Generalized (not taking the form of any particular current approach) network topologies for each case study. (LB = load balancer, GW = gateway, FW = firewall, PL = private link, DL = Direct Link)

onto the ExpressRoute for egress traffic to GCP or On-Prem. The other subnets in the virtual network contain VMs and a private link to an Azure service such as storage on the left and load-balanced VMs on the right. In another virtual network in Azure, a VPN gateway tunnels to a branch office. Ingress traffic is directed to a subnet containing a firewall which then allows traffic to reach VMs or another private link to a Microsoft service. Table 4 summarizes the complexity costs in this design. A script to create this deployment (again, ignoring instances, IPs, and some ExpressRoute setup) would require over 80 lines of code. While coming in the form of many different components, achieving basic connectivity via gateways, links, *etc.* continues to be the main source of complexity.

Metric	First-Party	Aviatrix	Invisinets
Boxes	6 (GW, FW, LB)	6 (GW, FW, LB)	2 (FW)
Links	5 (DL, PL, MPLS)	5 (DL, PL, MPLS)	0
Config. Point	22 (vnet, subnet, GW)	22 (vnet, subnet, GW)	4 (egress BW, FW)

Table 4: Complexity analysis for the heterogenous tenant network. See Fig. 3 for abbreviations.

7.2 Terraform Complexity

For a broader perspective, we now consider the impact of Invisinets on a larger pool of deployment scenarios. Specifically, we evaluate the scope for simplification in the Terraform files that a network administrator maintains. Terraform [32] is a popular language for specifying cloud infrastructure as declarative code directly using the first-party abstractions.

Methodology. We scraped GitHub for Terraform files creating virtual networks, selecting files that mention an AWS VPC and omitting files that only defined Terraform variables or outputs. For a scrape conducted on 9/15/2022, our filtering yielded 677 files for analysis.⁸ We use these configurations since they are publicly available but recognize that they may not fully represent the tenant use-cases that Invisinets targets (*e.g.*, mid/large scale enterprises). We believe our analysis could be easily repeated on large production deployments.

Results. We parse each Terraform file, identifying whether a code block corresponds to a virtual network component. Table 5 lists the components we identified and how often

Virtual Network Component	Occurrence Count	Line Count
VPC	2,493	26,731
Route Table	1,839	13,317
Subnet	1,514	14,677
Security Group	456	9,704
Internet Gateway	445	2,802
Route	339	2,184
NAT Gateway	209	1,661
Network ACL	141	2,841
Transit Gateway	82	587
VPN Gateway	40	316
Load Balancer	22	207
Network Interface	16	123
VPN Peering Connections	5	27
Customer Gateway	4	58
VPN Route	2	10
VPN Connections	1	13

Table 5: Breakdown of Terraform lines removed (across all 677 scraped files) by virtual network component.

they occurred in our files.⁹ We also calculate the lines of code within each of these code blocks and show the total per-component line count in the last column of Table 5. Unsurprisingly, VPCs are the most common component. Beyond this, we see that abstractions used to establish basic connectivity – *e.g.*, Internet Gateway, Subnet, Route Table, Route – constitute a significant fraction of the networking abstractions that an administrator must deal with. Moreover, even complex routing abstractions such as Transit Gateways are not uncommon. These findings thus support our thesis that an approach such as Invisinets, which altogether eliminates the need for virtual topologies and their routing configurations, can substantially simplify networking configurations.

The lines of code identified in Table 5 can be viewed as an upper bound on the lines of code that can be omitted by using Invisinets. To evaluate whether this is a significant portion of the overall Terraform configuration, Figure 4 shows a histogram of the percentage of lines-of-code that can be omitted from the Terraform files we consider.

While the fraction of omitted configuration lines may be surprising, these resource definitions rarely carry information critical to the four tenant goals around which the Invisinets API is designed. Instead, many of these lines specify details of unnecessary abstractions such as virtual networks and the gateways required to reach external endpoints. (We show an

⁸Github API search results are limited to the first 1000 results. Additional filtering on returned files reduced the number further.

⁹We believe this estimate is approximately equivalent to the set of network components (boxes, links, and configuration points) that we measure in §7.1.

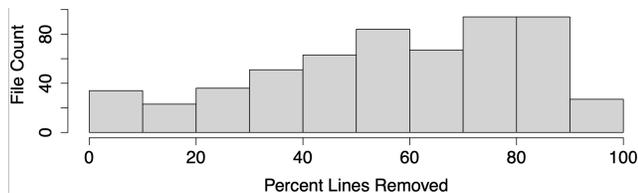

Figure 4: Histogram of percent lines of Terraform resource files that can be omitted with Invisinets API.

example of such a configuration in Appendix 14). Accordingly, the streamlined Invisinets API does not require much of this configuration.

We note that our estimates for omitted code in this section are an upper bound since we do not account for the lines of configuration that would be *added* by using Invisinets’s API. Nonetheless, our evaluation in the previous section suggests that Invisinets requires far fewer (90+% fewer) components to configure and hence we expect to be left with significant savings. Moreover, the permit lists that Invisinets requires contain information that is necessary even without Invisinets; *e.g.*, in the form of VPN access lists, firewall rules, NSG configurations, and so forth.

7.3 Scalability

As mentioned earlier, we focus on the scalability of the Invisinets API. Implementing the Invisinets API implies change along two main fronts: address management to support PRDO-only addressing, and enforcing per-tenant egress bandwidth reservations. We consider each in turn.

PRDO addressing. PRDO-only addressing changes the number of endpoints that are assigned public IP addresses and hence a natural question is whether cloud providers have a large enough public IP addresses to give one to every VM. From discussions with Azure operators, we learnt that Azure advertises over $1.4 \cdot 10^{20}$ addresses in total [46] and hosts $O(10M)$ VMs. Thus we can safely conclude that Azure has sufficient public addresses to support PRDO addressing. Similarly, GCP has over $7.1 \cdot 10^{26}$ advertised addresses in total [27], presumably plenty to allocate to all endpoints.

The next scalability concern may be the impact on the address translation infrastructure – specifically, the vswitch/NIC and SLBs used to translate PRDO addresses to internal private addresses and to enforce permit lists. Fortunately, the PRDO-only infrastructure does not increase the number or complexity of vswitch/NIC lookup operations, as every packet is translated to DIPs even today. Similarly, in considering the impact on the SLB, we note that Invisinets does not change the number of internal endpoints that need to be reachable from endpoints outside the cloud provider (defined as semi-private addresses in §3) since this depends on the tenant’s workload requirements rather than the addressing architecture. Today, the bindings and permit-list rules for these endpoints are programmed in per-tenant VPNs/NATs while Invisinets implements the same in the cloud provider’s SLB. Since cloud SLBs [21, 54] are already designed for elastic horizon-

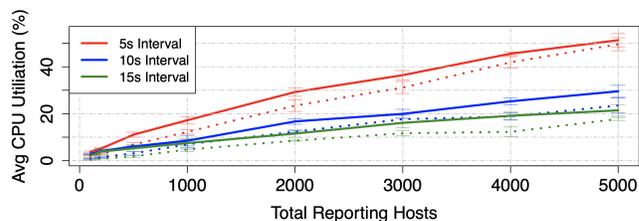

Figure 5: CPU utilization of QoS controller for different reporting intervals over 5 experiments. The report collection (solid) is the bottleneck over aggregation and reporting (dotted).

tal scaling, we do not anticipate any scaling challenges due to semi-private addresses.

QoS Enforcer. Invisinets adds per-tenant, per-region QoS controllers to a cloud provider’s infrastructure. We now benchmark the QoS components of our implementation to demonstrate that these QoS controllers could reasonably scale in a production setting. Our implementation consumes additional network bandwidth for communication between the QoS controller and enforcer modules. (The volume of tenant traffic remains unchanged with only ToS fields modified to reflect the class of traffic.) Using 32 traffic classes (chosen to be expressive), we record a worst-case overhead of only 800 bytes per host in one reporting interval for one reservation. For a VM with a 5 Gbps link, communication with the QoS controller consumes less than 0.00001% of its link bandwidth when reporting at 10 second intervals. At the QoS controller, this overhead is $n \times 800$ bytes per interval where n is the number of VMs per tenant per region. Discussions with a major cloud provider *CP-X* revealed that, for their deployments, n is under 50,000 per region in the worst case, and $O(10)$ on average. Hence, for a 10 second reporting interval, the total bandwidth consumed at the QoS controller is around 32Mbps in the worst-case and far lower for average tenant sizes.

Next, we measure the CPU utilization at our QoS controller for increasing numbers of reporting hosts, shown in Figure 5. Our QoS controller is comprised of two main processes: a gRPC [31] server to collect bandwidth reports and an aggregation process to calculate the mapping and report back to hosts. We run our QoS controller on a t3.small instance in AWS with 2 vcpus, 2 GB of memory, and 5 Gbps bandwidth, chosen to ensure that network capacity is not a bottleneck. One hundred t2.small instances were used as hosts, with many host processes per instance. As shown in the figure, stressing our 2vCPU instance requires 1000s of reporting hosts. We believe this is a reasonable expectation for region-scale deployments since the average number of VMs per tenant is $O(10)$. Depending on the interval, with enough hosts, the collection process cannot keep up with incoming reports at which point the controller size (*i.e.*, vcpus) can be scaled as necessary. Scaling up to support a tenant with potentially millions of hosts in one region would pose an additional challenge in aggregating bandwidth measurements; we leave that challenge to future work.

Finally, we consider the total resource consumption due

to QoS controllers (across all tenants). In Azure, there are roughly an average of 16,000 tenants in each region. Accordingly, we expect the QoS enforcer to consume fewer than 1,600 cores in each region on average (since the total utilization for 100 hosts and 5 s intervals is <10%).

Despite the additional packet-processing logic due to the enforcer, no significant overheads are seen in processing host traffic. We measured the latency and throughput of outbound traffic from a host with the QoS enforcer enabled and disabled. Neither metric demonstrated a noticeable overhead. Throughput measurements using `iperf` [1] between two `t2.medium` instances for 10 second flows produced an average of 64.9 Mbps across 100 flows with the rate limiting (though set to allow many Gbps to not interfere) and 64.8 Mbps without. Latency was tested with 200 pings to a remote host. With the rate limiter enabled, the average was 0.46 ms ($\sigma = 0.12$) while the average was 0.48 ms ($\sigma = 0.258$) without it.

Thus we conclude that Invisinets’s QoS infrastructure introduces little overhead for cloud providers.

8 Limitations

We acknowledge that Invisinets may not satisfy infrastructure requirements for all cloud tenants. Despite the layers of protection from the cloud provider, the tenant may deem public IPs to be an unacceptable risk for their endpoints. While addresses in Invisinets are default-off, this choice removes the layer of isolation provided by virtual network private address spaces. We note, however, that default-off semantics are present in both Invisinets and today’s virtual network abstractions. Only the placement of these parameters differ (*e.g.*, endpoint permit list vs. gateway rules). In addition, the workload may have security requirements defined in terms of today’s networking abstractions. Accordingly, we do not expect this interface to appeal to all tenants and target specifically cloud-native applications.

As mentioned in 5.4, our QoS API’s ability to simulate the effects of a direct link is dependent on the level of connectivity between the clouds. This assumption may be particularly precarious in areas with smaller cloud footprints.

Since our primary goal with the Invisinets API was to simplify the tenant interface, our evaluation is inherently limited. Complexity is a multifaceted issue and cannot be completely captured in any one metric. We proposed a variety of metrics to evaluate simplicity as fairly as we could, though the values are not necessarily exact.

9 Related Work

We build on the extensive literature on cloud and network virtualization [20, 24, 53, 54, 60]. As mentioned in §5, most of our API leaves this underlying architecture unchanged or extends it in relatively straightforward ways.

Distributed rate limiting has also been extensively studied [37, 39, 56, 58, 64]; *e.g.*, with work on optimizing end host traffic shaping [58, 64]. Systems such as [39, 56] make

network-wide rate limiting decisions similarly to the model we adopt, though [56] primarily seeks to limit traffic aggregates rather than provide a minimum guarantee. Such guarantees are provided by [40] with strategic resource placement while [37] modifies the end host networking stack.

We take the large body of work in network verification [14, 23, 26, 36, 38] as evidence of the overwhelming management complexity in networking. While verification has focused more on datacenter environments, virtual networks suffer similar complexity since they use similar abstractions. Generally, compiling high-level network intents into low-level device configs remains difficult and error prone [15].

This paper joins others in advocating a forward-looking view of cloud networking though prior proposals focused on performance guarantees [13, 50, 51] or declarative control [16] rather than the simplification we target. In [4], a platform to unify cloud services is developed by creating a substrate infrastructure across clouds. The vision in [61] takes the extreme stance of proposing a unified interface for all clouds. Invisinets can be viewed as an instantiation of their vision for networking, though we focus less on unification and instead hope that simpler APIs across clouds will result in some homogenization over today’s highly-siloed APIs.

10 Conclusion

To simplify networking for cloud tenants, we proposed a declarative and endpoint-centric API which takes L3 connectivity as a given and removes the burden of deep networking knowledge from tenant operators. We acknowledge that our model may not initially meet the requirements of all tenants. However, our proposed API can coexist with existing abstractions and, in fact, can provide a spectrum of simplicity where deployments may include both today’s building blocks as well as our proposed architecture. Our API requires consideration of fewer network components and obviates the need for network topologies to be constructed at all. Supporting this simple API requires minimal infrastructural changes to cloud datacenters and the new systems should be easily scaled. We believe the Invisinets API for virtual networking follows the evolution seen in cloud compute and storage from virtual replicas of physical components to higher-level services.

Appendix

11 Benefits of dedicated links.

Further, we conducted a small experiment to determine the benefit of these dedicated links. We provisioned an ExpressRoute from Azure in Northern California to a colocation facility in Silicon Valley and connected it to Direct Connect to AWS in Northern California. A diagram is shown in Figure 6. Both dedicated links were 50Mbps and the virtual router in the colocation facility can handle up to 500Mbps. In parallel to this dedicated connection between clouds, we connected two hosts in each deployment via the public Internet. We collected throughput measurements using iperf [1] every 5 minutes for a week and performed teppings [2] every minute. We found that at these low bandwidths, the primary performance benefit is consistent throughput (see summary in Table 6). Notably, the latency can even be worse across these dedicated links, though not significantly so considering the variability.

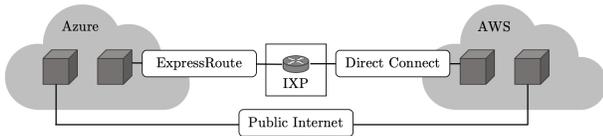

Figure 6: Direct link measurement setup.

Client Cloud	Direct Link?	Measurement	Mean	Std. Dev.
AWS	Yes	Throughput	51 Mbps	0.23 Mbps
AWS	No	Throughput	169 Mbps	85 Mbps
Azure	Yes	Throughput	50 Mbps	1.4 Mbps
Azure	No	Throughput	117 Mbps	80 Mbps
AWS	Yes	Latency	4.89 ms	1.74 ms
AWS	No	Latency	3.38 ms	1.73 ms
Azure	Yes	Latency	12.53 ms	9.36 ms

12 QoS Controller

More formally, the job of a QoS controller is as follows. Each tenant, t , can have n classes of traffic, decreasing in priority: $C_1, C_2 \dots$. Traffic in these classes must be mapped to the cloud provider best-effort and dedicated classes B and D . The tenant reserves some dedicated egress bandwidth, r_t . To map the classes, each host x reports x_t^i , the bandwidth tenant t consumed in class C_i every interval of k seconds to the per-tenant controller. Every interval, the controller calculates the total bandwidth for each class, C_i . Starting with the highest priority class, C_1 , the controller adds x_t^1 to the running total dedicated bandwidth, x_D , and maps the class to the dedicated cloud provider class, D . When $x_D > r_t$, the controller maps the current class C_s to a split class, S . All subsequent classes $C_{j>s}$ are mapped to B . The fraction of the bandwidth used by C_i which would fit into the reserved bandwidth $f_s = (x_D - r_t)/C_s$ is calculated as well. The controller sends f_s and C_s to all hosts that reported in the previous interval.

The (enforcement module at) hosts then install the calculated mapping between tenant and cloud provider classes. Traffic belonging to $C_i < C_s$ is simply marked as reserved (D) while traffic in $C_i > C_s$ is marked as best-effort (B). For traffic belonging to C_s , the host calculates the maximum allowed dedicated bandwidth in the split class $b_d = f_s \cdot x_t^s$. This value is used for per-flow admission to D for traffic in C_s . When a new flow in C_s arrives, a timestamp is recorded. After m time has passed, the flow is eligible for promotion to D . Its bandwidth over the last m seconds, b_{flow} , is compared against b_d . If $b_{flow} < b_d$ the flow is mapped to D and b_d is updated ($b_d = b_d - b_{flow}$), otherwise the flow is mapped to B . This evaluation is performed every m seconds for each flow in C_s which has not been admitted to D . Accordingly, this process requires per-flow state, though only proportional to the number of flows in C_s during a single reporting interval.

13 Case Study 1 Code

In Figure 7 is an excerpt of the code required to implement Case Study 1 using first-party cloud APIs.

```
def setup():
    vnet = network_client.virtual_networks.get(RESOURCE_GROUP, vnet_name)
    eip = network_client.public_ip_addresses.get(RESOURCE_GROUP, EIP1_NAME)
    eip1_config = network_client.\
        network_interface_ip_configurations.get(RESOURCE_GROUP,
                                                get_nic_name_from_ipconf_id(
                                                    eip.ip_configuration.id),
                                                get_resource_name_from_id(
                                                    eip.ip_configuration.id))

    eip2 = network_client.public_ip_addresses.get(RESOURCE_GROUP, EIP2_NAME)
    eip2_config = network_client.\
        network_interface_ip_configurations.get(RESOURCE_GROUP,

Abstract

DNN models across many domains continue to grow in size, resulting in high resource requirements for effective training, and unpalatable (and often unaffordable) costs for organizations and research labs across scales. This paper aims to significantly reduce training costs with effective use of preemptible instances, i.e., those that can be obtained at a much cheaper price while idle, but may be preempted whenever requested by priority users. Doing so, however, requires new forms of *resiliency* and *efficiency* to cope with the possibility of frequent preemptions – a failure model that is drastically different from the occasional failures in normal cluster settings that existing checkpointing techniques target.

We present Bamboo, a distributed system that tackles these challenges by introducing *redundant computations* into the training pipeline, i.e., whereby one node performs computations over not only its own layers but also over some layers in its neighbor. Our key insight is that training large models often requires *pipeline parallelism* where “pipeline bubbles” naturally exist. Bamboo carefully fills redundant computations into these bubbles, providing resilience at a low cost. Across a variety of widely used DNN models, Bamboo outperforms traditional checkpointing by $3.7\times$ in training throughput, and reduces costs by $2.4\times$ compared to a setting where on-demand instances are used.

1 Introduction

DNNs are becoming progressively larger to deliver improved predictive performance across a variety of tasks, including computer vision and natural language processing. For instance, recent language models such as BERT [66] and GPT [50] already have a massive number of parameters, and their newer variants continue to grow at a rapid pace. For example, BERT-large has 340 million parameters, GPT-2 has 1.5 billion, and GPT-3 increases to 175 billion; the next generation of models embed upwards of trillions of parameters [17].

Of course, model growth also entails larger training costs. For instance, GPT-3 consumes several thousand petaflop/s-days, costing over \$12 million to train on a public cloud (needing hundreds of GPU servers) [6]. Unfortunately, such costs are prohibitive for small organizations. Even for large tech firms, training today’s models incurs an exceedingly high monetary cost that eventually gets billed to the training

department. While pretrained models may be reused and fine-tuned for different applications, training new models is often required to keep pace with changing or emerging workloads and datasets.

Although there exists a body of work on improving the training of large models [38, 39, 26, 9, 7, 11, 12, 18, 54, 53, 64, 72, 24, 28, 31], existing techniques focus primarily on *scalability* and *efficiency*, with monetary costs often being neglected. However, when *affordability* and *accessibility* are considered, resource usage becomes a key concern and none of these techniques were targeted at improving *cost-efficiency* (e.g., performance-per-dollar) for training.

Preemptible Instances. This paper explores the possibility of using preemptible instances—a popular class of cheap cloud resources—to reduce the cost of training large models. There are several kinds of preemptible instances. For example, major public clouds provide *spot instances* with a price much cheaper than *on-demand instances*—e.g., the hourly rate of a GPU-based spot instance is only $\sim 30\%$ of that for its on-demand counterpart on Amazon EC2 [3]. As another example, large datacenters often maintain certain amounts of compute resources that can be allocated for any non-urgent tasks but will be preempted as urgent tasks arise [41, 5]. Similarly, recent ML systems [27, 69, 4] allow training jobs to use inference-dedicated machines to fully utilize GPU resources but preempts those machines when high-priority inference jobs arrive. The presentation of this paper focuses on spot instances, but we note that our techniques are generally applicable to any type of preemptible resources.

Despite their substantial cost benefits, preemptible instances pose major challenges in reliability and efficiency due the frequent and unpredictable nature of their preemptions. When and how many instances get preempted depends primarily on the number of priority jobs/users in a cluster. In a public spot market, preemption can also result from the market price exceeding the user’s bid price. While price-based preemption can be avoided via a high bid price (e.g., the on-demand price), capacity-based preemption is unavoidable. Preemption patterns vary drastically across clouds and even across families/zones on the same cloud (§3).

Given the unpredictable nature of spot instances, users can often only run short, stateless jobs and simply restart these jobs if they get preempted. Model training, on the contrary, is stateful and time-consuming. Discarding the state (e.g., learned weights) upon each instance preemption not only

♣ Contributed equally.

wastes computation but also prevents training from making progress. Checkpointing-based techniques can reduce wasted computation to a degree, but still spend a significant fraction of the training time (*e.g.*, 77% when training GPT-2 with 64 EC2 spot instances, see §3) on restarting and redoing prior work in the presence of frequent preemptions [20, 21]—a largely different scenario compared to conventional clusters where failures are rare.

Bamboo. This paper presents Bamboo, a distributed system that provides resilience and efficiency for DNN training over preemptible instances. Bamboo supports both pipeline parallelism and (pure) data parallelism with the same approach. Since pipeline parallelism is a more complex and general approach (for training large models), our discussion focuses on pipeline parallelism; we briefly discuss our support for pure data parallelism in §B. Bamboo currently does *not* support model parallelism.

Redundant Computation. Key to the success of Bamboo is a set of novel techniques centered around *redundant computation* (RC), inspired by how disk redundancies such as RAID [45] provide resilience in the presence of disk failures. A training system that uses pipeline parallelism runs a set of data-parallel pipelines, each training on a partition of the dataset. Each node¹ in a data-parallel pipeline performs (forward and backward) computations over a shard of NN layers with a *microbatch* of data items [24]. Bamboo lets each node in each data-parallel pipeline carry its own shard of layers as well as its successor’s shard. Each node performs *normal* computation over its own layers and *redundant* computation over its successor’s layers. The reason why we use a neighbor node (as opposed to a random node) to run RC is to exploit data locality in pipeline parallelism (see §5). Upon a node preemption, its predecessor has all the information (*e.g.*, layers, activations) needed for the training to progress; continuing training requires running a failover schedule on the predecessor node without wasting prior computations.

At first glance, running RC on every node appears infeasible due to concerns with both time and memory. Bamboo overcomes these challenges by taking into account pipeline characteristics to carefully reduce/hide these overheads.

First, to minimize the time overhead from RC, Bamboo leverages a key insight that *bubbles* [24, 51] inherently exist in systems using synchronous pipeline parallelism (§2). Bubbles are idle times on each node due to the gaps between the forward and backward processing of microbatches (Figure 1). Bamboo schedules the forward redundant computation (FRC) on each node asynchronously into the bubble. FRC entails a node doing the forward pass over its successor’s layers using the output of its own active layers and is the main way Bamboo achieves redundancy. For the part of FRC that cannot fit into the bubble, Bamboo overlaps it with the normal computation. As a result, FRC incurs a tolerable overhead

(*i.e.*, no extra communication is needed due to locality, and it can overlap with normal computation), and hence Bamboo performs it *eagerly* in each epoch. If a node is preempted during a forward pass, the pipeline continues after a node rerouting step whose overhead is negligible.

In addition to FRC, the system must find a way to generate the redundant version of the intermediate data related to backwards passes for the successor node. This can be accomplished by using the backward redundant computation (BRC), or a backwards pass over the node’s redundant layers (its successor’s layers). Unfortunately, for BRC, such a corresponding bubble does not exist. Eager BRC would require much extra work and data-dense communication on the critical path, which could delay training significantly (§5). As such, Bamboo runs BRC *lazily* only when a preemption actually occurs. If a node is preempted in a backward pass, continuing the pipeline requires a pause for the node’s predecessor to perform BRC to restore the lost state. However, since FRC is performed eagerly, when BRC runs, much of what it needs is already in memory, keeping pauses short.

Second, performing RC increases each node’s GPU memory usage. Note that the major source of the memory overhead is storing intermediate results (activations and optimizer state) from FRC, *not* the redundant layers, which take only little extra memory. To mitigate the memory issue, we leverage Bamboo’s unique way of performing RC described above. Note that the purpose of saving intermediate results of a forward pass is that these results are used by its backward computation. However, in Bamboo, BRC is performed lazily upon preemptions and the intermediate results of FRC are thus not needed in normal backward passes. Hence, Bamboo swaps out the intermediate results of each node’s FRC into the node’s CPU memory, leading to substantial reduction in GPU memory usage. These results are swapped back into GPU memory for BRC only upon preemptions.

Bamboo continues normal training with the help of RC in the presence of non-consecutive preemptions, *i.e.*, preempted instances are not neighbors in the same data-parallel pipeline. Once consecutive instances are preempted, RC can no longer provide resilience. More redundancies could be added to provide stronger resilience, but this would incur (compute and communication) overheads that are too significant to hide. Instead, based on our empirical observation that most concurrent preemptions come from the same allocation group (*e.g.*, a zone), Bamboo takes care to ensure that consecutive nodes in each pipeline come from different zones, minimizing the chance of consecutive preemptions at a small (<5%) overhead (see §6.5).

Results. We built Bamboo atop DeepSpeed [51] and evaluated it by training 6 representative DNN models using EC2 spot clusters comprised of p3 instances. Compared to a baseline using on-demand instances, Bamboo delivers a 3.6× cost reduction. Bamboo also outperforms a checkpointing approach by 3.7×. We developed a simulation

¹In this paper, “instance” and “node” both refer to a spot instance.

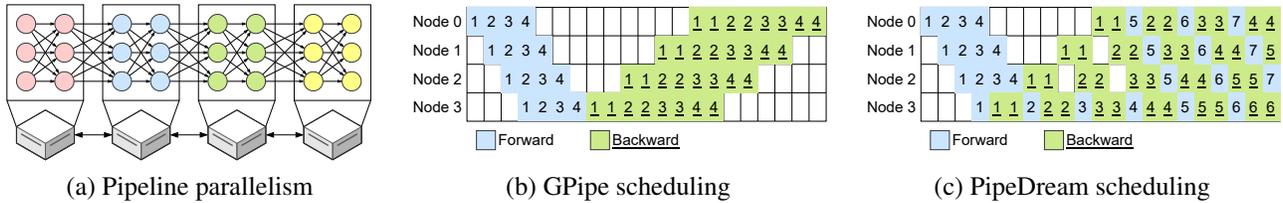

Figure 1: Illustration of pipeline parallelism on a 4-node cluster: (a) the model is divided into 4 shards, each with 2 layers; (b) and (c) show the scheduling of two recent systems GPipe [24] and PipeDream [38].

framework that takes preemption traces from real spot clusters and training parameters to simulate how training progresses with larger numbers of nodes. A deep-dive with BERT across a wide range of preemption probabilities shows that the *value* (i.e., performance-per-dollar) Bamboo provides stays constant and is much higher (2.48×) than that of on-demand instances. Bamboo is publicly available at <https://github.com/uclsystem/bamboo>.

2 Background

This section discusses necessary background for parallelism strategies. *Data parallelism* keeps a replica of an entire DNN on each device, which processes a subset of training samples and iteratively synchronizes model parameters with other devices. This strategy is often used with models that can fit entirely within a single GPU and used to both increase throughput or expand to batch sizes that cannot fit within a single GPU. Data parallelism can be combined with pipeline and/or model parallelism to train large models that do not fit on a single device. *Model parallelism* [13] partitions model operators across training devices. For example, the weights for a single matrix multiplication may reside across two separate GPUs, each performing a part of the full computation and then combining the results. This technique allows the model to expand beyond a single GPU by reducing the memory requirements of each operator. However, efficient model parallelism algorithms are extremely hard to design, requiring difficult choices among scaling capacity, flexibility, and training efficiency. As such, model-parallel algorithms are often architecture- and task-specific.

Pipeline parallelism [38, 24, 71] has gained much traction recently due to its flexibility and applicability to a variety of neural networks. Pipeline parallelism divides a model at the granularity of layers and assigns a shard of layers to each device. Figure 1(a) shows an example where the model is partitioned into four shards and each worker hosts one shard (with two layers). Each worker defines a computation stage and the number of stages is referred to as the *pipeline depth* (e.g., 4 in the example). One worker only communicates with nodes holding its previous stage or next stage. Each input batch is further divided into *microbatches*. In each iteration, each microbatch goes through all stages in a forward pass and then returns in an opposite direction in a backward pass. There are often multiple microbatches residing in the pipeline

and different nodes can process different microbatches in parallel to improve utilization.

A key challenge in efficient pipeline parallelism is how to schedule microbatches. GPipe [24] schedules forward passes of all microbatches before any backward pass, as shown in Figure 1(b) where each node processes four microbatches. This approach leaves a "bubble" (i.e., white cells) in the middle of the pipeline, leading to inefficient use of compute devices. PipeDream [38] proposes the one-forward-one-backward (1F1B) schedule to interleave the backward and forward passes, as shown in Figure 1(c). 1F1B can reduce the bubble size and the peak memory usage.

However, even with carefully-designed schedules, the pipeline bubble is still hard to eliminate. A fundamental reason is that it is extremely difficult to find the optimal layer partitioning to have each stage processed at the same rate. There exists a body of algorithms proposed recently to optimize layer partitioning and most of them are model- and hardware-specific [38, 16]. These algorithms are often time-consuming for large models, unsuitable for preemptible instances where the number of nodes keeps changing [2].

PipeDream [38] proposes asynchronous pipelining to eliminate the bubble—a node is allowed to work with stale weights to reduce the wait time. However, asynchronous microbatching introduces uncertainty in model convergence. In general, the effectiveness of synchronous v.s. asynchronous training is still open to debate. Furthermore, asynchronous training introduces inconsistencies in model state, which can create a more significant convergence issue when training occurs on preemptible instances, due to the need of frequent reconfigurations. For example, under synchronous microbatching, a reconfiguration can be performed at the end of each optimizer step (i.e., parameter update), and hence the reconfigured pipelines can start with the up-to-date parameters. This is impossible to do under asynchronous microbatching.

As a result, we built Bamboo atop synchronous microbatching where model state is always consistent. Instead of attempting to reduce the bubble, we explore an orthogonal direction—how to leverage the bubble to run RC efficiently.

3 Motivation

This section motivates Bamboo from two aspects: (1) high preemption rates and unpredictability of spot instances, and (2) high performance overheads of strawman approaches.

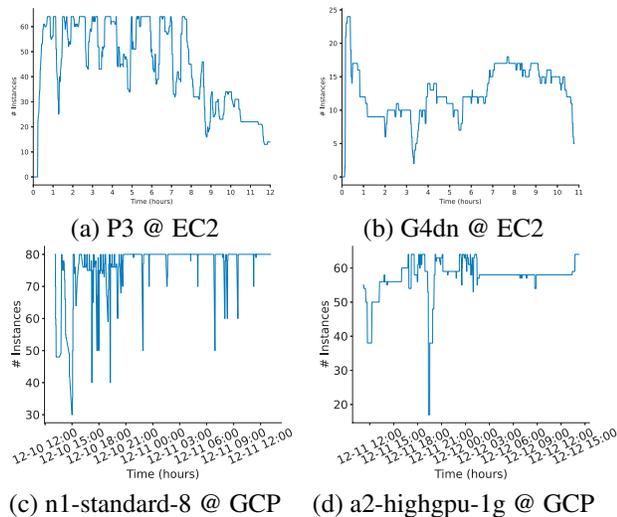

Figure 2: Preemptions traces for a target cluster of size 64 instances on EC2 and 80 instances on GCP. Each graph shows a full-day trace for a GPU family in a cloud.

Preemptions of Spot Instances. We first studied failure models with spot instances on major public clouds. Figure 2 shows a set of real preemption traces collected from running spot instances in two public clouds: Amazon EC2 and Google Cloud Platform (GCP). For EC2, we used two GPU families: P3 (NVIDIA V100 GPUs with 32GB of memory) and G4dn (NVIDIA T4 GPUs with 16GB of memory). For GCP, we used `n1-standard-8` (NVIDIA V100 GPUs with 16GB GRAM) and `a2-highgpu-1g` (NVIDIA A100 GPUs with 40GB GRAM). For each family, we collected traces for a 24-hour window. In each experiment, we used an autoscaling group to maintain a cluster of 64 with an exception of `us-east1-c` in GCP, whose cluster size is 80. The autoscaling group, provided by each cloud, automatically allocates new instances upon preemptions to maintain the size (though without any guarantee).

From both families, node preemptions and additions are frequent and bulky (*i.e.*, many nodes get preempted at each time). This can make a checkpointing-based approach restart many times in a short window of time, leading to large inefficiencies (discussed shortly). Furthermore, both preemptions and allocations are unpredictable. While the autoscaling group attempts to allocate new nodes to maintain the user-specified size, allocations are committed incrementally; new allocations are mixed with preemptions of existing instances, making the spot cluster an extremely dynamic environment.

To understand the nature of the nodes that are preempted at the same time, we carefully analyzed two 24-hour preemption traces collected respectively from EC2 and GCP. For the EC2 trace, preemptions occur at 127 distinct timestamps, each of which see many preempted nodes. Of these 127 timestamps, only 7 see preemptions from multiple zones; at each of the remaining 120 timestamps, all nodes preempted come from

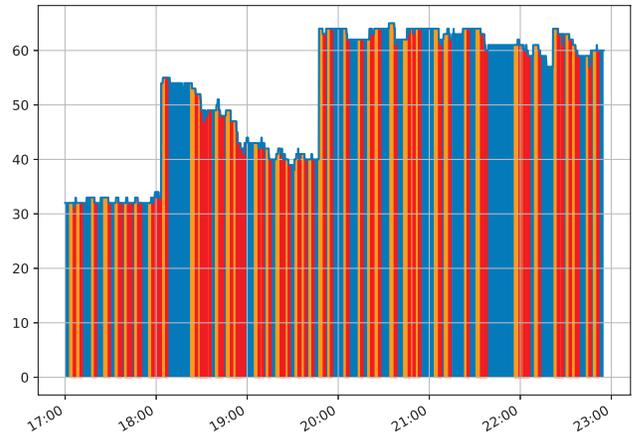

Figure 3: Training GPT-2 using checkpointing/restart with an autoscaling group of 64 P3 spot instances. Each color represents time spent in a distinct state, including Blue: training actively made progress; Orange: the cluster made progress that was then wasted; and Red: cluster restarting.

the same zone. A similar observation was made on the GCP trace (12 out of 328 timestamps see cross-zone preemptions). These results confirmed the observations made by existing works [21, 20]: preemptions tend to be independent based on each individual spot market and each availability zone has a different and independent spot market—this is because each availability zone maintains capacity separately and therefore capacity preemptions in one zone are not associated with capacity preemptions in another.

These observations motivate our design—even with 1-node redundancies, Bamboo can recover from a majority of preemptions if consecutive nodes are not preempted at the same time; we maximize this possibility with a best-effort approach that makes consecutive nodes in each pipeline come from different zones. Although this may increase communication costs, it does not lead to visible performance impacts for Bamboo because Bamboo only sends (small amounts of) activations data between nodes.

Strawman #1: Checkpointing. We next show why a technique based on checkpointing and restarting does not work. We developed a new checkpointing system on top of DeepSpeed [51], providing checkpointing and restarting functionalities similar to TorchElastic [47] and Varuna [2]. We modified DeepSpeed to checkpoint *continuously* and *asynchronously*. In particular, each worker moves a copy of any relevant model state to CPU memory whenever the state is generated; the CPU then asynchronously writes it to remote storage so that training and checkpointing can fully overlap. During restarting, our system automatically adapts the prior checkpoints to the new pipeline configurations.

To understand how well this technique performs, we used it to train GPT-2 over 64 p3.2xlarge GPU spot instances on EC2. We profiled the training process and collected the check-

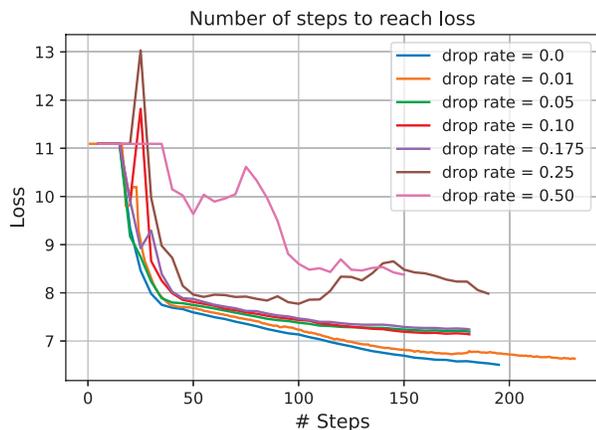

Figure 4: Effects of sample dropping under different rates.

pointing times, reconfiguration overheads, and total execution time. Figure 3 reports these results. The blue sections represent the times the system spent making actual progress for training. The red sections represent the times on reconfiguring (*i.e.*, restarting) while the orange sections show the times for wasted work—the computation that was done but not saved in checkpoints; the system ended up redoing these computations after restarting. This is because preemptions often occur during checkpointing, and hence, the system must roll back to a previous checkpoint. Frequent rollbacks slows down the training significantly. Note that systems such as Varuna and TorchElastic share this property and would have similar training patterns when facing regular preemptions. As shown, although checkpointing itself can be done efficiently, the restarting overheads (*i.e.*, for adapting existing checkpoints to new pipeline configurations) and the wasted computations take 77% of the training time.

Strawman #2: Sample Dropping. An alternative approach that has shown promise is to take advantage of the statistical robustness of DNN training and allow some samples to be dropped so that training can continue without significant loss of accuracy [67, 36]. These techniques are also known as *elastic batching* because dropping samples is equivalent to changing the effective batch size at a training iteration (with the learning rate dynamically adjusted).

In the case of pipeline parallelism, we implemented sample dropping by suspending a pipeline upon losing an instance while letting other data-parallel pipelines continue to run. The system performs optimizer steps with the gradients of whichever data-parallel pipelines are able to complete that training step. Learning rate was adapted linearly with respect to the effective batch size to make sure that the only effect on the accuracy is the lost samples, but *not* a mismatch between hyperparameters and training configurations. In doing so, the training can continue for sometime without a reconfiguration (which is needed upon allocations).

We conducted a set of experiments to simulate the effect of sample dropping on model accuracy with a range of drop rates.

Note that we could not obtain these results with the actual spot instances because we could not control the preemption rate. We ran a pre-training benchmark with GPT-2 using 16 on-demand instances from the same EC2 family, which form four data-parallel pipelines, each with four stages. To consider a range of different failure models, we used different rates of preemption to generate preemption events. Upon a preemption event, we randomly selected a pipeline and zero out the pipeline’s gradients in that iteration. We measured the model’s evaluation accuracy every 5 training steps. These results are shown in Figure 4 where each curve represents the function of the number of steps needed to reach a given loss for a particular drop rate.

Similarly to checkpointing, sample dropping works well for low preemption rates, but when frequent preemptions occur, many samples can be lost quickly and its impact on model accuracy quickly grows to be too significant to overlook. While this experiment was not an exact recreation of a sample dropping scenario, these results represent an *under-approximation* of the effect of the actual sample dropping (which can lose more accuracy than reported by Figure 4). This is because the actual sample dropping rate should be higher than the instance preemption rate—a preempted instance would likely be down for some time and consecutive samples would be dropped in a real setting. Note that training samples are shuffled before loading; hence, the effects of randomly dropping consecutive samples (*i.e.*, the actual scenario) and dropping random samples sporadically (*i.e.*, our experiment) should be similar.

4 Overview

Goal and Non-Goal. Our goal is *not* to automatically determine the cheapest way to train a given model (*e.g.*, which parallelism model can lead to the largest cost savings). Instead, Bamboo aims to enable efficient and preemption-safe training over cheap spot instances.

User Interface. To use Bamboo, a user specifies two system parameters D and P , as they normal would to use other pipeline-parallel systems, where D is the number of data-parallel pipelines and P is the pipeline depth. Due to the need of storing redundant layers, Bamboo requires a larger pipeline depth P than a normal pipeline-parallel system such as PipeDream [38]. We observed, empirically, that to avoid swapping data between CPU and GPU memory on the critical path, Bamboo’s pipeline should be $\sim 1.5\times$ (see §6.4) longer than an on-demand pipeline due to the extra memory needed to (1) hold the redundant layers and (2) accommodate potential pipeline adjustments. Given that spot instances are much cheaper (*e.g.*, 3-4 \times on EC2) than on-demand instances, training with $1.5\times$ more nodes still leads to significantly reduced costs. While we recommend $1.5\times$ more nodes, the number of active instances in a cluster is often much smaller due to preemptions and incremental allocations.

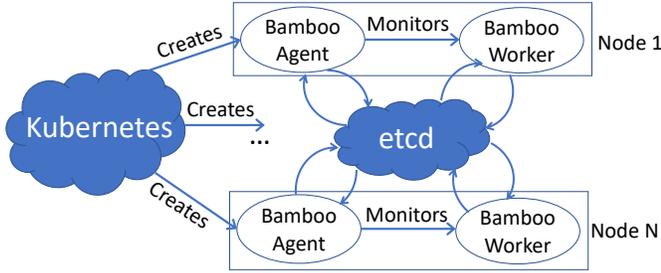

Figure 5: Bamboo runs one agent process per node (*i.e.*, spot instance). An agent monitors worker processes (each running a training script) that use our modified DeepSpeed. All workers and agents coordinate through `etcd` [42].

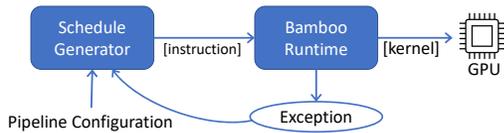

Figure 6: Bamboo worker.

$P \times D$ will be the size of the spot cluster Bamboo attempts to maintain throughout training. Preemptions can cause Bamboo to reduce the pipeline depth and/or the number of pipelines; in such cases, Bamboo would request more instances to bring the size of the cluster back to $P \times D$. However, Bamboo would never try to scale the training beyond $P \times D$. In other words, P and D are the *upper bound* of the pipeline depth and number of pipelines. It is important to note that the goal of the autoscaling framework we build for Bamboo is to adjust the pipelines *passively* in response to node preemptions and additions that we cannot control, rather than *proactively* finding an optimal cluster configuration to achieve better performance. This distinguishes Bamboo from existing works on autoscaling distributed training [43, 2, 25], whose goal was to find better configurations.

System Overview. Figure 5 shows an overview of our system. We built Bamboo on TorchElastic [47] and DeepSpeed [51]. In particular, we built the Bamboo agent, which runs on each node to kill/add a data-parallel pipeline, on top of TorchElastic. The agent monitors a Bamboo worker process on the same node, which is a DeepSpeed application enhanced with our support for redundant computation. Bamboo workers run D data-parallel pipelines that use an `all-reduce` phase to synchronize weights at the end of each iteration. Our spot instances are managed by Kubernetes [33], which is configured to automatically scale by launching a Bamboo agent on each new allocation. Our agents communicate and store cluster state on `etcd` [42], a distributed key-value store.

Each Bamboo worker uses a runtime to interpret the schedule, which produces a sequence of instructions, as shown in Figure 6. The schedule is generated statically based on the stage ID of the current worker and pipeline configurations, including the depth of pipeline and total number of micro-

batches. The instructions consist of a computation component (*i.e.*, forward, backward, and apply gradient), and a communication component (*i.e.*, send/receive activation, send/receive gradient, and all-reduce). The Bamboo runtime interprets these instructions by launching their corresponding kernels on GPU. Communication instructions can fail due to preemptions. Upon a failure, the runtime throws an exception and falls back to use a failover schedule.

5 Redundant Computation

For ease of presentation, our discussion focuses on one node running one stage in the pipeline. Support for multi-GPU nodes will be discussed shortly.

Preemption of a node is detected by its neighboring nodes in the same pipeline during the execution of communication instructions. If a node on one side of the communication is preempted, the node on another side will catch an IO exception due to broken socket and update cluster state on `etcd`. Bamboo detects preemptions based on socket timeout. Although we could let a node to be preempted actively notify its neighbors in the grace period before the preemption, the length of this period varies across different clouds and hence Bamboo does not use it currently.

Since the victim node communicates with two nodes in the pipeline, both of its neighbors can catch the exception. The observed exception will be shared between these two nodes through `etcd`. This two-side detection is necessary for Bamboo to understand which node fails and generate the failover schedule. In addition to the two neighbors, nodes in other pipelines involved in the `all-reduce` operation also need to be informed. To safely perform `all-reduce`, each node participating in `all-reduce` reads the up-to-date cluster state on `etcd` and, if another pipeline has a failure, waits until the failure is handled.

5.1 Redundant Layers and Computation

To quickly recover from preemptions, Bamboo replicates the model partition on each worker node in each data-parallel pipeline. Instead of saving these replicas to a centralized remote storage (like checkpointing), Bamboo takes a *decentralized* approach by letting each node replicate its own model partition (*i.e.*, layer shard) on its predecessor node in the same pipeline. The first node has its layer replica stored on the last node in the pipeline. Conceptually, the last node is considered the “predecessor” of the first node. For simplicity of presentation, we use *forward stage IDs* to identify nodes, that is, a node that runs the forward stage $n + 1$ is always considered as a successor of a node running the forward stage n (although in the backward pass, $n + 1$ is a stage before n).

Our key idea is to let each node run normal (forward and backward) computation over its own layers and redundant (forward and backward) computation over the replica layers for its successor node. Let FRC_n^m/BRC_n^m denote the forward/backward redundant computation that is per-

formed on node m for node n , respectively. In Bamboo, $n = (m + 1) \bmod P$ where P is the pipeline depth. Let $\text{FNC}_n/\text{BNC}_n$ denote the forward/backward normal computation on node n . In Bamboo’s pipeline, $\text{FRC}_{n+1}^n/\text{BRC}_{n+1}^n$ is exactly the same computation as $\text{FNC}_{n+1}/\text{BNC}_{n+1}$, working with the same model parameters and optimizer states. To enable the last node to perform RC for the first node, we let it fetch input samples directly.

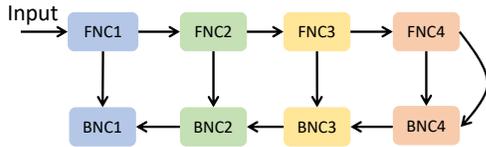

Figure 7: Dependencies between normal pipeline stages.

Why Neighboring Nodes? Due to our focus on pipeline parallelism, Bamboo performs RC on predecessor nodes to exploit *locality* for increased efficiency. To see this, we first need to understand the dependencies between different (backward and forward) pipeline stages that a microbatch goes through, as illustrated in Figure 7. For each forward stage FNC_n , it depends only on the output of its previous stage FNC_{n-1} . However, for each backward stage BNC_n , it has two dependencies: one on the output of stage BNC_{n+1} and a second on its corresponding forward stage FNC_n . The first is a *hard* dependency without which BNC_n cannot be done, while the second is a *soft* dependency primarily for efficiency—intermediate results produced by FNC_n can be reused to accelerate BNC_n . Without such cached results, BNC_n has to recompute many tensors (*i.e.*, tensor rematerialization [8]), leading to inefficiencies.

Figure 8 shows dependencies on an RC-enable pipeline where each node performs both normal and redundant (backward and forward) computation. Here solid/dashed arrows represent inter/intra-node dependencies. By running FRC for node $n + 1$ on node n , *locality benefit* can be clearly seen because FRC only creates intra-node dependencies, which do not incur any extra communication overhead. However, in a backward pass, such a locality benefit does not exist for BRC_{n+1}^n , which requires the output of BNC_{n+2} and incurs much extra communication. This motivates our eager-FRC-lazy-BRC design which does not perform BRC until a preemption occurs and hence eliminates the extra communication cost in normal executions.

Note that we could also perform FRC lazily, but this would significantly increase the pause time for recovery. This is because (1) recovering from preemptions at both forward and backward pass now require a pause; and (2) lazy FRC would not produce intermediate results that can be used to speed up BRC and hence BRC’s pause would be much longer. Since FRC can be scheduled in the pipeline bubble and overlap with FNC, performing it eagerly is a better choice.

The careful reader may think of an alternative approach that places node n ’s layer replica on node $n + 1$ as opposed to

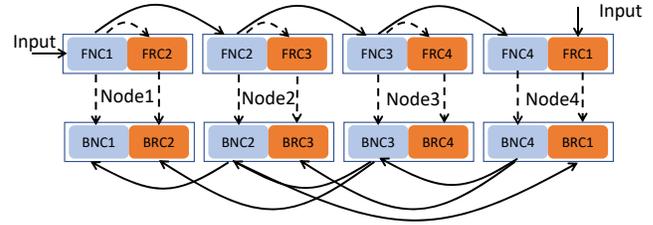

Figure 8: Dependencies between RC-enabled pipeline stages: solid/dashed arrows represent inter/intra-node dependencies; for simplicity, $\text{FRC}_n/\text{BRC}_n$ in the figure represents $\text{FRC}_{n-1}^n/\text{BRC}_{n-1}^n$.

node $n - 1$ (*i.e.*, its successor rather than its predecessor). This approach is symmetric to our design in that it turns inter-node dependencies for BRC into intra-node dependencies, but intra-node dependencies for FRC into inter-node dependencies. As a result, it eliminates the extra backward communication at the cost of increased forward communication. However, unlike Bamboo’s design that can use lazy BRC to eliminate the extra backward communication, it is not as easy to eliminate the extra forward communication with lazy FRC—if FRC is not done eagerly in each iteration, BRC (regardless of whether it is eager or lazy) must perform tensor re-materialization, which incurs a long delay.

Level of Redundancy. As with any redundancy-based systems, the more redundancies, the higher level of resilience. For example, since Bamboo performs redundant computations only for one node, it cannot provide resilience when preemptions occur on consecutive nodes in a pipeline, in which case a reconfiguration is needed (see §A). However, enabling RC for multiple nodes can significantly increase the FRC time, making it much longer than what the bubbles can accommodate. Furthermore, the locality benefit (*i.e.*, FRC only incurs intra-node dependency) does not hold anymore, because FRC now depends on the outputs of multiple nodes. This can slow down the training substantially.

Takeaway. Storing each node’s replica layers on its predecessor and running eager-FRC-lazy-BRC achieves low-overhead RC for pipeline parallelism. While this design does not support consecutive preemptions, Bamboo takes care to make consecutive nodes come from different zones. As discussed in §3, if multiple preemptions occur at the same time, the preempted nodes are highly likely to be from the same zone. As a result, our node assignment reduces the chance of consecutive preemptions, making RC effective for most preemptions. Although cross-zone data transfer can incur an overhead, this overhead is negligible (*e.g.*, $<3\%$), as reported in Appendix §6.5, because in pipeline-parallel training, each node only passes a small amount of activation data to its neighbors.

We refer to the preempted node as the *victim node*, and the node saving the replica of the victim as its *shadow node*.

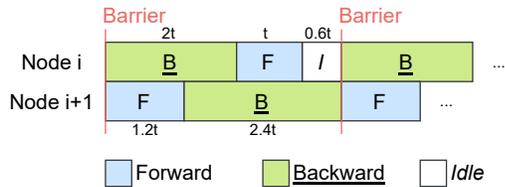

Figure 9: A closer examination of the pipeline bubble. Here we assume the forward pass on node i and $i + 1$ takes time t and $1.2t$, respectively. Hence, a bubble of $0.6t$ exists before each communication barrier.

5.2 Schedule Redundant Computation

It is straightforward to see that RC incurs an overhead in both time and memory. We propose to (1) schedule FRC into the pipeline bubble to reduce forward computation overhead, (2) perform BRC lazily to reduce backward computation/communication overhead, and (3) offload unnecessary tensors to CPU memory to reduce memory overhead.

Eager FRC. As discussed in §2, the pipeline bubble can come from either imperfect scheduling or unbalanced pipeline partitioning. To illustrate, consider Figure 9 with PipeDream’s 1F1B schedule. Suppose there are two consecutive nodes in the pipeline where both the forward and the backward computation of node $i + 1$ run $1.2\times$ slower than those of node i . The communication between these two nodes serves as a barrier. Since node i runs faster, it always reaches the barrier earlier and waits there until node $i + 1$ arrives. This wait period is where we should schedule FRC.

Bamboo builds on the 1F1B schedule (Figure 1(a)) due to its additional efficiency compared to GPipe’s schedule (Figure 1(b)). However, even for 1F1B, bubbles widely exist in a pipeline—as a microbatch passes different pipeline stages, the later a stage, the longer the (backward and forward) computation takes. This is because for the 1F1B schedule, the number of active microbatches in a later stage is always smaller than that in an earlier stage. In Figure 1(c), for example, node 1 has 3 active microbatches while node 2 only has 2. Consequently, later stages often consume less memory. To balance memory usage, the layer partition on a later node is often larger than that on an earlier node in the pipeline, and hence a later stage runs slower. A detailed analysis of bubble size can be found in Appendix §C.1.

Scheduling. Based on this observation, we schedule FRC on a node before the node starts communicating with its successor node. This is where a bubble exists. In cases where the FRC cannot fit entirely into the bubble (*i.e.*, for the last four stages in Figure 14), we overlap FRC and FNC as much as we can. However, for the same microbatch, FRC_{n+1}^n depends on FNC_n and they cannot run in parallel. To resolve this dependency issue, we focus on different microbatches for FNC and FRC. That is, Bamboo schedules FNC_n for the k -th microbatch and FRC_{n+1}^n for its previous ($k - 1$)-th

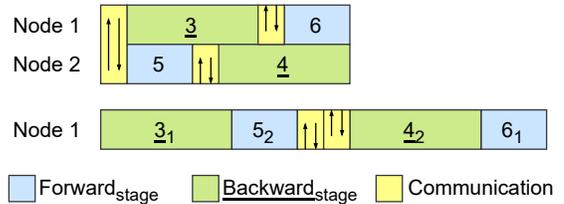

Figure 10: An example of merged instruction sequences in a failover schedule. We use PipeDream’s 1F1B schedule as shown Figure 1(c), and assume node 2 is the victim node and node 1 is the shadow node.

microbatch to run in parallel. Since there is no dependency between them, their executions can overlap.

To reduce memory overhead, Bamboo follows a well-known principle to offload less frequently used tensors to CPU memory. Specially, since BRC is *not* performed in normal training passes, FRC’s outputs and intermediate results are not needed until a preemption occurs and BRC is triggered. As a result, we swap out these data after FRC is done for each microbatch on each node. These data take the majority of FRC’s memory consumption; swapping them out significantly reduces FRC’s GPU memory usage [52]. However, we leave the redundant weights in GPU memory for efficient FRC because these weights are needed for FRC on each microbatch.

Lazy BRC and Recovery. BRC is executed by a *failover schedule* which a node runs when detecting its successor node fails. In particular, for the current iteration, all the lost gradients must be re-computed, while for the following iterations, all instructions of the victim node must be executed by its shadow node (until a reconfiguration occurs). Nodes that originally communicate with the victim node are transparently rerouted to the shadow node. The failover schedule is generated by merging the schedules of the victim and shadow node. In particular, a schedule consists of a sequence of instructions and we divide it into two groups—(1) continuous communication instructions, which is placed at the head of a group and (2) computation instructions that can be executed without remote data dependencies.

When the two instruction groups (from the victim and shadow nodes) are merged, the instructions are interleaved with the following rules. (1) Communication instructions are still placed in the beginning of the merged groups. (2) Communications that used to be inter-node between the victim and the shadow are removed. (3) External communications from the victim node are first performed. (4) Computation instructions are ordered such that backward computation is always executed earlier; after the backward computation is done, the memory occupied by intermediate results is freed. Figure 10 shows an example of merged instruction sequences if node 2 is the victim node and node 1 is the shadow node.

Model	Dataset	Samples	D	P
ResNet-152 [22]	ImageNet [32]	300,000	4	12
VGG-19 [63]	ImageNet [32]	1,000,000	4	6
AlexNet [32]	ImageNet [32]	1,000,000	4	6
GNMT-16 [68]	WMT16 EN-De	200,000	4	6
BERT-Large [15]	Wikicorpus En [15]	2,500,000	4	12
GPT-2 [49]	Wikicorpus En [15]	500,000	4	12

Table 1: Our models, datasets, pipeline configurations.

Support for Multi-GPU Nodes. Bamboo’s RC works for multi-GPU settings—this requires replicating all layers that belong to the GPUs of one node in the GPUs of its predecessor node. In other words, we use “group replicas” as opposed to individual replicas. However, in the presence of frequent preemptions, using multi-GPU would yield poorer performance—losing one node (with multiple GPUs) is equivalent to losing multiple nodes in the single-GPU setting. Our evaluation (§6) shows that it is much harder to allocate new multi-GPU nodes during training than single-GPU nodes.

Once Bamboo loses too many nodes or there are many idle nodes (*i.e.*, new allocations) waiting to join the pipelines, Bamboo launches a reconfiguration. Details of the reconfiguration process can be found in §A.

Support for Pure Data Parallelism. Bamboo supports pure data parallelism (without model partitioning). Due to space constraints, here we briefly discuss how it is supported. We use the same redundant computation strategy—Bamboo replicates the parameter and optimizer state of each node on a different node and uses these replicas as redundancies to provide quick recovery. For pure data parallelism, there is no bubble time to schedule RC. Eager FRC would be equivalent to overbatching (*i.e.*, each node processes its original minibatch plus a redundant minibatch). To reduce the FRC overhead and make RC fit into the GPU memory constraints, we over-provision spot instances (by $1.5\times$, in the same way as discussed in §5) to make each node process a smaller batch.

Enabling eager FRC doubles the batch size. However, it results only in a $\sim 1.5\times$ increase in the computation time due to the parallelism provided by GPUs. This overhead can be effectively reduced by slightly over-provisioning ($1.5 \times D$) nodes, increasing the degree of parallelism and decreasing the impact of overbatching. This enables us to run FRC eagerly without incurring much overhead (*i.e.*, $<10\%$).

Once Bamboo loses too many nodes or there are many idle nodes (*i.e.*, new allocations) waiting to join the pipelines, Bamboo launches a reconfiguration. Details of the reconfiguration process can be found in Appendix §A.

6 Evaluation

Bamboo is implemented in $\sim 7K$ LoC as a standard Python library. We evaluated Bamboo by pretraining a range of popular vision and language models, as shown in Table 1. For the first four (smaller) models that were also used in PipeDream [38] (which actually used smaller versions of these models), we

took the values of D (the number of data-parallel pipelines) and P_{demand} (pipeline depth) from PipeDream [38]’s configurations.

As discussed earlier in §4, to avoid swapping Bamboo needs $1.5\times$ more instances for each pipeline and hence each P reported in Table 1 equals $1.5\times P_{demand}$. For BERT and GPT2, we used 4 and $8\times 1.5=12$ as D and P . We have also evaluated with another pipeline depth $P_h = P_{demand} \times \frac{Price_{demand}}{Price_{spot}}$; these results can be found in §6.2.

We trained these models on a spot cluster from EC2’s p3 family where each instance has V100 GPU(s) with 16GB GPU memory and 61GB CPU memory. Each on-demand instance costs \$3.06/hr per GPU while the price of its spot counter-part (at the time of our experiments) is \$0.918/hr. Our evaluation uses two on-demand baselines: (1) p3 instances each with four V100 GPUs (Demand-M) and (2) p3 instances each with a single GPU (Demand-S). For both baselines, the pipeline configuration was the same and all nodes were obtained from one availability zone.

For all experiments, we trained each model to a target validation accuracy, which is a particular number of samples for the model. We did not train them to higher accuracies because large models take a huge amount of time to train (*e.g.*, weeks) to reasonable accuracies; using such a large amount of resources (even spot instances) goes beyond our financial capabilities. Furthermore, Bamboo uses synchronous training where the time per iteration is fixed; hence, training for extended time would not change our results.

For on-demand instances, we used the largest per-GPU minibatch that fits in one GPU’s memory—anything larger yields out-of-memory exceptions. This ensures that we hit peak achievable FLOPs on a single device. For data-parallel runs with n workers, the global minibatch size is $n \times g$ where g is the minibatch size. The global minibatch sizes we used are consistent with those used by the ML community and reported in the literature for these models. We used a per-GPU minibatch size of 256 per GPU for VGG-19, 512 for AlexNet, 2048 for ResNet-152, 32 for GNMT-16, 256 for BERT-Large, and 256 for GPT-2. For microbatch size, we always selected a small value and tuned it for different models/configurations. We trained the vision models with an initial learning rate of 0.001, respectively, with a vanilla SGD optimizer [29]. For language models, we used the Adam optimizer [30] with an initial learning rate of $6e^{-3}$. We used half (fp16) precision in all our experiments.

6.1 Training Performance and Costs

Overall Performance. To thoroughly and deterministically evaluate Bamboo’s performance over spot instances under different preemption rates, we first ran a 48-node cluster (*i.e.*, the configuration for ResNet, BERT, and GPT) and a 32-node cluster (*i.e.*, for VGG, AlexNet, and GNMT) on AWS and collected a 24-hour preemption trace for each. On these traces, the *hourly preemption rate* varies significantly, ranging from

Model	System	Time (Hours)	Throughput	Cost (\$/hr)	Value
ResNet	D-M	2.78	30.00	97.92	0.31
	D-S	2.60	32.00	97.92	0.33
	B-M	[4.31, 5.31, 10.14]	[19.35, 15.69, 8.22]	[44.33, 40.01, 37.21]	[0.43, 0.39, 0.22]
	B-S	[3.85, 4.29, 6.87]	[21.67, 19.41, 12.13]	[42.23, 40.39, 36.72]	[0.51, 0.48, 0.33]
VGG	D-M	1.41	197.00	48.96	4.02
	D-S	1.66	167.00	48.96	3.41
	B-M	[2.98, 3.67, 4.33]	[93.34, 75.75, 64.22]	[21.31, 19.55, 18.43]	[4.38, 4.11, 3.48]
	B-S	[1.81, 2.22, 2.83]	[153.31, 124.88, 98.21]	[20.19, 19.28, 18.36]	[7.59, 6.48, 5.35]
AlexNet	D-M	0.77	359.00	48.96	7.33
	D-S	0.78	336.00	48.96	6.86
	B-M	[1.02, 1.34, 1.93]	[271.06, 207.43, 143.57]	[21.31, 19.55, 18.43]	[12.72, 10.61, 7.79]
	B-S	[0.82, 0.86, 0.99]	[340.32, 321.65, 280.42]	[20.19, 19.28, 18.36]	[16.86, 16.68, 15.27]
GNMT	D-M	2.06	27.00	48.96	0.55
	D-S	2.31	24.00	48.96	0.49
	B-M	[3.98, 5.13, 8.78]	[13.95, 10.82, 6.33]	[21.31, 19.55, 18.43]	[0.65, 0.55, 0.34]
	B-S	[2.94, 3.41, 6.31]	[18.92, 16.31, 8.8]	[20.19, 19.28, 18.36]	[0.94, 0.85, 0.48]
BERT	D-M	5.89	118.00	97.92	1.21
	D-S	6.43	108.00	97.92	1.10
	B-M	[9.75, 12.31, 16.66]	[71.22, 56.41, 41.68]	[44.33, 40.01, 37.21]	[1.61, 1.41, 1.12]
	B-S	[7.02, 8.3, 11.46]	[98.87, 83.70, 60.59]	[42.23, 40.39, 36.72]	[2.34, 2.07, 1.65]
GPT	D-M	4.34	32.00	97.92	0.32
	D-S	4.63	30.00	97.92	0.30
	B-M	[7.83, 9.92, 12.04]	[17.73, 14.00, 11.54]	[44.33, 40.01, 37.21]	[0.40, 0.35, 0.31]
	B-S	[4.64, 6.12, 10.08]	[29.92, 22.68, 13.78]	[42.23, 40.39, 36.72]	[0.71, 0.56, 0.38]

Table 2: Comparisons between training with DeepSpeed over on-demand instances and Bamboo over spot instances. For Bamboo, we trained each model three times, and their results are explicitly listed in the form of $[a, b, c]$ for the 10% (average), 16%, and 33% preemption rates, respectively.

no preemption all the way to 16 nodes preempted (33%), with an average rate of 4-6 nodes per hour (8-12%). To account for such changes, we extracted from each trace three segments, each with a different hourly preemption rate: 10%, 16%, and 33%. We used AWS’ fleet manager to trigger preemptions by replaying these segments. Note that if we were to run Bamboo over the uncontrolled spot cluster, there would be no way to enable a direct comparison.

We trained ResNet, BERT, and GPT by replaying the three segments from the 48-node trace, and VGG, AlexNet, and GNMT by using the segments from the 32-node trace. These results are reported in Table 2. In addition to the time and monetary costs, we used a metric called *value*, which measures performance-per-dollar. Value is computed as $V = \frac{T}{C}$ where T is the training throughput, measured in terms of the number of samples per second, and C is the monetary cost per hour. Throughout the evaluation, we used both value and throughput as our metrics.

Our first observation is Demand-M slightly outperforms Demand-S due to reduced cross-node communication. However, the difference is marginal as the amount of data (*i.e.*, only activations) transferred over the network is small. Bamboo-S significantly outperforms Bamboo-M (*i.e.*, $1.4\times$ higher throughput and $1.5\times$ higher value) because (1) multi-GPU nodes are subject to more GPU failures with the same number of preemptions and (2) it is much harder to allocate new nodes in a timely fashion.

For Bamboo-S, the results in each bracket of the form $[a, b, c]$ show Bamboo’s performance under the three preemption rates. The higher the preemption rate, the worse Bamboo’s throughput and value. Given that the average preemption rate is $\sim 10\%$, the first number in each bracket (highlighted) represents Bamboo’s performance on the used spot cluster.

On average, Bamboo’s throughput (under the 10% preemption rate) is 15% lower than DeepSpeed running over $D \times P_{demand}$ instances. There are three major reasons.

First, the number of active instances in the spot cluster is actually lower than the requested size $D \times P$. For ResNet, for example, the average number of instances throughout the training is only 25.58 although the requested cluster size is 48 (and the on-demand cluster always has 32 nodes). The autoscaling group keeps attempting to add new instances but the total number of active instances only reaches the requested size for a small period of time.

Second, Bamboo’s reconfiguration contributes to reduced throughput—these overheads vary with environments and take an average of 7% of the total training time.

Third, the time for each iteration increases due to eager FRC. This is the major source of overhead for language models such as GPT-2. A detailed evaluation of RC’s overhead can be found in §6.4.

Despite the small throughput reduction, Bamboo delivers an overall of $1.95\times$ higher value compared to training with on-demand instances. The benefit in value remains clear for five models (ResNet, VGG, AlexNet, BERT and GPT) even when the preemption rate increases to 33% (*i.e.*, the worst-case segment of the collected trace).

To have a closer examination of Bamboo-S’ training, we showed the traces for BERT-large and VGG-19, and plotted them in Figure 11. The two rows show (a) preemption traces (under the 10% rate), (b) training throughputs, (c) monetary costs, and (d) values, for BERT-large and VGG-19, respectively. Since Bamboo-M underperforms Bamboo-S, we focus on Bamboo-S in the rest of the evaluation.

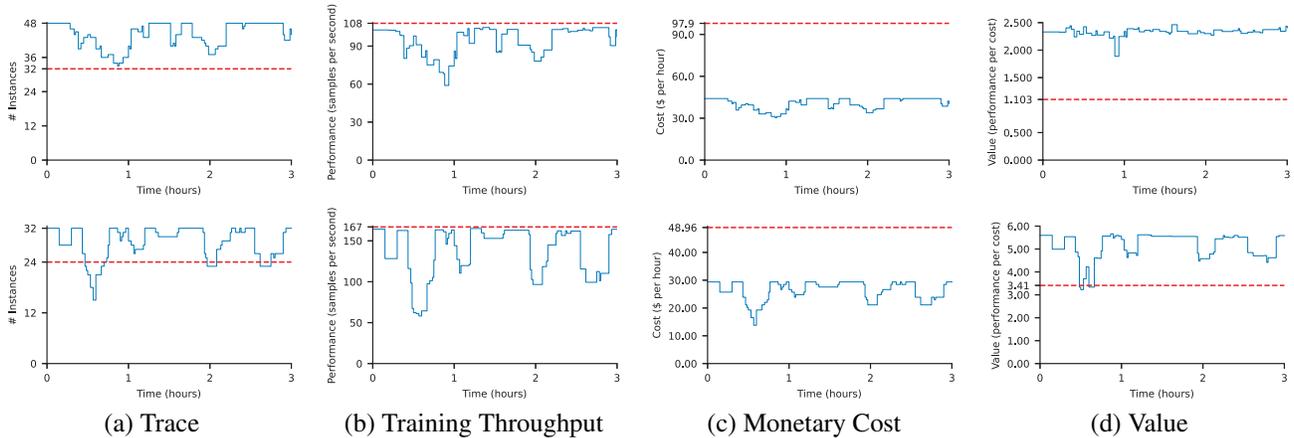

Figure 11: Bamboo’s training performance for BERT (top) and VGG (bottom), compared to on-demand instances (red lines).

Prob.	Prmt (#)	Inter. (hr)	Life (hr)	Fatal Fail. (#)	Nodes (#)	Thruput	Cost (\$/hr)	Value

(a) Results of simulating training BERT *until completion*; each preemption probability ran 1,000 times.

(b) Simulation results of training BERT-large with pipeline depth P_h (which is $3.3 \times P_{demand}$).

Table 3: Simulation results for more configurations.

6.2 Different Failure Models

This section demonstrates Bamboo’s ability to affordably train large DNNs across a wide range of failure models. To this end, we developed an offline simulation framework that takes as input (1) the preemption probability (including preemption frequency and the number of preemptions in each bulk), (2) per-iteration training time, and (3) Bamboo’s recovery and reconfiguration time, automatically calculating training performance, costs, and values. Here we focus on BERT-large and simulated its training until completion.

We experimented using 5 different preemption probabilities (*i.e.*, preemption rate per hour), and kept the preemption probability constant throughout the entire run (as opposed to replaying traces). To mimic realistic spot instance creation and preemption, we randomly generated different creation probabilities per hour and also randomly picked zones for allocations. For each preemption probability, Table 3a reports the average numbers of preemptions, intervals (*i.e.*, average time, in hours, between preemption events), average lifetime of an instance (in hours), average numbers of fatal failures (which require a restart from a checkpoint), average numbers of instances in the cluster, throughput (*i.e.*, #samples per second), costs, and values, across 1,000 simulations.

Our simulations show that Bamboo’s values match our real-world runs as just reported in §6.1. Further, regardless of the preemption probability, the value of Bamboo remains stable and is constantly higher than that of training with on-demand instances (which is 1.1). This is because most preemptions can be quickly recovered without introducing much overhead.

The higher the preemption probability, the less the active instances running training jobs; this is the major source of the performance slowdown. However, the cost is reduced also proportionally, leading to stable values.

Simulation for P_h . To understand the tradeoff in choosing P , we experimented with another value of P for BERT-large: P_h , which is $\frac{3.06}{0.918} \times P_{demand}$. This configuration represents the *upper-bound* of the spot training resources that can be obtained within the cost of training with P_{demand} on-demand instances (while D remains unchanged). Note that in practice the number of active instances can barely reach the requested size and hence the cost of using a spot cluster of size $P_h \times D$ is often still much lower than training with an on-demand cluster of size $P_{demand} \times D$.

To avoid incurring a large monetary cost, we used the same simulator to run this experiment. These results are reported in Table 3b. As shown, using P_h actually decreases both throughput (compared to 84 under P in Table 2) and value (due to significantly increased costs). This is because using too a large pipeline leads to poorer partitioning, underutilized resources and inferior performance.

6.3 Comparisons with Other Systems

We have reported the performance of training GPT-2 with asynchronous checkpointing and restart in Figure 3—the checkpointing-based approach spent only 23% on actual training, while Bamboo increases this percentage to **84%**. In fact, as shown in Table 3a, even for the preemption rate of 0.5, there are only 5.98 fatal failures that would require checkpoint-

ing/restart under Bamboo. On the contrary, a checkpointing-based approach would need to restart the pipeline for every one of the 709.83 preemptions. Similarly, sample dropping significantly slows down the training when the preemption rate increases, as shown in Figure 4.

Varuna. Varuna [2] is a system developed concurrently with Bamboo to enable training on spot instances. As with other existing techniques, Varuna provides resilience with checkpointing. We set up Varuna on the same spot cluster on AWS EC2 as we used in § 6.1. We ran Varuna with a $D \times P$ pipeline (*i.e.*, the same as on-demand instances) because Varuna does not use redundancies and hence not need to over-provision resources.

We trained BERT on Varuna with the same configurations, including the same datasets, model architectures, float precision, preemption rates, and hyperparameters. Varuna hung under the 33% preemption rate. For the 10% and 16% preemption rates, comparisons between Varuna and Bamboo-S are reported in Figure 12. As shown, Bamboo-S outperforms Varuna by $2.5\times$ and $2.7\times$ in throughput, respectively, under the 10% and 16% rates; and by $1.67\times$ and $1.64\times$, in value, under the two rates. Note that value benefits are lower than throughput benefits due to Varuna’s use of fewer instances. To understand the cause of Varuna’s slowdown, see §3. Varuna follows a similar pattern, having to frequently restart and redo lost computations.

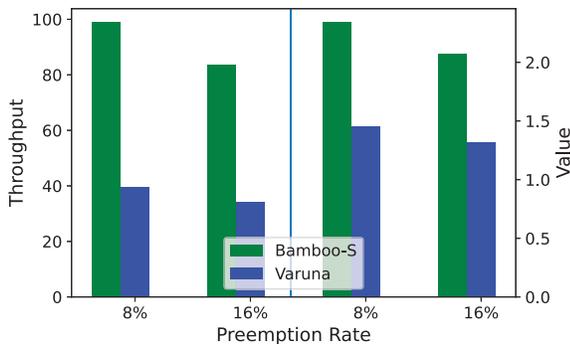

Figure 12: Throughput and value for Bamboo-S and Varuna running BERT at different preemption levels. Varuna hung at the 33% preemption rate.

6.4 Microbenchmarks of Redundant Computation

To fully understand the overhead introduced by RC, we compared time and memory among three versions of RC: eager-FRC-lazy-BRC (EFLB, Bamboo’s approach), eager-FRC-eager-BRC (EFEB), and lazy-FRC-lazy-BRC (LFLB), when training BERT and ResNet. Since the focus here is the RC overhead, we ran this experiment over on-demand instances.

Table 4 reports RC’s time overheads for the three RC settings. As expected, LFLB incurs the lowest per-iteration overhead because neither FRC nor BRC is performed with normal training iterations. The $\sim 7\%$ overhead comes primarily from the extra code executed to prepare for a failover

Redundancy Mode	BERT	ResNet
Lazy-FRC-Lazy-BRC	7.01%	7.65%
Eager-FRC-Lazy-BRC (Bamboo)	19.77%	9.51%
Eager-FRC-Eager-BRC	71.51%	64.24%

Table 4: Time overhead with different RC settings.

schedule. However, the recovery time is much longer under LFLB than the other two settings (discussed shortly). On the contrary, EFEB has the highest per-iteration overhead due to the eager execution of both FRC and BRC. The overhead incurred by EFLB, as used in Bamboo, is slightly higher than LFLB but much lower than EFEB. This is because eager FRC does not incur extra communication overhead and much its computation overhead can be hidden by scheduling it into the pipeline bubble and overlapping it with FNC.

Another interesting observation is the overhead for ResNet is lower than for BERT. This is because ResNet’s layer partitioning is much more imbalanced than that of BERT (which is a transformer model where most the middle layers are equivalent). As a result, the bubble in ResNet’s pipeline is much larger and hence it can accommodate a more significant fraction of FRC.

Eager FRC incurs an overall $\sim 1.5\times$ overhead in GPU memory (that is why Bamboo recommends creating pipelines with $1.5\times$ more nodes) while lazy FRC does not incur any memory overhead.

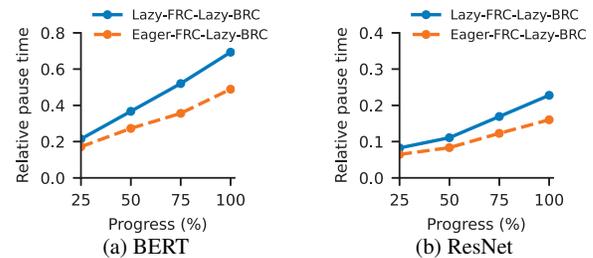

Figure 13: Relative pause time for BERT and ResNet under different RC settings. Bamboo runs into a pause when a pipeline stops training and waits for the shadow node to recover the lost state on the victim node.

To understand the pause time under these different RC settings, Figure 13 shows the relative pause time (*i.e.*, the actual pause time relative to the time of each training iteration without preemptions). As shown, lazy FRC reduces pause time by $\sim 35\%$ despite the slightly higher per-iteration overhead it introduces. In summary, eager-FRC-lazy-BRC strikes the right balance between overhead and pause time.

Model	Config	Throughput	Total Transferred Bytes
BERT	Spread	148.923	16.39 GiB
BERT	Cluster	151.124	16.39 GiB
VGG19	Spread	160.12	11.213 GiB
VGG19	Cluster	165.77	11.213 GiB

Table 5: Comparison of throughput when running across availability zones compared to running within a single zone.

6.5 Cross-Zone Communication

Because Bamboo allocates workers across availability zones to minimize the probability of reconfigurations, we measured the overhead incurred by cross-zone communication. We ran Bamboo in two configurations: (1) with nodes distributed across all zones (*i.e.*, Spread) and (2) in a single availability zone with AWS’ “Placement Group” option set to “Cluster” (*i.e.*, Cluster), and measured their performance differences. As reported in Table 5, the differences between these two configurations are quite low (*i.e.*, usually less than 5%). This demonstrates Bamboo’s choice of assigning nodes from different availability zones as consecutive nodes in each pipeline has little impact on training performance.

7 Related Work

Parallel Training. Data parallelism [28, 14, 32, 7, 12, 72, 35, 72] is the most common parallelism model that partitions the dataset and trains on each partition. The learned weights are synchronized via either an all-reduce approach [7] or parameter servers [35, 10]. Model parallelism [14, 31, 43, 60, 62] partitions the operators in a DNN model across multiple GPU devices, with each worker evaluating and performing updates for only a subset of the model’s parameters for all inputs. Recently, pipeline parallelism [24, 38, 71, 65] has been proposed to train large models by partitioning layers across workers and uses microbatches to saturate the pipeline. Popular DL training libraries such as DeepSpeed [51] and Megatron [40] support 3D parallelism, which combines data parallelism, model parallelism, and pipeline parallelism to train models at extremely large scale with improved compute and memory efficiency. Furthermore, DeepSpeed offers ZeRO-style data parallelism [52], which partitions model states across GPUs and uses communication collectives to gather individual parameters when needed.

Elastic Training. Distributed training experiences frequent resource changes. There are a number of systems [43, 21, 47, 23, 48, 25] built to provide elasticity for training over changing resources. TorchElastic [47] is a PyTorch [44]-based tool that can dynamically kill or add data-parallel workers. Huang *et al.* [23] considers elasticity for declarative ML on MapReduce, which does not work for modern deep learning workloads. Litz [48] is a system that provides elasticity in the context of CPU-based machine learning using the parameter servers. Or *et al.* [43] presents an autoscaling system built on top of TensorFlow [1] and Horovod [55], which dynamically adapts the batch size and reuses existing processes.

Exploiting Spot Instances. Proteus [21] exploits dynamic pricing on public clouds in order to lower costs for machine learning workloads through elasticity. Since Proteus does not explicitly consider modern deep learning workloads, Proteus simply reprocesses the input of a preempted node with another node. Varuna [2] is a system built concurrently with Bamboo for distributed training over spot instances. However, Varuna

focuses on elasticity, not quick recovery from preemptions. Bamboo, on the contrary, is designed specifically to deal with frequent preemptions.

There exists a body of work on enabling low latency and/or SLO guarantees when using preemptible spot instances. Tributary [20] is an elastic control system that exploits preemptible resources to reduce cost with SLO guarantees. Kingfisher [59] proposes a cost-aware resource acquisition scheme that uses integer linear programming to determine a service’s resource footprint among a heterogeneous set of non-preemptible instances with fixed prices. Flint [56] is a system that runs batch-based data-intensive jobs on transient servers. SpotCheck [58] selects spot markets to acquire instances in while always bidding at a configurable multiple of the spot instance’s corresponding on-demand price. BOSS [70] hosts key-value stores on spot instances by exploiting price differences across pools in different data-centers. ExoSphere [57] is a virtual cluster framework for spot instances. These systems are all orthogonal to Bamboo that is built specifically for deep learning training.

GPU Scheduling. There is also a large body of work on GPU scheduling [61, 69, 74, 46, 37, 19, 39, 40, 34, 73] for ML workloads. These techniques are orthogonal to Bamboo—they all focus on efficiency and throughput while Bamboo aims to perform redundant computation at a low cost.

8 Conclusion

Bamboo is the first distributed system that uses redundant computation to provide resilience and fast recovery for training DNNs over preemptible instances. An evaluation with 6 representative models shows that Bamboo provides a much higher value than (1) training on on-demand instances and (2) training with checkpointing/restart on spot instances.

A Pipeline Reconfiguration

Reconfiguration introduces a much longer pause to the training process than recovering using RC. The goal of reconfiguration is to rebalance pipelines so they can withstand more failures as training progresses and continue to yield good performance. Reconfiguration also attempts to allocate more instances to maintain the cluster size. As shown in §3, asynchronous checkpointing is very efficient (but frequent restarting is not), and hence, Bamboo periodically checkpoints the model state. These checkpoints will not be used unless Bamboo restarts the training from a rare fatal failure (*i.e.*, too many nodes are preempted so that training cannot continue).

Reconfiguration Triggering. Reconfiguration is triggered immediately when (1) consecutive preemptions occur simultaneously and (2) Bamboo determines that there is an urgent need to rebalance the pipelines at the end of an optimizer step. To do (2), the workers retrieve the cluster state from `etcd`, allowing them to see how many preemptions have occurred and in which pipeline they have occurred. They can also see how many workers are currently waiting to join the next rendezvous.

There are two main conditions for triggering reconfiguration at the end of an optimizer step: (a) the cluster has gained enough new nodes to reconstruct a new pipeline, and (b) Bamboo has encountered many preemptions and is close to a critical failure in the next step (*e.g.*, encountering another preemption would cause us to suspend training), in which case we must pause the training to allocate more nodes.

Reconfiguration Policy. Bamboo attempts to maintain the pipeline depth P specified by the user. Therefore, our top priority at a reconfiguration is to reestablish a full pipeline of depth P . In this case, if we have had F failures and $J (> F)$ nodes are waiting to join the cluster (*i.e.*, new allocations arrive as Bamboo runs on the “spare tire”), we can fully recover all pipelines to depth P . The remaining $(J - F)$ nodes are placed in a standby queue to provide quick replacement upon future failures. However, if the number of nodes joining is smaller than F , we may end up having a number of N nodes such that $N\%P \neq 0$. In this case, instead of creating asymmetric pipelines (which complicates many operations), we move some nodes into the standby queue and decrease the total number of data-parallel pipelines. A final case is that the number of nodes joining, together with those in the standby queue, can form a new pipeline, and in this case we add a new pipeline to the system. In all these cases, the redundant layers are redistributed among the set of nodes participating in the updated pipelines.

How to Reconfigure. Once a reconfiguration is triggered, each node must be assigned a new stage (with new layers, state, and redundancies); it also needs to figure out if it will need to send or receive model and optimizer state from other nodes. Whichever nodes hits the rendezvous barrier first

decides the new cluster configuration and puts the decision on `etcd` for all other nodes to read. To minimize the amount of data sent in layer transfer, Bamboo transfers layers in such a way that each node can reuse its old model and optimizer state as much as possible.

B Support for Pure Data Parallelism

Bamboo supports pure data parallelism (without model partitioning). Due to space constraints, here we briefly discuss how it is supported. We use the same redundant computation strategy—Bamboo replicates the parameter and optimizer state of each node on a different node and uses these replicas as redundancies to provide quick recovery. For pure data parallelism, there is no bubble time to schedule RC. Eager FRC would be equivalent to overbatching (*i.e.*, each node processes its original minibatch plus a redundant minibatch). To reduce the FRC overhead and make RC fit into the GPU memory constraints, we over-provision spot instances (by $1.5\times$, in the same way as discussed in §5) to make each node process a smaller batch.

Enabling eager FRC doubles the batch size. However, it results only in a $\sim 1.5\times$ increase in the computation time due to the parallelism provided by GPUs. This overhead can be effectively reduced by slightly over-provisioning ($1.5 \times D$) nodes, increasing the degree of parallelism and decreasing the impact of overbatching. This enables us to run FRC eagerly without incurring much overhead (*i.e.*, $<10\%$).

C Additional Experiments

C.1 Bubble Size

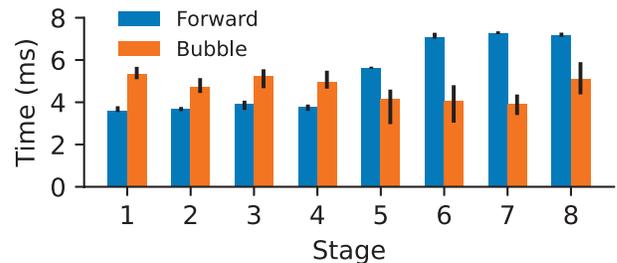

Figure 14: Comparison between bubble sizes and forward computations.

We measured the sizes of the pipeline bubble and forward computation of BERT with the same configuration as mentioned in Section 6, running on on-demand instances each with a single GPU. We manually inserted a barrier before each peer-to-peer communication, treating the time spent on the corresponding NCCL kernel as the bubble size. These results are reported in Figure 14.

To make memory evenly distributed across stages, more layers are placed on the last few stages. This explains the growth of forward computation. In this pipeline, for the first 4 stages, the bubble time is long enough to fit the entire FRC

(i.e., the bubble at stage 1 should run the forward computation for stage 2). For the last 4 stages, the bubble time is shorter than the forward computation time—it can still cover $\sim 60\%$ of its FRC. The rest of the FRC on these nodes is run in parallel with their regular forward computation, as discussed in §5.2.

C.2 Bamboo for Pure Data Parallelism

We ran two relatively small models such as VGG and ResNet using pure data parallelism with 8 workers (i.e., we partition the data but not the model). For Bamboo, we similarly over-provisioned $1.5\times$ additional workers. We implemented another baseline *Checkpoint*, which periodically checkpoints model state for each worker and restarts the worker on another node when its original node is preemption. We used the same global batch size for these models as reported in §6. The comparisons between Bamboo, *Checkpoint*, and on-demand training are shown in Table 6.

Note that our implementation of *Checkpoint* assumes that there is always a standby node that is ready to join and load the checkpoint (which is a unrealistic over-approximation of the allocation model on any spot market); as such, the training cost remains unchanged and its throughput is reduced as the preemption rate increases.

Model	System	Throughput	Cost (\$/hr)	Value
ResNet	Demand	24.51	24.48	1.01
	Checkpoint	[12.26, 8.42, 5.03]	[7.34, 7.34, 7.34]	[1.67, 1.15, 0.68]
	Bamboo	[21.22, 18.31, 12.31]	[10.56, 10.09, 9.18]	[2.01, 1.84, 1.34]
VGG	Demand	144.28	24.48	5.89
	Checkpoint	[83.21, 67.21, 45.31]	[7.34, 7.34, 7.34]	[11.33, 9.15, 6.17]
	Bamboo	[125.59, 96.51, 73.73]	[10.56, 10.09, 9.18]	[11.89, 9.56, 8.03]

Table 6: Comparison between pure data-parallel training over on-demand instances, a checkpoint-based approach on spot instances, Bamboo on spot instances. For *Checkpoint* and Bamboo, we trained each model three times, and their results are explicitly listed in the form of $[a, b, c]$ for the 10% (average), 16%, and 33% preemption rates, respectively.

As shown, Bamboo outperforms *Checkpoint* by $1.64\times$ and $1.22\times$ in throughput and value. Both *Checkpoint* and Bamboo deliver a higher value than on-demand training (by $2\times$ and $1.79\times$).

We make two observations on these numbers. First, Bamboo incurs a higher cost than *Checkpoint* due to resource over-provisioning. However, as discussed above, *Checkpoint* assumes the availability of standby nodes. In practice, guaranteeing such availability requires over-provisioning as well, but we did not take this into account when calculating costs (because it is hard to know exactly how many nodes we should over-provision). Hence, the cost and value reported for *Checkpoint* are the *lowerbound* and *upperbound* of those that can be achieved by any practical implementation of a checkpoint-based approach.

Second, *Checkpoint* works much better for pure data parallelism than for pipeline parallelism (as discussed in §3). This

is because recovering from a checkpoint in pure data-parallel training is much easier than pipeline-parallel training where a pipeline reconfiguration process is needed for each restart.

ONE WAN is better than two: Unifying a split WAN architecture

Abstract

Many large cloud providers operate two wide-area networks (WANs) — a software-defined WAN to carry inter-datacenter traffic and a standards-based WAN for Internet traffic. Our experience with operating two heterogeneous planet-scale WANs has revealed the operational complexity and cost inefficiency of the split-WAN architecture. In this work, we present the unification of Microsoft’s split-WAN architecture consisting of SWAN and CORE networks into ONEWAN. ONEWAN serves both Internet and inter-datacenter traffic using software-defined control. ONEWAN grappled with the order of magnitude increase in network and routing table sizes. We developed a new routing and forwarding paradigm called traffic steering to manage the increased network scale using existing network equipment. Increased network and traffic matrix size posed scaling challenges to SDN traffic engineering in ONEWAN. We developed techniques to find paths in the network and chain multiple TE optimization solvers to compute traffic allocations within a few seconds. ONEWAN is the first to apply software-defined techniques in an Internet backbone and scales to a network that is 10× larger than SWAN.

1 Introduction

The large-scale commercialization of cloud computing led cloud providers to provision private wide-area networks (WANs). These initial deployments connected both datacenters and Internet peering edges of the cloud using a unified cloud WAN. For instance, Microsoft’s cloud WAN, called the CORE (AS8075) network, interconnected Microsoft’s datacenters and Internet peering edges. However, as the cloud workloads evolved, inter-datacenter traffic began to dominate, shrinking the capacity available for carrying Internet traffic to peering edges. In response, Microsoft built a second WAN to offload inter-datacenter traffic. This WAN, called the software-defined WAN or SWAN (AS8074) used software-defined traffic engineering (TE) and bandwidth brokering to achieve higher network utilization [14] than RSVP-TE [2] in CORE. Deployment of two cloud WANs (Figure 1), one for Internet traffic and the other for inter-datacenter traffic is an

industry-wide trend with Google [17] and Meta [9] operating similar split-WAN architectures.

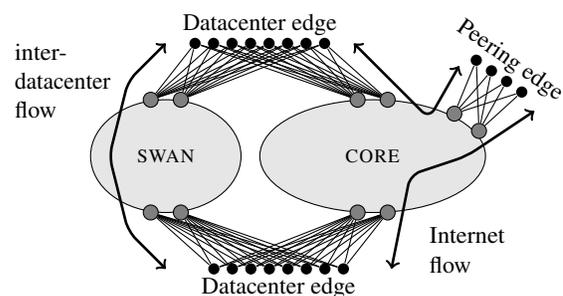

Figure 1: Before ONEWAN, there were two wide area networks, CORE (AS8075) and SWAN (AS8074). Datacenter edge connected to both networks, and peering edge only connected to CORE. Internet traffic was served by CORE and inter-datacenter traffic by SWAN. CORE used RSVP-TE and SWAN used SDN based traffic engineering.

Why is one WAN better than two? Maintaining two heterogeneous WANs specialized for inter-datacenter (SWAN) and Internet (CORE) traffic led to several operational challenges. First, the two-WAN architecture requires that datacenter edges connect to both SWAN and CORE routers (see Figure 1). The dual WAN connectivity from datacenter edges led to wasteful use of expensive network equipment and limited power supply. This problem was made worse by massive build outs of new datacenter regions and edge sites. Second, the split-WAN architecture makes capacity planning hard. At a given time, one WAN can be under-utilized while the other is over-utilized. Moreover, acquiring optical capacity for both WANs in every geographical region and building the required redundancy on each network, became prohibitively expensive. Finally, CORE and SWAN used routers with completely different protocol stacks. As a result, engineers were trained to configure, monitor and manage two distinct networks. Deploying new WAN sites took more time since different routers had to be deployed for the two networks.

In 2020, we observed a steady growth in Internet traffic from peering edges due to increased use of collaboration tools spurred by remote work (Figure 2). While the network capacity between Internet peering edges and the cloud WAN is scarce and expensive, it was not in the purview of TE in the split-WAN architecture. Thus, it became important to engineer

the growing traffic on WAN-facing links from peering edges but the key protocol of the CORE network, RSVP-TE, was not up to this task as it had reached scaling limits in our network.

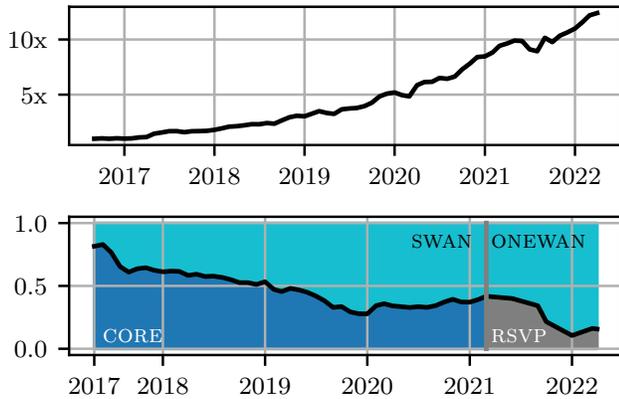

Figure 2: WAN traffic growth, the portions carried by CORE and SWAN when they were separate networks, and the portions of RSVP-TE and ONEWAN-TE traffic in the unified network.

Software-defined control in ONEWAN. Due to these operational challenges, we consolidated the split-WAN architecture into a unified ONEWAN. We decided to implement ONEWAN using SDN principles (like SWAN) instead of a standards-based approach (like CORE) for three main reasons. First, the key protocol of the CORE network, RSVP-TE, was reaching scale limits due the existing size of the CORE network topology. Second, RSVP-TE needed network-wide configuration changes which have a global blast radius. In contrast, we had deployed BLASTSHIELD to control the blast radius of faults in the SWAN network [22]. Finally, despite the earlier intention of using SWAN only for discretionary workloads, SWAN had evolved to carry mission-critical application traffic (e.g., Azure, Bing, Office, and Teams) in addition to discretionary inter-datacenter workloads (e.g., replication, backup). We measure our service level objectives (SLOs) as the daily average over percentage of successfully transmitted bytes in an hour. The SLOs of SWAN exceeded 99.999% for customer traffic, and 99.9% for discretionary traffic.

Challenges in evolving from SWAN to ONEWAN. In this work, we discuss the main technical challenges we overcame to unify the split-WAN architecture into ONEWAN (Table 1):

Increased routing table sizes. SWAN was responsible for routing datacenter prefixes only, which were few enough for all SWAN routers to run BGP and store the datacenter routing tables in the router memory. ONEWAN routers had to contend with Internet routing tables and it would be cost prohibitive to make every ONEWAN router hold the entire Internet routing table. Hence, ONEWAN assigned two roles to routers: (1) aggregation routers that hold full IP routing tables, and (2) backbone routers that act as forwarding only nodes that do not run BGP. We develop a new SDN function in ONEWAN called *traffic steering* on aggregation routers to encapsulate

WAN packets with information needed by backbone routers to do TE without IP routing (§ 3).

Fast failure repair. One of RSVP-TE’s strengths is *fast reroute*, which enables it to switch from primary to backup paths within milliseconds of a failure. This fast convergence is essential for performance-sensitive services like video streaming and virtual desktop over the WAN. *Local repair* is SWAN’s equivalent function of detecting and repairing failed paths using agents that run on the routers. Improving convergence times in ONEWAN required significant enhancements and was an area of new learnings (§ 4).

Scaling TE optimization. ONEWAN has ten times the number of devices of SWAN. The traffic engineering optimization techniques used in SWAN had to scale to a network size that is ten times larger. We developed scalable path and linear programming optimizations to deal with the increased scale of traffic engineering in ONEWAN (§ 5).

Estimating Internet traffic matrices. Accurate estimation of traffic matrices is crucial for engineering Internet traffic. Existing mechanisms for traffic matrix estimation fell short for ONEWAN since they did not contend with Internet-facing traffic. We developed a scalable pipeline for accurate traffic matrix measurement for ONEWAN (§ 6).

Hitless transition in the live network. Finally, the transition to ONEWAN was done in the live cloud network as it continued to carry user traffic. We devised techniques to enable both SWAN and CORE networks to undergo a hitless transition to ONEWAN (§ 7).

2 ONEWAN Architecture

The consolidation of SWAN and CORE networks into ONEWAN was a large undertaking that took years of engineering effort in planning, testing, implementing and verifying the new WAN architecture. In this section we motivate the design choices that led to the ONEWAN architecture.

Figure 3 shows a simplified view of ONEWAN with two datacenter regions and two edge sites. Datacenter regions are large campuses with routers at the root of the datacenter network connecting to aggregation routers in regional network gateways (RNGs). RNGs connect multiple datacenters in a geographical region with a maximum fiber distance under 100 kilometers. Backbone routers are present in all RNGs and additional transit gateways that are hubs for long-haul optical links. Peering edge routers at edge sites connect to aggregation routers in the same site. Aggregation routers connect to backbone routers in RNGs and gateways. ONEWAN traffic engineering (ONEWAN-TE) applies to inter-datacenter flows between datacenter regions, and Internet flows between edge sites and datacenter regions. The set of traffic engineered links consists of all backbone–backbone and aggregation–backbone links. The Clos interconnect between edge and aggregation

Challenge	Techniques used
Route scale increase	Only aggregation routers hold full IP routing tables. Controllers add routes for BGP next hops instead of BGP prefixes (§ 3).
Avoid costly new builds	Develop ONEWAN agents for four firmware versions to cover all existing routers. Interconnect CORE and SWAN with aggregation routers (§ 3 and § 4).
TE optimization scale increase	Traffic matrix-aware path computation. Optimize LP solvers (§ 5.1 and § 5.2).
Route convergence time	Fast local repair using diverse backup paths. Tunnel liveness probes that return to sender using controller routes (§ 4 and § 5.3).
Measuring real-time traffic matrix	Use IPFIX sampling with a high throughput pipeline. Anycast source-specific destinations determined from IPFIX flow records (§ 6).
Minimize risk of outages	Divide ONEWAN into geographies managed by separate controllers. Steering routes control what traffic is migrated ([22], § 7).

Table 1: Summary of ONEWAN challenges and our approaches for solving them.

routers is always intra-site or intra-campus, is built to high capacity, and hence is not a part of traffic engineering.

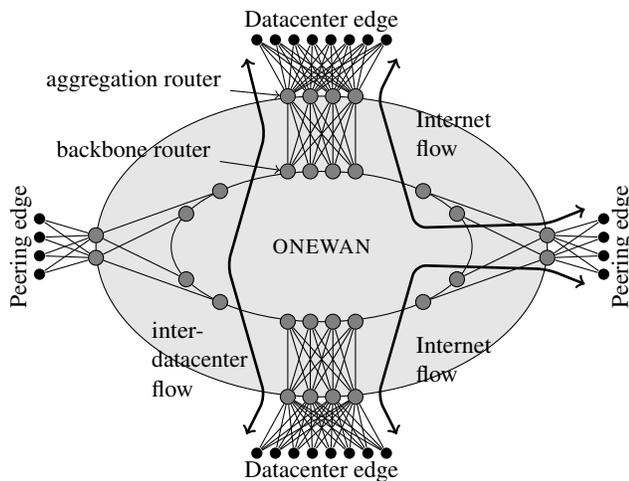

Figure 3: ONEWAN is a unified network that serves Internet and inter-datacenter flows using SDN TE. ONEWAN consists of aggregation routers at its boundary and backbone routers in its interior (gray dots). Datacenter and peering edge routers (black dots) connect to aggregation routers using a Clos interconnect. ONEWAN-TE applies to any inter-site flow between aggregation routers, be they inter-datacenter or between edge site and datacenter.

In-place conversion to ONEWAN. Since both CORE and SWAN networks carry mission-critical customer traffic, the unification of the two networks had to be done *in-place* with no visible impact to client performance. This goal necessitated incremental changes to both physical connectivity and network configuration to unify SWAN and CORE networks. The first step for the unification was to physically connect CORE and SWAN. Figure 4 shows new links that connect CORE aggregation routers to SWAN backbone routers. When CORE and SWAN were separate networks, they each had a set of aggregation routers. In the second step, we eliminated one set of aggregation routers and their links to save power. We merged the routing domains of the interior gateway protocol, which IS-IS [16] in CORE and SWAN, but did not merge the

BGP autonomous systems of the two networks to allow each network to carry its original traffic.

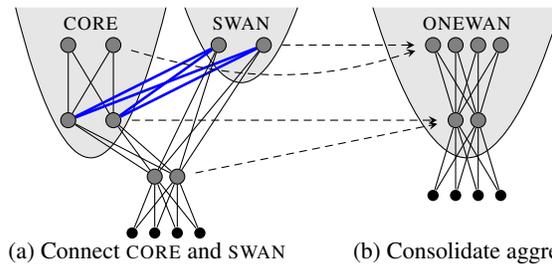

Figure 4: (a) Physically connect CORE and SWAN using aggregation routers (shown as thick lines). (b) Consolidate two sets of aggregation routers into one.

Leverage existing network hardware. Our goal was to repurpose the WAN routers in SWAN and CORE networks as opposed to building a clean-slate ONEWAN from the ground up with an entirely new fleet of routing hardware to reduce the capital expenditure in the consolidation process. SWAN had $O(100)$ routers and $O(10^5)$ datacenter routes while CORE had $O(1000)$ routers and $O(10^6)$ Internet routes. To leverage existing hardware for the increased scale in ONEWAN, only aggregation routers run BGP with the full Internet and datacenter routing tables. This allows the remaining backbone routers to be simpler commodity switches with smaller routing table memory.

Choice of tunneling mechanism. ONEWAN uses Multiprotocol Label Switching (MPLS) [31] to transport IP packets in a tunnel across the backbone. We note that ONEWAN does not use any TE protocols like RSVP-TE or TE extensions in the interior gateway protocols like IS-IS. We use MPLS for its efficient implementation of label stack encapsulation on existing routers in SWAN and CORE. Our approach could be generalized to other tunneling abstractions though it is outside the scope of this work.

Router roles. Aggregation routers implement a key function in ONEWAN, called traffic steering, described in detail in § 3. Aggregation routers are also used as transit routers in ONEWAN-TE tunnels. This enables the large number of legacy

devices in CORE and SWAN to make full use of available bandwidth in either network. Edge routers are sources or sinks for traffic. They are either datacenter routers or peering routers. These routers continue to perform the same function before and after the consolidation of SWAN and CORE.

3 ONEWAN Traffic Steering

Routing in ONEWAN occurs in three parts (see Figure 5). First, a *steering route* on the aggregation router encapsulates IP packets entering ONEWAN. Second, backbone routers forward packets received from aggregation routers along traffic engineered tunnels. In the final step, the egress backbone router uses a segment routed [10] path to route packets to the network destination. ONEWAN-TE controller computes and ONEWAN router agents program traffic steering and engineering routes on routers. IS-IS updates the segment routes.

Steering routes. BGP on aggregation routers receives routes announced by BGP route reflectors or its clients and chooses a set of one or more equal-cost BGP next hops for each prefix. The BGP next hops are typically aggregation routers at network egress sites though they could also be endpoints a few hops beyond the network egress site in legacy portions of ONEWAN. All ONEWAN sites are assigned a static identifier called the *site label*. When BGP looks up the route for the next hop, the highest preference route is the steering route added by the ONEWAN-TE controller. The steering route pushes a stack of two MPLS labels onto packets entering the backbone. The top label in the stack is the egress site label. The bottom label in the stack is the segment routing node segment identifier (node SID) of the BGP next hop learned from IS-IS.

The egress site label refers to the backbone exiting site on the shortest path to the packet's destination. It is the same site as the egress aggregation router, though it can be different in legacy portions of ONEWAN. Ingress backbone routers use the egress site label to determine the set of traffic engineered tunnels to use. IP flows are weighted load balanced to a specific tunnel based on their 5-tuple and traffic class. Once the tunnel is selected, the ingress backbone router swaps the egress site label with the traffic engineered tunnel label.

The bottom label serves two purposes. First, it provides forwarding from the egress backbone router towards the endpoint. Second, it provides a fallback if no traffic engineered tunnel for the egress site is up due to failures. When the ingress backbone router has no operationally up traffic engineered tunnels to a particular egress site, ONEWAN agent automatically adds a route to pop the egress site label and forward the packet using the segment route for the BGP next hop node SID. The advantage of this design is that failures in the network are quickly and transparently handled by the routers without immediate intervention of the controller.

Steering route weights. The steering route sprays packet flows to connected backbone routers using unequal load bal-

ancing. Although aggregation routers are directly connected with equal capacity to backbone routers, each backbone router is not an equal choice for ingress. For example, a backbone router may have a longer path to the endpoint or may have less available bandwidth to an egress site. Latency increases in the former and congestion can occur in the latter. The ONEWAN-TE controller excludes backbone routers with the shortest path latency from the ingress aggregation router to the egress site exceeding the best latency by a threshold. It then calculates weights using single commodity maximum flow from the ingress aggregation router to the egress site. Weights are recalculated whenever the topology changes. Figure 6 illustrates the weight calculation for flows from aggregation router a to endpoint f . Both backbone routers b and c are used to spread the load because they have similar shortest path latency to the egress site. The weight to b is 33% because the maximum flow bandwidth of $a - b - T$ is proportionately less.

Why have two stages of traffic splits? ONEWAN calculates traffic steering splits using single commodity max-flow and calculates traffic engineering splits using priority max-min fairness optimization (§ 5.2) for the following reasons. We were concerned that the TE optimization and path computation algorithms may not scale to the full size of ONEWAN and operating on a subgraph of backbone routers would ease the scaling challenges. Moreover, aggregation routers are connected with high capacity links to backbone routers and so do not need traffic engineering. Finally, we wanted steering routes to be updated quickly in case of failures and did not want the updates to be slowed down by an optimization phase.

In hindsight, the two traffic splitting mechanisms in ONEWAN can be unified since our improvements to the TE optimization (§ 5) enable it to handle the full ONEWAN topology of backbone and aggregation routers. Aggregation routers are transits for ONEWAN-TE tunnels between CORE and SWAN devices and so have to be part of TE optimization. ONEWAN agents in aggregation routers react to network topology changes faster than the controller.

Segment routing at the egress backbone router. TE tunnels terminate at the backbone router instead of the aggregation router for a separate reason. Segment routing implementations on vendor routers only allow penultimate hop popping, meaning that the penultimate router must remove the node SID before delivering the packet to the intended node. Routers do not easily support popping a label stack. This necessitated at least one segment routed hop and is why the TE tunnel is between backbone routers. Support for ultimate hop popping would eliminate the last segment routed hop.

4 ONEWAN Agent and Local Repair

ONEWAN agents are responsible for installing routes provided by ONEWAN-TE controllers. ONEWAN agents also perform *local repair*. The local repair mechanism detects

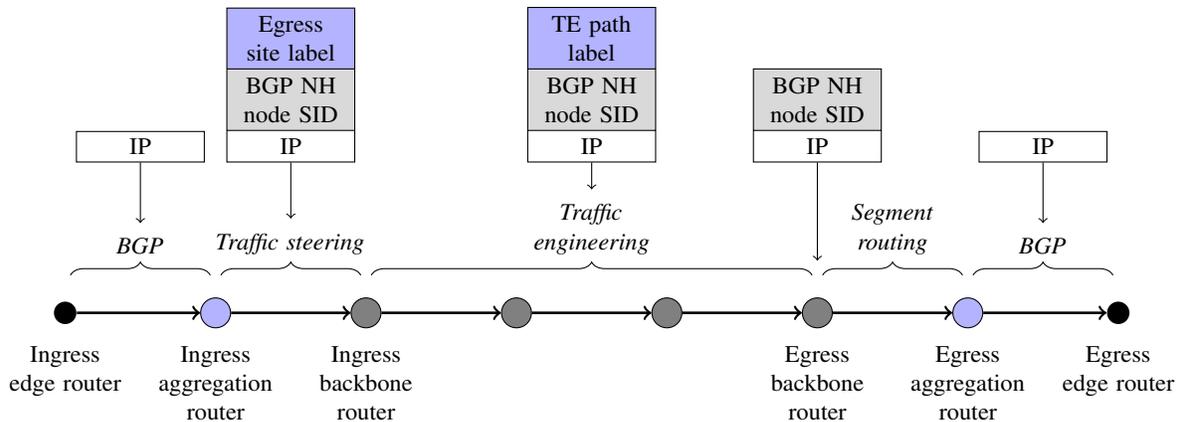

Figure 5: ONEWAN routing occurs in three parts. The first part is the steering route in the aggregation router, the second is the traffic engineered tunnel between backbone routers, and the third is the segment routed path from the egress backbone router to the network egress point. The traffic steering and engineering routes are added by the ONEWAN-TE controller.

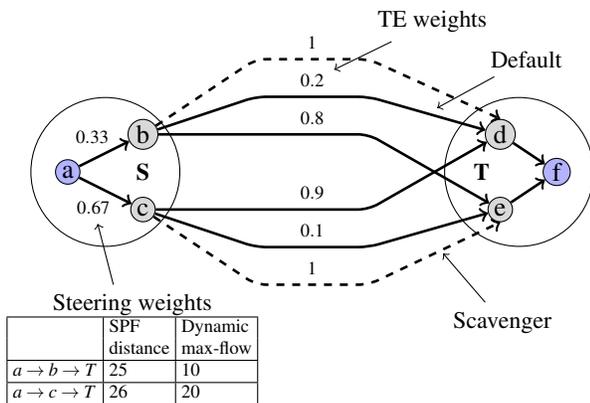

Figure 6: ONEWAN-TE example of flows from aggregation router a to endpoint f . Steering route load balances flows to selected backbone routers based on shortest-path distance and maximum flow from the backbone router to the egress site. The backbone routers perform full traffic engineering optimization.

the forwarding state of tunnels and reprograms actions to send traffic on surviving tunnels thereby minimizing transient packet loss due to route blackholes or congestion.

The ONEWAN agent runs as a process on all aggregation and backbone routers, optionally inside a Docker container. It is supported on four different firmware operating systems. To support the heterogeneity of firmware, the agent is structured as separate platform-independent and platform-dependent components, with well-defined APIs between them. The platform-independent portion has the bulk of the complexity in the agent. Figure 7 shows the agent organization.

Route programming. ONEWAN agents communicate with ONEWAN-TE controllers using an HTTPS server; no routing protocol is required. We use OpenFlow [28] match actions and groups to represent routes. Groups represent the set of traffic steering and engineering tunnels originating at ingress routers, tunnel weights for unequal load balancing, traffic class to indicate what type of traffic the tunnel is meant for, whether the

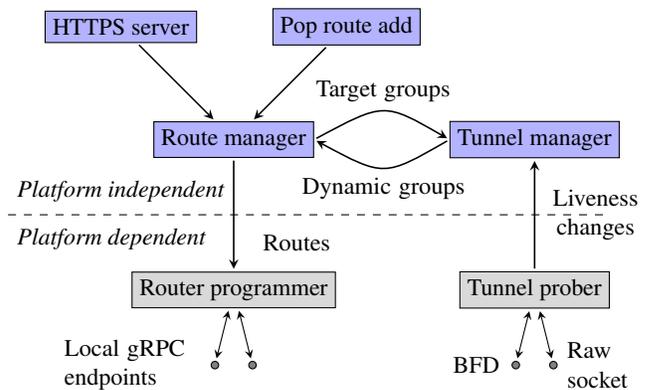

Figure 7: ONEWAN agent has platform dependent and independent components. The agent installs routes provided by ONEWAN-TE controller and switches off tunnels experiencing forwarding faults.

tunnel is primary or backup, and attributes for probing tunnel liveness. Transit routes use unary actions without groups.

The *route programmer* implements dynamic route operations through an internal gRPC or equivalent connection provided by the router firmware. It converts groups to weighted cost multipath (WCMP) next hops with 32 members and duplicates each tunnel in proportion to its weight.

The *target group* is the set of tunnels received from the controller and the *dynamic group* is the set of tunnels that are alive, with original weights redistributed among them. When a group has no primary tunnels alive, the backup tunnels are elevated to primary. A tunnel is associated with a traffic class, default matching any traffic class. When a group has no tunnels of default traffic class alive, the tunnels of the next traffic class are modified to be the default traffic class. In Figure 8, the target group has six tunnels A-F. The backup tunnels E and F become primary when A and B fail. If A comes back up, it is the sole primary default tunnel. We explain how ONEWAN-TE calculates diverse backup and class-aware tunnels in § 5.2 and § 5.3.

If no tunnels are alive, the agent replaces the dependent egress site label routes with pop-and-forward (on a backbone router) or removes the dependent BGP next hop steering routes (on an aggregation router). Part of agent initialization is the creation of pop-and-forward routes for the entire allocated egress site label space, to cover any stray traffic received.

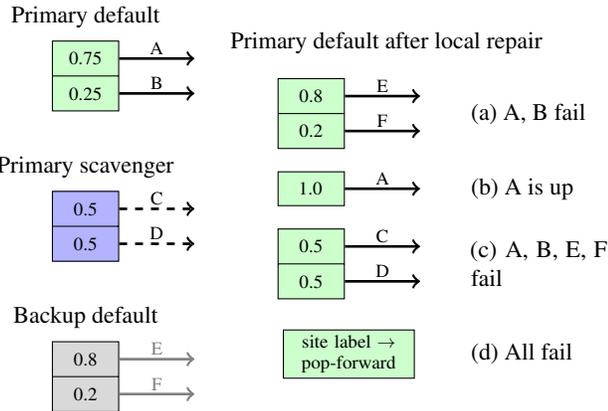

Figure 8: Local repair. The ONEWAN agent automatically adjusts the composition and weights of tunnels based on liveness. (a) If primary default tunnels A and B fail, then backup tunnels E and F become primary. (b) If A comes back up, it is the sole primary default tunnel. (c) If only scavenger tunnels C and D survive, they become primary. (d) If all tunnels fail, the site label route is replaced with a pop-and-forward action.

Tunnel probing. Aggregation routers use single-hop tunnel probing using Bidirectional Forwarding Detection [21] to check the links to backbone routers. Ingress backbone routers perform end-to-end tunnel probing using a labeled self-ping mechanism via a raw socket. Tunnel probes use the same routes as data packets in the forward direction.

Tunnel probes in SWAN relied on IS-IS in the return path. This caused backup tunnels to fail even though they did not use failed links in the forward path because the probe return path was affected by IS-IS route convergence. Without primary and backup tunnels, the agent removed the controller route and traffic reverted to IS-IS. Client traffic experienced IS-IS convergence times and congestion losses as long as the tunnels were still down. This significantly degraded user experience. Therefore, probes in ONEWAN return from the tunnel destination to the tunnel source using controller routes. The return hops are the reverse of the forward hops and thus do not share fate with links unrelated to the data tunnel. In Figure 9, the probe packets return on $d - b - a$, not $d - c - a$ even though the latter is shorter. The ONEWAN-TE controller reuses available data tunnels in the reverse direction when possible, and creates new tunnels otherwise.

Multiple probe packets can be in flight and the probing interval is independent of the path round-trip time. A loss of a configured number of probes marks a tunnel down, and a successful probe marks a tunnel up. We send probes at 100ms

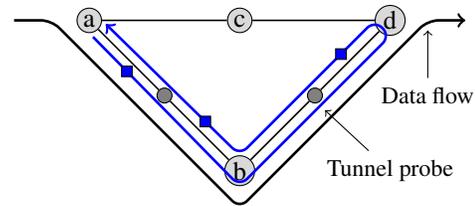

Figure 9: Tunnel probes use the same routes as the data packets in the forward direction and return from the destination using the same links to avoid false failures. The transit routes are programmed by the controller and agents of transit routers.

intervals and mark the tunnel down after loss of 3 probes. Fault detection time is thus 300ms plus the distance to the fault which in the worst case is the tunnel latency.

Local repair. In the split-WAN architecture, Internet traffic was handled by RSVP-TE in the CORE network. Standards-based RSVP-TE in the CORE network implements a fast reroute (FRR) [29] mechanism that allows it to recover from link failures in $O(10)$ ms. Fault detection time is the distance to the fault, which in the worst case is the link latency, plus a small delay for the optical transponder to notify the router. FRR switches to precomputed bypass tunnels at the point of fault and runs in or near the line card network processing unit. Switching times are a few milliseconds.

In contrast with FRR, ONEWAN's local repair happens at the ingress router of the tunnel not the point of fault. Faults in the first hop link are detected by interface down events and faults in subsequent hops are detected by lost probes. Repair is initiated in the route processor and subject to greater inter-process communication and scheduling delays. The route programmer modifies the WCMP in place to decrease the number hardware writes performed at the time of repair. As a result, ONEWAN convergence time is under one second. Although slower than FRR, ONEWAN meets the convergence time requirements of video streaming, video conferencing and other interactive applications currently served by the network. ONEWAN tunnel probes also validate forwarding because they exercise the routes used by data packets. The backup tunnels are chosen based on diversity and residual bandwidth and hence experience less transient packet loss due to congestion (described in § 5.3).

Route programming. ONEWAN is divided into geographical regions and regional ONEWAN-TE controllers program routes on devices in their region [22]. All routers program steering routes in parallel, in a single phase. The pop-and-forward routes on the backbone routers eliminate the need to synchronize programming steering and TE routes.

TE routes are also updated in parallel, using three phases with a barrier between each. A *make-before-break* sequence ensures that no route blackholes or loops form during programming. The set of routes for all routers is logically divided into two sets: the transit and tunnel egress routes T , and the

Metric	ONEWAN-TE
Per-device steering + TE routes	$O(10^3)$
Network level tunnels	$O(10^4)$
Per-device FIB update (p95)	2.0 sec
Network level FIB update (p95)	3.7 sec

Table 2: ONEWAN-TE scale in terms of routes, tunnels, and update times per device and for the entire network.

tunnel ingress routes G . Since the G routes depend on the T routes, make-before-break ensures that traffic cannot enter a tunnel until each subsequent hop has been programmed. An important property of ONEWAN-TE route generation is that the label spaces between successive iterations do not overlap, except where the paths they represent are identical. The label range is large enough to allocate unique labels in the worst case.

The phases of replacing the routes of iteration n , $T_n \cup G_n$, with routes of iteration $n+1$, $T_{n+1} \cup G_{n+1}$, are as follows:

- The initial state in all routers is $T_n \cup G_n$.
- $T_n \cup T_{n+1} \cup G_n$ is sent to agents which perform their route update and report success or error.
- $T_n \cup T_{n+1} \cup G_{n+1}$ is programmed. During this phase there may be a mix of G_n and G_{n+1} routes in the network, but all the T routes they depend on will be present.
- $T_{n+1} \cup G_{n+1}$ is programmed.

Traffic shifts in the second phase. Since a phase completes in under 4 seconds, a moderate scratch capacity avoids transient congestion. We reserve 15% scratch capacity to handle transients from programming and traffic microbursts. If an agent reports an error or connection is lost, the controller rolls back to the initial state in a single phase. Any inconsistencies after the rollback are corrected by the ONEWAN agent local repair.

4.1 Evaluation

Route scale. The number of traffic engineering tunnels was a significant scaling issue with RSVP-TE in CORE. Large number of RSVP-TE tunnels increased network convergence time after link failures and exceeded hardware resources in older aggregation routers. Table 2 shows that ONEWAN-TE uses 10 times fewer tunnels than RSVP-TE. When ONEWAN-TE optimizes, it simply reserves more bandwidth in existing tunnels, or creates new and destroys unused tunnels. On the other hand, RSVP-TE signals new tunnels with incremental bandwidth reservation, which it combines less frequently. Second, RSVP-TE requires a full mesh of label switched paths between nodes, but ONEWAN-TE only creates tunnels for nodes within a geography, and inter-geography flows reuse the intra-geography tunnels.

Steering routes scale with number of endpoints, and traffic engineering routes scale with number of backbone nodes. Both forwarding information bases of routes (FIB) have small sizes even for a large network. Time to update the FIB is

affected by the round-trip distance between the controller and router, and the number of routes in the FIB (see Figure 10).

Class based forwarding. An objective of ONEWAN-TE is to use underutilized links on longer paths for replication or backup traffic which are marked as scavenger traffic class but use diverse shortest paths for best-effort and higher traffic classes. ONEWAN agent installs the egress site label route with an intermediate policy lookup that is indexed by traffic class to change from default class WCMP to a class specific WCMP. Figure 11 shows that ONEWAN-TE assigns 55% of scavenger traffic to longer paths. Differentiated paths decrease scavenger drops due to microbursts in higher traffic classes. When best-effort and scavenger queues use weighted round-robin queue scheduling, differentiated paths also decrease best-effort transient drops due to scavenger microbursts. Figure 12 shows the successful transmission rate SLO for best-effort and scavenger traffic classes for a 3-month period in 2022.

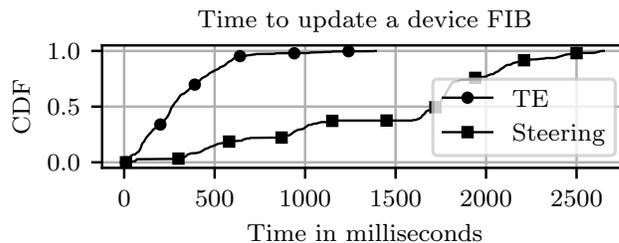

Figure 10: Per-device FIB update times for steering and TE routes.

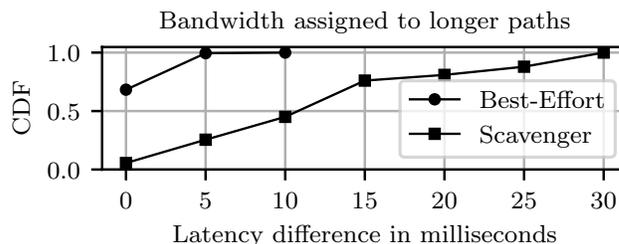

Figure 11: Class based forwarding uses paths for scavenger traffic class that are different from best-effort and higher classes. Longer paths carry 55% of scavenger bandwidth.

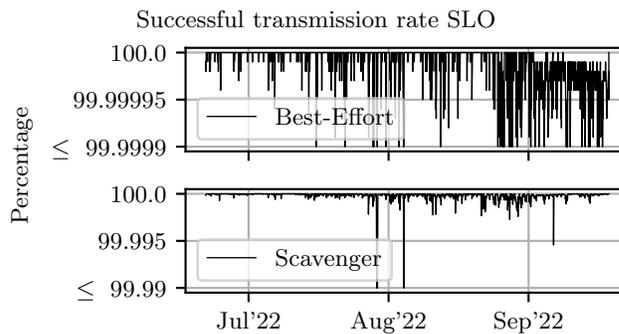

Figure 12: Successful transmission rate SLO for best-effort and scavenger traffic classes for a 3-month period in 2022.

5 Traffic Engineering Optimization

The ONEWAN TE optimizer has two inputs – predicted traffic matrix (TM) (described in § 6) and dynamic topology. A traffic trunk is an aggregate traffic flow from a source backbone router to a destination site for a specific traffic class, and the traffic matrix is a collection of predicted bandwidths for traffic trunks. The dynamic topology consists of sites, nodes and links. Nodes and links have tens of different attributes, including interface addresses, device role, link operational bandwidth, bandwidth reserved for RSVP-TE, link metric, whether a link or node should be avoided due to maintenance activity, and link reliability information. Each node is associated with a site, and all nodes in a site are equivalent destinations for a traffic trunk destined to the site. The TE optimizer operates in two phases: path computation phase and optimization phase.

In the path computation phase, we perform online computation of paths on the dynamic topology for all traffic trunks using efficient path finders (§ 5.1). We compute enough paths to enable the optimization phase to have adequate choices when allocating traffic.

In the optimization phase, the priority fairness optimization solver (§ 5.2) allocates traffic trunks to paths using the path formulation of multi-commodity flow problem. The TM is divided based on the traffic class of trunks and each traffic class is optimized differently. The priority fairness solver allocates demands of high priority trunks (best-effort and higher traffic classes) with the objective of minimizing the cost-bandwidth product. In contrast, it allocates low priority scavenger traffic trunks with the goal of minimizing maximum link utilization. The rationale to minimize maximum link utilization objective for low priority traffic is to decrease congestion drops in the scavenger class from microbursts in higher traffic classes, and to allow bandwidth broker [14] to serve more requested bandwidth using under-utilized links. High priority users expect the best latency the network can offer.

The priority fairness solver chains four solvers, max-min fairness, minimize cost, minimize maximum utilization, and diverse path, in different combinations based on traffic classes. The inputs to all solvers are paths computed in the first phase, TM, and upstream solver constraints.

5.1 Path computation

Path finders in ONEWAN implement techniques for exploring paths in the network topology. Over the years, we have developed many path finders. Today, we accumulate paths from two path finders in ONEWAN— penalizing and maximum flow path finders. The union of paths from the two finders has a mix of diverse shortest and maximum flow paths.

The penalizing path finder returns risk diverse paths with policies to never reuse a *risk group* for paths between the same source–sink pair or reuse only if necessary. Risk group is an

identifier for shared optical infrastructure used by two or more links. A link can have zero or more risk groups. The finder uses Dijkstra’s algorithm by setting link weights to penalties for risk groups used in previous shortest paths. Penalties are either infinity or a large value like the sum of all edge weights. The first path returned by the solver is the shortest path. Each subsequent path is the shortest path in the graph with modified weights. The finder operates on a graph where the risks groups have been expanded into virtual links (see Figure 13 (a)).

The maximum flow path finder uses maximum flow algorithms [11] and converts the augmenting paths into network paths. Link bandwidth is set to the reservable bandwidth for ONEWAN-TE. Link distance is not used in this finder.

Recall from § 3 that traffic engineered routes are not to individual routers, but to a group of routers in the destination site. Therefore, ONEWAN path finders compute paths from source nodes to destination sites using the technique of *sink aggregation*. In sink aggregation, we add a super sink node (ss) to the graph and connect sink nodes to it using directed edges of zero weight and infinite bandwidth (see Figure 13 (b)). Sink aggregation reduces the number of paths that ONEWAN-TE needs to allocate traffic on. Work is further reduced by computing paths only for source-sink pairs in the traffic matrix, instead of all pairs of nodes. This is called *TM-aware source sinks*. Figure 14 shows that these techniques reduce the path counts by a factor of 30. The resulting speed-ups extend into the optimization phase because fewer paths mean fewer columns in the linear programming constraint matrix. The average time to compute paths in ONEWAN is only 5 seconds.

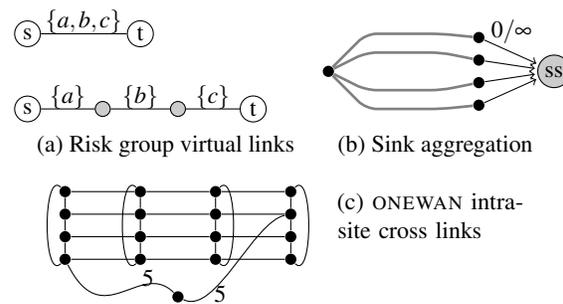

Figure 13: Path computation: (a) penalizing path finder expands risk groups to virtual links, (b) sink aggregation finds paths to all nodes in a site in the same exploration using a super sink, (c) cross-links within a site complicate k -shortest path exploration.

Why does ONEWAN not use k -shortest paths? Path computation using maximum flow algorithms works better than k -shortest path algorithms on the ONEWAN topology. This is because ONEWAN sites have a Clos or cross-link structure that requires k to increase exponentially with the number of inter-site hops (see Figures 3 and 13 (c)). There is dissimilar link bandwidth and cost for nodes in a site that make optimizations difficult. Switching from k -shortest paths to maximum flow algorithms gave a significant boost in path choice and speed.

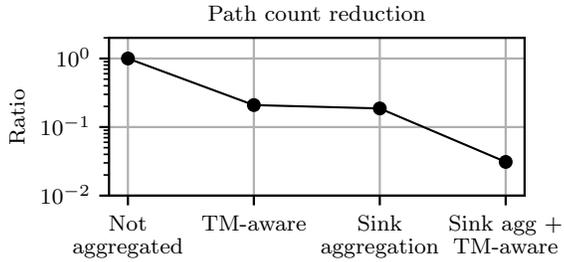

Figure 14: Path count reduction when paths are computed for traffic matrix aware source sinks and aggregated by sink nodes in a site.

5.2 Priority fairness solver

The priority fairness solver assigns priorities to traffic trunks based on their traffic class. Best-effort and higher traffic classes map to priority 0 (highest) and scavenger traffic class trunks are priority 1. Cloud network operators set a *committed data rate* for each priority. Committed data rate is the minimum percentage of link bandwidths guaranteed to a priority. If excess network bandwidth is available for use, traffic trunks receive more than the guaranteed allocation in priority order. By pre-committing link bandwidths based on priority, we ensure that lower priority trunks do not starve in the network.

The priority fairness solver runs in two stages. In the first stage, starting with the highest priority, it sets link bandwidths in proportion to the committed rate of the priority. This excludes the bandwidth committed to lower priorities, guaranteeing that lower priority demands are not starved for bandwidth. The fairness solver then allocates bandwidth for demands in this priority. It repeats this process for each lower priority demand set and accumulates all the downstream solver results into a single priority-aware solver result.

During the second stage, the solver walks through each set of demands in a priority and identifies fully satisfied demands. These demands are marked as frozen. For unsatisfied demands, it adds the credit allocated in the first stage back to the available link bandwidth. Adding the credits back to the links enables these demands to be run again as if none were allocated. In the first stage the demands were limited to available bandwidth after excluding committed rates of lower priorities. In this stage, unused committed rates are available and can be used for unsatisfied or partially allocated demands.

Solver chaining. ONEWAN-TE has multiple objectives. It allocates priority 0 traffic to achieve max-min fairness and minimum cost using a diverse set of network paths. It allocates priority 1 traffic to achieve max-min fairness and minimize the maximum link utilization. The priority fairness solver achieves these TE objectives by chaining multiple solvers to compute traffic allocations. Traffic allocations from upstream solvers in the chain constrain the solution space of subsequent solvers, achieving one TE objective per link of the solver chain. Solver chaining breaks ONEWAN’s TE problem into reconfigurable linear programming (LP) steps. The priority fairness solver (see Figure 15) uses four solvers. For brevity,

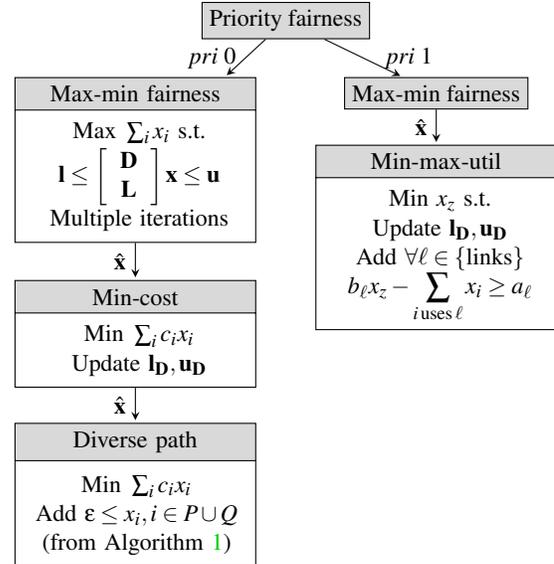

Figure 15: The priority fairness solver reserves bandwidth for traffic classes based on their priorities. It then invokes the chain of max-min fairness, min-cost and diverse path solvers for high priority traffic. High priority traffic does not consume bandwidth reserved for low priority traffic. After allocating high priority traffic, it invokes the max-min and min-max util solvers for lower priority traffic. Unused bandwidth after both high and low priority chains is made available for unmet demands in the second round of priority fairness solver.

we omit a detailed discussion of the optimization problems in the solvers, previously described in [3, 14, 19, 27]. \mathbf{x} has an element for each path and its solution $\hat{\mathbf{x}}$ is the allocation of bandwidths requested by trunks to paths. The solvers share a common core of demand and link constraints (\mathbf{D}, \mathbf{L}).

Chain of solvers. The *Max-min fairness solver* optimizes throughput using approximate max-min fairness. It uses multiple iterations of maximizing throughput with adjustments to demand constraint bounds. *Min-cost solver* uses the solution of max-min fairness to minimize the dot product of cost and allocations. For ONEWAN-TE, cost c_i is path metric, which is the sum of link metrics. It uses the solution of the max-min fairness to adjust the bounds in demand constraints. *Diverse path solver* solves the same objective but with diverse path constraints described in § 5.3. Priority 1 trunks are optimized with max-min fairness using the residual link capacity after deducting the allocations of priority 0. *Min-max-utilization solver* uses the upstream solution to adjust the bounds in demand constraints. To minimize maximum utilization with a linear objective, it adds a new variable x_z that represents maximum utilization, and utilization constraints where a_ℓ is previously allocated link bandwidth and b_ℓ is link capacity.

LP solvers. ONEWAN integrates two LP solvers, CLP [5] and GLOP [12]. They provide a $5\times$ speedup over the original solver used in SWAN. We achieve additional speedup by reducing the constraints sent to the solvers: the use of destination sites reduces the number of paths, and therefore columns in the constraint matrix are reduced 7-fold (§ 5.1). The biggest

gain in constraint reduction was achieved by pruning small traffic trunks that are under 500 Mbps. This decreased the constraint matrix rows and columns by factors of 5 and 7 respectively. The small trunks represent only 2.5% of network traffic (described in § 6.2) and get optimized within five minutes of growing large. Practicality of using LP solvers also depends on settings: dual simplex is superior to primal simplex for our LP models. Furthermore, pure cycling is possible as the max-min fairness models have high degeneracy — many columns are the same because the non-zero elements in the constraint matrix and the cost vector coefficients are 1. Cost perturbation is used to jiggle the values out of cycles.

5.3 Diverse path solver

A collection of paths is *risk diverse* if the intersection of risk groups of all paths in the collection is an empty set. ONEWAN applies diverse path protection to best-effort and higher traffic classes. In the ONEWAN-TE solver chain, the diverse path solver computes diverse paths using the primary paths from the min-cost solver. The goal of the diverse path solver is to decrease transient congestion in the interval between local and global repairs. ONEWAN agents perform local repair at the ingress router and ONEWAN controllers perform global repair based on the new topology. Spreading traffic on multiple paths without considering risk diversity can result in transient packet loss due to route blackholes or congestion since local repair is forced to use IS-IS routes.

The diverse path solver uses a greedy weighted set cover to find the minimum weight set of diverse paths that protects the shared risks in primary paths. Algorithm 1 outlines diverse path constraint generation. The WEIGHT function is configurable. Diverse paths can be configured to not exceed the primary path latency by a configurable jitter threshold, or diverse paths with more residual bandwidth can be preferred. We define jitter as a normalized ratio of path latencies, $(max - min) / \sqrt{min}$. Since high priority users expect the best latency in non-failure conditions, diverse paths with excess jitter are excluded. The diverse path solver re-solves the minimum cost objective with diversity constraints (see Figure 15). Diverse paths usually get the smallest possible weight since using them pulls the solution away from the minimum cost solution.

Figure 16 shows the percentage of total traffic on risk diverse paths. Without diverse path solver, any diversity is purely accidental, and was measured at 10%. When the agent only supported primary tunnels, jitter threshold of 5 was used to not adversely impact the latency of flows using the diverse paths. This constrained the choice of diverse paths and risk diverse traffic percentage was 75%. Once the agent implemented primary-backup tunnels, the jitter threshold was not required, and the protected traffic increased to 99%. The remaining 1% is due physical constraints on diversity of optical circuits.

Algorithm 1 Adds diverse path constraints

```

1: procedure DIVERSITYCONSTRAINTS( $P, U$ )
    $P$  is the set of primary paths.
    $U$  is the set of computed paths.
2:    $risks \leftarrow$  SHARED RISKS( $P$ )
3:    $ss \leftarrow$  SOURCE SINKS( $P$ )
4:    $candidates \leftarrow$  PATHS( $U, ss$ )  $\setminus P$ 
5:   for all  $q$  in  $candidates$  do
6:      $protect[q] \leftarrow$   $risks \setminus$  SHARED RISKS( $q$ )
7:      $residual \leftarrow$  residual bandwidth of  $q$ 
8:      $jitter \leftarrow$  latencies of  $q$  and  $P$ 
9:      $w[q] \leftarrow$  WEIGHT( $residual, jitter$ )
10:  end for
11:   $Q \leftarrow$  WEIGHTED SET COVER( $protect, w$ )
12:  for all  $i$  in  $P \cup Q$  do
13:    ADD CONSTRAINT( $\epsilon \leq x_i$ )
14:  end for
15: end procedure

```

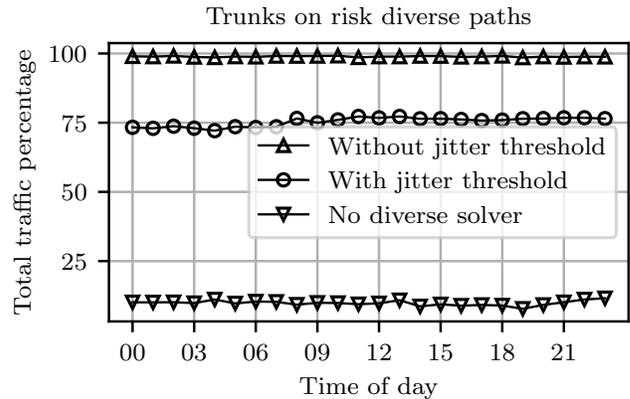

Figure 16: Percentage of total traffic on risk diverse paths in a typical day. 10% of the traffic is protected without diverse path solver, 75% with jitter threshold, and 99% without jitter threshold.

6 Measuring WAN Traffic Matrices

The traffic matrix (TM) is a key input to the traffic engineering optimizer. A traffic trunk is an aggregate traffic flow from a source backbone router to a destination site for a specific traffic class. There are four primary traffic classes in ONEWAN: voice, interactive, best-effort, and scavenger. The WAN TM is a collection of traffic trunks and bandwidths for each trunk. A trunk’s bandwidth can be a requested value for discretionary traffic, a measured value for Internet or non-discretionary traffic, or a prediction based on measured values. Bandwidth broker is a service that measures discretionary traffic at sending hosts and aggregates it into trunk-level requested bandwidth. The input to the traffic engineering optimizer is the complete traffic matrix that is a combination of the requested TM and predictions based on the measured TM.

Measured TMs are computed by sampling packets as they enter the WAN. SWAN sampled traffic using sFlow [30] at

backbone routers. On the other hand, ONEWAN sampled traffic using IPFIX [33] at aggregation routers. The sampling point and technique were dictated by which router exported the fields required for identifying traffic trunks. Flow record attributes such as sampling router address, input and output interfaces, BGP next hop, traffic class, and packet 5-tuple are used to identify the traffic trunk. ONEWAN required a high throughput data pipeline to process flow records from a larger number of devices at a faster sampling rate compared to SWAN. Since ONEWAN-TE re-optimizes traffic allocations every 5 minutes, TMs are measured at short, minute-level timescales.

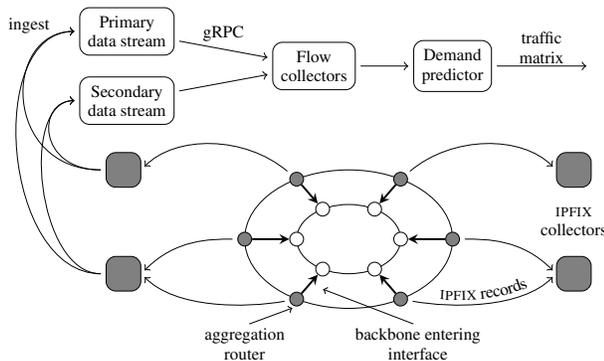

Figure 17: ONEWAN’s high throughput data pipeline for TM measurement. Aggregation routers export flow information to IPFIX collectors which process and store them in redundant data streams. Flow collectors query the data stream to compute bandwidths of traffic trunks. The demand predictor predicts the complete TM.

Challenges in measuring anycast traffic volumes. A large fraction of the traffic in CORE is anycast — traffic towards destination prefixes advertised by multiple sites in the WAN. Anycast traffic is routed to the router nearest to the *source* router using standard BGP path selection rules. Correctly identifying the destination of an anycast traffic trunk requires knowledge of the BGP route lookup result, which is different for each source. One way of solving this in software is to acquire copies of the routing tables of all aggregation routers and replay the route lookup. To avoid the overhead of copying tables and replaying routes, ONEWAN leverages IPFIX sampling where routers store the route lookup result in the BGP next hop attribute of IPFIX flow records.

IPFIX data pipeline to measure traffic matrices. In Figure 17, aggregation routers sample one in 4,096 IP packets, and export flow records using anycast to the nearest IPFIX collector cluster. The IPFIX collectors write the statistics to redundant data streams. Flow collectors query the data stream for flow records from aggregation routers to the connected backbone routers and build a traffic matrix. They also identify and tag discretionary traffic in the measured TM to help in combining with the requested TM. The demand predictor aggregates traffic matrices from all collectors and uses linear regression and autoregressive moving average models on

measured TMs to make predictions.

6.1 Error correction in measured TMs

We calculate the accuracy of traffic matrices measured using aggregations of IPFIX data against packet counters like interface counters, output queue counters, and RSVP-TE used bandwidth counters. Early versions of the IPFIX data pipeline had issues like invalid or missing attributes in flow records *e.g.*, missing BGP next hop attribute for IPv6 flows, or incorrect egress interface in certain flows. We detected and fixed such issues over time.

Flow record exporters use UDP, even though it is unreliable, because it needs less router resources. Hence, it is important that the data pipeline does not lose flow records due to traffic surges, unequal load distribution, or systemic or fault induced capacity crunch. The first generation of the data pipeline was lossy. The second generation of the pipeline used gRPC streaming from the data stream to the flow collectors (see Figure 17) and was not lossy. While operating with the first generation, we developed an error correction that gave similar results as the second generation. Since there is potential of failures in any pipeline, we outline the error correction technique used to improve reliability of our TM estimation.

We define the *interface error rate* as the ratio of input interface bit rate on the backbone entering interface measured by SNMP and calculated by IPFIX. Values greater than one indicate underestimation, and less than one indicate overestimation by IPFIX. The flow collector continuously calculates interface error rate, and scales the IPFIX measured bandwidths of individual traffic trunks in proportion to the interface error rate. The flow collector scales the bandwidth of each trunk separately based on its input interface error.

6.2 Traffic matrix characteristics

Figure 18 (a) shows typical diurnal and weekly traffic patterns seen in service provider networks. Interestingly, the number of traffic trunks in ONEWAN is $8\times$ the trunks in SWAN due to the doubling of source backbone routers, and increase in destination sites in ONEWAN.

In Figure 18 (b), 82% of trunks are under 100 Mbps and represent 1.3% of total traffic in WAN. The small trunks are uniformly distributed across the network, consist of many flow types, and do not pathologically contend for specific links. We take advantage of this distribution to speed up traffic engineering optimization by letting the smallest trunks go unengineered.

In Figure 18 (c), trunk distance is calculated based on fiber distance of the shortest path from source to destination. The largest traffic trunks have source and destination close to each other. 25th-percentile by distance is 95% of total traffic. We use this to define ONEWAN geographies such that 75% of the WAN traffic is intra-geography.

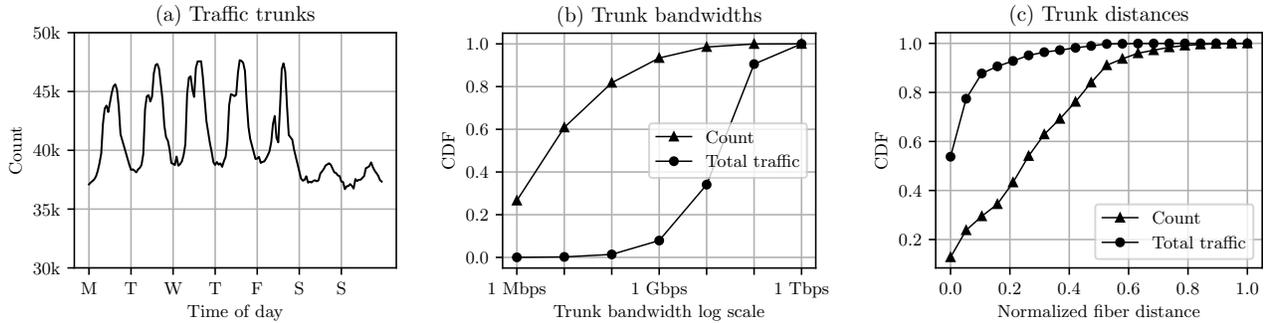

Figure 18: Traffic matrix characteristics for a typical week: (a) count of trunks by time of day, (b) distribution of trunks by bandwidth, (c) distribution of trunks by normalized fiber distance from source to destination.

7 Operational Experience

In this section we share lessons learned from the unification of SWAN and CORE networks into ONEWAN.

Traffic migration. We migrated traffic from RSVP-TE to ONEWAN-TE in the production network. So, it was important to perform this migration in a hitless manner. We used steering routes to migrate traffic from a specific set of source routers to another specific set of endpoints. We began by migrating traffic that was sourced and destined within the same geography because the configuration changes required for this are local to that geography. We used RSVP-TE maximum reservable bandwidth configuration on routers to control the percentage of link bandwidth made available to ONEWAN-TE. Initially, ONEWAN-TE had a small fraction of link bandwidth, sufficient to initiate traffic migration. We gradually increased ONEWAN-TE traffic and reduced the RSVP-TE maximum reservable bandwidth until RSVP-TE configuration could be entirely removed from the router.

Merging IS-IS routing domains. Merging the SWAN and CORE IS-IS domains posed a high risk for SWAN routers, whose IS-IS would observe a 7-fold increase in link state advertisements after the merge. IS-IS uses backoff timers to pace the shortest path first (SPF) execution. The purpose of backoff timers is to react quickly to the first few events but under constant churn, slow down to prevent the router from collapsing. The interactions of TE extensions still using IS-IS with interoperability issues caused IS-IS SPF to be persistently in backoff state slowing convergence. This prompted the design change to make ONEWAN-TE tunnel probing completely independent of IS-IS by using controller routes to return from the tunnel destination to the tunnel source (§ 4).

Cost savings with ONEWAN. ONEWAN brings the benefits of SDN TE to Internet traffic which was previously managed by RSVP-TE in the CORE network. SDN TE is known to make efficient use of network capacity, thereby reducing the need for capacity augmentation in the network. In Figure 19, we compare projected capacity augments needed with ONEWAN vs. SWAN + CORE to meet the organic traffic growth. We expect to reduce capacity augments by 10% of current installed

capacity in the next few years, which is of significant value for the size of our network. This does not include savings on inorganic growth like building new regions.

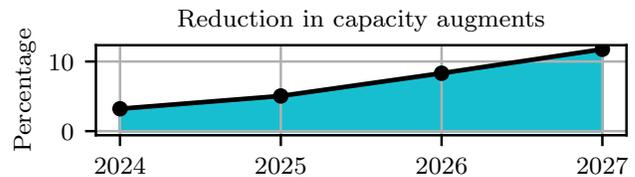

Figure 19: Reduction in capacity augments with ONEWAN compared to SWAN + CORE as a percentage of current installed capacity.

8 Related Work

We are the first to apply SDN techniques to replace RSVP-TE in an Internet backbone. SDN based traffic engineering was first used in inter-datacenter networks [9, 14, 15, 17, 20, 24, 25]. An inter-datacenter network has fewer points of presence, simpler scaling requirements, and easily built from scratch. We show that the challenges of scalability, reliability, feature parity, and migration can be overcome and replace RSVP-TE in an Internet backbone. This leads to unification of the cloud network with a single SDN controlled backbone.

SDN controllers for Internet peering have been discussed in [4, 7, 13, 34, 35, 37]. They tackle an important adjacent problem of Internet traffic engineering at the peering edge. These controllers enable performance-aware egress peer selection and inbound traffic engineering between autonomous systems. Our work focuses on the dynamic path selection and load balancing of this traffic between the peering edge and the end host in a datacenter, as it transits the backbone within the autonomous system. Microsoft peering edge uses a similar SDN controller that is outside the scope of this paper. ONEWAN controllers measure peering traffic and adapt the backbone to the needs of the peering edge traffic.

Traffic matrix estimation through models and link data have been studied in [8, 26, 32, 38]. In our experience, direct measurement of traffic matrices is, unfortunately, necessary for online TE in operational networks. We extend prior work

with an evaluation of our IPFIX sampling based measurement system, and present data on real world traffic matrices.

Prior work [14, 18, 23] states that programming end-to-end paths in WANs takes minutes, and the size of tables to store traffic engineering rules is a constraint. Our work shows that network updates take seconds, even in very large networks. A key reason for this difference is that prior work used TCAM-based policy engines that are flexible but limited resources, and our work uses IP and MPLS lookup tables, which are optimized and large even in commodity switches, and programming in parallel using make-before-break semantics. Path selection is usually done offline [6] and load balancing over selected paths is online. In ONEWAN-TE, both are done online using the dynamic topology and traffic matrix. Traffic engineering is studied as the optimization of one objective like minimizing link utilization [36]. ONEWAN-TE optimizes each traffic class with different objectives, and uses class based forwarding to achieve the intent in the data plane. [1, 25] study the TE problem with faults. ONEWAN-TE formulation is tuned for a larger network. It protects faults at the granularity of optical risk groups and balances the opposing requirements of proactive fault protection without increasing latency in non-failure conditions.

9 Conclusion

Our journey with using SDN for traffic engineering has completed a full circle. SDN-TE technology matured in our network while managing inter-datacenter traffic, and has now replaced legacy TE in the Internet backbone. ONEWAN represents a $1000\times$ increase in traffic volume and a $100\times$ increase in network size compared to SWAN a decade ago. Some key elements of SWAN have withstood the test of time. For example, traffic engineering optimization retains the same structure and formulation. We still use router agents on WAN routers which run on multiple firmware operating systems, but have modified them to deal with greater scale and functionality. ONEWAN brings the benefits of smaller fault-domains from BLASTSHIELD to the Internet backbone, making it more reliable. We hope ONEWAN expands the scope of future work in wide-area TE, standardization of the controller-agent programming abstraction, and analysis of traffic matrix characteristics of cloud WANs. ONEWAN marks the progression of SDN into an Internet backbone. It is driven by scaling our backbone to serve today's users. We continue to expand the roles and functionality of ONEWAN as new opportunities emerge with the growth of network demands.

RHINE: Robust and High-performance Internet Naming with E2E Authenticity

Huayi Duan, Rubén Fischer, Jie Lou, Si Liu, David Basin, and Adrian Perrig
ETH Zürich

Abstract

The variety and severity of recent DNS-based attacks underscore the importance of a secure naming system. Although DNSSEC provides data authenticity in theory, practical deployments unfortunately are fragile, costly, and typically lacks end-to-end (E2E) guarantees. This motivates us to rethink authentication in DNS fundamentally and introduce RHINE, a secure-by-design Internet naming system.

RHINE offloads the authentication of *zone delegation* to an end-entity PKI and tames the operational complexity in an *offline* manner, allowing the efficient E2E authentication of *zone data* during *online* name resolution. With a novel logging mechanism, Delegation Transparency, RHINE achieves a highly robust trust model that can tolerate the compromise of all but one trusted entities and, for the first time, counters threats from superordinate zones. We formally verify RHINE's security properties using the Tamarin prover. We also demonstrate its practicality and performance advantages with a prototype implementation.

1 Introduction

The importance of DNS as an integral part of the Internet cannot be overstated. If DNS is corrupted, so would be all relying Internet services [33]. Yet, this critical system has no built-in protection for data at rest or in transit. The infamous Kaminsky attack [57] raised worldwide awareness of the severity of DNS cache poisoning and thereafter spurred the deployment of several protocol-level defense mechanisms. Recent years have, however, witnessed a flurry of new vulnerabilities [17, 66, 67, 90] that revive the threat of cache poisoning and DNS hijacking in general [50].

The implications of these attacks are profound: they enable the sabotage of a wide spectrum of online systems, ranging from web applications and email to time synchronization and cryptocurrencies [33]. One of most alarming facts is that DNS plays an essential role in bootstrapping the Internet's security. In the modern web PKI, certificate issuance relies on

DNS-based channels for domain validation. If such channels are unauthenticated, attackers can manage to acquire fraudulent TLS certificates and impersonate domains [25, 27, 81]. Hence, an end-to-end (E2E) authenticated naming system is necessary for E2E secure communication.

DNS Security Today. Strengthening plain DNS with security guarantees has been a decades-long but still largely ongoing endeavor. DNSSEC [18] is by far the most important security extension to DNS. It allows a zone owner to cryptographically sign DNS records which, at least in theory, averts the threat of DNS hijacking. However, the deployment of DNSSEC is still far from complete (e.g., it is estimated that only 25% of DNS responses worldwide are validated as of mid-2022 [15]), and years' of practical experience indicates that it is highly fragile and fraught with problems.

The complexity of DNSSEC makes its operation an error-prone and expensive process. It requires each zone to synchronize its keying materials with its parent. Any inconsistency in an authentication chain will cause validation and hence resolution failure. This has caused frequent outages at all levels of the DNS hierarchy [54]. Validation failure can incur severe overhead to DNS servers and the name resolution process [53]. Partly because of these factors, and partly by design [88], end hosts rarely validate signed records by themselves but rely on validating recursive resolvers at best [64]. As a result, DNSSEC fails to provide E2E data authentication in practice, despite pervasive DNS interception [65, 71, 77].

The trust model of DNSSEC is also controversial. DNS is not designed for security, and mismanagement of DNSSEC by DNS operators is commonplace [29, 82]. Compromising a zone's secret key implies the control of all its subzones. This raises the concern that DNSSEC consolidates the power of the few Internet governance bodies and state governments over the DNS namespace [83]; in fact, large-scale DNS hijacking campaigns sponsored by state agencies have already been observed in the wild [46]. DNSSEC requires a validating entity to trust all zones on an authentication chain; any one of them can provide correctly signed yet bogus data [2].

These issues have their root in DNSSEC's underlying ar-

chitecture, which mirrors the hierarchical namespace, and therefore they cannot be resolved within DNS. This poses the question: *Is it possible to build a DNS-compatible yet robust naming system that enables efficient E2E authentication?*

Introducing RHINE. We provide an affirmative answer to this question with the design, verification, implementation, and evaluation of a system called RHINE. Our key insight is that the authentication of *zone data* and *zone delegation* in DNS, while treated identically by DNSSEC, should be decoupled. The latter form of authentication, which is more delicate and costly, can be performed by external trusted entities in an *offline* manner. Specifically, we employ certificate authorities (CAs) from the web PKI to certify zone delegation, allowing clients that already rely on these CAs to efficiently validate zone data during *online* name resolution.

Despite its promising opportunities, this architecture also raises unique challenges. Certifying a zone’s authority with CAs creates a *circular dependency*, because, as mentioned earlier, secure certificate issuance hinges on a secure naming system in the first place. On a different front, the corruption of a single CA may put the entire DNS namespace at risk. Moreover, malicious DNS and PKI authorities can interact in subtle ways to subvert a zone’s authenticity.

What we strive for is a system of *checks and balances* where the parties involved (zone owners, CAs, and loggers) watch over each other so that no single party or partial collusion between them can undermine a zone’s authority. RHINE systematically addresses security threats arising from the envisioned architecture, offering a set of protocols for secure zone management and E2E-authenticated name resolution. At its core is Delegation Transparency (DT), a novel public logging mechanism to maintain global zone delegation status.

It is essential to rigorously establish the expected security properties for our design. Using a state-of-the-art security protocol verifier, Tamarin [68], we have formally proved that RHINE guarantees E2E data authenticity for legitimately delegated zones in a highly robust trust model.

Our evaluation with a prototype implementation shows that RHINE can cope with real-world certificate issuance rates (millions per day) and, compared with DNSSEC, achieve lower resolution latency and higher resolver performance.

2 Problem Statement

We start by introducing the basic concepts of DNS. Afterwards, we contextualize the data authentication problem and analyze the intrinsic weaknesses of DNSSEC.

2.1 Name Resolution Basics

The global DNS namespace is organized as a tree structure, where each node is a *zone* that manages *resource records* mapping names to IP addresses and other data. Delegating a portion of a zone creates another node in the tree and hence a (sub)zone. Below the root zone lie top-level domains (TLDs)

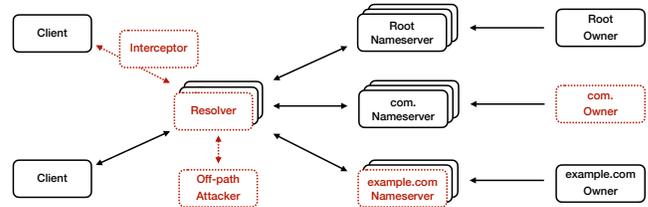

Figure 1: A simplified DNS infrastructure. Components in red and dotted lines indicate various threats to data authenticity.

such as `.com` and `.org`, second-level domains (SLDs) such as `a.com`, and so forth. A zone should be authoritative for all names under it except those under its *delegated* subzones. For example, assuming the zone `b.a.com` exists but `c.a.com` does not, then the zone `a.com` is authoritative for `c.a.com` and `d.c.a.com` but not `b.a.com` or `d.b.a.com`. A zone’s apex is the name identifying the zone itself.

DNS runs on a distributed infrastructure. We consider a simplified infrastructure with four types of entities depicted in Figure 1. The *owner* of a zone is a logical entity with legitimate authority over it. When the context is clear, we extend the term “zone” to also indicate its owner. A zone hosts its data on multiple (*authoritative*) *nameservers*, which in many cases are not under the control of the zone owner [58, 76]. In the name resolution process, a (*recursive*) *resolver* handles name lookup queries from *clients* (aka stub resolvers), by iteratively asking nameservers for matching record(s) in a top-down manner. Caching at resolvers reduces the overall lookup costs and helps DNS operate at Internet scale.

2.2 Authentication in DNS

Plain DNS offers no authentication of resource records. They can be corrupted anywhere before reaching a client, as highlighted in Figure 1. Any on-path network node can access, modify, and fabricate DNS messages. An off-path adversary can also intervene in the resolution process and inject bogus data, as demonstrated by the Kaminsky attack and its variants [66, 67]. Nameservers and resolvers may deviate from their expected behavior due to domain hijacking [85], malware infection [32], business incentives [87], or regulatory pressure [72]. Less obvious threats are posed by malicious zone owners themselves, who can surreptitiously (and somewhat rightfully) manipulate their subzones [2, 83].

Network attackers can be thwarted by secure channels. DNSCurve [23] was proposed to protect the communication between a resolver and nameservers using an in-band key exchange scheme. More recent and widely deployed protocols include DNS over TLS (DoT) [52] and DNS over HTTPS (DoH) [47], which focus on securing the last-mile communication between a client and a resolver. These solutions fail to mitigate risks arising from nameservers, resolvers, and any intermediary servers on the resolution path.

As the most prominent security addition, DNSSEC enhances DNS with data integrity and origin authentication.

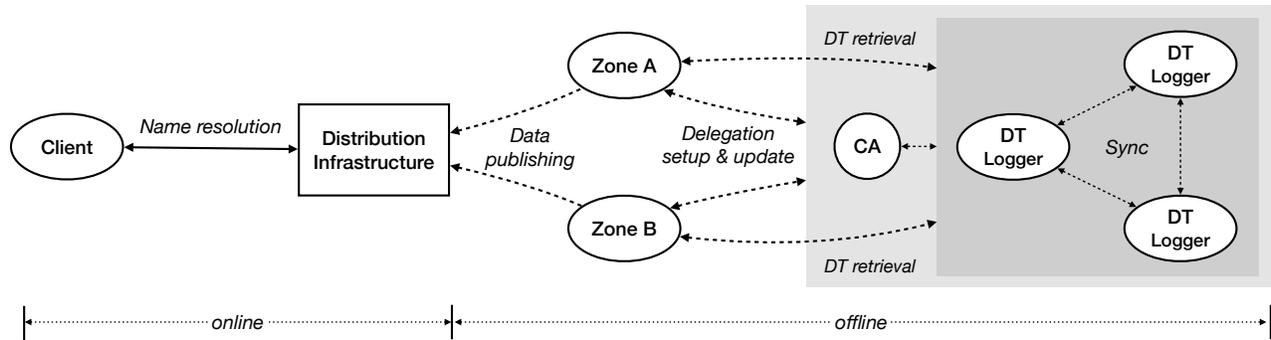

Figure 2: The high-level architecture of RHINE, where operational complexity (e.g., the authentication and management of zone authority) is pushed towards an *offline* phase. The arrows represent interactions between (groups of) entities.

It allows a zone to cryptographically sign its records using a secret key, with the corresponding public key signed by the parent zone. A security-aware resolver can verify a signed record by following an authentication chain all the way up to the root zone (key), without trusting any on-path servers.

2.3 Problems with DNSSEC

Since the signing of the root zone’s key in 2010, DNSSEC has seen gradual uptake, but the deployments are not all smooth. It is often cited by practitioners as overly complicated and not worth the costs it exacts [54]. We analyze its drawbacks in practical operation and from a security perspective.

Fragile Operation. DNSSEC requires synchronization between each pair of adjacent nodes in an authentication chain. Any inconsistency (e.g., missing or mismatching keys or security parameters) between a zone and its parent will cause validation and hence resolution failure, blocking not only the failed zone but also all its subzones. It is thus unsurprising that Internet outages caused by DNSSEC happen frequently *at all levels* including the root, TLDs and SLDs, and *across various organizations* including DNS governance bodies themselves (e.g., ICANN and RIPE) as well as large service providers (e.g., Verisign, Dyn, and Google) [54].

While DNSSEC already imposes significant performance overhead with respect to plain DNS resolution, validation failure can further boost its costs. It is estimated that with failure factored in, the authoritative nameservers of a DNSSEC-signed zone should be prepared to handle 10 times the query traffic volume and 100 times the response traffic volume of their unsigned counterparts for an Internet-wide deployment [53]. The potential of abusing DNSSEC for denial of service (DoS) is well-recognized and many real-world attacks have been reported [1].

The operational complexity, high failure rate, and performance overhead all contribute to the fact that end hosts rarely validate DNSSEC-signed records [64]. It is actually by design that end hosts should rely on validating recursive resolvers to verify records [88]. As a result, DNSSEC almost never provides E2E data authentication in practice.

Fragile Security. The security of DNSSEC rests on DNS itself. However, unlike PKIs, DNS is not designed for security; and unlike CAs, zone owners and operators may not be security-savvy. Real-world measurements have revealed widespread mismanagement of DNSSEC with flawed security practices (using weak keys, reusing keys for multiple zones, etc.) [29, 82]. The compromise of a zone’s secret key endangers not only the zone itself but also all its subzones.

A common criticism of DNSSEC is that it consolidates the Internet’s governance [83]. The root zone is governed by ICANN, the most important TLD `.com` is managed by Verisign under the jurisdiction of US law, and each country-code TLD is ultimately controlled by the corresponding sovereign state. Large-scale DNS hijacking campaigns sponsored by state agencies have been observed in real world [46].

While the governance model of DNS remains a subject of controversy, from a technical point of view, DNSSEC’s trust model is fundamentally fragile in that it provides clients with no option but to trust all zones on a delegation chain. A malicious zone can surreptitiously claim and serve authenticated data for names belonging to any subzone. This problem has just begun to gain attention from the Internet community, and there is a proposal to mark the root zone and TLDs as delegation-only so that their ability to serve authoritative data is limited [2]. However, implemented within DNS, this mechanism cannot solve the inherent limitations of DNSSEC.

2.4 Desired Properties

Our analysis of DNSSEC reveals the following properties desired by an ideal authenticated Internet naming system.

- **P1: End-to-end (E2E) data authenticity.** A validating client must be assured that any verified resource record is indeed generated by the genuine authoritative zone.
- **P2: Authentication efficiency.** The computation and communication costs of authenticating resource records, especially in case of failure, are lower than DNSSEC.
- **P3: Operational robustness.** The authentication of a zone’s data is unaffected by any superordinate zone’s op-

erational faults in managing security, e.g., misconfigured security policies or keying materials.

- **P4: Robust trust model.** If a zone relies on a group of entities (including its parent and any external trusted parties) to establish its authority, then no single entity or partial collusion between them can claim authority over the zone.

3 RHINE Overview

RHINE is a naming system with built-in security, satisfying all the properties listed in Section 2.4. Our starting point is the observation that the authentication of a DNS zone consists of two parts: authenticating resource records during name resolution and, when the zone is created, authenticating the delegation’s legitimacy. The latter can be offloaded from clients to external trusted entities: in particular, the CAs in today’s web PKI that billions of clients already rely on. Once a zone is delegated and certified, it can serve authenticated data and manage its security independently, without synchronizing with its parent as in the case of DNSSEC. This isolates the failures caused by a zone’s security mismanagement from its subzones. The reduction in validation failure and authentication chain length also improves name resolution performance.

This new security architecture simultaneously achieves the desired properties **P1**, **P2**, and **P3**. Yet, it introduces both unprecedented opportunities and challenges to meet **P4**, without which the system can be broken in many ways. This is the main focus of our design (Section 3.3).

RHINE Architecture. We depict our architecture in Figure 2. It consists of two parts. In the *offline* part, zone owners establish new delegations by acquiring publicly logged RHINE certificates (RCert) from a CA and loggers (Section 5.1). An existing zone can update its RCert or delegation status (Section 5.2). It also periodically retrieves delegation status proofs (DSP) (Section 5.3) from a public transparency log (Section 4). A zone signs its resource records using its RCert and publishes them to a distribution infrastructure. During *online* name resolution, a client who already relies on the web PKI can easily verify an answer’s authenticity using the associated RCert and DSP (Section 5.4).

This architecture shifts much of DNSSEC’s complexity to offline operations, minimizing the risk of failure during the name resolution process. It also clearly separates the distribution and authentication of DNS data. While we intend to reuse the existing DNS infrastructure consisting of authoritative nameservers, recursive resolvers, forwarders, etc., RHINE can be instantiated with other distribution architectures such as a peer-to-peer network [14], or enable client authentication of records received through DoT or DoH.

3.1 Notation and Primitives

We use *uppercase* letters (e.g., X) to identify entities (zone owners, CAs, and loggers) that run RHINE protocols, and *lowercase* letters in the subscript to identify zones (e.g., \mathbb{ZN}_x)

Table 1: Summary of Notation.

Notation	Definition
pk_X, sk_X	The key pair of entity X (in <i>uppercase</i>)
\mathbb{ZN}_x	A zone identified by x (in <i>lowercase</i>)
$\text{RCert}_x, zpk_x, zsk_x$	The RCert and associated key pair of \mathbb{ZN}_x
$:=$	Definition/assignment operator
(a, b, \dots)	A tuple of values encoded as a string
$H(\cdot)$	A secure hash function
$\langle m \rangle_X$ or $\langle m \rangle_x$	A message signed with sk_X or zsk_x
$\Sigma.\text{Vf}(k, m)$	Verify a signed message m with a key/cert k
$\text{Acc.Vf}(ac, p)$	Verify a membership proof p with digest ac

and their associated data (e.g., RCert_x). For brevity, we sometimes refer to the pair of zones related by delegation and their corresponding owners simply as the *parent* and *child*.

We use standard cryptographic primitives including secure hash functions and digital signatures. The public keys of CAs and loggers are known to all entities. To design succinct data structures, we also use cryptographic accumulators [34] that can commit sets of values into small digests and generate compact membership proofs. Classic constructions include the Merkle hash tree (MHT) [69] and its variants. Table 1 summarizes our notation.

3.2 Threat Model

Table 2 summarizes the adversaries we consider in the design of RHINE and the expected security properties.

\mathcal{A}_1 is a conventional Dolev-Yao network attacker [37] (who can eavesdrop, modify, and inject messages transmitted over the network) augmented with the ability to control the entire DNS distribution infrastructure.

The next two types of adversaries pertain to today’s web PKI ecosystem: \mathcal{A}_2 can issue arbitrary certificates by compromising a CA; \mathcal{A}_3 can compromise some loggers and provide fake or inconsistent log data to users. Since we repurpose the web PKI to authenticate delegated zone authority, RHINE must also deal with these adversaries.

For the first time, we systematically address an adversary (\mathcal{A}_4) that controls a zone and attempts to subvert its subzones by declaring authoritative data for them. This capability is inherent in the hierarchical naming structure of DNS, i.e., a name under a zone is also under its parent zone. For an authenticated naming system where zone data is cryptographically signed, \mathcal{A}_4 has access to the private key of the zone it controls. As an example, an \mathcal{A}_4 attacker compromising the TLD xyz can generate valid records for $abc.example.xyz$, despite that the SLD $example.xyz$ has been legitimately delegated.

Overall, we consider attackers that seek to, given the stated capabilities, break the naming system’s *data authenticity but not availability*—that is, tricking clients into accepting malicious data rather than preventing clients from receiving any answer. We assume that the attackers cannot break the cryptography primitives used by RHINE, and that privacy aspects of DNS are outside this paper’s scope.

Table 2: Summary of adversaries considered in DNS and the web PKI. We also list the corresponding security properties and representative defense mechanisms to achieve them.

Adversary	Capability	Security property (informal)	Defense mechanisms
Dolev-Yao \mathcal{A}_1	controls communication networks + DNS distribution infrastructure	channel security data authenticity	DoT/DoH/DoQ, DNSCurve DNSSEC, GNS [14]
\mathcal{A}_2	controls some CA(s)	certificate misissuance prevention	ARPKI [21], F-PKI [28]
\mathcal{A}_3	controls some logger(s)	tolerating all but one compromises	LogPicker [36], CTng [63]
\mathcal{A}_4	controls a DNS zone (e.g., a TLD)	authority independence (of subzones)	-
$\mathcal{A}_1 + \mathcal{A}_2 + \mathcal{A}_3 + \mathcal{A}_4$ (strongest possible adversary)		E2E authenticity with robust trust	RHINE

3.3 Design Rationale

RHINE strives to counter the strongest possible adversary that combines all capabilities as shown in Table 2. Before fleshing out RHINE’s design, we discuss the main aspects to be considered, analyze why existing approaches fail, and highlight the intuitions behind our solutions.

3.3.1 Validating Zone Ownership (\mathcal{A}_1)

Secure delegation in RHINE requires the expected zone owner to request an RCert from a CA. The issuing CA must verify that a requesting entity indeed controls the zone to be certified. Commonly known as domain validation (DV), this process is mandatory for the issuance of TLS certificates. In standard practice [20], the requester proves its ownership of a domain by publishing a challenge token specified by the contacted CA. A network attacker can exploit an insecure channel in this process to obtain a fraudulent certificate. Unfortunately, all practical DV channels hinge on DNS and are therefore exploitable by an \mathcal{A}_1 attacker [24, 27, 81]. Applying these standard DV methods to our case will lead to a *circular dependency*: the CA depends on an authenticated zone for ownership validation and RCert issuance, but meanwhile, the zone needs an RCert to authenticate its data in the first place.

RHINE solves this dilemma by engaging the parent to approve the delegation. This is indeed necessary, as the parent still legitimately controls the child before it is established. Specifically, the parent must sign a delegation request using its own RCert. The CA can then verify that the *current* owner of the child zone approves the delegation. In doing so, RHINE creates an *implicit offline* authentication chain of delegated authority, as opposed to what is explicitly constructed by DNSSEC, and shifts the heavy authentication workload away from the client side of DNS.

3.3.2 Preventing Certificate Misissuance (\mathcal{A}_2 & \mathcal{A}_3)

Security breaches of CAs [49] spurred the deployment of Certificate Transparency (CT) [61], which employs public logs to make misissued certificates detectable. Mainstream browsers have mandated public logging for TLS certificates to be valid [3, 6]. One limitation of CT is that it provides *deterrence* rather than *prevention*. Fraudulent certificates may still be used before being detected and revoked. CT loggers

passively accept certificates that meet basic validity criteria (properly formatted and signed, non-expired, etc.) but never validate domain ownership as CAs do. Also, the compromise of loggers has already occurred in practice [79].

RCerts are more critical than TLS certificates in terms of security, because the naming service is one of the weakest links in many Internet systems including the web PKI itself [33]. In addition, the detection of fraudulent RCerts is more involved in that it requires investigating delegation chains rather than individual domains. Therefore, we need preventive measures to foil the misissuance and logging of unauthorized RCerts.

There are proposals to make today’s web PKI more resilient to the compromise of CAs and loggers [21, 28, 36, 63]. Yet, they are not applicable to the new security architecture we envision for RHINE. This is because: (1) they are designed for TLS certificates and so they will suffer from the bootstrapping dilemma discussed earlier (Section 3.3.1), and (2) their log data models, either reusing or building upon CT, do not meet our security and performance requirements (Section 3.3.3).

We address the \mathcal{A}_2 and \mathcal{A}_3 adversaries from several aspects: (1) integrating loggers into the certificate issuance process for proactive verification of the data to be logged, (2) enabling a zone to choose its own trusted loggers rather than relying on whichever loggers are chosen by CAs (as in the case of CT), and (3) enforcing loggers and CAs to crosscheck each other throughout the certificate issuance and logging process. This allows RHINE to defeat attackers that can compromise multiple trusted entities designated by a zone.

3.3.3 Countering Parental Attacks (\mathcal{A}_4)

A zone gains *authority independence* if its ancestors cannot claim authoritative data under its authority. The cryptography of DNSSEC makes the situation even worse than in regular DNS. Our new security architecture does not immediately address this challenge. In particular, a malicious parent can still serve authentic records for delegated children, using its own RCert or alternative child RCerts acquired by it. In order to counter such parental attacks, we must enable a dependent entity (client or CA) to verify the status of the delegations in question without trusting zone owners themselves.

Since delegation status can be inferred from logged RCerts, it seems plausible to design a solution atop CT. A closer

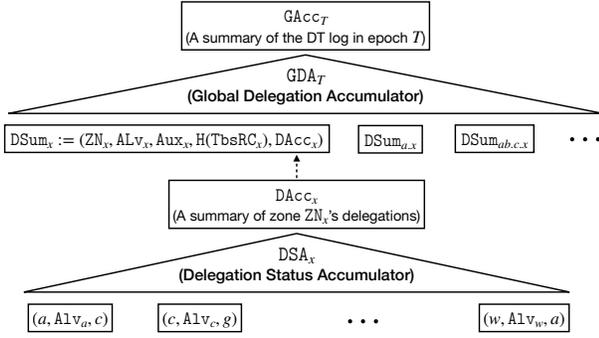

Figure 3: The data structures used by DT.

look reveals several pitfalls. First, a dependent entity needs to ascertain that a zone in question does *not* exist, but CT has no native support for *absence proofs*. Second, such proofs must have global coverage, but CT loggers operate independently and maintain only partial views of all issued certificates. It would be onerous to assemble and synchronize data from all CT logs with correctness and performance guarantees. Third, the data structures used by CT are too heavy to represent and authenticate global delegation status.

These inefficiencies motivate us to create a more efficient transparency mechanism dedicated to keeping track of the entire namespace’s delegation structure.

4 Delegation Transparency

At the heart of RHINE is Delegation Transparency (DT), a lightweight verifiable log design. In contrast to CT, which maintains the *history* of all certificates ever issued, DT offers an up-to-date *snapshot* of global zone delegation status. A single DT log is replicated to a consortium of loggers. The loggers receive requests to update delegation status and periodically synchronize with each other to maintain a consistent log. They also provide publicly verifiable delegation information. Below we introduce the basics of DT. Its operation as an integral part of RHINE is described in Section 5.

Log Data. Figure 3 depicts DT’s data model. We define the delegation status of a zone ZN_x as a tuple $(ALV_x, Aux_x, CSet_x)$, where the first item is the *authority level* of ZN_x (explained below), the second is auxiliary information for ZN_x (e.g., expiration time or revocation status of the delegation), and the third is a set representing ZN_x ’s child zones and their authority levels: $CSet_x := \{(c_1, ALV_{c_1}), (c_2, ALV_{c_2}), \dots\}$.

We encode the delegation status of ZN_x into a data structure called $DSum_x$ (delegation summary). $DSum_x$ contains a cryptographic digest of the zone’s $RCert$. This ensures that at any time there is only one valid $RCert$ per zone, capturing that the authority over a zone should be unique. Since a zone may have many delegations, $DSum_x$ stores the digest ($DAcc_x$) of an accumulator DSA_x over $CSet_x$ rather than $CSet_x$ itself. This reduces the cost of authenticating a specific child’s (non)existence. Each input element of DSA_x contains the label

	TER	$\neg TER \wedge \neg DOL$	DOL	
IND	$(1, 0)^*$	$(1, 1)^*$	$(0, 1)^*$	EOI
$\neg IND$	$(1, 0)^*$	$(1, 1)^*$	$(0, 2)^*$	$\neg EOI$

Figure 4: The authority level matrix derived from the interaction of constraint flags. The shaded area indicates the division caused by the EOI flag. In each pair (a, b) , $a \in \{0, 1\}$ encodes a zone’s ability to serve authoritative data for all its names excluding those of its independent subzones; $b \in \{0, 1, 2\}$ encodes a zone’s delegation capability (0: not allowed; 1: non-independent child only; 2: any child). The cases marked with * permit fast data validation (see Section 5.4).

and authority level of one child as well as the label of the next child in a *canonical order* [19]. This allows a single membership proof from the accumulator to prove either the presence or absence of a child zone.

For efficient synchronization and auditing of the DT log, we introduce a global accumulator GDA over all $DSum_x$ s. Loggers can commit GDA ’s digest ($GAcc$), along with the necessary data to replay logged changes, into an authenticated data structure that supports succinct consistency proofs [62].

Authority Level. While we envision that authority independence is desired by many zones (including all TLDs and SLDs), this may not always be the case, for instance when the parent and child are managed by the same entity. To enable fine-grained control over zone authority, we introduce the concept of *authority level*, which places constraints on what a zone can do to its data and delegation. We define authority levels using *constraint flags*, as depicted in Figure 4.

The flag IND indicates a zone’s authority independence. By definition, an independent zone has the sole authority over its names, whereas a non-independent ($\neg IND$) zone’s names are also under the authority of its parent. The data served by a zone comes in two types: authoritative and delegation. A *terminating* (TER) zone can serve only authoritative data; all leaf zones are by default terminating. A *delegation-only* (DOL) zone can serve only delegation data (i.e., NS records in DNS); all TLDs are supposed to be delegation-only. Note that these two flags cannot be set simultaneously as this would lead to an empty and useless zone. Since a non-independent zone can never delegate to an independent child, authority independence can end at some non-leaf zone on a delegation path; such a zone is marked as *end-of-independence* (EOI).

Delegation Status Proof (DSP). Clients make use of the DT log in the form of DSP, which consists of a timestamped $DSum_x$ signed by loggers and, if necessary, a membership proof from DSA_x for some child zone ZN_y of ZN_x . A DSP enables clients to determine a zone’s realm of authority and hence whether to accept an answer signed with the corresponding $RCert$. A malicious parent may use an outdated

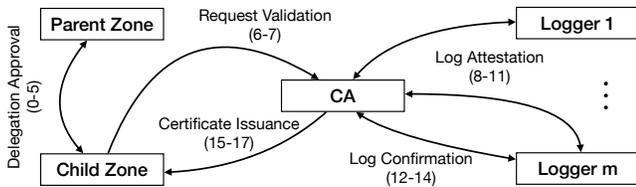

Figure 5: Overview of the delegation setup protocol.

DSP to trick clients into accepting fraudulent data for the names belonging to a delegated child. Prudent clients should accept only DSPs that are recent enough.

5 RHINE Protocols

We specify RHINE’s core functions with a set of protocols, including the secure management of zone delegation, the maintenance and usage of DT, and E2E-authenticated name resolution. The entire system operates in *epochs*, which are consecutive time windows of a predetermined length. This is necessary to keep DT loggers in synchrony and to establish the system’s security. In each epoch, zone owners can securely set up new delegations or update existing ones until a cut-off time. The resulting changes in these zones’ delegation status will be applied to the DT log within the same epoch and take effect from the next epoch. Zone owners can actively monitor the log for unexpected events like attacks or operational faults, and take action accordingly. They also regularly retrieve signed log entries to prove their authority over answers served during name resolution.

5.1 Secure Delegation Setup

In RHINE, delegating a zone ZN_c begins with the intended owner C negotiating the delegation with P , the owner of the parent zone ZN_p . This follows standard DNS practices, e.g., domain registration. Afterwards, C should run the secure delegation setup protocol specified in Figure 6 to obtain an RCert. This protocol follows the design intuitions presented in Section 3.3. An overview of its flow is depicted in Figure 5.

In the initial phase (Steps 0-5), C asks for a signed approval (*apv*) for its delegation request (*sdr*) from P . The request encodes the trusted entities selected by C , the delegation parameters negotiated with P , and most importantly, the public key to be certified. The corresponding private key is also used to sign the request. There must be a way for P to authenticate the association between C and the key. This is done using an initial secure out-of-band key registration procedure (Step 0), for example, via a secure web portal with account-based client authentication when P is a domain name registrar.

Next, C sends the request to a CA for validation (Steps 6-7). In addition to verifying the parent’s approval, the CA checks the delegation’s legitimacy using the DT log. If everything is correct, the CA sends a pre-logging request (*prl*), which includes a to-be-signed certificate, to the designated loggers for crosschecking (Steps 8-11). After assembling the loggers’

attestations, the CA randomly picks one of them to store the logging request (*lreq*) as an input to the later aggregation process (Steps 12-14). Finally, C receives an RCert accompanied by attestations and a confirmation that the zone ZN_c ’s delegation status will be added to the DT log (Steps 15-17).

Our design ensures that the entire delegation setup process is witnessed by multiple parties and any misbehaving party will be held accountable for the messages it signs. Any verification failure will cause the protocol execution to abort, broadcasting a failure message to all the involved parties. It is impossible to obtain a valid logged RCert without faithfully following the protocol. Even in the presence of an omnipotent attacker whose capabilities go beyond our threat model, RHINE still allows a zone owner to detect and counter attack attempts before harm is caused (see Section 6).

Secure Bootstrapping. The delegation setup protocol assumes the parent’s RCert already exists. A bootstrapping problem arises at the top of the namespace. Representing a critical Internet authority in itself, the root zone should not depend on another CA. Therefore, we treat the root zone as a root CA that signs its own RCert. Similarly, TLDs resemble intermediate CAs with their RCerts signed by the root RCert. This allows the root zone and TLDs to retain their innate power over the namespace, effectively restricting an external CA’s influence over the namespace to SLDs and below.

5.2 Secure Delegation Update

Once delegated, a zone can manage itself mostly independently of its parent. This includes updating its RCert and other delegation parameters. Similarly to delegation setup, processing an update request involves some CA and loggers as witnesses. The parent’s involvement is required only for a request to extend the delegation’s validity period or to change the child’s authority level from non-independent to independent. RHINE has built-in support for certificate revocation. An updated RCert automatically revokes the old one, because by design a zone can only have one valid RCert at any time; a zone can also request for explicit revocation.

The update protocol is similar to the delegation setup protocol for the message flow and verification procedures. The major difference is that a zone should now sign the update request using its own RCert (instead of the parent’s) to prove its authority. We provide further details in Appendix A.2.

5.3 DT Aggregation and Retrieval

In each epoch, loggers will receive disjoint sets of requests to update the DT log. To ensure the log’s global consistency, they must aggregate all requests by synchronizing with each other. Wanner et al. formalized this problem as *secure log replication*—a special case of state machine replication—and proposed Logres, a formally verified log replication protocol with Byzantine fault tolerance that is optimal in terms of round complexity and the number of tolerable faults [86].

<p>0. C generates a key pair (zpk_c, zsk_c) and register zpk_c to P via a secure out-of-band channel.</p> <p>1. C : select A (a CA) and \mathcal{L}_c (a set of loggers) <i>// t_0 is a timestamp within the current epoch T, al is the requested authority level, aux is auxiliary information.</i> : $rid := H(ZN_c, zpk_c, A, \mathcal{L}_c, t_0, al, aux)$ <i>// rid is implicitly included in all subsequent messages</i></p> <p>2. $C \rightarrow P$: $sdr := \langle rid, SDRReq(ZN_c, zpk_c, A, \mathcal{L}_c, al, aux) \rangle_c$</p> <p>3. P : Verify $\Sigma.Vf(zpk_c, sdr)$ and whether al, aux : match what are agreed upon with C.</p> <p>4. $P \rightarrow C$: $RCrt_p, apv := \langle SDAprv1(H(sdr)) \rangle_p$</p> <p>5. C : Verify $\Sigma.Vf(RCrt_p, apv) \wedge Match(apv, sdr)$</p> <p>6. $C \rightarrow A$: $sdr, apv, RCrt_p$</p> <p>7. A : Verify $\Sigma.Vf(RCrt_p, apv) \wedge \Sigma.Vf(zpk_c, sdr)$: $\wedge Match(apv, sdr)$: Retrieve $dsp := \langle DSum_p, T' \rangle_{\mathcal{L}_c, mem}$: from local cache or the loggers \mathcal{L}_c. <i>// Check if DSP is valid and the delegation is legit</i> : Verify $\Sigma.Vf(pk_{\mathcal{L}_c}, \langle DSum_p, T' \rangle_{\mathcal{L}_c})$: $\wedge Match(RCrt_p, DSum_p) \wedge T' = T \wedge$: $Acc.Vf(DAcc_p, mem) \wedge Legal(ALv_p, al)$: $tbsrc := TBSCert(ZN_c, zpk_c, A)$ <i>// Pre-logging requests to all designated loggers</i></p>	<p>8. $A \rightarrow \mathcal{L}_c$: $prl := \langle PreLog(sdr, apv, tbsrc) \rangle_A, RCrt_p$</p> <p>9. L_i : Verify $\Sigma.Vf(pk_A, prl) \wedge L_i \in \mathcal{L}_c$: $\wedge \Sigma.Vf(RCrt_p, apv) \wedge \Sigma.Vf(zpk_c, sdr)$ <i>// Check if the to-be-signed cert matches the requested</i> : $\wedge Match(apv, sdr) \wedge Match(sdr, tbsrc)$ <i>// Check the delegation's legitimacy using local DT log</i> : $\wedge ZN_c$ not delegated $\wedge Legal(ALv_p, al)$: $nds := (T, A, \mathcal{L}_c, ZN_c, al, aux, H(tbsrc))$</p> <p>10. $L_i \rightarrow A$: $att_i := \langle LogAttest(L_i, H(nds)) \rangle_{L_i}$</p> <p>11. A : Verify $\Sigma.Vf(pk_{\mathcal{L}_c}, \{att_i\}) \wedge Match(prl, \{att_i\})$ <i>// L is randomly selected from \mathcal{L}_c by A</i></p> <p>12. $A \rightarrow L$: $lreq := \langle LogReq(L, nds, \{att_i\}_{L_i \in \mathcal{L}_c}) \rangle_A$</p> <p>13. L : Verify $\Sigma.Vf(pk_A, lreq) \wedge Match(nds, \{att_i\})$: $\wedge \Sigma.Vf(pk_{\mathcal{L}_c}, \{att_i\}) \wedge L \in \mathcal{L}_c$: Add $lreq$ to a pending pool for aggregation</p> <p>14. $L \rightarrow A$: $lc := \langle LogCfm(L, H(nds)) \rangle_L$</p> <p>15. A : Verify $\Sigma.Vf(pk_L, lc) \wedge Match(lc, lreq)$: $RCrt_c := \langle FinalRCert(TbsRC_c, \mathcal{L}_c) \rangle_A$</p> <p>16. $A \rightarrow C$: $RCrt_c, \{att_i\}_{L_i \in \mathcal{L}_c}, lc$</p> <p>17. C : Verify $\Sigma.Vf(pk_A, RCrt_c) \wedge Match(sdr, RCrt_c)$: $\wedge \Sigma.Vf(pk_{\mathcal{L}_c}, \{att_i\}) \wedge Match(sdr, \{att_i\})$: $\wedge L \in \mathcal{L}_c \wedge \Sigma.Vf(pk_L, lc) \wedge Match(sdr, lc)$</p>
--	---

Figure 6: The secure delegation setup protocol. A party stores the messages it sends and receives whenever necessary. The function `Match()` checks the consistency between two data objects and `Legal()` checks a delegation's legitimacy. Other functions, such as `SDReq()` and `TBSCert()`, construct proper data objects from the input parameters.

This protocol however cannot be directly applied to our case, because it is agnostic to the validity of inputs: a malicious logger that participates in the consensus process faithfully can still inject arbitrary bogus data into the log.

To this end, we enhanced Logres with input validation (among other technicalities), requiring each logging request to be attested by the specified trusted entities (Steps 10-13, Figure 6). Using the modified version as a core consensus routine, we designed a secure aggregation protocol (Appendix A.3) that allows a majority of honest DT loggers to efficiently maintain a consistent log even in case of Byzantine faults.

Within an epoch, DT loggers can run the aggregation protocol multiple times according to some system-wide policies, e.g., at regular intervals or whenever their pools of pending request become filled up. Pipelining log aggregation with delegation setup and update improves overall system efficiency. Loggers should stop accepting new requests when the number of pending requests is estimated to exceed what they can aggregate after the cut-off time. This ensures that all requests confirmed in an epoch (Step 15, Figure 6) can be applied to the DT log by the end of the epoch.

After a successful execution of the delegation setup or update protocol in epoch T , the owner of a zone ZN_x should actively monitor the DT log. Once the change to its delegation status has been admitted, it can retrieve from its designated loggers \mathcal{L}_x a signed log entry $\langle DSum_x, T+1 \rangle_{\mathcal{L}_x}$ (and DSA_x as well if it is updated), which will be used to generate DSPs in

epoch $T+1$. Each zone should retrieve its (re-)signed log entry once per epoch, even if its delegation status is not changed. Note that using the epoch counter, instead of higher-precision time units, to timestamp log requests and DSPs effectively guarantees RHINE's synchrony while reducing the system's reliance on secure global time synchronization (e.g., [40]).

Parameter Selection. Epoch length is an important system-wide parameter and its selection comes with trade-offs. A large value means long waiting time for zones' delegation status changes to take effect. A small value leads to frequent retrieval of the DT log and thereby performance issues. On balance, we suggest a practical epoch length of 48 hours and a cut-off time 24 hours before the end of an epoch. This is based on our evaluation results as well as CT's Maximum Merge Delay of 24 hours [62]—the longest time period within which CT loggers must add promised certificates to their logs. We consider doubling the waiting time in DT acceptable because the administration of zone delegation happens less frequently than the management of TLS certificates for domains in already established zones. With the suggested parameters, it takes 24–48 hours to set up an operational zone.

5.4 Authenticated Name Resolution

With only minor changes, RHINE can augment the plain name resolution of unprotected DNS (or any other distribution infrastructure) with E2E data authentication. A zone owner

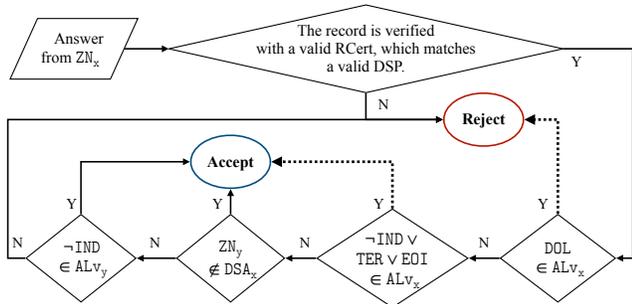

Figure 7: The flow of validating an answer received from zone ZN_x , which has a potential child ZN_y that encloses the queried name. Dashed arrows indicate shortcuts for verification.

needs to sign its resource records using the zone’s RCert before publishing them to nameservers. Whenever an authoritative answer is to be provided, a nameserver will also return the corresponding RCert and DSP to the querying client.

Figure 7 depicts the data validation flow. It starts with the verification of the signed records using RCert, similarly to DNSSEC. The client then additionally verifies whether the RCert matches the cryptographic digest contained in the DSP. Afterwards, the client decides whether the queried name falls within ZN_x ’s realm of authority by checking its authority level ALV_x . In most cases (Figure 4), a shortcut can be taken to make a quick decision: an answer for a non-apex name from a delegation-only zone is always rejected by definition; an answer from a non-independent, end-of-independence, or terminating zone is always accepted because there exists no further independent subzone. If none of these applies, the client will examine ZN_x ’s potential child zone ZN_y that encloses the queried name, which involves verifying a membership proof from DSA_x , and accepts the answer only if ZN_y does not exist or is non-independent.

6 Formal Security Analysis

The overall security goal of RHINE is to preserve a zone’s data authenticity against powerful adversaries. This can be broken down into two concrete objectives: (1) preventing attackers from obtaining a valid RCert to take over a zone that is *not yet delegated*, and (2) preventing the forgery of authoritative data from an *already delegated* zone. In the first case, a victim zone is still under the legitimate control of its parent, and therefore the parent must be assumed trusted for a meaningful notion of security. In the second case, the additional protection of a zone from its malicious parent leads to the notion of authority independence.

We define these two objectives with the following theorems (presented informally). Table 3 summarizes the main security parameters in RHINE. The constraint $f < n/2$ is required by Logres [86]. We additionally require that $m \leq f + 1$ holds for any zone, as otherwise an attacker with the \mathcal{A}_3 capability can inject arbitrary data into the DT log.

Table 3: Main Security Parameters in RHINE

Definition	Constraint
n Number of loggers in a global DT setup	-
f Number of tolerable faulty loggers	$f < n/2$
m Number of loggers chosen by a zone	$m \leq f + 1$

Theorem 1 *If a zone ZN_x is delegated with $RCrt_x$ issued and logged in epoch T , then a corresponding secure delegation request must have been approved by the parent earlier in epoch T , even if an $\mathcal{A}_1 + \mathcal{A}_2 + \mathcal{A}_3$ attacker formed by the entities specified in $RCrt_x$ is present throughout epoch T .*

The security guarantee provided by Theorem 1 resembles that of the ACME protocol, which also concerns unauthorized certificate issuance [24], but RHINE deals with much stronger attackers. In fact, RHINE allows even better security than is promised by this theorem. We discuss the following situations where the threat assumptions are violated.

It may happen that an adversarial parent, despite having approved a legitimate delegation for a child, front-runs the delegation setup protocol for the child zone with different parameters (in particular the key to be certified) in the current epoch. Yet, the expected owner of the child zone can detect from the DT log the misissued RCert, which will remain unusable until the associated DSP becomes valid in the next epoch (see Section 5.3). The owner being impersonated can then request to revoke the illegitimate delegation before it takes effect, by presenting the parent’s approval as evidence to the relevant CA and loggers.

An even worse, though unlikely, case is that an attacker manages to control a CA and m loggers. This enables it to issue an RCert for a target zone and log the corresponding entry to DT. Still, the zone’s real owner can actively monitor the log and take action to defeat such attack attempts.

Theorem 2 *For a DT-logged zone ZN_x with $RCrt_x$ in epoch T and its delegation status not updated between T and $T+k$ ($k > 0$), if a client accepts an answer for a name under ZN_x using $RCrt_y$ in epoch $T+k$, then it must be that $RCrt_x = RCrt_y$, even if an $\mathcal{A}_1 + \mathcal{A}_2 + \mathcal{A}_3 + \mathcal{A}_4$ attacker formed by the entities specified in $RCrt_y$ is present between epoch T and $T+k$.*

There are several technicalities in the definition above. First, between epoch T and $T+k$ ($k > 0$), $RCrt_x$ is zone ZN_x ’s only valid certificate whose secure digest is logged in DT; ZN_x may have been delegated and updated before T . Second, because of the hierarchical naming structure, ZN_y is either ZN_x or its ancestor, but not an arbitrary zone. Third, the attacker is defined with respect to the $RCrt_y$ received by the client instead of $RCrt_x$. This captures the reality that a client has no prior knowledge of an RCert’s validity.

Theorem 2 formalizes data authenticity for established zones. It covers various scenarios where an attacker may acquire and use invalid, fraudulent or outdated RCerts to trick clients into accepting bogus data. RHINE maintains security

Table 4: Summary of our implementation in Go.

Component	LoC	Supporting System	Used by
librhine	2.2K	gRPC, CBOR [26]	Common
rmanager	0.6K	BadgerDB [4]	Zone owner
rhine-ca	0.68K	BadgerDB	CA
dt-log	0.76K	BadgerDB, SMT [10]	Log operator
rserver	0.35K	CoreDNS [7]	DNS operator
rresolv	0.7K	SDNS [16]	DNS operator
rdig	1K	miekj/dns [41]	End user

as long as one of the involved loggers stays non-compromised. This assumption is much weaker than that of DNSSEC, which rests on every node on the chain being honest.

Formal Verification. An informal argument or even pen-and-paper proof of these theorems can hardly lead to high assurance of RHINE’s security guarantees. We have formally proved them using the Tamarin prover [68], an advanced tool for the verification of security protocols [22, 31, 42]. This approach helped us identify many subtle flaws in our early designs. We have modeled all the core protocols of RHINE, covering the secure setup and update of a zone delegation, the aggregation and retrieval of the DT log, as well as the authenticated distribution and resolution of the zone’s data. This amounts to around 1500 lines of formal specification. We refer the reader to Appendix B for further details.

7 Implementation

We developed a prototype of RHINE. Table 4 summarizes our implementation efforts and the system’s dependencies. The lines of code (LoC) reported do not count the supporting systems. Our prototype provides two software suites.

Offline Management. This suite includes four components. The library `librhine` defines common data structures and utilities. `rmanager` is intended to be an all-in-one toolbox for zone owners: key registration and delegation approval (in parent mode), request generation and validation (in child mode), log data retrieval, etc. `rhine-ca` offers all functions needed by a CA. `dt-agg` realizes a DT logger. It implements a self-balancing MHT for DSA (the per-zone accumulator) and a sparse MHT for GDA (the global accumulator).

These components operate in synchronous mode. For every protocol instance, they each create a `goroutine` that blocks itself after sending out a request and resumes upon receiving a response. All components can handle concurrent requests up to the available computing, memory, and bandwidth resources.

Name Resolution. We implement our nameserver (`rserver`) and recursive resolver (`rresolv`) with existing DNS frameworks. RHINE introduces new data types, RCert (encoded in the X.509 format) and DSP. We store them using TXT records encoded as base64 strings and call them RoA (realm-of-authority) records. For DSP we store DSum and the member-

ship proofs from DSA separately, as the latter are not required in most cases. Each zone has just one DSum, whereas the number of membership proofs equals the number of delegated child zones. Below are example records for zone `eg.com`.

```
_rcert.eg.com 60 IN TXT "Ed25519 MIIBITCB..."
_dsum.eg.com 60 IN TXT "rZXAwGzEZMBcGA1U..."
eg.com        60 IN DNSKEY 257 3 15 8fcCpq...
eg.com        60 IN RRSIG DNSKEY 15 2 60 2...
abc.eg.com    60 IN TXT "DSAPf u+EuVu6xX+..."
xyz.eg.com    60 IN TXT "DSAPf t9GsbAeavK..."
```

We do not use the private key of an RCert to directly sign regular records but instead treat this key as an equivalent of DNSSEC’s key signing key (KSK). A KSK authenticates a zone signing key (ZSK), which in turn signs regular records. The record `eg.com` of type `DNSKEY` in the example above is a ZSK, followed by a `RRSIG` record authenticating it using the RCert. This layer of indirection in key usage allows a zone owner to securely store an RCert’s private key offline and fetch it on demand, reducing the risk of security breaches.

We modified two built-in plugins of CoreDNS for `rserver` to serve RHINE-related data: the `file` plugin parses RoA records loaded from a zone file and, when processing a query, places them in the additional section of a response message; the `sign` plugin provides signing functions using RCerts.

`rresolv` augments `SDNS` with the functions to query, cache, validate and serve RoA records, reusing most of its codebase for the resolution of regular DNS records. `rresolv` always validates authoritative answers received from nameservers using RoA records and caches only verified data. It also always attaches the corresponding RoA records in the response message to a client, enabling E2E data authentication by default.

On the client side, we developed `rdig`, a `dig`-like tool for DNS-style name lookup with mandatory data validation.

8 Performance Evaluation

We evaluated our RHINE prototype in a private cloud network with 2Gbps bandwidth, using cloud servers with dedicated 8-core CPU (2.6GHz) and 16GB RAM running Ubuntu 22. Unless otherwise specified, the round-trip time (RTT) as reported by `ping` between any pair of servers is expanded to 100 ms using the `tc` utility. For the cryptographic algorithms in both RHINE and DNSSEC, we use Ed25519 for digital signatures and SHA256 for secure hash functions. In line with RHINE’s architecture, the evaluation consists of two independent parts for offline and online operations.

8.1 Offline Management Performance

The first part of our evaluation aims to answer two questions. (1) *Can RHINE’s offline protocols cope with real-world certificate issuance rates?* (2) *Is DT practical and scalable in terms of computation, communication, and storage cost?*

RCert Issuance. We measured the throughout of the secure delegation setup protocol, using two servers to run `rmanager`

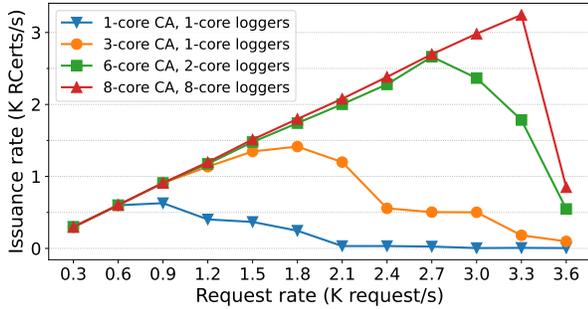

Figure 8: RCert issuance throughput.

(one for the child and the other for the parent), one server to run `rhine-ca`, and two servers to run `dt-log`. The child server generates delegation setup requests for predefined child zones whose keys have been registered at the parent server. The log maintained at the logger servers is initialized with an entry for the parent zone without any child. We limit the number of CPU cores used by the most critical CA and logger servers to understand their scaling behavior.

Figure 8 reports the results. With one core, the CA is the slowest server capping the issuance rate at around 600 RCerts per second. Using three cores, it can catch up with the loggers for a throughput of 1.4K RCerts per second. Doubling this configuration also doubles the achievable throughput. The decay in throughput with increasing request rates is due to the child server overwhelming itself with too many pending requests. Overall, our setup with these 8-core servers can issue a maximum of 3.3K RCerts per second.

To put this number in context, we consider the performance requirement of Let’s Encrypt, the largest ACME-backed CA that accounts for around 80% (5M) of all daily logged CT entries [11]. Our test servers with moderate resources can already issue nearly 12M RCerts per hour. This indicates that our design can easily cope with real-life certificate issuance workloads. Such a performance is explained by RHINE’s streamlined issuance process, which unlike ACME does not involve a time-consuming challenge-response procedure.

DT Consensus. We evaluate the performance-critical DT consensus process with different numbers of loggers (each on a separate server). We consider only delegation setup requests as the main consensus routine is agnostic to the type of requests. We limit the bandwidth between each pair of loggers to 1Gbps to simulate a common network setup. Each server pre-loads 50K requests into its memory before the protocol starts. With $n = 5$ and $f = 2$, it takes merely 54 seconds for the honest loggers to achieve consensus. The time increases slightly to 71 seconds with two more honest loggers. When considering one more faulty node ($n = 7, f = 3$), the consensus process finishes after 208 seconds. This trend in performance is expected as more faulty nodes mean more rounds of message exchanges in the consensus routine. Assuming the loggers run instances of the protocol consecutively with input batches of size 50K, it will take roughly 2.5 hours to process

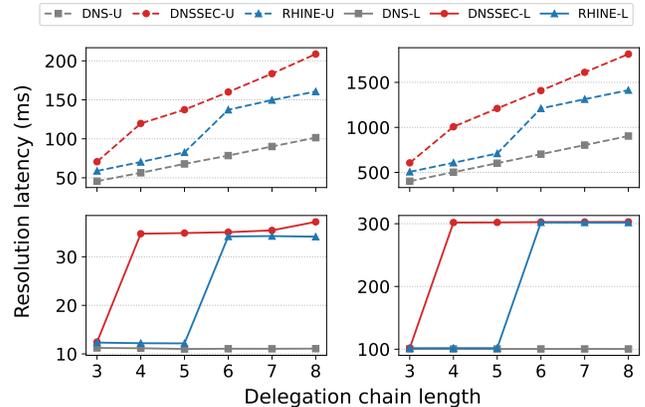

Figure 9: Upper and lower bounds of resolution latency under two network settings (left: RTT=10 ms; right: RTT=100 ms). The similar trends on the left and right plots suggest that network delay dominates the overall resolution latency.

2M requests. This meets the above-mentioned requirement for daily certificate issuance.

We observe that bandwidth is the determining factor for the overall performance, as the protocol runs n consensus routines in parallel. Yet, the bottleneck in our experiment setup is the memory size of individual servers, each of which needs to cache the input from all others. With more memory, the servers can exchange larger batches of requests. We can thus expect higher performance in a production environment with more powerful hardware.

Log Size. We estimate the DT log’s overall size by taking into account the DSums and DSAs of all zones as well as the GDA. The size is determined by the distribution of zone delegations. The number of children of each TLD is publicly known from domain registries (e.g., 159M for `.com`) [13], but zone enumeration is required to learn the exact number of children for SLDs and further subzones. Developing an accurate view of the global DNS delegation tree is a challenging task in itself, and we leave it for future work.

Our estimation uses the statistics collected by enumerating sample zones from the Tranco list [74] and assumes an exponential decay in delegation: on average, $x\%$ of all SLDs have 4 children (and the rest of them have no child), $x\%$ of all third-level domains have 3 children, and so forth. The DT log’s size is estimated to be 48GB with $x = 1$, 75GB with $x = 10$, and 779GB with $x = 50$ (which is likely an overestimation). This is only a fraction of the space requirement of CT logs, each of which can consume TBs of storage [5].

8.2 Name Resolution Performance

The second part of our evaluation investigates how E2E authentication affects name resolution performance from the perspectives of end users and naming service operators.

We compare RHINE with plain DNS and DNSSEC. For the

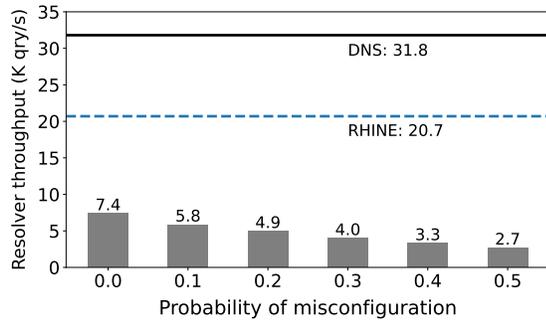

Figure 10: The resolver’s query processing capacity in different systems. For DNSSEC (data shown as bars), we vary the probability of inconsistency between a zone and its children.

latter two, we use the unmodified `CoreDNS` as the nameserver and `SDNS` as the resolver. For DNSSEC, we implement a validating client and modify `SDNS` to always return a complete authentication chain. For RHINE, we consider fast validation without membership proof as this covers the vast majority of cases (Section 5.4). The resolver is preloaded with a root zone key for DNSSEC and a CA certificate that is used to sign RCerts. The experiments used synthetic zone files populated with random resource records. Each record’s name contains one more label than its residing zone. All labels have a fixed length of 6, the average calculated from the Tranco list [74].

Resolution Latency. End users are sensitive to the latency of name lookup queries. We inspect the bounds of resolution latency as determined by the resolver’s cache. The upper bound is obtained when a resolver iteratively queries all the relevant nameservers for a non-cached record. The lower bound is obtained when a resolver returns an answer directly from its cache. We set up eight nameservers, which host a delegation chain of zones, one client, and one resolver. We run the experiments with two network settings: one with the RTT between the cloud servers expanded to 10 ms, and the other to 100 ms. The data reported for each experiment is averaged over 100 trials. Figure 9 depicts the results.

As can be seen, RHINE constantly outperforms DNSSEC, and its performance edge comes mainly from the savings in network communication. If a UDP message carrying a DNS response exceeds the size limit (512 bytes by default [35]), the client will retry the query using TCP. Since RHINE has fewer data authenticating records than DNSSEC, retransmission is triggered less frequently. This advantage is most pronounced in case of cache hits. RHINE can sustain its negligible cost over plain DNS for longer delegation chains than DNSSEC. The performance gap will further increase should more expensive cryptographic algorithms be used. In fact, most DNSSEC-signed zones still use RSA signatures [70], which are much larger than the Ed25519 signatures used in our evaluation.

Resolver Overhead. Since augmenting regular name resolution with E2E data authentication requires the most changes to a resolver’s behavior, we focus on analyzing the perfor-

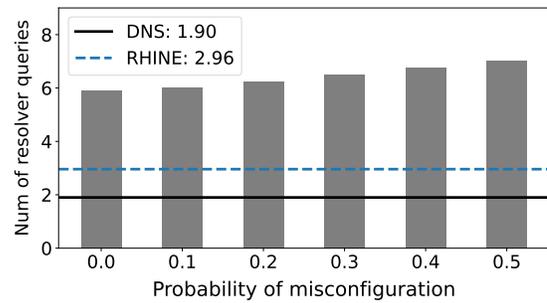

Figure 11: The average number of resolver queries per client request in case of cache miss. DNSSEC data is shown in bars.

mance overhead of a validating resolver. Our experiments use separate cloud servers for one client (running `dnstperf` [8] as the load generator), four nameservers each hosting a level of zones from the root to third-level zones (aka subdomains, which are common in modern cloud-based web services [45]), and one resolver under test. More specifically, we generate 15 TLDs each with 8K SLDs; each SLD further delegates to one third-level zone with one A record for a terminal name. The client’s query trace contains 480K names randomly sampled from the 120K terminal names. The resolver’s cache size is set as 100K¹ and the cache is warmed up by querying all terminal names once before each experiment. With this setup, we manage to maintain a typical cache hit ratio of around 80% for client queries [30, 56]. For DNSSEC, we simulate common security mismanagement that causes inconsistencies in authentication chains and hence validation failure [54], by programming the nameservers to return incorrect DS records with a given probability.

Figure 10 reports the resolver’s throughput in terms of the number of client queries processed per second. The results indicate that RHINE has a moderate impact on the resolver’s processing capacity, with a reduction of 34.9% in the overall throughput. Suffering from higher costs to retrieve and validate authentication chains, DNSSEC already reduces the throughput by 76.7% with successful validation and by even wider margins as the failure rate rises.

Figure 11 reports the average number of queries that the resolver sends to authoritative nameservers in case a client query cannot be directly answered from the cache. RHINE introduces roughly one additional query per client request (35.8% increase); this is attributed to the retrieval of RoA records (Section 7). DNSSEC increases the resolver’s query load by 2× even in the absence of validation failure. Such overhead is higher than expected and can be explained by the

¹SDNS has several cache instances for different purposes. What matter in our experiments are the primary PCache for A and RRSIG records as well as the NSCache for NS and DS records; for RHINE we have another RoACache. All their sizes are set as 100K. The only exception is that for the evaluation of DNSSEC we set the size of PCache as 190K, in order to maintain the 80% client query cache hit ratio for fair comparison. This is because SDNS also stores DNSSEC’s DNSKEY records in PCache. With this setup, our measurements show that for DNSSEC, half of all the attempts to look up DNSKEY records in PCache fail and thereby trigger extra queries.

contention between `DNSKEY` and `A` records in the cache.

Our measurement results suggest that a fine-grained cache design, which separates security-related records from regular records, is crucial to a validating resolver's performance.

9 Related Work

Authenticated Naming Services. Building a decentralized naming service over a peer-to-peer (P2P) network was first attempted by CoDoNS [75]. It adopts DNSSEC for data authentication and thus suffers from the same drawbacks. The GNU Name System (GNS) [14] is a modern incarnation of this idea. It allows one to define a zone using a unique key and create its own namespace rooted at the zone. However, when used for a global consistent namespace, GNS will establish a chain of trust similarly to DNSSEC with the same fragility problems. Deploying these radical systems is well recognized as a practical challenge [43]. In contrast, RHINE can be deployed on the existing DNS infrastructure.

Several projects use blockchain to design tamper-proof naming systems [9, 12, 55], but whether they can achieve the same level of performance and scalability as DNS remains open. Donovan and Feamster [38] propose to reduce the overhead of DNSSEC by letting resolvers trust each other for signed records, but this does not provide E2E authentication.

In an early position paper [39], Fetzer et al. re-purpose SSL certificates to sign DNS records, each with a separate certificate. Yet, the authors only sketched a preliminary scheme, without thoroughly exploring the challenges and large design space of authenticating DNS with the web PKI as we do.

DNS and PKI. The interplay between DNS and PKIs has a long history. DANE allows a DNS domain to certify its own certificates using DNSSEC [48]. To reduce the risk of users accepting misissued certificates, a domain can also specify the CA authorized by it using the CAA record [44]. A fundamental problem with these designs is that they move users' trust from CAs to DNS authorities. It is unlikely that the latter are more trustworthy, since they are not even in the security business as CAs are. RHINE does not simply reverse the flow of trust, i.e., relying on CAs for the authentication of name data, but rather creates a robust system where all authorities counterbalance each other's power over the namespace.

Transparency Logs. With the widespread deployment of CT, transparency logs have proven to be an integral part of modern PKIs. Many enhancements to their functionality, security, and performance have been proposed. CIRT [80] extends CT to store certificate revocation information. CTng [63] and Log-Picker [36] aim to relax the trust assumptions in CT by having multiple entities (loggers or monitors) attest log entries. DT's design also follows this generic approach. F-PKI [28] introduces a map server to provide a global view of all certificates and associated policies; this role is akin to a DT logger. New authenticated data structures are proposed to improve the efficiency of transparency logs [51, 84]. They can be potentially

incorporated into DT for performance improvement.

Formal Analysis of PKI. Bhargavan et al. formally model an early draft of the ACME protocol and discovered several attacks [24]. Our formal approach has also helped us identify many subtle flaws in RHINE's early designs. ARPKI [21] and DTKI [89] are PKI designs formally verified with Tamarin. Compared with them, RHINE involves more subtly interacting entities and hence is more challenging to model and verify.

10 Conclusion and Discussion

After much recent activity in the DNS space (e.g., discovery of new attacks, frequent service outages, and growing concerns about privacy), a window of opportunity is opening up for a fundamental re-design of DNS to achieve high levels of security. We revisit the existing security architecture of DNS through a modern lens, pinpointing the intrinsic limitations therein and proposing RHINE as our solution to these long-standing problems. It offloads the heavy and error-prone authentication task away from the client-facing side of DNS, enabling efficient authenticated name resolution all the way to end hosts. The deployment of RHINE can bootstrap the security of today's web PKI and Internet at large.

Deployment. We briefly discuss the incentives and costs for different entities to deploy RHINE. There is no doubt that the global Internet community shares a common interest for E2E-authenticated name resolution.

From the perspective of DNS zone owners and operators, RHINE can offer better security, lower failure rate and operational costs, and more robust naming services than DNSSEC; RHINE indeed requires fewer changes to their existing hardware and software, because it obviates the need to frequently maintain, distribute, and validate DNSSEC-style authentication chains in regular operation. The extra investments in operating the offline part of RHINE, which can be fully automated with our well-defined protocols similarly to ACME, are comparable to what is already required by the web PKI.

CAs are likely among the most enthusiastic proponents of RHINE, because the issuance of RCerts will significantly expand and consolidate their security services. The operators of transparency logs have the same motivations; DT loggers will be a select subset of CT loggers.

For end users, RHINE is easier to adopt than DNSSEC because they already rely heavily on the web PKI. For instance, the RCert-based data validation function can be easily integrated into web browsers, which have built-in support for name lookup (e.g., DoT and DoH) and certificate validation.

Acknowledgment

We would like to thank the reviewers and our shepherd, Matthew Caesar, for their valuable comments that help us substantially improve the paper. We gratefully acknowledge support from ETH Zurich, and from the Zurich Information Security and Privacy Center (ZISC).

```

Figure 12: Authenticated name resolution protocol.

A Protocol Specifications

A.1 Authenticated Name Resolution

RHINE's name resolution protocol is presented in Figure 12. It is agnostic to the underlying distribution infrastructure D , which can be instantiated, for example, with the existing DNS infrastructure (consisting of authoritative nameservers, recursive resolvers, forwarders, etc.) or a P2P network such as GNUet [14]. RHINE mandates that each answer to a client query contains, in addition to the authoritative resource records, the RCert and DSP of the zone that claims the authority, and that a client always validates answers by itself, thereby enforcing E2E authentication.

A.2 Secure Delegation Update

Figure 14 describes RHINE's secure delegation update protocol. An established zone uses its own RCert and the associated

0. Each $L_i \in \mathcal{G}$ has a set \mathcal{X}_i of requests ($lreq$) as input.
 1. Run n rounds of $O_i := \text{LogresConsensus}+(L_i, \mathcal{X}_i)$ with each L_i as the leader proposing input data in a round. After that, all loggers obtain the same set $O := \bigcup_{i=1}^n O_i$ as output.
 2. Each L_i filters the requests in O by keeping only the earliest one in case of conflicts, applies the resulting operations to its local GDA_T , and computes a new digest GAcc_{T+1} . Broadcast $\langle \text{GAcc}_{T+1} \rangle_{L_i}$ to \mathcal{L}
 3. Each L_i accepts and finalizes the aggregation result if it receives f valid signatures over GAcc_{T+1} .

Figure 13: DT aggregation protocol.

DSP to prove its realm of authority. The protocol's overall flow resembles the delegation setup process, except that the parent's involvement is needed only in a few cases.

A zone can freely update its RCert and DT entry within the validity period of the delegation. The parameter to update must not include a delegation expiration time beyond what is currently specified in the zone's DSUM. To extend the validity period before the delegation expires, a zone must negotiate with its parent (e.g., renewing the business contract) and get the latter's approval. Another type of update that requires the parent's consent is changing a non-independent zone to an independent one, as this affects the parent's realm of authority. The update of authority level is subject to additional restrictions. For example, a zone cannot change itself to terminating unless all its existing delegations become invalid (expired or revoked); similarly, a zone cannot change itself to end-of-independence if it still has any independent child. A zone can only update its delegation status (except its DAcc, which is affected by the changes to its subzones' delegation status) once per epoch. For ease of presentation, we abstract away these checks of an update request's legitimacy in the protocol specification.

It is possible for a zone to update the CA and loggers it relies on, which is important after security breaches of these trusted entities. In this case, the zone will run the update protocol with a set of new trusted entities.

The revocation of a secure delegation comes in two forms. Since RHINE mandates one RCert per zone at any time, the issuance of a new RCert for a zone implicitly revokes the old one. A zone can also make an explicit revocation request through the update protocol. This will fail the validation of the zone's data signed with its current RCert. The operation is irreversible, meaning that a revoked zone can only be re-established through the secure delegation setup protocol.

One caveat in enforcing one RCert per zone is that the loss of a zone's private key may lock up the zone until the existing delegation expires. This conundrum can be addressed by having a zone pre-generate a signed revocation request, preferably immediately after the delegation setup. The zone

Figure 14: Secure delegation update protocol (simplified). Messages and operations in square brackets [m] are optional.

can then revoke the existing delegation in case of key loss. Clearly, the pre-generated revocation request itself should be stored separately from the private key in a secure place.

A.3 DT Aggregation with Modified Logres

Figure 13 presents the DT aggregation protocol, with the core modified Logres consensus routine depicted in Figure 15. Logres obviates the need for leader selection by having each participating node lead and run an instance of the consensus routine in parallel with all others. Each consensus instance contains up to $f + 1$ rounds of message exchanges among the nodes, where f is the number of Byzantine faulty nodes tolerable by the system. In normal situations where the leader is honest and correctly operates, the consensus routine will terminate in just two rounds.

Our main modification of Logres is in lines 13–17 of Figure 15, which describes the additional data validation required by RHINE. Only valid input values will be added to the output set. Another important change is that we refine the algorithm to allow taking sets of values as input, as the original version abstracts the input data as a single value. This entails several technicalities including whether to have nodes' witness on valid values that may only constitute a subset of the input. For simplicity, we always treat the witnesses on the original input set even if it may contain invalid data. This results in redundant data validation in each round. Optimizing performance in this regard is an interesting future work.

The final output set O from the consensus process may contain duplicate or conflicting operations as a result of attacks (when RHINE's threat assumptions are violated; see Section 6) or operational faults. For example, two requests may contain different parameters to create a new log entry for a just delegated zone. This is possible because there is a delay for the DT log to be synchronized across loggers. In such

situations, the loggers will keep the earliest operation and discarding other conflicting operations for the zone in question; any potential attacks and faults will become detectable once the current execution of the aggregation protocol ends.

B Formal Verification of RHINE

This section introduces important aspects of our formal specification of RHINE and the security properties we verify. We refer the reader to the project repository [78] for full details.

Abstractions. The formalization of non-trivial protocols using Tamarin can run into the state explosion problem, which makes the analysis intractable. To this end, we use several abstractions to reduce the complexity of our model while still faithfully capturing the essence of RHINE protocols.

First, rather than modeling the entire namespace, we focus on a few zones represented symbolically that suffice to describe generic zone delegation. This includes a parent zone that can be malicious, a child zone in question (i.e., ZN_x in Theorem 1 and 2), and another child zone (of the same parent) serving to validate our model's correctness. We consider all of them to be independent zones for meaningful a security analysis. This also obviates the need to model the processing of authority level.

For the time dimension, we model three epochs. In T_0 , the pre-established parent zone can publish data for name resolution and approve delegation requests. Only one child zone can be delegated in T_0 and the other in T_1 ; the first child zone can also be updated in T_1 . Zone delegation or update is not permitted in the last epoch T_2 . These symbolic epochs are intended to enforce the sequence of events and they are not necessarily consecutive. This arrangement allows the model to capture security threats throughout a zone's life cycle.

For the DT aggregation process, we model only RHINE-specific input validation without specifying the Logres con-

```

0. This is one of the  $|\mathcal{L}|$  parallel runs of the consensus
   process with  $L_i$  being the leader. The code is for  $L_j$ .
1. If  $j = i$ :
2.   broadcast  $\langle X_i, L_i \rangle_{L_i}$  to all other loggers
3.   return  $O_i := X_i$ 
4. Else:
5.    $\mathcal{W} := \emptyset$  // witnessed values
6.    $O_i := \emptyset$  // agreed-upon output
   // Start  $f + 1$  rounds of message exchanging
7.   For round  $r = 1, \dots, f + 1$  :
   // A timeout is needed to stop waiting for the mes-
   // sages from faulty nodes.
8.      $\mathcal{M} :=$  received messages
9.      $\mathcal{V} := \emptyset$  // valid input values
10.    For  $\langle X, L_i \rangle_{L_W} \in \mathcal{M}$ 
   // Logres-specific checking
11.      If  $|\mathcal{L}_W| \geq r \wedge \Sigma.Vf(pk_{L_W}, \langle X, L_i \rangle_{L_W})$ 
12.         $\mathcal{Y} := \emptyset$ 
   // RHINE-specific data validation.  $A, L_c$  are from  $op$ 
13.      For  $lreq \in X$  :
14.         $lreq := \langle \text{LogReq}(L, op, attset) \rangle_A$ 
15.        If  $\Sigma.Vf(pk_A, lreq) \wedge L = L_i$ 
            $\wedge \Sigma.Vf(pk_{L_c}, attset)$ 
            $\wedge \text{Match}(op, attset)$ 
16.           $\mathcal{Y} := \mathcal{Y} \cup \{lreq\}$ 
17.         $\mathcal{V} := \mathcal{V} \cup \{\mathcal{Y}\}$ 
   // Continue Logres processing on valid RHINE input
18.    If  $\mathcal{V} \setminus \mathcal{W} \neq \emptyset$ :
19.      If  $|\mathcal{V} \cup \mathcal{W}| = 1$  :
20.         $O_i := \mathcal{V}$  // Only one element in  $\mathcal{V}$ 
21.      Else :
22.         $O_i := \emptyset$  // No agreed-upon value yet
23.       $\mathcal{N} := \emptyset$  // Messages for next round
   // Add witness to the original input
24.    For  $\mathcal{Y} \in \mathcal{V} \setminus \mathcal{W}$  :
25.      Find  $\langle X, L_i \rangle_{L_W} \in \mathcal{M}$  s.t.  $\mathcal{Y} \subset X$ 
26.       $\mathcal{N} := \mathcal{N} \cup \{\langle X, L_i \rangle_{L_W \cup \{L_j\}}\}$ 
27.      multicast  $\mathcal{N}$  to all non-leader loggers
   // Update witnessed value
28.     $\mathcal{W} := \mathcal{V}$ 
   // In the end of this protocol run, all honest loggers
   // will have the same  $O_i$ , which contain all valid log
   // operations as a subset of  $X_i$ .
29.   return  $O_i$ 

```

Figure 15: The $\text{LogresConsensus}^+(L_i, X_i)$ protocol.

sensus routine, as its security has been formally verified by its authors [86] and is inherited by our enhanced version. For the update protocol, we consider updating the certified key as well as the designated CA and loggers without the need for parental approval. This reflects a zone owner’s ability to independently manage the zone’s security.

We refrain from modeling explicit servers and the name resolution algorithm, as this would result in a overcomplicated model. Instead, we create an abstract distribution infrastructure by taking advantage of Tamarin’s underlying pattern matching mechanism. Moreover, we represent all data structures (RCerts, DT log, resource records, etc.) as sets of values and omit non-essential data such as Aux.

B.1 Protocol Specification

Tamarin models a security protocol as a labeled transition system (LTS) where a state of the LTS consists of the local states of the protocol participants, the adversary’s knowledge, and messages on the network. States are modeled as a finite multiset of *facts*. The system’s dynamics are specified by labeled multiset rewriting rules that transform the facts.

Protocol Roles. Our model introduces five roles: P is the owner of an established parent zone, C is an entity wishing to securely establish a child zone, CA is an RCert issuer, L is a DT logger, and U is an end user trying to resolve a name under a child zone. The state space of a protocol in a symbolic Tamarin model generally grows exponentially with the number of involved actors, which are instances of roles in interleaved protocol sessions. We model P as a singleton that is instantiated only once. No limitation is imposed on other roles. RHINE allows a zone to choose the number m of relying loggers. We set $m = 2$ for all zones in the model. This keeps the complexity of verification manageable without weakening the security properties we verify. The other parameters f and n are irrelevant in the model because of the simplified aggregation process.

Adversary. Tamarin provides a built-in network model with a Dolev-Yao adversary: any outbound message is added to the adversary’s permanent knowledge; any inbound message is constructed by the adversary from its knowledge. We leverage this feature to create an adversary-controlled distribution infrastructure without any explicit servers: publishing a zone simply means sending its signed records to the network, and name resolution is realized by sending a query to and receiving the matching record (and associated RCert and DSP) from the network. To model the compromise of an entity, we reveal its private key to the network, which enables the adversary to impersonate the entity by forging its signatures. We also allow malicious child zone owners so that the adversary’s capability is not limited by the model itself.

Protocol Rules. We use several example rules to explain our modeling style and choices. Figure 16 lists two rules modeling the CA’s processing of an initial request in the secure delegation protocol. A rule is defined in the form of

$$[\text{state facts}] \text{ --} [\text{event facts}] \text{ -->} [\text{state facts}].$$

(premise) (conclusion)

The lines in a `let ...` in block defines macros that are expanded in the respective rule.

```

```

Figure 16: Two rules from our model describing the CA's actions in Step 7, Figure 6

A fact $F(t_1, t_2, \dots)$ involves symbolic terms t_1, t_2, \dots that contain variables, constants, functions, network messages, etc. The execution of a rule consumes facts in the LTS's current state that match the rule's premise, and produces new facts that are added to the state. Persistent facts of the form $!F(t_1, t_2, \dots)$ are never removed from the state, once added. A public variable $\$t$ (often used to identify an actor) or a constant $'t'$ is always known to the adversary. A fresh variable $\sim t$ is typically used to model random numbers such as keys. We use several Tamarin's built-in functions, including pair ($\langle t_1, t_2 \rangle$), hashing ($h(t)$), and signing ($sign(t_1, t_2)$) and $verify(t_1, t_2, t_3)$). We also defined our own functions including $zone(t)$, $name(t)$, and $epoch(t)$. Although we use them to simply record constants in our current model, it is possible to introduce equational theories for them to capture a hierarchical naming structure and unlimited epoch transition.

The rule `CA_Preissuance_1` models $\$CA$ receiving a secure delegation request from $\$C$ over the insecure network using Tamarin's built-in `In()` fact. Facts `!CA_St_0()`, `CA_St_1()` record $\$CA$'s local state. `!ZPk_P()` models the access to the parent zone's public key. The event facts `Eq()` and `NotEq()` specify equality and inequality checks using Tamarin's *restriction* mechanism. We apply them to model the bulk of an actor's local processing of a message, including signature verification and consistency checking. According to the protocol specification (Figure 6), the CA needs to re-

trieve the parent zone's DSP from the designated loggers over an out-of-band secure channel. The facts `DSPReq()` and `DSPResp()` model such a channel. At the end of the rule `CA_Preissuance_1`, the CA makes a retrieval request with a random id generated using the built-in fact `Fr()`.

In the rule `CA_Preissuance_2`, the CA continues to verify the received DSP and send out a pre-logging message over the insecure network using the built-in `Out()` fact. Event facts such as `CAPreissued()` there facilitate the definition of properties in a model-independent way.

One of the most important event facts we consider is `ZoneDelegated()`, which signifies the successful establishment of a child zone. It should not be placed at the last step of the secure delegation protocol, but where the zone owner has verified the updated DT log (within the distribution window of an epoch). Our model precisely captures this consideration in the rule `Child_Accept_T0` shown in Figure 17.

A zone delegated in an epoch can publish its data in the subsequent epochs. To model this, we introduce a linear fact `ZonePublishable()` that allows a zone to publish at most once in an epoch. The rule `Child_Accept_T0` states that a zone delegated in T_0 can publish once in T_1 and once in T_2 . The parent zone is initialized in T_0 and so it can publish in all three epochs.

The reason why we model three epochs instead of two is to cover the scenario where an attacker attempts to acquire an `RCert` in T_1 for a zone delegated in T_0 . Such an attack sce-

```

rule Child_Accept_T0:
  let // The following are macros used to improve the specification's readability

  , ZonePublishable(epoch('T2'), zone, $C, ~zskC, rcert) ]

```

Figure 17: A rule modeling the child zone owner's acceptance of an RCert in epoch T0.

nario is different from acquiring an RCert for a non-existent child zone of an existing zone. The former case is captured by Theorem 2 and the latter case by Theorem 1.

As mentioned, our model uses constants to encode zones and names. There must be a way to specify the relations between them. We employ a few hard-coded rules and restrictions to model and enforce a hierarchical name structure.

```

rule Zone_Record_Generator_CX:
  [ GenRecord(zone('ChildX')) ] --[]->
  [ Record(zone('ChildX'), name('NameX')) ]

```

```

restriction Naming_Structure:
  "All z n #i.
  NameInZone(z, n)@i ==>
  (z = zone('Parent') & n = name('NameX')) |
  (z = zone('ChildX') & n = name('NameX')) "

```

These two rules state that the name 'NameX' is under both zone 'Parent' and zone 'ChildX', and both of them can publish records for the name. This allows the model to capture attack scenarios where a malicious parent zone serves bogus

records for an existing child zone.

B.2 Property Specification

In Tamarin, the execution of a protocol generates a *trace*—a sequence of event facts, associated with timepoints, from rules triggered during the execution. A trace property is a set of traces defined using guarded first-order logic formulae over event facts and timepoints (denoted as terms of the form $\#t$). We specify the security theorems introduced in Section 6 as trace property (defined using keyword `lemma`) shown in Figure 18. The formal specification is self-explanatory with the event facts serving as predicates that encode the informally presented theorems. We discuss a few technicalities.

Using the `Compromised()` fact, we can flexibly configure the adversary's capabilities. The adversary by default has the \mathcal{A}_1 capability and can compromise any actor except an entity requesting the delegation for a child zone. Not allowing the compromise of the parent zone owner and at least one of the designated loggers leads to an $\mathcal{A}_1 + \mathcal{A}_2 + \mathcal{A}_3$ attacker. Imposing only the latter constraint gives the adversary the $\mathcal{A}_1 + \mathcal{A}_2 + \mathcal{A}_3 + \mathcal{A}_4$ capabilities.

In the lemma `E2E_Authenticity`, we do not specify the order of the event `ZoneDelegated` and `UserAccept`, as the order is implied by the epochs they occur, i.e., the latter hap-

```

lemma Delegation_Security:
  "All epoch zone P C zskC
    CA L1 L2 #i1 #i2.
    ( RCertRequested(epoch, zone, P, C,
      zskC, CA, L1, L2)@i1
    & ZoneDelegated(epoch, zone, P, C,
      zskC, CA, L1, L2)@i2
    & not (Ex #j. Compromised(P)@j & j<i2)
    & ( not (Ex #j. Compromised(L1)@j & j<i2)
      | not (Ex #j. Compromised(L2)@j & j<i2)
    )
  )
  ==>
  ( Ex #k. SDApproved(epoch, zone, P,
    C, pk(zskC), CA, L1, L2)@k
    & k < i2 ) "

lemma E2E_Authenticity:
  "All P czone C_0 epoch zone U qid qname #i1 #i2
    zskC_0 CA_0 L1_0 L2_0 zskC CA L1 L2.
    ( ZoneDelegated(epoch('T0'), czone, P, C_0,
      zskC_0, CA_0, L1_0, L2_0)@i1
    & UserAccept(epoch, zone, U, qid, qname,
      pk(zskC), CA, L1, L2)@i2
    & (epoch = epoch('T1') | epoch = epoch('T2'))
    & not (Ex #j. UpdateLogged(epoch('T1'),
      czone)@j)
    & ( not (Ex #j. Compromised(L1)@j & i1<j) |
      not (Ex #j. Compromised(L2)@j & i1<j) ) )
  )
  ==>
  ( zone = czone & zskC_0 = zskC
    & CA_0 = CA & L1_0 = L1 & L2_0 = L2 ) "

```

Figure 18: The specification of Theorem 1 (left) and Theorem 2 (right) we proved for RHINE.

pens only in T1 and T2. For the adversary, we do not limit its capabilities in epoch 0, which ends at $i1$ when the concerned zone $czone$ is delegated. This does not affect security analysis, because our model allows only one zone to be delegated per epoch and disallows the adversary to obtain a child zone owner’s private key.

To capture the update protocol’s security, we also formalize the following property. It states that once a zone is delegated, its RCert (in particular, the certified key $zskC_1$ and trusted entities $C1_1, L1_1, L2_1$) can be updated only by the zone owner generating a signed request using the genuine key ($zskC = zskC_0$), even if an $\mathcal{A}_1 + \mathcal{A}_2 + \mathcal{A}_3 + \mathcal{A}_4$ is present after the initial delegation setup.

```

lemma Update_Security:
  "All P C_0 zskC_0 CA_0 L1_0 L2_0 #i1
    C_1 zskC_1 CA_1 L1_1 L2_1 #i2
    zone zskC.
    ( ZoneDelegated(epoch('T0'), zone, P,
      C_0, zskC_0, CA_0, L1_0, L2_0)@i1
    & ZoneUpdated(epoch('T1'), zone,
      C_1, zskC, zskC_1, CA_1, L1_1, L2_1)@i2
    & (not (Ex #j. Compromised(L1_1)@j & i1<j) |
      not (Ex #j. Compromised(L2_1)@j & i1<j))
    )
  )
  ==>
  ( Ex #i3. UpdateRequested(epoch('T1'), zone,
    C_1, zskC, zskC_1, CA_1, L1_1, L2_1)@i3
    & zskC = zskC_0
    & i3 < i2 ) "

```

All these properties are defined over *all* traces. Tamarin also supports proving lemmas that hold when there *exists* a fulfilling trace. This is commonly used for sanity checks of the specification. We have defined multiple such lemmas to test whether our model implements the expected semantics. The following example checks whether the parent zone can legitimately serve records in T0 when no child is delegated.

```

lemma Normal_Resolution_Parent_T0:
  exists-trace
  "Ex P zpk CA L1 L2 U
    qid qname #i1 #i2 #i3.
    ParentInit(zone('Parent'), P, zpk,
      CA, L1, L2)@i1
    & UserSentQuery(U, qid, qname)@i2
    & UserAccept(epoch('T0'), zone('Parent'),
      U, qid, qname, zpk, CA, L1, L2)@i3
    // no compromise of any actor
    & not (Ex A #k. Compromised(A)@k) "

```

C Achieving High Availability

DNS is a frequent target of (distributed) DoS attacks [58]. A massive DNS outage can make a wide swath of online services unavailable, for example the historic Facebook outage in October 2021. By decoupling the authentication and distribution of a naming system’s data (see Section 3), RHINE also separates the concerns of data authenticity and service availability, allowing them to be addressed independently.

One promising direction to ensure the naming service’s availability, even amid large-scale DDoS attacks, is to protect the distribution infrastructure with SCION [73], a next-generation secure Internet architecture. With an array of orchestrated mechanisms, including high-speed packet (source) authentication, traffic monitoring and filtering, as well as lightweight bandwidth reservation, SCION can defend against all types of network-level DoS attacks that target network links and nodes and end hosts, offering guaranteed control-plane operation and data delivery. SCION has seen real-world deployments with proven scalability and performance [59].

We plan to deploy RHINE in SCIONLab [60], a full-fledged global Internet testbed, and thoroughly evaluate its practicality, usability, and availability against DDoS attacks.

Enabling Users to Control their Internet

Ammar Tahir, Radhika Mittal
University of Illinois at Urbana-Champaign

Abstract

Access link from the ISP tends to be the bottleneck for many users. However, users today have no control over how the access bandwidth (which is under the ISP’s control) is divided across their incoming flows. In this paper, we present a system, CRAB, that runs at the receiver’s devices – home routers and endpoints – and enforces user-specified weights across the incoming flows, without any explicit support from the ISP or the senders. It involves a novel control loop that continuously estimates available downlink capacity and flow demands by observing the incoming traffic, computes the max-min weighted fair share rates for the flows using these estimates, and throttles the flows to the computed rates. The key challenge that CRAB must tackle is that the demand and capacity estimated by observing the incoming traffic at the receiver (after the bottleneck) is inherently ambiguous – CRAB’s control loop is designed to effectively avoid and correct these ambiguities. We implement CRAB on a Linux machine and Linksys WRT3200ACM home router. Our evaluation, involving real-world flows, shows how CRAB can enforce user preferences to achieve $2\times$ lower web page load times and $3\times$ higher video quality than the status quo.

1 Introduction

This paper tackles a common and seemingly simple problem: how can users control how their Internet access link gets shared across their incoming flows? For instance, how can a user ensure that their Youtube video streaming is not impacted when the Dropbox app on their device starts downloading large files at the same time, and the two flows compete at the user’s Internet access link?

At a glance, a plausible solution is to exploit the traffic shaping features provided in many home routers (e.g. mechanisms for weighted fair queuing or prioritization) [1, 15, 18]. However, these mechanisms are effective only when the bottleneck is at (and queues build up at) the home router – this happens when the bottleneck is the uplink from the router to the Internet Service Provider (ISP) for outgoing flows or the downlink from the router to the end-devices for the incoming flows [1]. Our work targets a different problem as illustrated in Figure 1, where the bottleneck for the incoming flows is the downlink from the ISP to the home router, and queues build up in the ISP. This is a common scenario [36, 50], with the Internet access bandwidth being governed by contractual agreements between an end-user and their ISP, and the median broadband download speed being less than 35Mbps in more than half the countries worldwide [3].

Existing literature provides us with two options for man-

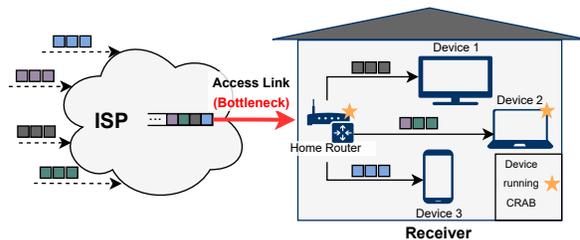

Figure 1: CRAB’s Target Scenario. The user may own multiple devices, each downloading multiple flows over the Internet. These flows arrive at the user’s home router via the access link from the ISP, from where they get routed to individual devices. The Internet access link is often the bottleneck for the incoming flows [3, 36].

aging flow shares at the Internet access link, both of which are beyond the receiving user’s control. The first option is to directly schedule or shape traffic at the bottleneck (e.g. via prioritization or weighted fairness) [17, 25, 43, 49]. However, the access bottleneck is controlled by the ISP. ISPs are unaware of user preferences and do not deploy any mechanisms that enable end users to configure how their traffic is scheduled and shaped at the access bottleneck.¹ The second option is for the senders to appropriately control the rate at which flows arrive at the bottleneck. For example, low-priority senders can use “scavenger” protocols that yield bandwidth more readily to higher priority flows [34, 38, 41, 48]. This is again outside the receiving user’s control – it is up to the sender to use and configure such protocols.

We design a system, CRAB,² that enables users (receivers) to control how their Internet access bandwidth gets shared across their incoming flows without any explicit support from external entities (i.e. the ISPs and the senders). Here we use the term receiver to collectively refer to devices in the receiving domain that an end user can directly access and configure – these include end devices (phones and computers) as well as home routers (attached to the access link). More generally, CRAB provides a mechanism to control flow shares exclusively from a vantage point that is topologically placed *after* the bottleneck – where queues don’t build up naturally, and where one has seemingly zero control.

CRAB allows a user (i) to configure the home router with weights across each end-device, and (ii) to optionally configure end-devices with weights across their incoming flows

¹Although a few research proposals of this form exist [19, 24, 27, 35, 54], they have not been realized in practice, given the inherent difficulty of coordinating across multiple domains.

²For Customizable Receiver-driven Allocation of Bandwidth.

(defined based on application, web domain, etc). It then strives to throttle the incoming flows at the home router (grouped by destination device) and individually at the end devices (if enabled) to their respective *max-min weighted fair share rates*. CRAB's key challenge lies in correctly computing these rates after the bottleneck (as discussed below). While this after-the-bottleneck throttling cannot *directly* control how the access bandwidth is divided across the incoming flows, it signals the senders (which typically run some form of congestion controller [22, 26, 30, 32, 39, 46, 52]) to lower their sending rates to the throttled values, thus enabling the flows to eventually converge to their desired shares.

So what makes it difficult to compute the weighted fair share rates after the bottleneck? Given flow weights, computing the correct (max-min) weighted fair rates for each flow requires knowing the bottleneck link capacity and the flow demands. Once the absolute weighted share of a flow has been computed from the link capacity and flow weight, the max-min weighted fair rates can be computed by re-allocating any excess capacity, that is unused by flows with demands smaller than their absolute share, to other flows in the proportion of their weights. While the capacity and the flow demands are naturally available at the bottleneck, CRAB (placed after the bottleneck) must estimate them by observing the incoming traffic at the receiver. This introduces multiple challenges:

- (1) It is not possible to distinguish whether the total traffic observed at the receiver is limited by the access link capacity or by the flows' cumulative demands – the latter would result in underestimating capacity.
- (2) The arrival rate of a flow at the receiver depends on the rate at which it was served at the bottleneck. A flow that got a small share of bandwidth at the bottleneck (less than its weighted share or demand) could be wrongly perceived as having low demand.
- (3) If the receiver incorrectly throttles flows to rates lower than their weighted shares (due to spuriously low capacity or demand estimates), the flows' sending rates (and their observed arrival rates at the receiver) would end up matching the throttled rates. As a result, the link capacity and demand estimates would stay unchanged and the system will not self-correct. Similar reasoning makes it difficult to adapt to an increase in link capacity and flow demands.

The centerpiece of CRAB is a control loop that is designed to tackle the above challenges (§3). It continuously loops between (i) measuring flow arrival rates (over timescales of hundreds of milliseconds) to estimate link capacity and flow demands, and (ii) re-computing and enforcing weighted fair-share rates based on these estimates. By waiting for rates measured over long enough timescales before reacting, CRAB avoids fast reaction to spuriously low demand estimates – it allows for the impact of any flow throttling to kick in, and for the sending (and observed) rates for the remaining flows to grow to their true demands (or weighted shares), before reallocating any unused capacity. When re-allocating capacity

from a flow with low demand, CRAB leaves some headroom to detect growing demand, at which point it immediately reclaims all of the flow's re-allocated bandwidth, again allowing the flow to grow to its true demand or its weighted share. To self-correct capacity underestimation, it periodically probes for more bandwidth by explicitly increasing the total rate assigned to flows and checking for any consequent increase in observed rates.

CRAB runs the same logic at the home router and at the end-points, without requiring any explicit coordination among them. CRAB at the home router enforces per-device shares based on estimated access link capacity and per-device demands. CRAB at the end-point independently adapts its capacity estimate to the per-device rate enforced by the home router and controls per-flow shares. When directly attached to the ISP's link (without a home router) or when the router and end-device are owned by different entities (e.g. in airports, cafes, etc), an end-device with CRAB enabled can self-sufficiently enforce its desired shares across its incoming flows.

CRAB's cautious re-allocation of unused capacity can leave the bottleneck link under-utilized at times. As we illustrate in §2, some amount of link under-utilization is inevitable when shaping traffic *after* the bottleneck (maximally utilizing the link would imply no flow gets throttled at the receiver, and consequently no impact on how the bottleneck bandwidth is shared). The link under-utilization with CRAB typically manifests as transient dips in the throughput for lower priority (throttled) flows, below their max-min weighted shares. This is a reasonable price to pay for better performance for higher priority traffic that is achieved by enforcing user-specified flow shares with CRAB.

We implement CRAB (§4) on a Linux endhost and a Linksys WRT3200ACM router. Our end-host implementation also includes hooks for classifying flows that are broadly defined by users based on applications and web domains, and involve cross-origin requests (e.g. to CDNs and ad networks). Our experiments involving real-world flows with different sender-side congestion controllers (YouTube videos, web browsing, and bulk downloads), show how CRAB comes close to achieving the desired weighted fair share rates. In particular, CRAB achieves 2.5-3× higher video quality and 2× lower web page load times in presence of lower-priority bulk flows than the status-quo (that cannot enforce desired preferences), with 10-20% decrease in overall link utilization.

2 Overview

CRAB enables the user to manage how their Internet access link (that is often the bottleneck for downloads [3, 36]) gets shared across the incoming flows. Figure 1 illustrates a typical target scenario. CRAB at the home router controls how the access bandwidth is shared across traffic destined to each end-device. CRAB at the end-device (if enabled) controls how its router-enforced bandwidth share is divided across its incoming flows. Note that all end devices need not run CRAB

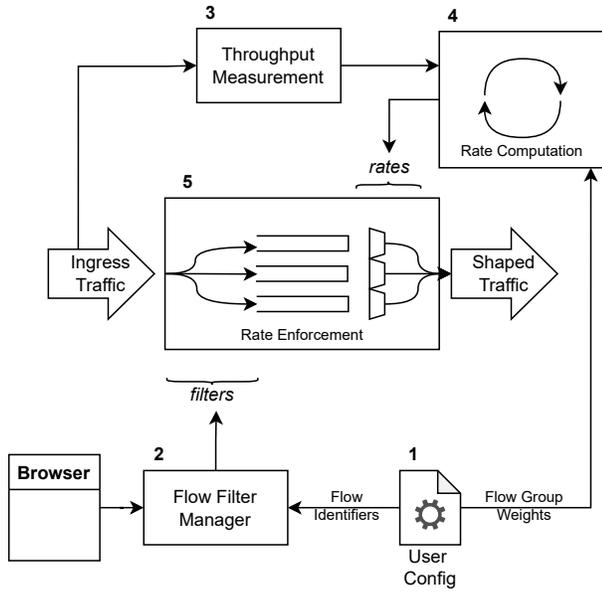

Figure 2: CRAB’s high-level workflow (detailed in §2.1).

– only an end device that wishes to control the bandwidth sharing across its own flows needs to enable CRAB.

2.1 CRAB Framework

We provide an overview of the CRAB framework at the end-device (noting the small differences in CRAB’s router design towards the end). CRAB sits in front of the ingress interface, where it intercepts and shapes the incoming traffic before forwarding it to the kernel’s TCP/IP stack. Figure 2 shows the key elements in CRAB’s architecture.

1. User Interface. Our current prototype allows users to define flows based on three criteria: (i) all traffic destined to a specified application running on the end-device, (ii) all traffic associated with a specified web-domain, and (iii) all traffic originating from a specified source address.³ The user can group multiple flows into a flow-group, and specify a weight for each flow-group. Users can also specify a weight for a default flow group, where traffic not classified in any other flow group is mapped. Henceforth, we use the terms flow and flow-group interchangeably.

2. Flow Filter Manager. It maps high-level flow identifiers (as specified by the user) into TCP/IP header fields that the system can use to classify packets as and when they arrive at the interface. Mapping a web-domain into header fields requires some inputs from the browser (we detail this in §4).

3. Throughput Measurement. CRAB sniffs the incoming traffic to measure (i) throughput of each flow group to estimate demands, and (ii) the cumulative throughput over all flows to estimate link capacity. The link capacity estimated by CRAB at the end-device corresponds to the device’s bandwidth share as enforced by the home router.

4. Rate Computation. CRAB computes weighted fair share

³Future extensions of our system can support more criteria.

rates for each flow, based on user-specified weights and the capacity and demand estimates obtained from flow throughput measurements (as detailed in §3).

5. Rate Enforcement. CRAB uses the mappings from the flow filter manager to classify incoming traffic into user-defined flow groups. It puts the traffic for each group into separate queues, and throttles each queue to its computed weighted fair share rate. Since CRAB throttles traffic *after* the bottleneck, it cannot *directly* control how flows are scheduled at the bottleneck. However, it induces packet losses and queuing delay at the receiver, which signals the senders to adjust their rates to the throttled value, thus eventually achieving the desired bandwidth shares at the bottleneck.

We considered a few other alternatives for signalling sending rates from the receiver, e.g. by adjusting TCP receive windows. We decided to use throttling for rate enforcement because of its generality – all senders that run some form of congestion controller (either over TCP [22, 26, 30, 32, 52] or UDP [39, 46]) would naturally react to queue buildups and/or packet drops induced by throttling.

CRAB framework at the home router is same as that at the end-device. The only difference is that since users configure the home router with weights across each end-device (directly identified by the destination IP address), an explicit flow filter manager is not required.

Note that, in principle, one could have managed flow-group shares directly at the home router, instead of the end-device. But then classifying the incoming traffic based on flow-groups at the router would have required explicit coordination with the applications running at the end-device in real-time (as explained in §4), which would have complicated system deployment. Our current division of functionality between the home-router and end-points requires no explicit coordination among them, which greatly simplifies CRAB’s deployment and use, and extends CRAB’s utility to other contexts beyond home users (as discussed in §7). It also reduces computational complexity at the router, with the router managing only per-device queues, and each device then managing the rates for their own flows.

2.2 Goals and Challenges

We use a series of experiments to illustrate some of the challenges that CRAB must tackle. We consider a scenario where a Linux end-host is directly attached to the access link from the ISP (without a home router). For repeatable experiments, we emulate an ISP-controlled access link by routing all traffic for the end-host via a router that mimics the ISP and throttles the traffic to 30Mbps. When we only stream a 4K YouTube video on the end-host, we find that the video quality stays at the maximum level (Figure 3a). We then stream the same video in presence of two long-lasting bulk downloads⁴ over

⁴Bulk downloads of games and movies are fairly common among users with limited bandwidth because of inaccessibility of high quality video streaming or cloud gaming [29, 31].

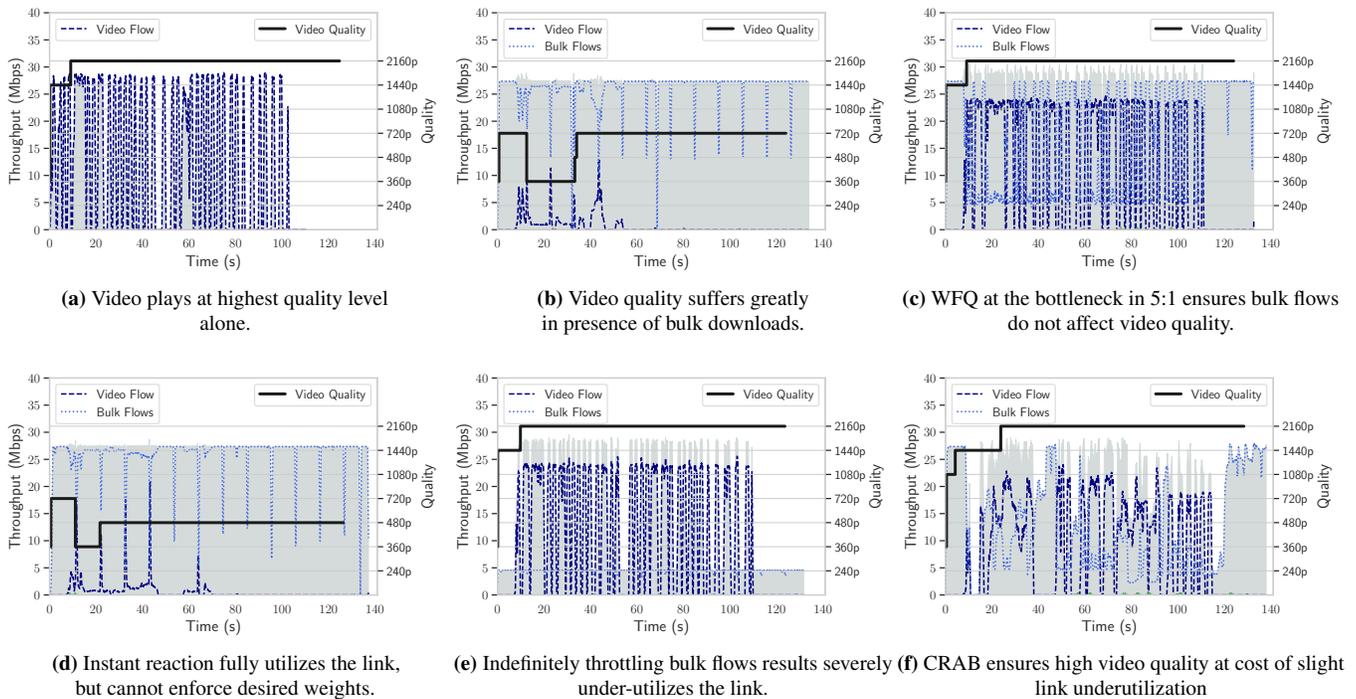

Figure 3: Video quality suffers in presence of bulk download flows, we look at different possible ways to ensure this does not happen. In all experiments, link bandwidth is set to 30 Mbps.

the Internet, and evaluate the results under different settings. **Status Quo.** Today, there is no way for a user to enforce how their access bandwidth gets divided across their flows. We find that with the bulk downloads consuming a large share of the access bandwidth, the status-quo achieves very low video quality (Figure 3b).

This degradation in video quality is clearly undesirable and can be mitigated if the user can specify and enforce a higher weight (say $5\times$) for the video flow.

Impractical Ideal: WFQ at the bottleneck. We next model the ideal, but impractical scenario where the ISP enforces user preferences at the bottleneck via WFQ. For this, we configure the router in our setup (that mimics the ISP) to use weighted deficit round-robin (DRR) [49], with the video flow to bulk flows ratio set to 5:1. As shown in Figure 3c, the video flow is able to use its absolute share of 25Mbps, and achieve the highest video quality, while bulk downloads get at least 5Mbps. WFQ is *work-conserving* – whenever the video flow consumes less than its share of 25Mbps (e.g. when its playback buffer is full), the remaining capacity is used by the bulk downloads, keeping the link maximally utilized.

Impossible to mimic WFQ after the bottleneck. CRAB strives to mimic the ideal WFQ-enforced rates. However, while WFQ at the bottleneck can achieve both desired bandwidth shares and maximal link utilization, there is an inherent trade-off between the two when shaping traffic *after* the bottleneck. We highlight this trade-off by illustrating two extreme strawmen for rate computation at the receiver.

(i) *Work-conserving re-allocation cannot enforce weighted fairness after the bottleneck.* In order to maximally utilize the link, whenever the video flow’s demand becomes less than its absolute share, any unused capacity should be explicitly reallocated to the bulk flows. It is natural to use the arrival rate of the video flow at the receiver as an estimate of its demand. However, if the video flow gets a small share of bandwidth at the bottleneck due to competing flows, it will have a low arrival rate at the receiver and will be incorrectly perceived as having low demand. We now evaluate the effects of instantaneously re-allocating unused capacity based on such spurious demand estimates.

For this, we configure the end-device to use Linux HTB (Hierarchical Token Bucket) [5] to throttle the incoming flows to their absolute shares (25Mbps for video and 5Mbps for bulk), and enable HTB’s “bandwidth borrowing” feature which immediately re-allocates any capacity that is unused by a flow with a smaller arrival rate. Since the total arrival rate at the receiver is already capped by bottleneck link capacity, such instantaneous re-allocation induces no throttling – while this achieves maximal link utilization, it cannot enforce desired bandwidth shares and produces the same outcome as the status-quo (Figure 3d). For the setup in Figure 1, enabling WFQ for the incoming flows at the home router (after the bottleneck), will produce the same effect.

More generally, maintaining maximal link utilization is fundamentally at odds with CRAB’s mechanism of enforcing desired rates. In order to signal any change in the sending

rates, CRAB must throttle some flows at the receiver – the link under-utilization thus induced is what gives room to the remaining flows to grow to their true demands or absolute weighted shares.

(ii) *No re-allocation leads to severe under-utilization.* At the other extreme, indefinitely throttling bulk flows to their absolute weighted fair rates, oblivious of video flow demand estimates, allows the video flow to grow to its true demand and ensure high video quality, but decreases the link utilization by 46% compared to the status quo (Figure 3e).

CRAB achieves desired shares with high link utilization.

CRAB navigates the above trade-off by re-allocating unused capacity more cautiously (at timescales of a few hundred milliseconds) – this allows the impact of any throttling to kick in, and for the flows to grow to their true demands or absolute shares, before the unused capacity is re-allocated. For flows consuming less than their absolute shares, CRAB provisions for detecting a growth in demand, upon which it immediately reclaims all lent out capacity. This cautious reallocation and aggressive reclamation may under-utilize the link at times, which is inevitable (as discussed above) and primarily affects the bulk flows. On the whole, as shown in Figure 3f, we find that CRAB can effectively enforce the desired shares while lowering the link utilization by only 19% with respect to the status quo. CRAB has 2× higher link utilization than the extreme alternative of no re-allocation or of the user explicitly pausing the bulk flow while the video lasts.

Other Challenges. CRAB was able to correctly estimate link capacity in the above experiments. However, link capacity estimation can be more challenging in other scenarios. In particular, if the total incoming traffic at the receiver is limited by flows’ cumulative demand (as opposed to the access link capacity), it would result in underestimation of link capacity – CRAB should be able to self-correct its capacity estimate to ensure correct bandwidth shares if flows’ demands increase. Link capacity could also vary over time – CRAB should be able to detect any changes and accordingly recompute weighted share rates. What makes such self-correction and adaptation particularly difficult is that once flows have been throttled to a spuriously low rate, their sending rates (and, consequently, their arrival rates and CRAB’s capacity estimates) could stay stuck at the throttled values. CRAB handles this by explicitly probing for more bandwidth.

We detail CRAB’s control loop, i.e. its re-allocation, reclamation, and bandwidth estimation logic in §3.

The specific control loop we describe in this paper is one way of using CRAB’s framework for controlling flow shares at the receiver. There can be alternative ways of using our framework while complying with our observation that some amount of link under-utilization is inherently needed to control flow shares from the receiver. For instance, we can directly throttle the *cumulative* rate of all incoming traffic at the receiver to a value lower than the overall link capacity that CRAB estimates (via its throughput observation and band-

width probing logic). This creates an artificial bottleneck at the receiver where we can enforce the desired scheduling policy (prioritization, weighted fair queuing, etc) across the flow classes maintained by CRAB. While effective at controlling flow shares, such an approach would be more sensitive to precise bandwidth estimation and may lead to unnecessary wastage of bandwidth due to consistent link under-utilization. We evaluate this alternative in §5.4.

2.3 CRAB’s Scope

CRAB’s scope is limited in the following key ways:

1. CRAB relies on the fact that flows have a sender-side rate control mechanism that is responsive to throttling. This holds for most of the traffic on the Internet that either uses TCP’s congestion control mechanism or runs adaptive rate control over UDP [39]. CRAB is not effective in scenarios where a flow is not responsive to throttling.

2. CRAB cannot directly control the fine-grained queuing behavior at the bottleneck. It can only influence the rates achieved by different flows over long-enough timescales (a few hundred milliseconds), as it requires the senders to react to the throttled rates or the increased room for growth in rates. This allows CRAB to effectively control bandwidth shares across long-lived flow groups, e.g. video streaming, conferencing, web browsing sessions, bulk downloads, etc. However, CRAB cannot effectively control the queuing delay experienced at the bottleneck by short intermittent downloads that terminate before CRAB gets a chance to react (e.g. a flow group comprising of only interactive chats). Though CRAB cannot actively help such flows, it will not hurt them either.

3. CRAB can only actively control how a user’s incoming flows share their common bottleneck (at the ISP’s access link or at the access router). If a flow is bottlenecked elsewhere (e.g. at the sender’s uplink), it is simply perceived by CRAB as having a lower demand at the shared access bottleneck, and CRAB accordingly reallocates the access link capacity unused by this flow across the remaining flows.

4. Since CRAB must react at slow timescales (of hundreds of ms) to build correct capacity and demand estimates, it is not a good fit for volatile cellular networks where link capacity changes by large magnitudes at much smaller timescales due to high mobility, hand-overs, etc [23, 37, 51, 57]. In comparison, we found broadband connectivity and home WiFi networks to be significantly more stable (see Appendix B).

3 CRAB Control Loop

We now describe CRAB’s control loop that continuously iterates between (i) measuring flow throughput to estimate capacity and demand, and (ii) computing and applying new per-flow rates. Table 1 lists different attributes that CRAB maintains for each flow and uses for rate computations.

3.1 Throughput Measurement

Two parameters govern the granularity of our throughput measurement: the observation period (t) and the number of

Flow Attribute	Description
<i>weight</i>	The weight assigned by the user
<i>observed_tpt</i>	The measured throughput of the flow (its arrival rate at the ingress)
<i>true_bw</i>	The absolute weighted fair share of the flow computed from estimated link capacity and flow weight
<i>lent_bw</i>	The unused bandwidth the flow lends out to other flows
<i>borrowed_bw</i>	The amount of bandwidth the flow borrowed from other flows
<i>assigned_bw</i>	The rate assigned to a flow (set to $true_bw + borrowed_bw$)
<i>saturating</i> (bool)	set to true if the flow's demand is potentially higher than its assigned bandwidth
<i>non_saturating</i> (bool)	set to true if the flow's demand is smaller than its assigned bandwidth
<i>growing</i> (bool)	set to true if the flow needs to reclaim its lent bandwidth

Table 1: Attributes of a flow in CRAB

observations (n). In each observation, CRAB measures the throughput (or arrival rate) for each flow over time t (i.e. number of bytes received in t time divided by t). It makes n such observations and picks the maximum value as the observed throughput of a flow. We use the max filter instead of mean or median to capture bursts which are common for applications like web browsing and video streaming.

The values of t and n govern how long we wait before making any changes to flow rates. A very small value of t would result in inaccurate throughput measurements, whereas a very high value can mask spikes in demand.⁵ A very small n will not give flows enough time to adjust to new rates skewing demand estimates, and a very large n would induce much slower reactions to changes in demands and capacity. In practice, $n \times t$ should be as high as a few RTTs to allow the senders enough time to react. We find that setting t to 200ms and n to 5 works well across different scenarios. We evaluate the impact of these parameter settings in §5.6.

After every throughput measurement (over $n \times t$ s), CRAB sets following flags of each flow f :

Growing: A flow is determined to be growing if f had previously lent out bandwidth but its observed throughput indicates an increase in its demand (i.e. it is using more than what it was using earlier). $f.growing = (f.lent_bw > 0)$ and $(f.observed_tpt \geq f.assigned_bw - f.lent_bw)$.

Saturating: If the flow f is either growing or it is utilizing almost all of its assigned bandwidth, i.e., $f.saturating = f.growing$ or $(f.observed_tpt + \delta \geq f.assigned_bw)$. Here, δ masks noise in throughput observations, and is set to $\max(0.1 \times f.observed_tpt, 0.25Mbps)$. Note that we consider all growing flows to be saturating, but a saturating flow (that is simply utilizing all of its assigned bandwidth) may not necessarily be growing.

Non-saturating: If f is under-utilizing its assigned bandwidth (after subtracting its lent out bandwidth): $f.non_saturating = (f.observed_tpt + \delta) < (f.assigned_bw - f.lent_bw)$.

⁵The value of t should be at least as high as the inter-arrival time between multiple consecutive 64KB chunks to correctly compute throughput (with TSO/LRO enabled, packets arrive in bursts of 64KB).

3.2 Rate Computation Overview

Figure 4 shows a simplified state diagram for CRAB's control loop. Followed by a throughput measurement, we take one of the four actions in the exact priority order.

- (1) If there exists any growing flow, we do reclamation for it (i.e. reclaim any bandwidth it has lent out to other flows).
- (2) Otherwise, if there is at least one non-saturating and one saturating flow, we reallocate (or lend out) bandwidth unused by non-saturating flows to saturating flows.
- (3) If observed throughput has dropped and there does not exist any saturating flow, we decrease the bandwidth estimate and divide it between flows according to their weights.
- (4) In all other cases, we try to probe for more bandwidth.

We return to the throughput measurement after each action. The following sub-sections describe these actions and their triggers in more detail.

3.3 Reallocation

Reallocation takes place if there is at least one non-saturating flow (which can lend out bandwidth) and at least one saturating flow (which can potentially utilize this lent bandwidth).

CRAB first computes the bandwidth each flow f can lend:

$$f.lent_bw = f.assigned_bw - f.observed_tpt - headroom$$

We keep a small headroom (set to 0.25Mbps) to enable detecting when the flow needs to grow back (§5.6 evaluates the impact of this parameter).

If $f.lent_bw > f.borrowed_bw$, this means that the flow can no longer make use of the bandwidth it has previously borrowed and instead has extra unused bandwidth to lend. In this case, CRAB subtracts $f.borrowed_bw$ from $f.lent_bw$ and resets $f.borrowed_bw$ to zero. CRAB computes the global excess (unused) bandwidth by summing up the lent bandwidth across all such flows. It then resets the assigned bandwidth for each flow f to $f.true_bw$, after which it reallocates the excess bandwidth across all flows in proportion to their weights until their demands are satisfied, accordingly updating $f.borrowed_bw$ and $f.assigned_bw$ (set to $f.true_bw + f.borrowed_bw$) for each flow. The algorithm for this redivision is given in Appendix A.

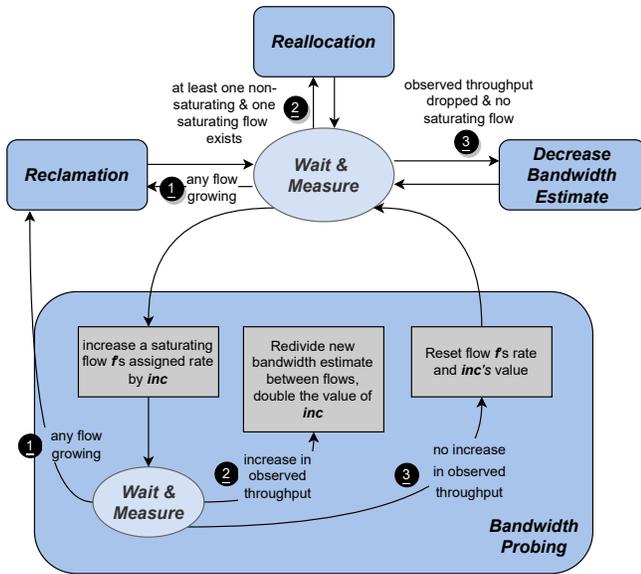

Figure 4: State diagram of CRAB’s control loop.

3.4 Reclamation

Notice that we do not decrease the assigned bandwidth of the non-saturating flow during reallocation. This, combined with the lent bandwidth headroom, ensures that CRAB can detect growth in a flow’s demand, and classify such a flow as *growing* (as noted in §3.1). To enable faster reclamation, CRAB terminates the throughput measurement sooner than $n \times t$ s, once it detects that any flow f is growing. It reclaims all bandwidth lent out by the flow f by setting $f.lent_bw = 0$. It reduces the global excess if $f.lent_bw$ (before updating to 0) was greater than $f.borrowed_bw$, and accordingly recomputes how the updated excess bandwidth is redivided across flows (using the same logic from §3.3). Note that when redividing excess bandwidth, we consider a growing flow to be a saturating flow because it can potentially utilize more bandwidth as its demand is still unknown.

3.5 Bandwidth Estimation

CRAB keeps track of estimated bandwidth ($estimated_bw$) based on the overall observed throughput across all flows ($total_observed_tpt$). We now discuss CRAB’s mechanism for detecting a change (increase or decrease) in capacity. This is required for (i) correcting spuriously low capacity estimates caused by limited demand, and (ii) adapting to potential capacity variations (e.g. due to change in an end-device’s share of bandwidth triggered by changes in another device’s demands).

Decrease in Bandwidth. A drop in $total_observed_tpt$ can happen due to two reasons – either the total bandwidth has dropped, or a flow’s demand has decreased. Bandwidth estimate should not be decreased in the latter case – reallocating the bandwidth now unused by the flow can increase observed throughput. Since there is no way to tell these two scenar-

ios apart, we first let reallocation try to fix things before we reduce $estimated_bw$. More specifically, as long as there is a saturating flow (that can potentially use more bandwidth), CRAB keeps trying to reallocate excess capacity. If no flow can be classified as saturating and $total_observed_tpt$ remains lower than $estimated_bw$,⁶ it can assume that the bandwidth has dropped and reduces $estimated_bw$ to the $total_observed_tpt$. This assumption can still be incorrect because it is possible that it is not the bandwidth, but the demand for all the flows that have actually decreased. However, in such a case, decreasing $estimated_bw$ does not hurt the flows, and later when flows grow back, we can re-estimate bandwidth through bandwidth probing as discussed ahead.

After updating $estimated_bw$, CRAB resets global excess bandwidth to zero and assigns each flow its absolute weighted share of the new bandwidth estimate. This eradicates the effect of erroneous reallocations that happen before decreasing the bandwidth estimate. Correct reallocation (if needed) can then take place in subsequent iterations of the control loop.

Increase in Bandwidth. Detecting an increase in bandwidth is particularly tricky because CRAB itself limits the arrival rates of flows by throttling them. Thus, it needs to explicitly probe for more bandwidth. To do so, CRAB increases the assigned rate of a saturating flow and then waits to take a throughput measurement. If it detects any significant increase in $total_observed_tpt$,⁷ it updates $estimated_bw$ to $total_observed_tpt$. It accordingly computes the absolute weighted share for each flow (setting it as the flow’s true and assigned bandwidth). It then accordingly increases the global excess bandwidth and redivides the bandwidth across all flows in proportion to their weights until their demands are satisfied (as in §3.3).

The above requires careful consideration of two aspects – which saturating flow should we select for bandwidth probing and what should the increment value be. We select a new saturating flow in a round-robin fashion in each bandwidth probing round, such that any one flow does not get an advantage over the other. We calculate the increment in proportion of $estimated_bw$ i.e. $increment = inc \times estimated_bw$. To prevent large disruptions in flow shares, we start off with a small value of inc (0.125), but every time bandwidth probing results in an increase in estimated bandwidth, we double the value of inc . When probing does not result in an increase, we reset the increment to its starting value. We continuously keep probing for bandwidth until this happens. The only time we terminate bandwidth probing prematurely is if we detect a flow to be growing, in which case we skip to reclamation.

Bootstrapping. CRAB bootstraps by calculating weighted fair share rates of flows based on an arbitrary initial estimate of bandwidth. By keeping this estimate large, we can avoid doing

⁶To be robust against minor throughput changes, the precise condition we check for is $total_observed_tpt < 0.9 \times estimated_bw$.

⁷If the increase in $total_observed_tpt$ is greater than $\max(0.1 \times total_observed_tpt, 1\text{Mbps})$

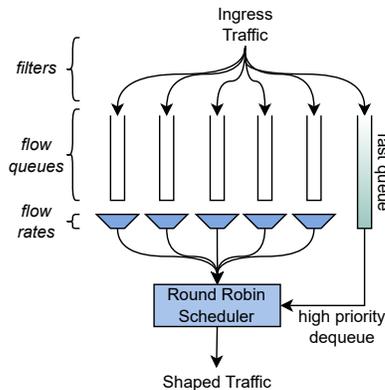

Figure 5: Linux’s HTB scheduler.

bandwidth probing at startup time. Once the first measurement interval is over, CRAB is able to fix this estimate. CRAB can maintain a historical average estimate of bandwidth in the persistent state to feed as an initial value for more efficient bootstrapping.

3.6 CRAB’s Router Control Loop

CRAB runs the same control loop at the home router, except for one change: each throughput measurement takes $3n$ observations, so the length of throughput measurement is $3n \times t$ s. This ensures that CRAB in end-devices is able to adjust their flow rates to per-device rate changes made by the home router, before the router’s next measurement.

4 System Implementation

We implement CRAB’s end-host logic on a 2.4GHz 8-core Ubuntu 20.04 machine with Linux 5.11 kernel, and its home-router logic on a 1.8GHz dual-core Linksys WRT3200ACM router running Linux-based OpenWRT firmware. We start with discussing the end-host implementation (§4.1-§4.5), and then discuss router implementation (§4.6).

4.1 CRAB’s Placement

The inbound traffic arrives at an ethernet (eth) or wireless (wlan) interface. Since Linux does not have rich options to shape ingress traffic, we redirect the inbound traffic to an intermediate function block (ifb) [6] interface, where CRAB can shape traffic using Linux TC [10] (§4.3). The shaped traffic then gets picked up by the receiver’s TCP/IP stack for further (normal) processing.

4.2 Throughput Measurement

We measure the flow throughputs (or arrival rates) by using scapy [16] to sniff and record the incoming traffic at the original ingress interface (eth or wlan).

4.3 Rate Enforcement

We enforce the computed weighted fair share rates for each flow group at the ifb interface using Linux’s HTB (Hierarchical Token Bucket) scheduler [5].

```
Flow Groups : {
  Video Streaming: {
    flow identifiers: ["app>netflix", "web>youtube.com", "web>hulu.com"],
    weight: 5
  },
  Work: {
    flow identifiers: ["app>dropbox", "ip>1.2.3.4"]
    weight: 5
  },
  Default: {
    weight: 1
  }
}
```

Figure 6: An Example of a CRAB Config File.

Primer on HTB. Figure 5 shows the basic working of HTB. HTB allows a user to classify traffic into different classes (based on filters defined by packet header fields such as IP address, protocol type, TCP/UDP ports, etc) and specify different rates for throttling each class. If an incoming packet cannot be classified into a class defined by the filter rules, it is put into a special queue called the *fast queue*. Each class consists of a FIFO queue (to buffer packets) and a token bucket filter. Tokens are added to the bucket at the specified rate. If the amount of tokens in the bucket is greater than or equal to the size of the head packet in the queue, then the packet is dequeued. Otherwise, the queue blocks. If the queue is full, new incoming packets for that class are dropped.

A round-robin scheduler moves between classes to dequeue packets. If a class cannot dequeue a packet because it does not have enough tokens, the scheduler moves to the next class without blocking. The scheduler prioritizes dequeuing from the fast queue before any of the HTB classes.

HTB supports work-conserving traffic shaping by allowing unused tokens to be borrowed by other classes – we do not enable this feature in CRAB for reasons discussed in §2.2, and use the re-allocation logic described in §3 instead.

HTB in CRAB. We maintain a class for each flow group. The flow filter manager (detailed in §4.5) installs the filter rules for classifying incoming packets into their respective classes. We set the throttling rate for each class to the weighted fair share rate of its respective flow-group (as computed by CRAB’s control loop), and accordingly adjust the queue size.⁸

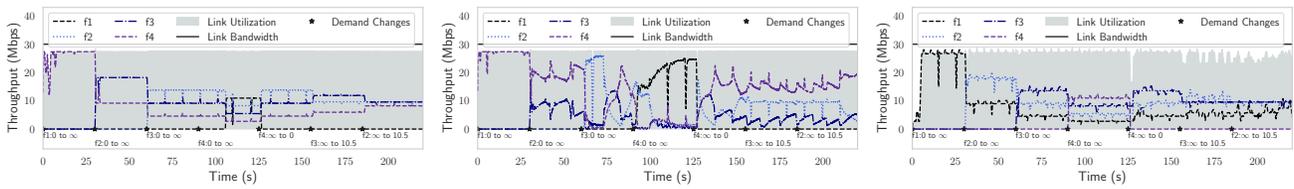

4.4 User Interface

The user specifies their preferences in a config file. Figure 6 shows a sample config file. It contains different flow groups, where each flow group consists of a list of flow identifiers and a weight associated with the flow group. Our current implementation allows a user to give three kinds of flow identifiers – *ip* (for traffic coming from the specified IP address), *app* (for traffic destined to the specified application), and *web* (for traffic destined for webpages from the specified web domain).

4.5 Flow Filter Management

Flow filter manager (FFM) maps user-specified high-level flow identifiers into packet header fields that can be used for

⁸Queue size is adjusted to $2BDP = 2 \times \text{rate} \times \text{RTT}$, where we assume RTT to be 50ms.

(a) WFQ@bottleneck

(b) Status Quo

(c) CRAB@end-host

Figure 7: Weighted sharing of 30 Mbps bottleneck between 4 flows in a ratio of 4:3:2:1, where f1 has a weight of 1 and f4 has a weight of 4. The bottom part of each graph shows flow demand changes in Mbps, where ∞ means unknown demand.

filtering packets at HTB. When we encounter a packet from an unknown *source* IP address (that does not correspond to an installed filter rule), we copy the packet header to FFM. FFM determines the mapping for the packet (as detailed below) and installs a new filter rule for it. Note that FFM installs filter rules asynchronously, and we do not block traffic while this happens. Instead, the unclassified packet is put (and served) in HTB’s fast queue. Once FFM installs the corresponding rule, it is used to correctly classify future packets from that flow. This ensures that if the unclassified packets are of a potentially important flow, their service is not degraded. Typically, FFM is able to install new filter rules fast enough, such that only the first couple of packets for an unclassified flow land up in the fast queue. FFM installs filter rules as follows:

(i) *Source IP Mapping:* If the source IP address of a packet arriving at the ingress matches with an *ip* field in the config file, we install the corresponding filter simply based on that.

(ii) *Application:* If the source IP is not found in the config file, we use psutil [7] to reverse map the destination port on the packet header to find which application has opened that port. If the application is specified in any flow group in the config file, we install a filter that maps traffic from the packet’s source IP address to this flow group. If the application does not match any identifier in the config file, we map it to the default flow group (unless the app is the web browser, which we handle as a special case as discussed below)

(iii) *Web Domain:* Mapping packets to the web pages (identified by web domains) is tricky for multiple reasons:

(a) Web pages from the same web domain may be hosted on several different machines.

(b) Web pages make many cross-origin requests e.g. to CDNs and ad servers. Since these requests are often dynamic (e.g. due to load balancing in CDNs or real-time bidding in ad networks), it is not possible to pre-populate a list of IP addresses a webpage from a certain web domain would access.

(c) Packet headers do not carry any information about which web domain the packet belongs to. The packet payload of HTTPS traffic, which does carry some information, is encrypted at the ingress (where CRAB sniffs) and is decrypted only at the browser.

Thus, if the application using the destination port is a web browser, FFM needs more context from the browser to correctly classify the packet. We built a Google Chrome plugin

that provides this context. As soon as the browser starts receiving an HTTPS response, the plugin prepares and sends a message to FFM that contains the source IP address of the response, and the URL of the webpage that initiated the corresponding HTTPS request. Using this mapping, the FFM can extract the web domain from the URL and find its match in the config file. If there is a match, we install a filter for the source IP address, mapping it to the corresponding flow group. Otherwise, we map it to the default flow group.

FFM may not be able to correctly classify packets if the relevant packet header fields are encrypted (as in the case of VPNs). In such cases, application integration similar to the plugin we built for Google Chrome can help remove FFM’s dependency on encrypted packet headers and enable the classification of non-encrypted fields. Note that DNS encryption does not affect FFM, as it does not rely on DNS packets.

4.6 Home Router Implementation

Similar to our end-host implementation, CRAB at the router sniffs incoming traffic (using tcpdump [12]) at the ingress (eth) interface, and redirects the traffic to the ifb interface. It classifies the traffic based on the destination IP address at the ifb interface and enforces the per-destination rates computed by CRAB’s control loop using Linux HTB.

5 Evaluation

We now evaluate the following:

- CRAB’s ability to adapt to changes in flow demands and link capacity in synthetic scenarios involving real-world bulk flows (§5.1).
- Performance (QoE) improvement enabled by CRAB for real-world video streaming (§5.2) and web browsing (§5.3), when competing with bulk downloads.
- An alternative way of using CRAB’s framework to enforce user preferences, and the trade-offs involved (§5.4).
- The need for CRAB’s home router logic with multiple active devices in the user’s domain (§5.5).
- The impact of changing CRAB’s key parameters, i.e. throughput observation length and lending headroom (§5.6).
- CRAB’s robustness to diverse traffic characteristics and its overheads (summarized in §5.7, and detailed in the appendix).

We use the same setup as in §2.2, that models a single end-host directly attached to the ISP’s link (for repeatable experiments, we emulate a 30Mbps access link by throttling

traffic at our home router). The only exception is §5.5, where we extend the home router logic to implement CRAB after the throttle point.

Unless otherwise specified, we compare CRAB with two baselines: (i) ideal WFQ (implemented at the access link emulated by our router), and (ii) status quo (i.e. no traffic shaping). We also conducted experiments using HTB with bandwidth borrowing *after* the bottleneck – since this produces almost exactly the same outcome as the status quo (as discussed in §2.2), we omit presenting those results.

Our workloads span real-world flows with a diverse set of sender-side rate control mechanisms: (i) bulk download flows that likely use TCP Cubic [30], (ii) YouTube video streaming that uses BBR [11, 22] along with an adaptive bitrate (ABR) algorithm for adapting video quality, and (iii) web page-loads over Google Chrome that potentially use a mix of BBR [22, 33] and Cubic [30] over QUIC [33, 39] and TCP⁹.

5.1 CRAB in action

We design synthetic scenarios to visualize CRAB’s fine-grained reaction to changes in flow demands and/or link bandwidth, using real-world flows that download large Linux images from different servers. We configure each download as a separate flow group with different weights. Each flow individually has a demand higher than 30 Mbps as it is a backlogged flow with no server-side bottleneck.

Testing Reallocation and Reclamation. We test a scenario with 4 flows sharing a 30 Mbps link, with a desired sharing ratio of 4:3:2:1 between them. We emulate dynamic flow demands by shaping traffic at two interfaces in the home router. The first interface throttles rates of individual flows (to emulate flow demands limited by low sending rates or other upstream bottlenecks). The second interface then cumulatively throttles all the traffic to 30 Mbps, emulating an ISP’s access link (as mentioned before).

Figure 7a shows the flow shares when we do WFQ at the ISP, which sets a perfect, but impractical baseline. Flow 1, which has the lowest weight of 1, starts at 0 seconds. Because there is no other active flow, it gets to utilize the entire link bandwidth. Flows 2, 3, and 4 become active after every 30 seconds respectively, and at each point, the link is shared in the proportion of active flows’ weights. At 125 seconds, flow 4 stops, and link bandwidth is redivided between the remaining three flows in the proportion to their weights. At about 155 seconds, flow 3’s demand drops to 10.5 Mbps, and its remaining share is taken up by flow 1 and flow 2. At 185 seconds, flow 2’s demand also drops to 10.5 Mbps, at which point flow 1 gets all the remaining unused share.

Figure 7b shows how the flows share the link arbitrarily without any shaping with the status quo.

Figure 7c shows that, on the whole, CRAB is able to imitate

⁹We can only guess the protocols used by different content providers based on public knowledge.

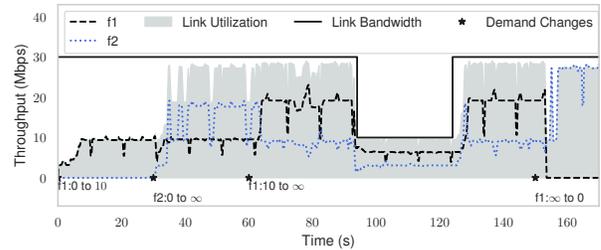

Figure 8: 2 flows sharing a link in 2:1 ratio with CRAB. Flow 1’s demand and link bandwidth vary over time.

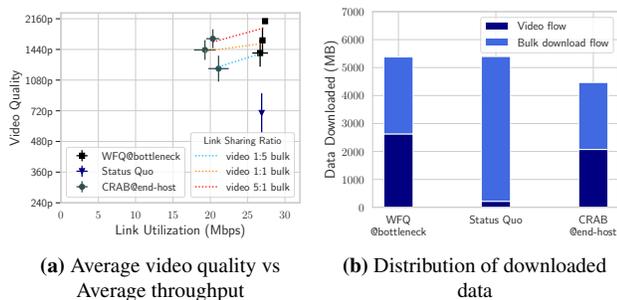

the ideal WFQ baseline very closely despite being at the other side of the bottleneck (although there are some transient, and inevitable, dips in link utilization).

Testing Bandwidth Estimation. In Figure 8, we evaluate CRAB’s reallocation and reclamation, in addition to bandwidth estimation due to varying link bandwidth. We have two flows configured to share a 30Mbps link in the ratio of 2:1. CRAB builds a spuriously low estimate of bandwidth when flow 1 (with demand limited to 10Mbps) starts at 0 seconds. CRAB is able to probe for more bandwidth once flow 2 (with a demand more than 20Mbps) starts at 30s. It reallocates the unused bandwidth of flow 1 to flow 2 as well. Flow 1’s demand then increases at 60 seconds, CRAB reclaims its lent bandwidth and the link bandwidth is correctly shared in a ratio of 2:1 between flows 1 and 2 respectively. Then the link bandwidth drops to 10Mbps at 90 seconds, CRAB detects this change and adjusts the flows’ rates to 6.66Mbps and 3.33Mbps respectively. When bandwidth increases again to 30Mbps at 125 seconds, CRAB is able to probe for more bandwidth and divide it according to the flows’ weights. Finally, when flow 1 stops at 155 seconds, its bandwidth is reallocated to flow 2. Appendix D presents a similar experiment, except that instead of starting a single flow f2 at 30s with a demand of more than 20Mbps, we start 3 new flows, each with a demand of 10Mbps.

5.2 Video Streaming

We repeat the experiment in §2.2 with 7 different Youtube videos of varying playtime¹⁰, competing with bulk download. Figure 9a reports the average video quality and link utilization across all experiments. We record the quality of each video over time using Youtube’s API [13]. We then calculate the average video quality for each video by averaging the video quality weighted by the amount of time played at that quality. We calculate the average link utilization as the sum of data received during the video playback, divided by playback time. For CRAB and WFQ, we also try different weight assignments between video flow and bulk downloads, 5:1, 1:1, and 1:5 respectively. Figure 9a shows how CRAB maintains comparable video quality to WFQ for each weight assignment setting (i.e. within [92-94]% of WFQ), but with [15-20]% lower link utilization compared to status quo. The

¹⁰shortest video is 1 minute, while longest is 10 minutes

(a) Average video quality vs Average throughput (b) Distribution of downloaded data

Figure 9: Video streaming in presence of bulk downloads.

video quality achieved by status quo is worse than that with CRAB even with weighted sharing of 1:5 between video and bulk flows (this indicates that the video flow gets less than 17% of bandwidth share with the default status quo).¹¹ Figure 9b shows the cumulative amount of video and bulk flow data downloaded across all videos for the experiment with a weighted sharing of 5:1 between video and bulk download. With CRAB and WFQ, video flow consumes almost half of the data which translates to much higher video quality. In comparison, with status-quo, video amounts to only 3% of total downloaded data.

5.3 Web Browsing

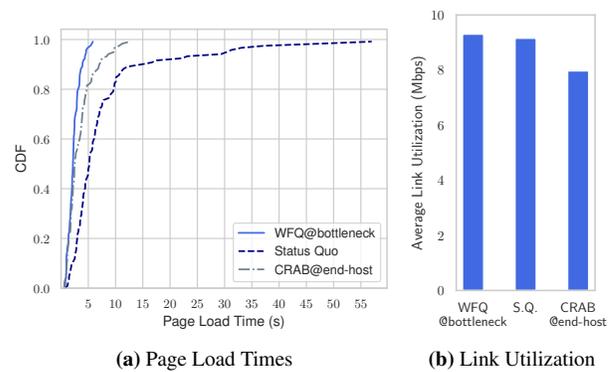

In this experiment, we show how CRAB helps improve web page load times despite background download flows. We emulate a user’s browsing behavior by visiting 125 webpages (around 300 MBs of data) in total from 4 popular web domains (facebook.com, google.com, bbc.com, yahoo.com) in different sessions of browsing using Selenium [8]¹². We separate each session by a Poisson inter-session time determined with a mean of 60 seconds. Within each browsing session, we separate each web page’s download by a Poisson distribution with a mean of 5s to emulate a user’s page read-time. We download two competing large files from two different servers. We throttle the access downlink to 10 Mbps at the router for these experiments and configure weights in the ratio of 7:3 between web traffic and bulk downloads. To fairly compare link utilization, we run the experiment for each baseline for the same amount of time. Figure 10a shows the CDF of page load times with CRAB, ideal WFQ, and status quo. The median page load time with CRAB is 2× smaller than with the status-quo and is within 15% of ideal WFQ. Figure 10b shows that CRAB under-utilizes the link by about 13%.

5.4 Alternative way of using CRAB’s framework

We now evaluate the alternative mechanism for using CRAB’s framework (referred to earlier in §2), where we directly throttle the cumulative rate of all flows arriving at the ingress to a value lower than the overall link capacity that CRAB

¹¹Lower video throughput translated to lower resolution in all cases, and we did not notice any re-buffering events.

¹²Selenium allows us to automate webpage loads and user clicks.

(a) Page Load Times (b) Link Utilization

Figure 10: Page load times vs link utilization for CRAB, WFQ and Status quo

estimates (via its throughput observation and slightly modified bandwidth probing logic), and then enforce the desired scheduling policy on the artificial bottleneck that gets created. To understand the trade-offs involved with this approach, we evaluate it under two different scenarios. We emulate (and assume) a static link capacity of 30Mbps, and do not implement bandwidth estimation for the alternative approach for simplicity. We also disable bandwidth estimation in the original CRAB implementation for a fairer comparison.

(a) We first consider the scenario from §5.2, where a YouTube video competes with bulk download on a bottleneck link with a capacity 30Mbps. We prioritize the video flow at the receiver without throttling the flows in one case, and after throttling the incoming flows to a cumulative rate of 25Mbps in the other. We compare these strategies with the status-quo (that does not enforce user preferences) and the original CRAB design. Figure 11a shows the results. Prioritizing the video flow without throttling cannot enforce user preferences very effectively (for reasons discussed in §2). However, prioritizing the video flow after throttling the incoming traffic to a rate of 25Mbps (which is lower than the link capacity) is effective. It results in slightly higher video quality but slightly lower link utilization than the original CRAB design.¹³

(b) We next evaluated a scenario where the 30Mbps bandwidth is to be divided across three backlogged flows in the ratio 1:2:3. We now apply weighted fair queuing at the receiver without throttling, and after throttling the incoming traffic to 25Mbps, and compare the outcomes with original CRAB and the status-quo (Figure 11b). Again, we observe that the desired shares could not be effectively enforced without throttling the flows to a rate lower than the link capacity. WFQ applied after throttling at 25Mbps was able to enforce the desired flow shares similar to the original CRAB. However, the original design achieved 19% higher link utilization

¹³The difference in video quality potentially stems from the difference in scheduling policy – strict prioritization vs 5:1 weighted fair sharing with original CRAB.

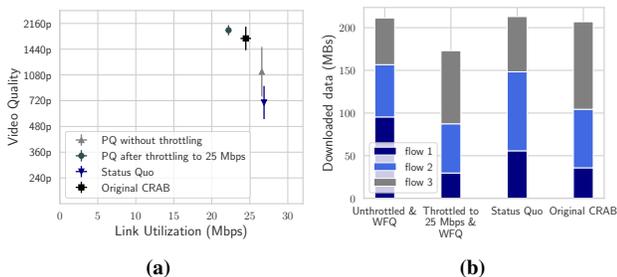

Figure 11: Creating chokepoint by throttling to less than known link capacity (a) helps control traffic (e.g. by using priority queues) (b) but results in avoidable bandwidth wastage.

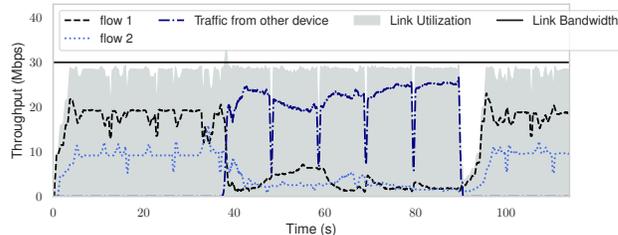

(which was very close to the status quo).

These results highlight that the original CRAB design *strives* to achieve maximal link utilization. The link underutilization is transient and less notable when flow demands are stable (as in the second scenario), and is more notable when flow demands vary due to more frequent re-allocation and reclamation (as in the first scenario). In contrast, the alternative approach of throttling the cumulative rate of incoming flows will consistently suffer from lower link utilization by design. The amount of link underutilization can be reduced by reducing the gap between the throttling rate and the link capacity, but this would also impact how effectively user preferences get enforced (e.g. resulting in lower video quality for the first scenario). This makes it difficult to correctly configure the cumulative throttling rate, especially as link capacity varies or is estimated imprecisely. Nonetheless, this alternative design effectively demonstrates the potential of using CRAB’s framework in more than one way.

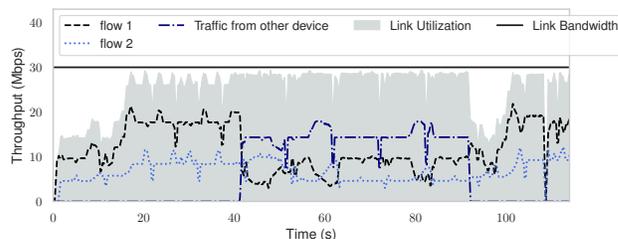

5.5 Multiple end-devices need CRAB at home-router

In this section, we show the need for CRAB at the home router to ensure proper enforcement of bandwidth shares when there are multiple devices actively using the Internet in the user’s domain. We connect two machines (M1 and M2) to the home router. M1 runs CRAB to enforce 2:1 weights between two bulk download flows, while M2 does not run CRAB. Initially, we just have two flows from M1 sharing the bottleneck link in the 2:1 ratio enforced by CRAB. When the flow from M2 starts at around 40 seconds, in absence of CRAB support at the home router, it ends up stealing M1’s bandwidth share (as shown in Figure 12a). When CRAB at M1 throttles its lower weight flow, the bandwidth yielded by this flow at the access link is taken up by the flow from M2, instead of the other higher-weighted flow at M1.¹⁴ With CRAB enabled at the home-router, CRAB at an individual device can correctly control how its router-enforced bandwidth share is divided between its flows (as shown in Figure 12b). Thus, in case of multiple devices sharing the home Internet connection, it is important to enable CRAB at the home router to enforce

¹⁴Note that sender side protocols to yield bandwidth [41, 48] would suffer from a similar issue.

(a) Without CRAB@Router

(b) With CRAB@Router

Figure 12: With multiple active devices, CRAB at the home router is required to ensure correct working of CRAB at the end-host.

bandwidth shares across different devices, and to prevent the devices from stealing bandwidth from one another.

5.6 Impact of CRAB’s Parameters

The value of n (number of observations) \times t (observation interval) determines how long we spend in estimating throughput, before making a change in assigned rates. Figure 13 shows the effect of changing it from its default value of $(5 \times 0.2s)$ to higher $(10 \times 0.3s)$ and lower $(5 \times 0.1s)$ value for the video streaming experiment from §5.2. Higher value of $n \times t$ means we are much slower in our reactions – we reallocate late which improves video quality (very slightly) but at the cost of greater link under-utilization. In contrast, a smaller value of $n \times t$ implies quicker decisions – we have slightly better link utilization, but video quality also slightly drops. If we keep making observation length smaller, it would boil down to doing instantaneous reallocation similar to bandwidth borrowing with HTB (which, like status-quo, can maintain high link utilization, but cannot enforce bandwidth shares).

We also experimented with changing CRAB’s lending headroom parameter from its default value of 0.25Mbps to higher (0.5Mbps) and lower (0.05Mbps) values. This had no significant impact on CRAB’s performance – we present detailed results in Appendix E.

5.7 Other Results

We briefly summarize some of our other results, providing the details in the appendix:

- CRAB is quite robust to differences in RTTs and congestion control algorithms across flows, and it scales well with the increasing number of flow groups (Appendix C).
- CRAB has a negligible impact on packet delay and forwarding rates. It has a CPU utilization of 10.74% on a 2.4GHz

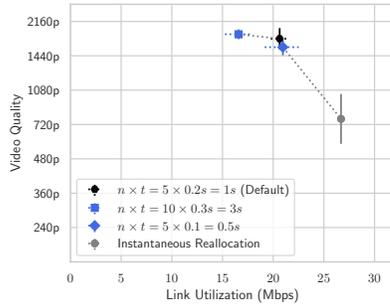

Figure 13: Effect of observation length ($n \times t$) on video quality vs link utilization.

8-core machine, which largely stems from the throughput measurement module (Appendix F). This is because our current implementation uses Scapy [16], a Python-based packet sniffer. Using a more efficient sniffer (e.g. libtins [4]) would reduce this overhead.

6 Related Work

There have been a number of proposals for enabling differentiated services (in the form of weighted fair sharing or prioritization) at network switches [17, 21, 25, 49, 53, 56]. However, these policies must be applied at the bottleneck, which is controlled by the ISP and not the users. There exist proposals that allow a user to send their preferences to the ISP [19, 24, 27, 35, 54] which are difficult to deploy in practice. CRAB allows the user to control the access bottleneck *without seeking any support from the ISP*.

There exist mechanisms for the device to control the uplink bandwidth usage when sending data [5, 44, 45], e.g. prioritizing latency-sensitive uploads over file backups [14] – the bottleneck occurs at the user device in these cases. Another category of work allows the end user to configure their home routers to do traffic prioritization [18, 40, 47], assuming that the bottleneck is at the wireless link in the home network. CRAB tackles the harder problem of controlling downlink bandwidth usage by shaping traffic *after* the bottleneck (that is likely to occur at the access link from the ISP), and naturally helps in scenarios where the bottleneck is at the home-router.

With bottlenecks at the ISP, it can even be challenging to do sender-side traffic prioritization. Bundler [20] solves this problem in context of site-to-site traffic by estimating the bottleneck rate in the ISP and enforcing that rate at the sender. This shifts the bottleneck at the sender’s site instead of the ISP, which lets the sender enforce its desired scheduling policies. CRAB enforces desired bandwidth shares solely from the receiving domain, without seeking any explicit coordination with the senders.

Receiver-driven protocols [28, 42, 55] provide a receiver with greater control over their downlink bandwidth, by letting them explicitly dictate the sending rates. Some senders can also use bandwidth-yielding protocols (e.g. [41, 48]), if they know their flow has a relatively lower priority. However, the

onus of using these receiver driven or yielding protocols is on the senders – a receiver can use these protocols only if the senders also support them. CRAB allows receivers to unilaterally control their access bandwidth shares.

7 Conclusion and Discussion

This paper presents CRAB, a system that enables end-user to unilaterally control how their Internet access bandwidth is shared across their incoming flows. In particular, we show how home users can exploit CRAB to enforce their preferences and achieve better performance for their video and web flows. Our source code is publicly available.¹⁵ Our work opens up several interesting future directions:

Theoretical analysis of performance. Formal characterization of CRAB’s performance, e.g. by analyzing the upper-bound on link utilization for effective enforcement of user-specified shares under different scenarios, can inform future designs for improved performance.

Other deployment modes. CRAB does not require any explicit coordination among the home router and the endpoints. This extends CRAB’s utility to scenarios where multiple users share a common Internet connection, e.g. in coffee shops, enterprises, airports, etc. The domain owners can advertise their use of CRAB at the access routers for enforcing fairness across users (they can also use other scheduling mechanisms at the routers [1, 15, 18] if it is known that the bottleneck is at the downlink from the router to the end-devices). Each user can then use CRAB at the endpoint to independently control how their share of bandwidth is divided across their flows.

Setting Flow Weights. It might be difficult for users to set the appropriate weight for a flow group that CRAB requires as an input. Future work can explore how to design a more intuitive user interface. For instance, we can auto-classify incoming flows across broad categories (video streaming vs browsing vs downloads, etc), and then automate weight assignments based on coarse-grained user preferences across these categories and learned estimates of bandwidth requirements for different flows. Such bandwidth requirements are already known for many standard applications, e.g. video streaming [2, 9]. CRAB can also ship with some default configurations for popular traffic classes, which can be further customized by users according to their needs.

Support for phones. We currently implement CRAB on a Linux PC. We plan on porting our system to Android phones.

Appendix

A Pseudocode for Redivision of Excess Bandwidth

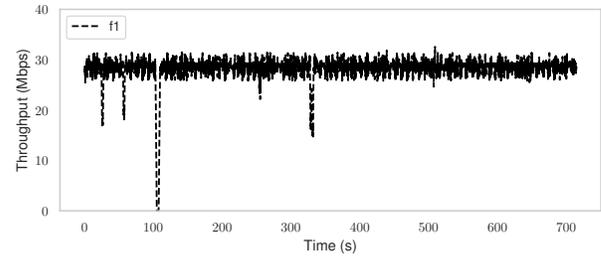

We first calculate the demand of each flow based on the amount of bandwidth it lends out. Then excess is divided based on this demand. If a flow's demand is fulfilled with bandwidth less than its share of excess, we can redivide this residual excess share between other flows.

Algorithm 1 Redividing Excess Bandwidth between all flows

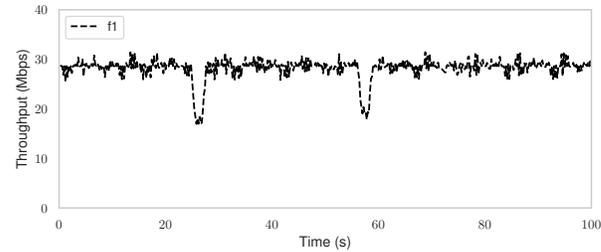

```
1: procedure REDIVIDE(excess)
2:   // First we calculate demand of each flow based on
   // the bandwidth it lends out
3:   for f in flows do
4:     if f.lent_bw > 0 then
5:       f.demand ← f.true_bw + f.borrowed_bw -
         f.lended_bw
6:     else
7:       f.demand ← ∞
8:     f.assigned_bw ← f.true_bw
9:     if f.demand > f.assigned_bw then
10:      f.lent_bw ← 0
11:      f.borrowed_bw ← 0
12:   // Based on the calculated demand, we divide excess
   // between all flows. When a flow's demand is met, its
   // residual excess is again divided between other flows.
13:   while excess > 0 do
14:     residual_excess = 0
15:     for f in flows do
16:       if f.demand > f.assigned_bw then
17:         excess_share ← excess × (f.weight
           /weight_sum)
18:         f.assigned_bw ← f.assigned_bw + ex-
           cess_share
19:         f.borrowed_bw ← f.borrowed_bw + ex-
           cess_share
20:       if f.assigned_bw > f.demand then
21:         residual_excess ← residual_excess +
           (f.assigned_bw - f.demand)
22:         f.lent_bw ← f.lent_bw +
           (f.assigned_bw - f.demand)
23:     excess ← residual_excess
```

B Stability of Wifi Connection

Cellular networks are known to be highly unstable due to factors like high mobility and handovers. Wifi connections are relatively more stable. We evaluated this by sending iPerf data over UDP at a fixed rate of 30Mbps to a Linux machine via a WiFi router. We measured the throughput over 200ms granularity at the ingress of the Linux end-host using tcpdump. Figure 14 shows the results. The observed throughput was

(a)

(b) Zoomed into first 100 seconds.

Figure 14: Throughput of a 30 Mbps flow over Wifi measured in 200ms intervals.

largely stable with minor fluctuations around 30Mbps and only a handful of dips.

C Robustness to Different Traffic Characteristics

We now evaluate CRAB's performance under diverse traffic characteristics – flows with different RTTs, using different congestion controllers, and varying the number of flow groups. For these experiments, we generated iPerf flows with different characteristics using a local server, which then arrived at our receiver side setup used in our other experiments so far.

In the first experiment, we vary the RTT of flows by adding artificial delay in packet delivery using Linux tc at the server that generates flows. We start three backlogged flows sharing a 30 Mbps link in a 1:2:3 ratio. We fix the delay of the first flow (with weight 1) and the third flow (with weight 3) to 1ms and 50ms respectively, and vary the delay of the second flow (with weight 2) from 1ms to 500ms. We stop the third flow after 30 seconds and continue to run the other two flows until 100 seconds. We then study the effect of different RTTs for the first two flows as CRAB redivides the third flow's share between them in a 1:2 ratio. As shown in figure 15a, CRAB is pretty robust to the difference in RTTs. The slight mismatch in flow shares seen with an extremely high RTT difference of 200-500ms stems from the natural RTT unfairness that occasionally manifests in CRAB during the bandwidth probing phase when both flows share the bandwidth increment in a non-isolated manner.

We use a similar setup as above for our second experiment, except that the flows now have the same RTTs (20ms), but use different congestion control algorithms. The third flow uses

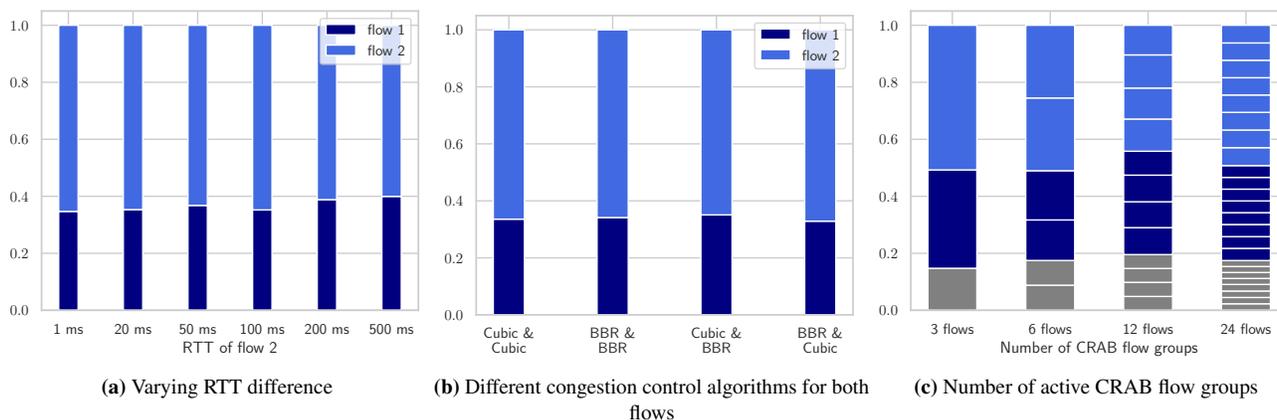

Figure 15: CRAB maintains weighted sharing despite different characteristics of flows.

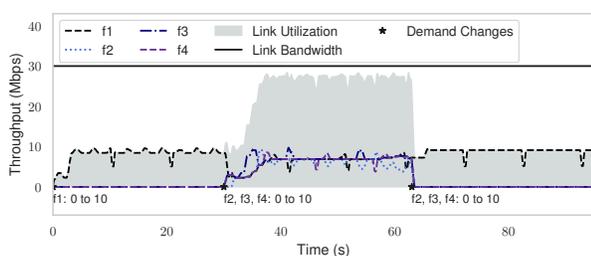

Figure 16: CRAB is able to estimate link capacity even with finite demand flows.

TCP Cubic and stops after 30 seconds. We vary the congestion control algorithms used by the other two flows as shown in figure 15b and observe how that impacts their flow shares. We find that CRAB’s enforcement of weighted fair shares is robust to different congestion controllers. **[New]** CRAB is unaffected by the unfairness that could manifest because of RTT and congestion controller difference because it reacts at super-RTT time scales thus forcing underlying flows to adhere to throttled rates.

In the last experiment, we test CRAB’s robustness as we increase the number of flow groups from 3 to 24. In the first run, we have three flows sharing a 60 Mbps link in a 3:2:1 ratio. In the next run, we double the number of flows associated with each weight, and so on. Figure 15c shows the bandwidth share received by each flow, with different colors indicating flows with different weights. We find that CRAB can effectively tackle a large number of flows. **[new]** As long as flows are large enough to react to CRAB, any number of flows can be handled by it. The only breaking point may be when a flow group consists of a large number of short-lived flows which finish before reacting to CRAB’s throttling. However, such a case is unlikely to exist in our target scenario of a home network.

D Bandwidth Probing with Limited Demand Flows

Extending on our discussion in §5.1, here we evaluate the scenario when we do not have a convenient infinite demand flow to rely on for bandwidth probing. CRAB is still able to quickly probe for bandwidth by alternating between different finite demand flows for bandwidth probing. Figure 16 shows a scenario where we initially have one flow with a demand of 10 Mbps, at 30 seconds, 3 new flows each with a 10 Mbps demand start. Since their cumulative demand is more than 30 Mbps, the bandwidth probing algorithm is able to estimate link capacity by alternatively picking a flow for bandwidth probing and dividing capacity equally between them.

E CRAB’s Sensitivity to Lent Bandwidth Headroom

The lent bandwidth headroom ensures that a flow has some room in the link to send at least a few packets so CRAB can detect it to be growing and reclaim for it. When the bandwidth of a flow is detected to be exceeding this headroom, CRAB quickly reclaims for it. Figure 17 shows CRAB’s sensitivity to this parameter through the video experiment discussed in §5.2. Overall, CRAB is not very sensitive to this parameter, but

A larger value of headroom ensures better guarantees on early detection for reclamation, thus, slightly better video quality. However, overprovisioning may result in under-utilization, especially if we have a much higher number of flow groups. This effect can be avoided easily by having a cap on the collective headroom of all flow groups combined. A smaller value of headroom may not guard very well against pressure from other flows, which may result in CRAB not being able to detect flow growth in time and therefore slightly worse video quality. Another hidden effect that deteriorates link utilization in case of small headroom is spurious reclamations. Small values of headroom are not able to mask minor fluctuations and noise, which results in spurious reclamation, as a result,

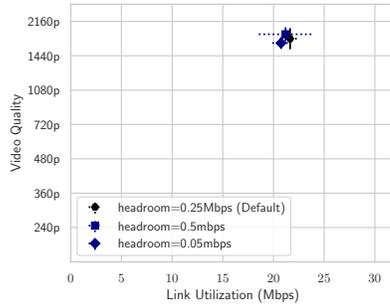

Figure 17: Effect of lent bandwidth headroom on video quality vs link utilization.

	With CRAB	No CRAB
Throughput	28.93 Mbps	28.98 Mbps
Delay	0.94 ms	0.88 ms
CPU Usage@end-host	10.74%	N/A

Table 2: Overheads of CRAB

we see slight link under-utilization. Overall CRAB is not very sensitive to this parameter.

F Overhead of CRAB

We evaluate CRAB’s overhead by measuring the throughput and delay of a single bulk download flow with and without CRAB. To measure throughput, we record the flow’s rate at ifb’s egress (i.e. after shaping) with CRAB, and at eth0’s ingress (as the raw arrival rate) without CRAB. We measure processing delay by recording the difference between timestamps for when a packet arrives at the eth0 and when its acknowledgment passes through eth0. Since CRAB’s components are placed after the eth0 interface on the path of ingress traffic, this calculation captures any extra delay inflicted by CRAB. Table 2 shows that CRAB does not induce any significant overhead (the throughput remains largely unchanged, and the processing delay increases by only 0.06ms (i.e. 6.8% over baseline).

We also measure the CPU utilization of all CRAB threads during the experiment using Linux utility top. On a 2.4GHz 8-core machine, CRAB has an overall utilization of 10.34%. Almost all of the CPU usage stems from the throughput measurement thread of CRAB due to traffic sniffing. This is because Scapy, the Python-based packet sniffing library we use, copies the entire packet even though we just need access to a few packet header fields. The corresponding CPU overhead at the home router, which uses tcpdump for sniffing, is 16.65% on two cores at 1.8GHz. Writing a custom sniffer for CRAB that copies only a few packet header fields can potentially reduce the CPU overhead. We are working on shifting our throughput measurement module to a faster packet sniffing library like libtins [4].

xBGP: Faster Innovation in Routing Protocols

Abstract

Internet Service Providers use routers from multiple vendors that support standardized routing protocols. Network operators deploy new services by tuning these protocols. Unfortunately, while standardization is necessary for interoperability, this is a slow process. As a consequence, new features appear very slowly in routing protocols.

We propose a new implementation model for BGP, called xBGP, that enables ISPs to innovate by easily deploying BGP extensions in their multivendor network. We define a vendor-neutral xBGP API which can be supported by any BGP implementation and an eBPF Virtual Machine that allows executing extension code within these BGP implementations. We demonstrate the feasibility of our approach by extending both FRRouting and BIRD.

We demonstrate seven different use cases showing the benefits that network operators can obtain using xBGP programs. We propose a verification toolchain that enables operators to compile and verify the safety properties of xBGP programs before deploying them. Our testbed measurements show that the performance impact of xBGP is reasonable compared to native code.

1 Introduction

Internet Service Providers (ISP) are continuously challenged by their users and customers to provide value-added services that go beyond best-effort connectivity. Among others, these new services include traffic engineering techniques to prioritize some flows over others and improve network load, fast reroute mechanisms to swiftly retrieve connectivity upon failures, or anycast routing. In addition, ISPs are trying to improve their internal operations in order to provide an ever better service to their customers. This can be done by implementing a monitoring system, re-architecting or tuning the internal network.

Almost invariably deploying these services require extending routing protocols. And among all protocols, the Border Gateway Protocol (BGP) is probably the most used one given its flexibility: for many network operators, BGP has become a true “Swiss-army knife”. Originally designed to distribute interdomain routes, BGP has been extended several times to support different types of services [41, 55].

While extending BGP is possible, it is certainly not easy, for two main reasons. First, ISP networks often include routers from different vendors [17, 69]. This diversity is inherent and required for technical, safety, and economic reasons. Unfortunately, this diversity means that operators can only use the *intersection* of the features set across all their routers, hindering flexibility.

Second, it can take years for even a subset of the vendors to implement new features as these need to be first standardized by the Internet Engineering Task Force (IETF). Many view this as a form of ossification of the routing protocols. As an illustration, a recent paper [79] showed that the median delay before RFC publication of BGP extensions is *3.5 years*, and that some features required *up to ten years* before being standardized.¹ This is only the tip of the iceberg though: only a small subset of the BGP extensions proposed by network operators have been discussed and later adopted by the IETF.

Of course, this is not a new story. Frustrated by these delays and the difficulty to innovate in networks, researchers have argued for Software-Defined Networks (SDN) [48] for more than a decade. Instead of relying on a myriad of distributed protocols and features, SDN assumes that switches and routers expose their forwarding tables through a standardized API. This API is then used by logically centralized controllers to “program” routers and switches.

While SDN has enabled countless new research works [21, 42], it has not been widely adopted by ISPs. One of the main hurdles is that deploying SDN requires a major network overhaul, both at the control-plane level, to deploy scalable and robust logically-centralized controllers, *and* at the

*Thomas Wirtgen is supported by a grant from F.R.S.-FNRS FRIA.

¹Note that this delay ignores the time elapsed between the initial idea and its first adoption by the working group, making the actual delay even longer.

data-plane level, to deploy compatible network devices. Thus far, only large cloud providers managed to perform this overhaul [36, 39].

Of course, instead of relying on commercial routers, network operators could decide to adopt open-source implementations of routing protocols [16, 23, 33, 67] running on servers or custom hardware [3]. A network operator could for instance fork a BGP implementation to add a desired feature. Maintaining this fork requires a lot of software development effort though. Such an approach is feasible for large cloud providers [62] but not for ISPs. Another approach is to use a modular routing implementation to take full control of the protocol. The network operator is responsible for the entire routing implementation. Unfortunately, it is too difficult to maintain and evolve because the network operator must have a complete understanding of the routing protocol and must have software programming skills, which they often do not have. To provide flexibility in the administration and automation of their routers, router vendors have added a Python interpreter to their operating systems [40]. However, the interpreter only handles the administration part of the router and does not provide an interface to add or modify protocol features. Finally, the use of active networks with centralized approaches or descriptive configuration languages [10, 27] is not possible in today's Internet, as autonomous systems still use decentralized protocols to establish peering links.

In this paper, we argue for much lighter weight and practical approach to network control plane programmability by *allowing the network operators to easily extend the distributed routing protocols that they already use*. Our new approach, which we call *xBGP*, is inspired by the success of the extended Berkeley Packet Filter (eBPF) in Linux [26, 35] and Windows [49]. eBPF is an in-kernel Virtual Machine (VM) that relies on a custom instruction set. Thanks to eBPF, programmers can easily (and securely) deploy new programs that can access a subset of the kernel functions and memory [26]. Similarly, in *xBGP*, different BGP implementations expose an API and an in-protocol VM with a custom instruction set to access and modify the intrinsic protocol functions and memory. Thanks to this API and the VM, the *same* code can be executed on different implementations. Note that the instructions set and the in-protocol VM still need to be adopted and implemented by each vendor, but this is a one-time effort, instead of a *per-feature* effort.

Naturally, opening up BGP implementations to external programs opens the door to many (research) questions: *Which API should BGP expose? How to implement this API efficiently or What about the correctness and the safety of these extensions?* We answer these questions in this paper and make four main contributions.

First, we introduce the *xBGP API* which defines a set of functions that should be supported by an extensible BGP implementation. We present this API in Section 2 and describe how we modified two different BGP implementations, BIRD

and FRRouting, to support *xBGP*.

Second, we present a complete validation workflow that enables operators to validate that their extensions correctly terminate, do not interfere with the memory of the host implementation, produce syntactically valid BGP messages, or only use the *xBGP* API functions authorized by the network operator. We envision this workflow to become one element of the qualification tests that operators already carry out before deploying any new BGP feature in their network.

Third, we showcase the practicality of *xBGP* by implementing eleven use cases with *xBGP* to: support a new BGP attribute; introduce new selection rules; restrict the set of paths it can compute; detect unused routes (zombies); or monitor BGP operations. Each use case involves the same *xBGP* bytecode running on both FRRouting and BIRD.

Fourth, we demonstrate the practicality of *xBGP* by measuring its overhead compared to native implementations. Even for complex extensions (re-implementing BGP Route Reflection), our benchmarks show that the overhead of *xBGP* is always under 13%, a reasonable value given the flexibility benefits.

Similarly to what OpenFlow [48] achieved, we believe that programmable distributed routing protocols have the potential to open up *many* promising avenues for research, while being fundamentally more practical and deployable.

2 Architecture

At a high level, *xBGP* enables network operators to customize or extend any compatible BGP implementation by injecting and directly executing *xBGP* programs. As an illustration, we consider how to expand a BGP implementation to support a new BGP attribute, *GeoLoc*, that stores the geographic location (i.e., longitude and latitude) of where each BGP route was learned. Among others, this attribute can be used to adapt router decisions, e.g., by filtering away routes learned more than *x* kilometers away. Supporting such an attribute has been discussed within the IETF but never standardized [13]. Yet, large-scale ISPs reportedly use iBGP filters [71] to achieve the same effect. Using iBGP filters is risky though as doing so can lead to permanent oscillations [71].

To implement the *GeoLoc* extension, we need to support several operations in a BGP implementation. (1) When a route is received over an eBGP session, the router adds a new attribute, `Geo_Originator` that contains the geographic coordinates of the router that learns the BGP route in an import filter. (2) If the BGP route already contains the `Geo_Originator` attribute, the router needs to decode it. (3) When exporting the route to another peer, the router can use the `Geo_Originator` attribute to filter routes that are too far away. (4) To be usable by other iBGP peers, the attribute needs to be added to the BGP Update message.

To add this extension, we need to understand how BGP implementations are designed. There are many ways to organize

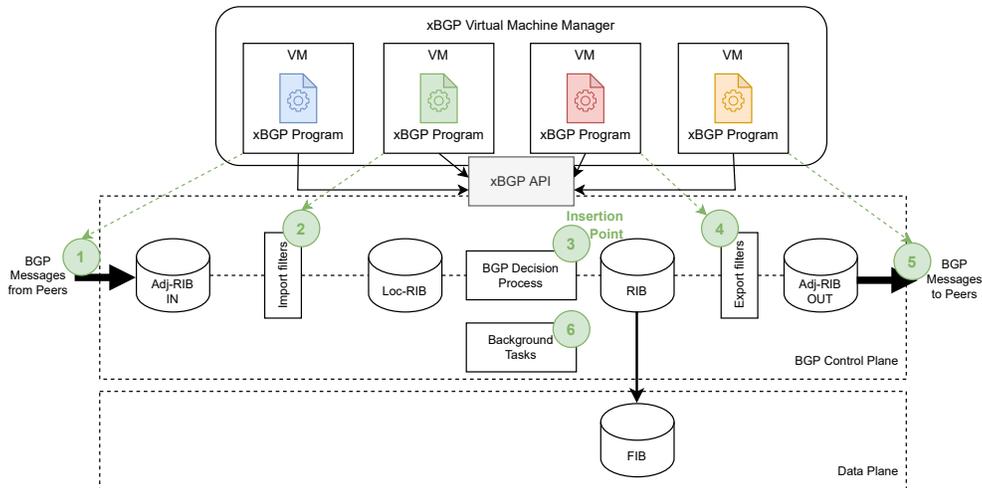

Figure 1: An *xBGP* compliant implementation exposes the abstract BGP data structures defined in RFC4271 through a generic API and uses *libxBGP*'s Virtual Machine Manager to attach the bytecode that implements extensions to specific insertion points (green circles). The four bytecodes in this example support a simple GeoLoc BGP attribute. For each *xBGP* program, we provide the set of helper functions used to retrieve data from the host implementation.

a BGP implementation. Each implementer selects a particular software architecture and the associated data structures based on their own requirements. However, all BGP implementations must adhere to the protocol specification [54]. This specification defines the format of the BGP messages, an abstract BGP Finite State Machine that manages each BGP session, and also an abstract workflow and data structures that describe how BGP update and withdrawal messages should be processed. This workflow is illustrated in black in Figure 1. Starting from the left, a received BGP message is stored in the *Adj-RIB-in*². It then passes through the *import filters* that may decide to discard the message or modify attributes such as *local-pref*. If the route is accepted by the import filters, it is inserted in the *Loc-RIB*. The *Loc-RIB* contains all the BGP routes accepted by the router. The BGP decision process extracts from the *Loc-RIB* the best routes that are placed in the *RIB*. These routes then pass through the *export filters* before being advertised over BGP sessions.

Going back to our *GeoLoc* extension, we can see that it can be added to the different parts of the BGP workflow. (1) needs to be added to the part that parses a BGP attribute. (2) and (3) must be designed as import and export filters respectively. And (4) will be added to the serialization part of the BGP implementation. The question now is how to add those subcomponents to the main BGP implementation. To answer this, we defined the insertion points depicted in Figure 1 with the green circles on which functionalities can be added or modified. These insertion points correspond to the major BGP events. It is now easy to add the four components of our simple

²Some implementations do not explicitly maintain a separate *Adj-RIB-{in,out}* to reduce their memory consumption and store everything in the *Loc-RIB*. We ignore this implementation detail in this paper.

extension to the BGP implementation in their respective insertion points. (1) is attached to the *BGP_RECEIVE_MESSAGE* ① insertion point. First, it queries the BGP neighbor's table and determines the type of the eBGP session. Then, it retrieves the contents of the received BGP update in network byte order. Finally, it attaches the new GeoLoc attribute to the route. The second program (2) is attached to the *BGP_INBOUND_FILTER* ② insertion point. It retrieves the router coordinates from the router configuration to add them to the attributes of the route. The program (3) attached to the *BGP_OUTBOUND_FILTER* ④ retrieves the neighbor information and the *GeoLoc* attribute to check if the route can be advertised to the peer. Finally, the fourth program (4) is attached to the *BGP_ENCODE_MESSAGE* ⑤ insertion point. It uses the BGP GeoLoc attribute received over an iBGP session decoded by the first program and sends it to the peer.

To be able to dynamically augment the BGP implementation, the four *xBGP* programs are executed inside a Virtual Machine and are attached to specific *insertion points* in the BGP implementation. An *xBGP* program is composed of eBPF bytecode executed by a user space virtual machine that is included in any *xBGP* compliant implementation. Thanks to this eBPF virtual machine, the same *xBGP* program can be executed on the CPUs used by different router platforms.

An *xBGP* program is not a standalone executable that performs computations autonomously. It can interact with the underlying BGP implementation, access its data structures, and call some of its functions. In contrast with operating system kernels such as Linux, FreeBSD or macOS that expose a similar POSIX interface, there is no standard API for BGP implementations. *xBGP* must then propose a common API to support several BGP implementations. If we take our ex-

tension, when the *GeoLoc* program has finished decoding the *Geo_Originator* attribute, it must update the BGP route stored in the BGP implementation. Thus, our extension needs to fetch or set data from the host implementation. For this, the BGP implementation must propose a set of functions, the *x*BGP API [75], that enable the interactions between the extension and the internal data structures. For example, with a call to the function `set_attr`, the extension can add a new attribute to the BGP route being processed.

An important data structure of a BGP implementation is its Routing Information Base (RIB). It contains the routes selected by the BGP decision process and pushed in the Forwarding Information Base (FIB). The BGP RIB stores, for each known destination prefix, its BGP route containing its BGP attributes, including its AS-path and the address of the BGP next hop. The RIB also contains information from the intradomain routing protocol such as the cost to reach each next hop. BGP implementations use various data structures to store their RIB. Some implementations simply store the BGP attributes as they were received from the wire. Others use a specific structure for each type of attribute. To ensure that the same *x*BGP program can be executed on any compliant implementation, *x*BGP defines its own representation for IP prefixes, next hops, and BGP attributes. For the latter, *x*BGP simply relies on the wire format [54]. *x*BGP also defines a neutral representation of the BGP neighbor's table. With these representations, *x*BGP programs can access the data structures of the underlying BGP implementation. When required, *x*BGP converts the internal representation to its own format before returning data to *x*BGP programs and vice versa.

The remaining of this section describes the composition of the *x*BGP API enabling *x*BGP programs to interact with BGP implementations in Section 2.1. Section 2.2 shows how we execute an *x*BGP program inside the BGP implementation. We explain in Section 2.3 which challenges we faced to make two BGP implementations, BIRD and FRRouting, *x*BGP compatible.

2.1 The *x*BGP API

Besides some utility functions (memory management, conversion between network and host byte orders, simple math functions, etc.), most of the *x*BGP API is specific to BGP [75].

To modify internal BGP data structures, *x*BGP programs rely on `getters` and `setters` to access data structures stored on the host implementation. This ensures (i) an isolation layer between the host and the *x*BGP program and (ii) a uniform method of accessing data regardless of the BGP implementation. These functions convert the internal representation into a universal one understood by *x*BGP programs. In addition, extension codes require access to the BGP internal state (e.g., list of peers, the route attributes, the route next hop). Hence, *x*BGP requires BGP implementations to provide routines translating their internal data structures into *x*BGP

ones. These include `getters` and `setters` to access/modify a BGP route including its attributes, next hop and the data that identifies a BGP peer. We also provide functions to iterate the RIB. These enable searching for a route other than those provided by the insertion points, and therefore for searching routes already installed in the BGP routing table.

Existing router OSes do not provide a common way to access internal routing data. The *x*BGP API provides functions to access IGP data, e.g., to retrieve the next hop for routes and use them in use cases described in Section 5.

An *x*BGP program can deliberately send a custom BGP message to any peer it wants. Instead of relying on an insertion point to generate the message, the *x*BGP API contains functions to send BGP messages allowing a program to send an urgent message like a BGP notification because the *x*BGP program detected a problem with a given peer.

To access non-standard data such as the geographic coordinates of the router, an extension code may require additional configuration. One approach is to directly include the data inside the code of the *x*BGP program. However, this is not scalable if the operator wants to deploy it on a large number of routers. This induces a recompilation of the code for each of its router. Instead, the *x*BGP API proposes to the network operator to include a configuration data part in a structured textual file accompanying *x*BGP programs called *manifest*. The *x*BGP program uses it later to retrieve what it needs. This extra configuration part is not directly accessible to the *x*BGP program but can be accessed through a set of API functions.

Finally, *x*BGP programs can be executed as background tasks ⑥ that are called when a timer expires. These tasks are not triggered by a specific BGP event like an insertion point but are rather executed when a timer expires. Background tasks are only used for processes that do not interact with the BGP workflow. Each task controls its timer and *x*BGP deliberately restricts one timer per task to avoid timer explosions. However, the task may ask to queue forever as long as the BGP router is alive. This is particularly interesting for *x*BGP programs that make routine maintenance for example. Each background task is executed in a dedicated thread to allow the original BGP implementation to run in parallel. If the *x*BGP program must access or update data, the *x*BGP API must be thread safe. This constraint must be respected when implementing the *x*BGP API.

2.2 Executing *x*BGP programs

An *x*BGP program is a set of eBPF bytecodes, either attached to different insertion points or executing background tasks. Each *x*BGP bytecode has its own dedicated memory, including a stack and a heap that are automatically freed after execution. This memory isolation between extension codes is guaranteed by the eBPF virtual machine. This ensures that orthogonal extensions will not interfere with each other. Yet, *x*BGP programs may need to keep persistent storage or to

exchange data between the different bytecodes that compose a program. For this, the `xBGP` API provides a key-value store that is similar to the BPF maps used in the Linux kernel.

Each `xBGP` implementation includes userspace eBPF virtual machines that are controlled by a manager. The *Virtual Machine Manager* (VMM) attaches bytecode with an associated virtual machine to one specific insertion point exposed by the host implementation. Each `xBGP` program includes a manifest listing the extension codes and their insertion point. Different extension codes can be attached to the same insertion point, and the manifest defines in which order they are executed. The manifest also lists the different `xBGP` API functions that the bytecode may use.

An `xBGP` program can be attached at different insertion points, i.e., specific code locations in a BGP implementation from where the program can be called. These insertion points correspond to specific operations that are performed during the processing of BGP messages, enabling `xBGP` programs to modify the router's behavior. `xBGP` defines six generic insertion points (green circles in Fig. 1) based on the original definition of BGP [54]. The sixth insertion point is dedicated for background tasks.

By default, the VMM only runs one `xBGP` program per insertion point. `xBGP` programs must explicitly tell the host implementation to run the next `xBGP` program if any through the `next()` function. This mechanism avoids executing useless code. For example, if we attach two `xBGP` programs that parse different BGP attributes into the insertion point that processes a single BGP attribute, and the first program successfully parses the message, there is no need to run the second one.

2.3 Adding `xBGP` to BGP implementations

To demonstrate the feasibility of `xBGP`, we have adapted two open-source implementations: BIRD v2.0.7 [16] and FRRouting v7.3 [23].

Adding the `xBGP` API. Implementing the API induced a total of 400 and 589 additional lines of code [78] on BIRD and FRRouting, respectively. The difference between both is their internal representations of the BGP data structures. The `xBGP` functions that deal with BGP messages and attributes always manipulate them in network byte order (`xBGP`'s neutral representation), performing the translation to the storage format used by the implementation if required. FRRouting uses an internal representation that is different from our neutral one. We thus had to implement several functions to do the conversion between the two representations. Another difference is the handling of BGP attributes. BIRD includes a flexible API to manage BGP attributes. `xBGP` simply extends this API. FRRouting does not include such an API, so we had to implement one to be able to manipulate BGP attributes in BGP updates.

Integrating `libxbgp`. `libxbgp` is a portable library, im-

plemented as 432 lines of header code, which consists of two parts: (i) the utility functions of the `xBGP` API; and (ii) the VMM. The VMM is in charge of executing the right extension code according to the state of the host implementation. This layer acts as a multiplexer. To include `xBGP` operations, the BGP implementation calls the VMM to execute the associated extension codes. Then, the VMM proceeds as follows. It first checks if there are attached extension bytecodes to the called `xBGP` operation. If not, the VMM executes the default function provided by the implementation. Otherwise, it runs the first extension code mentioned in the manifest. Two outcomes are possible. First, the extension code provides a result for the operation and the VMM returns the output to the caller. Second, the extension code delegates the outcome to another one by calling the special `next()` function. In that case, the VMM checks whether there are remaining codes in the ordered queue. If there are, the VMM runs the next extension code in its virtual machine. Otherwise, the behavior of the `xBGP` operation falls back to the default function provided by the BGP implementation. For instance, two extensions can attach bytecode to the `BGP_RECEIVE_MESSAGE` operation that processes their own dedicated BGP attribute, calling `next()` once they are done.

Technical challenges. While adding the `xBGP` API and integrating `libxbgp`, we encountered some interesting technical issues. To successfully use the `xBGP` API, data must be available when the function is called. In some cases, data in the host implementation was not available when the insertion point was called to execute the extension code. For example, in FRRouting, export filters are applied to a set of peers sharing the same type of outbound policies. This set is not passed to the code checking the outbound policies but is required to implement the helper function that retrieves data about the BGP peers of the router. We had to write 5 extra lines of code to get the set of peers before calling the insertion point. Also, some data structures were not flexible enough to fully support the `xBGP` API such as the function that adds or modifies a new attribute to a BGP route. However, the internals of FRRouting do not allow adding unsupported attributes that are not defined by any standard (e.g., `ORIGINATOR_ID`). We rewrote this part of FRRouting. To address those issues, we had to add 30 and 10 lines of code to FRRouting and BIRD respectively.

Each API function is called within a context of execution. This context is hidden within the extension code but visible in the host BGP implementation. This makes it possible to control which extension code has called the function. The context is also used to retrieve variables that cannot be directly used inside the extension code. For example, if an extension code needs to allocate extra memory (ephemeral or not), the ephemeral memory is also automatically freed when the extension code terminates its execution. Similarly, the context enables helper functions to access data structures that are out of the extension code's scope. For instance, a dedicated helper

function enables an extension to add a new route to the RIB. When setting an insertion point, the BGP implementation can pass a set of arguments. While some are visible inside the extension code, others are not. The RIB function leverages such hidden arguments to access the data structure while being transparent to the extension code.

Limitation of *x*BGP. To better understand what can and cannot be done with *x*BGP, we analyzed the complete list of RFCs, which defines extensions to BGP, that have been published since the publication of RFC4271 [54]. The RFCs can be classified into two different types. (1) The RFCs that modify the original definition of RFC 4271 (6 RFCs) and (2) those that add features on top of BGP (30 RFCs). For (1), *x*BGP cannot be used to implement these types of RFCs because it requires a direct modification of the underlying BGP implementation. For example, increasing the internal buffer size of the BGP message size [9] is not feasible with *x*BGP. For (2), *x*BGP can be used. However, it turns out that our current prototype focuses only on the messages that BGP speakers exchange once the session is established (BGP Updates and BGP Withdraw). Not all session-level extensions to BGP can be handled by *x*BGP. For example, our current prototype cannot extend the BGP Open or BGP Route-Refresh [12] message. However, *x*BGP contains a generic insertion point, `DECODE_BGP_MSG`, that can handle future types of BGP messages. If the underlying BGP implementation does not support route refresh, we can implement it as an *x*BGP program. Modifying *x*BGP to allow it to support the session level could be implemented at a later time, but *x*BGP cannot change the architectural design of the underlying implementation. This is an important limitation of our solution. For example, no *x*BGP program can increase the size of the BGP transmit and receive buffers as defined in the corresponding RFC [9]. The internal structure of an implementation cannot be modified on the fly by a program since the definition of the structures is strongly integrated in the program binaries.

In addition to the limitation of the features that can be implemented, *x*BGP focuses mainly on the internal network, we assume that the network operator enables the necessary *x*BGP programs on the relevant routers. However, if the BGP routers decode an unknown message, it will be silently discarded and will not harm the router but will compromise the other router's computation. BGP capability negotiation messages can be exchanged to indicate whether the extension implemented by the *x*BGP program is supported by both routers implied in the BGP session. Capability support is beyond the scope of this paper.

3 Ensuring the safety of *x*BGP programs

BGP implementations generally run 24/7 and never stop. When operators deploy a new router or a new version of a router operating system, they typically run extensive tests

to verify that the new feature will not break their network. From an operator's viewpoint, injecting an *x*BGP program is always risky since the program will be executed within the BGP implementation. A simple approach would consist in letting the VMM monitor their execution and stop them in case of error. This could be too late for errors that could disrupt BGP sessions. Network operators typically need some safety guarantees from the *x*BGP program. The Linux kernel copes with a similar problem by using a custom online verifier [1] that checks different aspects of eBPF programs *before* they are injected into the kernel.

Verifying *x*BGP programs. *x*BGP also relies on verification techniques to ensure that programs can be safely injected. However, instead of developing a custom verifier [24], we (i) establish a list of properties that an *x*BGP program should respect to be considered as safe and (ii) we build a toolchain embedding three existing and well-tested software verification tools allowing the verification of our properties. Our *x*BGP toolchain receives the *x*BGP programs as input. They consist of C code that uses the *x*BGP API and a manifest provided by the network operator containing the configuration data. This code is by nature untrusted and must be manually augmented with various annotations providing hints to the code verifiers, given the specificities of each one. Such annotated extensions can then enter the *x*BGP toolchain which executes in parallel each verifier. The bytecode is produced only if the code passes all of them. Once the bytecode is generated, it is added to the integrated *x*BGP store. A network operator can safely select and load *x*BGP programs coming from this store. We expect that initially each ISP will have its own store. Later, third parties or router vendors could also develop their own stores. We consider this toolchain as trusted, i.e., we select a particular compiler, `clang`, and specific verifiers, all considered as correct. Therefore, we do not need to reason about the produced bytecode and ignore problems such as handling maliciously formatted bytecode.

Embedded verification tools. The whole *x*BGP toolchain, illustrated in Figure 2, is designed to prevent four types of problems that a program can cause. First, if an *x*BGP program enters an infinite loop, it will block the underlying BGP implementation. We use the Terminator 2 (T2) automated termination checker [15] to verify the termination of *x*BGP programs.

The second set of possible problems is the way *x*BGP programs interact with the memory of the underlying BGP implementation. We use CBMC [43] and SeaHorn [31] to verify memory-related properties.

The third type of problem is related to *x*BGP and BGP themselves. *x*BGP programs can create new BGP attributes or messages that are sent over a BGP session. We use SeaHorn to verify that the BGP messages emitted by *x*BGP programs are fully compliant with the BGP RFCs and that their return values respect the *x*BGP requirements.

Finally, operators may want to be able to impose restric-

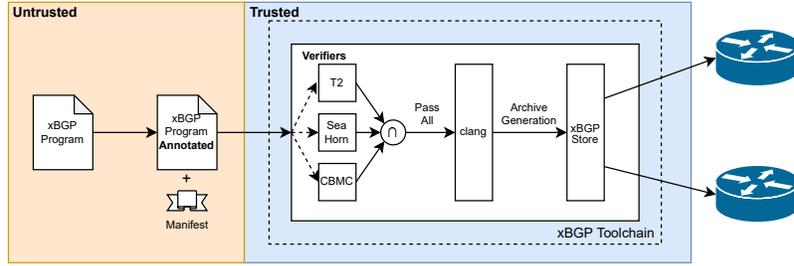

Figure 2: High-level view of the xBGP verification toolchain.

Property	Verifier	Type
Termination	T2	Safety
Reads/Writes within xBGP program's memory space	CBMC	Safety
No buffer overflow, use after free memory, invalid read, etc.	CBMC	Safety
All strings must be null terminated	SeaHorn	Safety
Correct size/buffer combination	SeaHorn	Safety
RFC-compliant syntax of BGP attributes	SeaHorn	BGP
Valid return value	SeaHorn	Safety
Checking attribute reads/writes	SeaHorn	BGP
Checking API function accesses	libxbgp	Safety + BGP
Call the next () function to trigger the next xBGP program	SeaHorn	Safety

Table 1: Properties that xBGP programs must satisfy.

tions on the xBGP functions and data structures that a given xBGP program can use. For example, a customer filter should only be able to set a local-pref value in a chosen range and to change nothing else. So it could never add a new BGP attribute to a route it filters. These restrictions are enforced with (i) SeaHorn that checks the validity of the arguments of the API functions and (ii) libxbgp which restricts the available API functions at loading time.

To be considered valid, any xBGP program must satisfy the properties listed in Table 1. If every xBGP bytecode satisfies this list, the router is guaranteed (i) not to crash and (ii) to still follow the definition of the protocol. These properties ensure the local stability of each router. Ensuring the global stability of BGP [28–30, 46] is a problem that goes beyond the scope of this paper.

Verification macros. Because of their diversity, the verification tools do not offer a common way to annotate programs. In the case of xBGP, this would mean annotating the plugin 3 times with different annotations and running the 3 tools manually. For a network operator, manually using several tools can be a long, tedious, and error-prone process. To ease the annotation process, we define a set of multipurpose macros `PROOF_INSTS_*()` abstracting the annotation syntax of the verifiers. Those are only expanded if the corresponding verifier is invoked. When the extension programs are compiled

```

buf[0] = attribute->flags;
buf[1] = attribute->code;
buf[2] = attribute->length;
buf[3] = attribute->data;
CHECK_ORIGIN(buf);

```

(a) Annotated Code.

```

assert(buf[0] == ATTR_TRANSITIVE);
assert(buf[1] == ORIGIN_ATTR_ID);
assert(buf[2] == 1);
assert(((buf[3] == 0 || \
         (buf[3] == 1 || \
          (buf[3] == 2)))));

```

(b) Expanded Code (verifier).

Figure 3: Example of a verification macro that checks the origin attribute of a BGP route. The macro can be extended or not according to its use. (a) is the original source code and (b) is the code viewed by a verifier.

for routers, the annotations are not expanded and thus will not interfere with the normal BGP execution. Figure 3 shows an example of such verification macro.

Aside from the verifier syntax abstraction, we mainly bring two contributions. First, we define a set of macros helping network operators to verify the properties listed in Table 1. Network operators can use them to annotate their xBGP programs. The macros are translated to their corresponding annotation to the right software verifier. For example, a network operator can use the `BUF_CHECK_*` macros to verify if the BGP attributes sent to a BGP peer are formatted as stated in the RFCs.

Second, we set up a verification toolchain that automatically performs verification on the xBGP programs. It automatically and transparently calls all the verification tools and verifies the annotations contained in the source code of the programs. If all properties are satisfied, the system stores the verified plugins in a “plugin store”, which the programmer or network operator can use to inject into their routers. The routers will only accept plugins that have been verified and signed by the plugin store.

Those macros, in conjunction with our verification toolchain, allow a complete abstraction of the verification process. This makes the usage of xBGP simpler for network operators. The entire set of verification macros is defined in Appendix B.

3.1 Proving xBGP Programs' Termination

T2 (TERMINATOR 2) is a program analysis tool for termination [15] and temporal property [7] verification. We were

successfully able to prove the termination of every *x*BGP program that implements the use cases defined in this paper. Table 3 reports the total time taken by the verification toolchain to verify all the properties defined for the *x*BGP programs, including the termination checks. However, to check the termination we had to slightly modify the source code since some specific features of the C language were not supported by the prover. First, when using fixed-width integer types (e.g., `uint8_t`), T2 was not able to generate the proof of termination. We had to convert those types to their primitive type. Second, all the loops of the program must be explicitly bounded. For example, if the *x*BGP program needs to parse a BGP attribute, we must explicitly bound it to 4096 iterations, the maximum size of a BGP message [54]. Third, T2 does not handle bit shift operations. To solve this issue, we encapsulated the bit shift computation in a non-deterministic function. This is a function that is not defined in the source code of the *x*BGP program but simply tells T2 that it returns an arbitrary integer value that T2 can handle. Such non-deterministic function is also considered to terminate by T2.

3.2 Preventing Memory and C Errors

C is a permissive language and programmers can easily make mistakes in their programs while handling memory. A bug in an *x*BGP program that causes a buffer overflow or leads to using freed memory could crash the underlying BGP implementation. An earlier prototype automatically instrumented the eBPF code to verify these properties online [79]. The verification was made at runtime by adding memory check instructions to the *x*BGP bytecode. However, this had a performance impact. Our new *x*BGP toolchain uses the CBMC bounded model checker [43] to verify the absence of simple memory-related issues and SeaHorn [31] to detect more complex issues. That being said, the online verification of the memory bounds remains in *x*BGP and the operator can enable it or not at *x*BGP bytecode load time.

CBMC is a C Bounded Model Checker that uses loop unwinding methods. It requires that loops are strictly bounded [43] which implies that the code of *x*BGP programs must be adapted. It automatically annotates code, generates a formula and proves it *via* an integrated SAT solver. It can spot common C programming errors [14]. However, more complex properties cannot be checked automatically. For example, *x*BGP programs can log data to syslog. The functions used for that take a string as arguments. Nevertheless, C strings are not safe by design. We must ensure that each string is correctly null-terminated to prevent buffer overflows. Another example is the alteration of BGP attributes. An *x*BGP program needs to call an API function that takes as arguments a pair `<buffer, length>`. Those two values must correlate: if the actual buffer length is shorter than the announced length, the host implementation is vulnerable to a buffer overflow. We use SeaHorn [31] to prove properties written directly in

the code as assertions.

We provide a set of C macros that operators call in the *x*BGP programs they verify. The first one is verified by searching for a null byte within the string. For the second one, we verify before each API call if the length passed to the function matches the buffer length. This is achieved by inserting custom annotations in the *x*BGP programs and passing them to SeaHorn.

3.3 Ensuring BGP and *x*BGP Compliance

*x*BGP programs can (i) send new BGP messages or (ii) modify the internal representation of BGP routes. If such a program sends a message deviating from the standardized BGP syntax [54], it could disrupt BGP sessions and have a huge impact [47]. For (i), we verify that the syntax of the BGP message generated by an *x*BGP program conforms to the BGP RFCs. For (ii), we check that the modification is correctly formatted. A corrupted BGP route accessed outside the *x*BGP program could result in a crash of the *x*BGP implementation. For this, the code is annotated with assertions representing BGP invariants that are checked by SeaHorn. We also created a set of C macros verifying that standard attributes comply with their definitions (correct flags, size, etc.). For non-standard attributes, we check that they respect a TLV format. For BGP messages, we check that the buffer containing the message conforms to the BGP syntax [54].

In addition, *x*BGP programs also have to comply to *x*BGP requirements. Some insertion points require a “communication channel” with `libxbgp` to change the behavior of the host BGP implementation. This is achieved by using the return values of the executed bytecode. Therefore, bytecodes cannot deviate from predefined values. For example, an *x*BGP filter returns a specific value to tell the host to reject the current route. This property is verified with SeaHorn by considering the *x*BGP program as a function called inside a “fake” `main`. The return value is then retrieved and verified using a custom assertion.

3.4 Enforcing Operator-Imposed Restrictions

Thanks to the manifest, the operator can list the *x*BGP API functions and the data structures that each *x*BGP program can use. Imagine a filter that only checks the validity of the route without modifying any data related to this route. To decrease the risk of introducing bugs in *x*BGP programs, the operator can restrict the set of API functions the program can call. In this example, the filter should have a read-only view, and thus should not call any function altering BGP data structures.

To settle this, we implemented a permission manager inside `libxbgp` that verifies, at load time, the functions that a given *x*BGP program calls according to its manifest. Just before being loaded, `libxbgp` checks the *x*BGP bytecode to look for unauthorized API function calls.

Network operators use BGP communities [20, 64] to enable their customer to activate specific features such as setting `local-pref`, AS-path prepending, or selective advertisements on a per-route basis. With `xBGP` they could provide even more advanced services. Imagine you are a network provider that proposes to attach filters developed by its clients to their eBGP sessions. You define a set of BGP attributes the client can modify such as MED, `local-pref`, etc. When they use communities, operators establish policies on the attributes which can be modified in a BGP route. For example, they define ranges of possible values for the `local-pref` attribute [20]. To modify an attribute for a route, an `xBGP` program calls the `set_attr` API function. When the `xBGP` toolchain processes such a program, SeaHorn verifies if the arguments of the API functions respect the policies defined in the manifest, i.e., if both the argument to change and its new value are legitimate. This is done by adding assertions in the source code of the `xBGP` program supplied by the customer.

4 Overhead of the current `xBGP` prototype

Using `xBGP` in BGP implementations brings flexibility for a network operator since they can use a simple abstraction to program their router. However, this flexibility has a price in terms of performance. To evaluate the overhead of `libxbgp`, we consider three different features that are already implemented in both native FRRouting and Bird to have a fair comparison with `xBGP`. The first is a simple filter adding an arbitrary MED value to all exported routes. The second provides support for extended communities [59]. The third is a complete implementation of Route Reflection [4]. While we expect operators to mostly develop simple plugins such as the first two, the Route Reflection extension demonstrates the of flexibility `xBGP` by covering the whole BGP workflow described in Section 2. Furthermore, since Route Reflection is supported by both FRRouting and BIRD, this extension enables us to compare the overhead of an `xBGP` implementation with native ones.

To evaluate the performance impact of `xBGP`, we use the simple network described in Figure 4. We measure the delay between the first BGP update sent by the Upstream router and the last update received by the Downstream one. This reflects the time needed for the Device under Test (DuT) router to process the routes sent by the Upstream router. The Upstream and Downstream routers are running an unmodified implementation of BIRD v2.0.8 while the DuT router is running the `xBGP` version of BIRD or FRRouting according to the test. The DuT router is running an Intel® Xeon® X3440 @2.53GHz with 16 GB of RAM, Linux kernel v5.15.29 and Debian 11.

The Upstream router sends a full routing table from a recent RIPE RIS snapshot (June 3, 2021, at 4:15 PM) containing 873k IPv4 routes and 120k IPv6 routes. We consider multiple executions of the BGP daemon located in the DuT router.

Figure 4: Simple network used for `xBGP` evaluations.

Use Case	Processing Time	
	xFRR	xBIRD
No <code>xBGP</code> program	+1.05%	+1.6%
Filter Set MED	+6.67%	+2.59%
Extended Communities	+5.93%	-0.67%
Route Reflection	+12.97%	+7.43%

Table 2: Performance impact of running `xBGP` programs to `xBIRD` and `xFRR`.

Table 2 shows the relative performance impact of running the extensions with `xBGP` programs compared to their native implementation in both BIRD and FRRouting. For each `xBGP` compatible implementation, we run 10 times the `xBGP` programs and compute the convergence time. The convergence time is the time between the first BGP update message is received from Upstream to DuT and the last BGP update message sent from router DuT to Downstream.

Before even loading any `xBGP` extensions, bringing support of `xBGP` in a BGP implementation involves an initial overhead. More specifically, the host implementation must first construct the argument to be passed to the `xBGP` program, then request execution of the corresponding insertion point, and finally execute the `xBGP` termination routine. These additional steps increase the total number of instructions to be executed compared to the native non-`xBGP` implementation. To quantify the cost that `libxbgp` takes in BIRD and FRRouting, we ran both implementations of `xBIRD` and `xFRR` without plugins and compared them to their non-`xBGP` compatible versions. Making both implementations of `xBGP` compatible adds a cost in the convergence time of 1% and 1.6% in FRR and BIRD respectively.

We now consider the MED filter (one insertion point) and the extended communities (two insertion points) extensions. When implemented as `xBGP` programs, these slightly increase the convergence time compared to their native version. The Just-In-Time compiler used inside the virtual machine does not optimize as efficiently as the one producing native code. In particular, computation-intensive bytecode involving additions, subtractions, and multiplications take 50% more time to run than native code. This overhead is even worse when considering division and modulo operations.

Yet, we observe a higher convergence time increase for FRRouting than BIRD. By analyzing the execution of each `xBGP` bytecode with a code profiler, we identified two main reasons for this difference. First, to communicate with the host implementation, the `xBGP` program must pass through a dedicated `xBGP` API. For security reasons and because of

the internal mechanism of `libxbgp`, the data of the host implementation are first translated into a neutral representation, then copied into a dedicated memory area, accessible in writing and reading by the bytecode. Translation and copying play an important role in the execution of a plugin but are needed to run the same `xBGP` program in several BGP implementations. BIRD internally uses data structures that are closer to the `xBGP` neutral representation than the FRRouting ones, hence involving less translation overhead. Second, FRRouting and BIRD have different internal architectures. The interactions between the `libxbgp` API and the BGP implementations are different. FRRouting is less flexible as its implementation is not designed to be quickly extended with new functionalities. While in BIRD, most of the insertion points map to a specific place, in FRRouting some insertion points must be repeated at different code places, involving up to four times more `xBGP` program calls than BIRD.

We now consider the Route Reflection extension covering the whole BGP workflow. Supporting this feature requires a list of all iBGP client peers. Routers' implementations use their dedicated CLI syntax to define all their iBGP client peers. `libxbgp` does not have access to this CLI configuration since it is implementation-dependent. Instead, it relies on its configuration data within the manifest that can be accessed at any time by the `xBGP` program. On average, the BIRD's convergence time is 7.5% slower than the native code while FRRouting's one is 13% slower. The previous elements still hold to explain the difference between BIRD and FRRouting. In particular, there are more calls to `xBGP` programs in FRRouting due to its code architecture than in BIRD (`BGP_ENCODE_MESSAGE` is called 4 times more), and the translation time to convert data structures is non-negligible in FRRouting (up to 40% overhead for the import filter). Still, the performance overhead of `xBGP` remains in acceptable bounds.

5 Use Cases

Section 2 presented the *GeoTLV* feature to demonstrate that `xBGP` programs can create new attributes that influences the router. Section 4 presented the MED filter, extended communities, and route reflectors to make a performance comparison. This section presents other use cases, which are not implemented natively in FRRouting and BIRD, that illustrate the advantages of `xBGP` for various classes of problems that the operator wants to solve. It is true that the features of this section can be implemented in any BGP implementation without `xBGP`. However, feature support depends on the pace of implementation by all vendors. Thanks to the `xBGP` design, an operator can quickly design its features and introduce them into the network before they are implemented by the vendor. `xBGP` is the first step to bring extensibility to the network. The first use case defines an `xBGP` program (Section 5.1) to influence the decision process and the import and export

Use Case	C LoC	eBPF Insts	Total Verif Time(s)
Geo TLV (§2)	388	1340	664
MED Filter (§4)	55	149	79
Extended Communities (§4)	196	322	86
Route Reflection (§4)	509	3853	27
Route Selection (§5.1)	62	148	27
Zombie Detection (§5.2)	1071	5697	277
Decision Monitor (§5.3)	306	437	29
Propagation Time (§5.4)	560	805	73
Valley Free (§A.1)	143	960	182
Prefix Origin (§A.2)	150	661	57
IGP Data (§A.3)	36	149	3

Table 3: Verification of the `xBGP` programs supporting our use cases.

filters from the BGP client point of view. The second use case detects zombie routes (Section 5.2). These are routes that are installed in the routing table but are no longer reachable. Third, operators always try to understand the state of their network to improve it as much as possible. We present two use cases (Section 5.3 and 5.4), where BGP is monitored using communities. Due to space limitations, we detail three other extensions in appendix. The fifth use case is related to route filtering in data-centers (Section A.1). It demonstrates that `xBGP` can provide a programmable interface to design complex import and export filters. Our sixth `xBGP` program (Section A.2) gives another example of a special filter that checks the origin of a route. Finally, our seventh use case (Section A.3) shows that an `xBGP` compatible implementation can leverage IGP information to make routing decisions.

Table 3 reports the size of the `xBGP` bytecode, the number of lines of code and the time taken to validate every `xBGP` program according to the properties defined in Section 3.

5.1 Customer Selecting Routes

A BGP router only selects one route for each prefix even though it learns multiple routes. As a result, it will only send one route to each BGP neighbor, which decreases the path diversity. Consider Figure 5 to illustrate the situation. AS1, a multihomed stub network having peering links with Transit 1 and AS2. We are interested in the propagation of the routes to the destination network depicted in gray. To maximize path diversity in AS1, it should learn the purple path from AS2 to leverage the two different transits. However, AS1 cannot influence the decision process of AS2's routers.

Enabling the dissemination of multiple routes can bring several benefits such as load-balancing [45], avoiding route oscillation [29] and faster local recovery upon a network failure [61]. With `xBGP` it becomes possible to influence the border router to announce the route the client prefers. To design such an `xBGP` program, all edge routers must enclose their BGP client to one Virtual Routing and Forwarding table

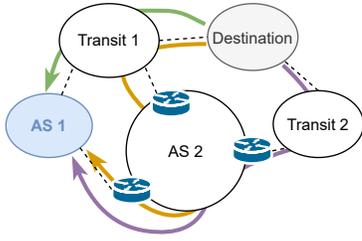

Figure 5: Path Diversity in a Network.

(VRF) [70]. All the routes learned from all neighbors will be exported to the main BGP-VPN RIB's router and then exported to the VRF of each client so that they can have a full view of the routes. Since all clients are in their respective VRFs, the BGP decision process is different for each of them and can therefore be influenced by an *x*BGP program that decides which route to advertise.

We designed a simple *x*BGP program that randomly selects one of the available routes in the VPN RIB thanks to the *x*BGP API function `get_vrf`. It demonstrates that *x*BGP allows the operator to create a customized and more powerful route selection compared to the traditional router CLI. Accessing the VPN RIB through a simple router configuration is something that cannot be done with traditional BGP implementation. Furthermore, an *x*BGP program has access to the entire BGP route and the internal data structure of the BGP router. *x*BGP therefore provides greater flexibility compared to the classical CLI.

We were successfully able to check the termination with T2, the C errors with CBMC, its compliance to the *x*BGP return values. We also verified that the program does not use API functions altering the BGP internal state.

5.2 Detecting BGP Zombies

When a route becomes unavailable, a BGP router sends a withdraw message to all its peers. Because of software bugs [22], it may happen that one of these BGP peers fails to process such a withdraw message. As a result, the route is still considered reachable by the failed router. This is an operational problem because the withdrawal is not propagated, and part of the network still believes that the route is available. If packets still follow this zombie route, they will be black holed. Measurements indicate that these zombie routes are common and affect many ASes [50].

To detect zombie routes, we designed an *x*BGP program that is executed periodically. It uses the timestamp of the arrival of a route in the RIB to detect the routes that are older than *x* days. Our threshold is arbitrarily fixed to a day. Our *x*BGP program is configured to be executed during the maintenance window. It parses the entire BGP RIB thanks to the API functions `*_rib_iterator`. If a route is older than the configured threshold, it is flagged as a possible zombie.

To confirm the status of the route, the router needs to request it again from the peer that announced it. This could be done with standardized mechanisms such as Graceful Restart [58] or Route Refresh [12, 51]. However, those two approaches require the remote router to announce again its entire BGP routing table. For the sake of performance, we decided to only ask the remote peer to reannounce the routes flagged by the *x*BGP program. We introduce a new type of BGP message called `BGP Refresh`. It contains a list of prefixes that the router wants to confirm. The peer receiving the `BGP Refresh` message will announce a withdraw or an update message if the routes are not available anymore or still in its BGP routing table respectively. *x*BGP allows sending BGP messages via the `schedule_bgp_message` API function.

It is difficult with a traditional BGP implementation to detect such a zombie route. Indeed, there is no mechanism to analyze and perform an action according to the state of the BGP routing table. To include this feature, the network operator must convince each router vendor to add this feature into its implementation. This use case demonstrates that *x*BGP can outperform the current configuration method that is proposed in classical BGP implementation.

This *x*BGP program successfully passes the T2 and CBMC verifications. As it manages BGP messages, we verified their compliance to the RFC. We also checked that the size of the buffers announced to the API function matches their real size. This program *x*BGP is an example of functionality that cannot be performed with the traditional router CLI while the router is running.

5.3 Monitoring the BGP Routing Decision

Currently, if a network operator would like to debug its BGP routers, he only has monitoring information from the routers it directly controls. This is due to the fact that the traditional BGP specification only provides the exchange of local routing information but does not provide any abstraction to send monitoring information about the routing process. Yet, a support of a dedicated monitoring channel has been proposed [60] but this is still not implemented on all vendor's routers. In a nutshell, a BGP router can ask its neighbor to give different metrics such as its number of reachable prefixes, its ADJ-RIB-IN, its current state, etc. This shows that many network operators need to monitor the BGP session to enable better control of routing information in the network. Some router vendors actually provide commands to retrieve the local state of a router. However, the information is restricted to the router view only and does not include the status of routers that are outside the operator's management scope. Having statistics from other routers could bring many benefits such as the selection of a better route. More specifically, if the BGP router sends its best routes with the step at which routes have been decided, the remote BGP router can learn much information about the route diversity in a network. If the routes are al-

ways decided at the very end of the BGP decision process, it indicates a lack of diversity in the remote network. On the contrary, if the routes are decided early in the process such when the `AS_PATH` is shorter than the previous best route, it can indicate a higher level of diversity. Thanks to this information, the BGP router can adapt its behavior to prefer a path with more diversity to be more resilient to a router or link failure.

We leverage *x*BGP to instrument the BGP implementation to retrieve at which step of the BGP decision process the route has been chosen. Each time it runs, an *x*BGP program retrieves the reason of the decision in the process. It can be retrieved through the arguments passed to the *x*BGP program. To inform other BGP routers, this information is added as a BGP community when sent to other BGP speakers. This is done by the API function `set_attr_to_route`. This way, other routers can parse and use this information to adapt their routing strategies. This *x*BGP program also collects statistics about the other steps of the BGP decision. Each time a route is selected, the *x*BGP program increments an internal counter. It repeats the operation for each decision step. When a route is sent to any peer, these statistics are attached as a community. The BGP router receiving the statistics can have a broader view of the current routing table of its peer. If all the routes have been decided by the BGP tiebreaker that compares the IP address of the router that sends the route then it shows a lack of path diversity. The network operator could then attribute a lower preference to the route advertised by the remote router.

This *x*BGP program successfully passes all the verifiers. Since it handles the BGP community attribute, we verified if the format is respected according to the corresponding RFC.

Since this information cannot be retrieved with traditional router CLI, this new approach could enable more fine-grained routing decisions. Indeed, this new type of active monitoring cannot be achieved with traditional monitoring tools such as BMP, SNMP, etc. as these later tools do not modify the BGP message they sent to the BGP neighbor. Network operators have thus at their disposal new information from outside their network.

5.4 Measuring BGP Route Propagation Times

For mission critical systems, the convergence time of a routing protocol is an important metric to know. It helps to better understand what could be the cause of a slow convergence. Discussions with network operators indicated that commercial router vendors provide undocumented CLI commands to access profiling points. However, this profiling information is local to each router. It could be useful to exchange such information within an entire network. This could open new opportunities to better understand the current state of the network. One example of such monitoring is the time taken by a BGP route to traverse an AS. To support such monitoring information, BGP must be augmented to add in

each route its arrival time at each AS border router. Our *x*BGP program defines a new non-transitive BGP attribute, called `RECEIVED_TIME`. It adds this attribute when a route is received over an eBGP session (thanks to the `set_attr` *x*BGP API function family). It traverses the AS with the BGP route until it reaches an edge router. The `RECEIVED_TIME` attribute is removed when the associated route is sent over an eBGP session and the border router computes the difference between its current NTP time and the one of the attribute. As for the previous use case, exchanging such monitoring information is not currently feasible with traditional routers. These two use cases show that *x*BGP can perform a new type of active monitoring by exposing the internal data of the BGP implementation itself to inform the other neighbor of the current BGP routing state.

6 Related Work

Protocol programmability. In the late nineties active networks were proposed as a solution to bring innovation back inside the network that was perceived as being ossified [65]. Most of the work in this area focused on the possibility of placing bytecode inside network layer packets. PLAN [66], ANTS [73] and router plugins [19] are examples. In the control plane, researchers built upon this idea to propose new solutions such as the 4D architecture [25], the Routing Control Platform that centralizes routing [11] or Metarouting [27] that proposed to open the definition of routing protocols using a declarative language. While these previous works propose configuration languages or centralized approaches to deal with network programmability, *x*BGP relies on an existing decentralized control plane protocol on which an operator can add its new functionality to locally influence the routing.

Bringing flexibility to an implementation of a network protocol has been studied in the literature. Researchers have proposed using extension codes to extend transport protocols like STP [52], QUIC [18] and the FRRouting implementation of OSPF and BGP [80]. However, the architecture of these pluginized approaches is close to the internal architecture of a single protocol implementation and does not offer the flexibility to pluginize different implementations of the same protocol. *x*BGP goes one important step further by enabling very different implementations to execute the same *x*BGP program. *x*BGP tries to determine what all implementations of a protocol have in common to try to find a common usable interface.

To ease the automation and the configuration of their devices, routers vendors added scripting languages that enable the network operator to execute recurrent tasks [6]. However, this acts as a simple shell that cannot be used to extend the router implementation. Other vendors integrated the python language into their router OS [40] to perform automation task more easily, such as configuring the router or executing a monitoring routine when a particular event occurs.

Reducing the BGP implementation to its minimum has been studied with CoreBGP [74]. However, it only manages the basic BGP Finite State Machine on which plugins written in the Go language are inserted. The remainder of the BGP logic such as sending BGP messages or managing the routing table is passed to the plugins. CoreBGP plugins react to an FSM events while *x*BGP programs react to protocol events defined by the insertion points depicted in Figure 1.

XORP [33, 34] was introduced to propose an open-source software router platform. This solution has been designed to allow researchers to easily develop their own extensions to a routing protocol. Other open-source routing stacks have been developed such as Quagga [2], FRRouting [23] or BIRD [16]. While these open-source stacks allow modifying the source code of the routing software, *x*BGP goes one step further by introducing a simple API to interact with the routing software. There is no need to look directly in the code of the implementation to understand how to integrate an extension. Anyone who wants to add their own extension will interact with the router through *x*BGP. Throughout this paper, we demonstrated that an *x*BGP extension code written only once can be successfully executed by two open-source routing stacks, FRRouting and BIRD.

Virtual Machines. `libxbgp` is based on a user-space implementation of the kernel eBPF VM [53]. In recent years, Linux kernel developers have integrated a virtual machine called eBPF [63] which enables programs to inject executable bytecode at specific locations inside the kernel. It was initially targeted at monitoring kernel operations [35], but also for fast packet processing [35]. Researchers have used eBPF to support networking programming with IPv6 Segment Routing [83] and extend TCP [68]. Other frameworks could have been used such as WebAssembly [32] or lua [38] that is widely used in industrial systems. Using another type of VM can be studied to measure its performance and its relevance to routing protocols.

Verification tools. The PDS (Plugin Distribution System) [57] provides secure verification and distribution of extension code for Pluginized QUIC [18]. It allows the automation of different types of verification for several extension codes at the same time. Our *x*BGP toolchain includes more verifiers and checks more properties. While the PDS uses a Merkle tree to secure the distribution of plugins, the *x*BGP toolchain simply keeps them in a store that is used by the network operator.

7 Conclusion

We presented *x*BGP, a new paradigm that enables network operators to innovate in routing protocols. *x*BGP allows them to write their extensions or modifications in the form of an *x*BGP program that can be executed inside the protocol implementation. This programmability could help network operators innovate with existing distributed routing protocols

as Software Defined Networking lead to the development of programmable switches. Our solution has been proposed for BGP but could also be adapted to support other routing protocols. We further introduced the *x*BGP toolchain that allows operators to annotate *x*BGP programs to verify their safety. It checks if the *x*BGP program meets the local properties of the router such as the termination, the memory constraints and if the *x*BGP program meets the definition of BGP. If it passes the verification step, the *x*BGP program can be safely added to the BGP implementation and is guaranteed not to corrupt the router. Finally, we demonstrated *x*BGP's capabilities by proposing several use cases that have been implemented with our solution. Among them, *x*BGP enables the operator to add new attributes to a BGP route, implementing complex filters, allowing a client to influence the BGP decision process and executing background tasks.

Future Directions. We see two directions to improve *x*BGP. The first would be to look at how to structure an existing BGP implementation to support *x*BGP more efficiently. The second is related to the virtual machine used. eBPF was the most mature virtual machine during the development of *x*BGP. However, other virtual machines such as WebAssembly seem more promising and start to perform well. It might be interesting to see the advantages of using them in the context of *x*BGP.

Software artifacts

To encourage other researchers to reproduce and extend our results we provide the entire source code of `libxbgp` [78] composed of 3506 LoC, the eBPF virtual machine we use (2236 LoC), the two versions of FRRouting [77] (+2675 LoC) and BIRD [76] (+2083 LoC) *x*BGP compatible, the whole *x*BGP programs (15 programs) we developed on top of *x*BGP [81], the experimental scripts we use to evaluate the impact of the performance with our approach (853 LoC) [78] and our verification toolchain based on the PDS [56]. We will also provide the set of annotation to verify *x*BGP programs (1121 LoC) [82].

A Additional use cases

This section describes some additional use cases for xBGP.

A.1 BGP in data centers

Although BGP was designed as an interdomain routing protocol, it is now widely used as an intradomain routing protocol in data centers [44]. This is mainly because BGP scales better since it does not rely on flooding in contrast with OSPF or IS-IS. Another benefit of BGP is its ability to support a wide range of configuration knobs and policies. However, BGP suffers from several problems that forces the network operators to tweak their BGP configurations [44]. These tweaks make BGP configurations complex and more difficult to analyze and validate [5]. To illustrate this complexity, let us consider the data center shown in Fig. 6. Routers $S1$ and $S2$ are the Spine routers, $L10 \dots L13$ the leaf routers, and $T20 \dots$ the top-of-the rack routers. In such a data center, there is no direct connection between the routers at the same level in the hierarchy. Data center operators usually want to avoid paths that include a valley (e.g. $L10 \rightarrow S1 \rightarrow L11 \rightarrow S2$). To achieve this, they usually run eBGP between routers, but configure the same AS number on $S1$ and $S2$ (even if these routers are not connected). Similarly, $L10$ and $L11$ (resp. $L12$ and $L13$) use the same AS number. With this configuration, when $S2$ receives a BGP update with an AS-Path through $S1$, it recognizes its AS number and rejects the route. This automatically blocks paths that include a valley and also helps to prevent path hunting.

Unfortunately, using the same AS number on separate routers can cause problems. First, operators can no longer

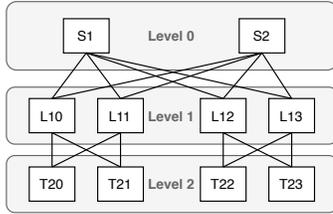

Figure 6: A simple data center.

look at the AS Paths to troubleshoot routing problems since different routers use the same AS number. Second, by prohibiting valley-free paths, the operator implicitly agrees to partition the network when multiple failures occur. Consider again Figure 6. If both links $L10 - S1$ and $L13 - S2$ fail, then the only possible path between $L10$ and $L13$ is $L10 \rightarrow S2 \rightarrow L12 \rightarrow S1 \rightarrow L13$. If the same AS number is used on $S1$ and $S2$, this path will never be advertised.

With x BGP, a network operator can use different AS numbers for their routers and implement specialized filters on the spine and leaf routers. For example, if $S1$ and $S2$ are both connected to transit providers and can reach the same prefixes, then $L10$ should never reach $S2$ via $S1$ and $L11$. However, this path should remain valid if the final destination is a prefix attached to below $R13$.

To implement such a filter, we load a manifest containing every eBGP session from a router of level i to a router of level $i + 1$ in a pair having the following form: (AS_{i}, AS_{i+1}) . For each route, the filter checks each consecutive pair of the AS-Path. If a pair of this manifest is included in the AS-Path, the filter rejects the route since it is not valley-free.

This x BGP program successfully passes T2 and CBMC checks. SeaHorn confirms its x BGP compliance relative to its use of the API functions and the return values.

A.2 Validating BGP Prefix Origins

The interdomain routing system is regularly affected by disruptions caused by invalid BGP advertisements originated from ISPs. Examples include the AS7007 incident in 1997, the announcement of a more specific prefix covering the YouTube DNS servers by Pakistan Telecom in 2008, or BGP prefixes leaked by Google in 2017 that disrupted connectivity in parts of Asia. These problems and many similar ones were caused by configuration errors.

To illustrate the flexibility of x BGP, we consider a RPKI-based route origin [37] validation variant. The network operator includes in the configuration data of the manifest all prefixes it knows the origin. We assume the operator has themselves validated the ROA signatures before generating the file. This file is used by the x BGP program each time a BGP route is received by a peer to check if the origin AS of the route matches with the one contained in the file.

To evaluate the performance of our prefix origin validation,

we use the same testbed as in Section 4 excepted that we use eBGP sessions for links L1 and L2. Our DuT does not implement the RPKI-Rtr protocol [8, 72] but loads configuration data that considers 75% of the injected prefixes as valid. For this test, our extension code checks the validity of the origin of each prefix but does not discard the invalid ones.

Table 2 compares our extension codes running on BIRD and FRRouting to their native implementations without any prefix validation. We do not compare our solution with the RPKI-Rtr protocol since we do not totally implement the RPKI protocol. We only check the origin of the route. The difference in execution between the two implementations is also explained by the difference in the internal representation of the data structures used.

The termination and absence of C errors were proved with T2 and CBMC. SeaHorn also confirms that the x BGP program does not write any data in the memory of the host implementation and its compliance on the return values.

A.3 Filtering Routes Based on IGP Costs

Since the x BGP API provides access to the data structures maintained by a BGP implementation, network operators can leverage it to implement new filters. As a simple example, consider an ISP having a worldwide presence that wants to announce to its peers the routes that it learned in the same continent as the advertising BGP. This policy can be implemented by tagging routes with BGP communities on all ingress routers and then filtering them on export. While being frequently used [20], this solution is imperfect. Consider an ISP having two transatlantic links terminated in London, UK, and Amsterdam in The Netherlands. This ISP has a strong presence in Europe and two links connect the UK to other European countries. If these two links fail, packets between Germany and London will need to go through Amsterdam, the USA, and then back to the UK. When such a failure occurs, the ISP does not want to advertise the routes learned in the UK to its European peers. With BGP communities, it would continue to advertise these routes after the failure.

Using the x BGP API, the operator could implement this policy as follows. First, he configures the IGP cost of the transatlantic links at a high value, say 1000 to discourage their utilization. Second, he implements a simple export filter that checks the IGP cost of the next-hop before announcing a route. The complete source code of such a filter is shown in Listing 1. It is attached to the `BGP_OUTBOUND_FILTER` ④ insertion point. If the IGP cost to the BGP next hop distance is acceptable, the function calls the special function `next()`. This informs the VMM to execute the next bytecode attached to the insertion point. If the extension code is the last to be executed, the insertion point proposes to fall back to the native code. To reject the route, the extension code returns the special value `FILTER_REJECT` to the host implementation.

For this x BGP program, we used SeaHorn to ensure return

Flag	Enables
PROVERS	Verification macros.
PROVERS_ARGS	next() call verification macros.
PROVERS_T2	T2 related macros.

PROOF_INSTS_T2	T2.

Table 5: Macro allowing to provide pieces of code for a specific verifier.

values were meaningful to `libxibgp`. T2 and CBMC are also used to check the termination and the absence of any C errors. We also verify that the xBGP program has only a read-access to the host implementation.

```
uint64_t export_igp(bpf_full_args_t *args UNUSED) {
    struct ubpf_nexthop *nexthop = get_nexthop(NULL);
    struct ubpf_peer_info *peer = get_peer_info();
    if (peer->peer_type != EBGP_SESSION) {
        next(); // Do not filter on iBGP sessions
    } if (nexthop->igp_metric <= MAX_METRIC) {
        next(); // the route is accepted by this filter;
    } // next filter will decide to export route
    return FILTER_REJECT;
}
```

Listing 1: An export filter rejecting BGP routes having a too large IGP nexthop metric.

B Verification macros

This appendix provides in Tables 5, 6, and 7 exhaustive lists of our custom-made verification macros. Those are enabled at compile time with different flags described in Table 4.

Macro prefix	Attribute name/macro suffix	Check
BUF_CHECK_*	LENGTH ORIGIN ASPATH NEXTHOP MED LOCAL_PREF ATOMIC_AGGR AGGREGATOR COMMUNITY ORIGINATOR CLUSTER_LIST EXTENDED_COMMUNITIES AS4_PATH AS4_AGGREGATOR AIGP LARGE_COMMUNITY	The correct formatting of the attribute which is stored in a buffer.
CHECK_*	LENGTH ORIGIN ASPATH NEXTHOP MED LOCAL_PREF ATOMIC_AGGR AGGREGATOR COMMUNITY ORIGINATOR CLUSTER_LIST EXTENDED_COMMUNITIES AS4_PATH AS4_AGGREGATOR AIGP LARGE_COMMUNITY	The correct formatting of the attribute which is stored in a <code>path_attribute</code> structure.
CHECK_IN_BOUNDS_*	LOCAL_PREF MED	The given attribute lies in the range specified by the operator.
CHECK_*	ARG ARG_CODE OUT RET_VAL_FILTER	The next() function is called if the xBGP program cannot parse the current attribute.

Table 6: BGP attributes verification macros used by SeaHorn.

Macro prefix	Target	Check
CHECK_*	BUFFER	The given buffer respects the specified size.
	STRING	The given string is null-byte terminated.
	COPY	The copied buffer is unchanged.

Table 7: Memory check macros used by SeaHorn.

TACCL: Guiding Collective Algorithm Synthesis using Communication Sketches

Abstract

Machine learning models are increasingly being trained across multiple GPUs and servers. In this setting, data is transferred between GPUs using communication collectives such as ALLTOALL and ALLREDUCE, which can become a significant bottleneck in training large models. Thus, it is important to use efficient algorithms for collective communication. We develop TACCL, a tool that enables algorithm designers to guide a synthesizer into automatically generating algorithms for a given hardware configuration and communication collective. TACCL uses a novel *communication sketch* abstraction to get crucial information from the designer to significantly reduce the search space and guide the synthesizer towards better algorithms. TACCL also uses a novel encoding of the problem that allows it to scale beyond single-node topologies. We use TACCL to synthesize algorithms for three collectives and two hardware topologies: DGX-2 and NDv2. We demonstrate that the algorithms synthesized by TACCL outperform the Nvidia Collective Communication Library (NCCL) by up to $6.7\times$. We also show that TACCL can speed up end-to-end training of Transformer-XL and BERT models by 11%–2.3 \times for different batch sizes.

1 Introduction

Machine-learning models have been dramatically increasing in size over the past few years. For example, the language model MT-NLG has 530 billion parameters [31] and the Switch-C mixture-of-experts model has 1.6 trillion parameters [18]. Model sizes are expected to further grow to increase model accuracy and perform more complex tasks. These models are too large for the resources of a single GPU and have to be distributed across multiple servers, each with several GPUs, using different parallelism strategies like data, model, pipeline, and expert parallelism [18, 27, 43] for training and inference. Intermediate data and parameters of the model at each GPU are accumulated, shuffled, and transferred over the network between other GPUs for distributed machine learning, depending on the type of parallelism strategy used.

*Work was partially done during an internship at Microsoft Research.

The inter-GPU communication bottleneck. Recent work has shown that GPU idle time spent waiting for network communication can be significant in practice [2, 19, 26, 28]. For instance, BERT [15] and DeepLight [14] spent 11% and 63% of time, respectively, with GPUs idle on a 100 Gbps Ethernet cluster of P100 GPUs [2]. Newer generations of faster GPUs will only make this problem worse. This inefficient use of GPUs shows that there is significant model performance to be gained by optimizing inter-GPU communication.

Collective communication primitives and algorithms. Efficient communication between GPUs is the key to enabling fast distributed ML training and inference. Modern GPU systems use message passing interface (MPI)-based *collective communication primitives*, such as ALLREDUCE, ALLGATHER, and ALLTOALL to perform inter-GPU communication (Figure 2 in §2). *Collective algorithms* implement collective communication primitives. They route data along various paths in the network and schedule the necessary computation (e.g., a sum in ALLREDUCE) while optimizing for latency and bandwidth characteristics of each link in the network. For example, a common collective algorithm for ALLGATHER (all GPUs gather data from all GPUs) is a Ring algorithm, in which all GPUs are logically arranged in a ring and each GPU receives data from its predecessor in the ring and sends a previously received data to its successor. Inefficiencies in collective communication algorithms can cause poor network utilization, causing GPUs to remain idle until inter-GPU transfers complete [53], and thus reducing the overall efficiency of distributed training and inference.

Challenges in designing GPU communication algorithms. Designing algorithms for efficient collective communication on GPU topologies is challenging. First, these algorithms have to strike the right balance between latency and bandwidth optimality. For instance, the commonly used Ring algorithm for ALLREDUCE is not efficient for small input sizes as it has a high latency. Second, GPU communication algorithms have to manage the heterogeneity of connectivity in the underlying topology. For instance, GPUs within a machine (also referred to as a node) are usually connected using fast NVLinks [38] (up to 300 GBps aggregate bidirectional bandwidth per GPU) while GPUs across nodes are connected using slow Infini-

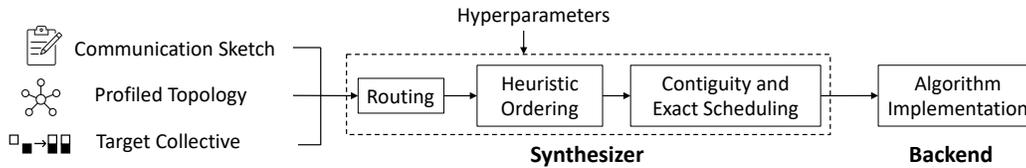

Figure 1: TACCL’s novel synthesizer takes as input a communication sketch, profiled topology, and target collective along with synthesizer hyperparameters to generate an algorithm for the collective. The synthesized algorithm is implemented on the hardware cluster using TACCL’s backend.

Band [36] links (12.5-25 GBps per NIC). Moreover, these topologies vary significantly between vendors. And finally, searching over the entire space of routing and scheduling algorithms to find optimal ones for communication collectives is computationally prohibitive. In fact, previous approaches that synthesize collective communication algorithms are limited to single-node topologies [9] or 8 GPUs at most [51].

Managing scale for automated algorithm design. Our goal is to automatically obtain efficient algorithms for a given hardware configuration and communication collective. We encode the problem of finding optimal algorithms for communication collectives into a mixed integer linear program (MILP) with the goal of minimizing the overall execution time. Unfortunately, this problem is NP-hard; state-of-the-art commercial solvers like Gurobi [20] can spend several days exploring the search space without finding an optimal algorithm. In this work, we propose a *human-in-the-loop* approach that incorporates high-level inputs of an algorithm designer to efficiently synthesize collective communication algorithms for heterogeneous GPU topologies. We argue that it is easy for algorithm designers to provide a few simple inputs that constrain the search space of algorithms which allows synthesis engines to scale to large GPU topologies.

Communication sketches as user input. It is crucial that the input required from algorithm designers is simple and intuitive. For this, we introduce a new abstraction: *communication sketches* (§3). Inspired by the technique of *program sketching* [47] from program synthesis, in which developers supply a partially specified program with holes that capture the high level structure of the desired program, communication sketches allow algorithm designers to provide high-level intuitions that constrain the search space of algorithms. A synthesis engine fills in the remaining details such as routing and scheduling of the final collective communication algorithm, analogous to how a constraint solver in program synthesis searches the reduced space to fill the holes.

Our solution. We develop TACCL (Topology Aware Collective Communication Library), a system that synthesizes communication algorithms for a given topology and a target collective communication primitive. Algorithm designers can use communication sketches to guide TACCL into synthesizing efficient algorithms for a large range of hardware

topologies. We develop a novel encoding of the problem in TACCL’s synthesizer to scale beyond single-node topologies. Figure 1 shows an overview of TACCL’s design.

Synthesizing algorithms from communication sketches.

TACCL’s synthesis approach builds on the solver based synthesis approach in SCCL [9], where the space of possible algorithms is directly encoded in a *satisfiability modulo-theories* (SMT) solver. SCCL does not scale to the sizes of clusters used by modern machine learning workloads. We present a novel *mixed integer linear programming* (MILP) encoding of the collective algorithm synthesis problem that improves scalability by first solving a bandwidth-relaxed version of the problem to decide on *routing*, followed by ordering heuristics and a second bandwidth-constrained problem to find a valid *scheduling* (§5). In addition to improving scalability, TACCL’s MILP formulation allows modeling of heterogeneous links with different per-message overhead characteristics. This overcomes the limitation in SCCL [9] that prevents it from faithfully targeting distributed GPU clusters.

Results. We use TACCL to synthesize efficient algorithms for a range of collectives like ALLGATHER, ALLTOALL, and ALLREDUCE, and for different hardware backends like Azure NDv2 [6] and Nvidia DGX-2 [35] (§7). We compare TACCL to the state-of-the-art Nvidia Collective Communication Library (NCCL). TACCL synthesized an ALLGATHER algorithm for two Nvidia DGX-2 nodes (32 GPUs). This algorithm is up-to $6.7\times$ faster than NCCL for small-to-moderate input sizes. For large input sizes on the same hardware, TACCL synthesized a different ALLGATHER algorithm that nearly saturates the inter-node bandwidth and is up-to 25% faster than NCCL. TACCL synthesized an ALLTOALL algorithm for two Azure NDv2 nodes (16 GPUs) that is up-to 66% faster than NCCL. Finally, we replaced NCCL with TACCL using only a two-line code change in PyTorch and found that TACCL achieves a speed-up of 17% in end-to-end training of a mixture-of-experts model that uses ALLTOALL and ALLREDUCE, and a speed-up of 11% - $2\times$ in end-to-end training of a Transformer-XL model distributed over 16 GPUs for varying batch sizes. TACCL’s codebase is open-source and is actively in use by researchers at universities and practitioners at Microsoft for Azure’s GPU virtual machines.¹

2 Background and Motivation

Collective communication in distributed ML workloads.

Multi-GPU ML workloads typically communicate using MPI-style collectives like ALLGATHER, ALLTOALL, and ALLREDUCE shown in Figure 2. These primitives capture the application’s intent behind the communication, thus allowing collective communication libraries to optimize for specific hardware configurations. In ALLGATHER, every GPU receives the data buffers of all other GPUs (left diagram in Figure 2). In ALLTOALL, every GPU receives different parts, or chunks, of the data buffers present on all GPUs. This effectively transposes the data chunk from buffer index to GPU index as can be seen in center diagram in Figure 2. In ALLREDUCE, every GPU ends up with a data buffer that has the results of performing a point-wise computation (e.g., sum in right diagram in Figure 2) over the same data index of all GPUs.

The parallelism strategy for the distributed ML workload determines which collective communication primitive is used. Data parallelism and some tensor model parallelisms [43] make use of the ALLREDUCE collective to aggregate gradients and intermediate data respectively from multiple GPUs. Expert parallelism [18, 27] and common deep learning recommendation models (DLRM) [32] make use of the ALLTOALL collective to shuffle intermediate data between experts and embedding lookup data between GPUs respectively. DLRLMs [32] also make use of the ALLGATHER collective and another REDUCESCATTER collective to perform embedding lookups from embedding tables sharded over multiple GPUs.

Existing approaches to collective algorithms. Collective algorithms must be designed considering the target input sizes and the heterogeneity of the target topology. However, most collective communication libraries used for distributed ML today, including the state-of-the-art NCCL, use pre-defined templates of collective algorithms superimposed onto a target topology. For example, for collectives like ALLGATHER and REDUCESCATTER, NCCL identifies rings in the target topology and uses the Ring algorithm. For n GPUs, this algorithm requires $n - 1$ link transfer steps per data chunk and is not ideal for smaller data sizes where link transfer latencies dominate. Further, this algorithm treats the slow inter-node and fast intra-node links similarly, scheduling equal number of data transfers across both. The communication is thus bottlenecked on the slower inter-node links, when it could have benefitted by sending more node-local data (i.e. data of GPUs local to the node) over the faster intra-node links instead.

For the ALLTOALL collective, NCCL implements the collective algorithm as peer-to-peer data transfers between all pairs of GPUs. This algorithm is topology-agnostic and often inefficient. For the ALLREDUCE collective, NCCL chooses between two algorithms — Double-Binary-Tree [34] and Ring. This decision is made according to the communication input size and number of nodes, but might not be most accurate, as it is based on hardcoded latency and bandwidth

profiling done previously by Nvidia on their machines.

Designing efficient collective algorithms requires careful analysis of the topology and its performance with different buffer sizes. Recent work [9, 51] has shown that synthesis is a promising approach for generating collective algorithms for different topologies and to achieve bandwidth and latency optimality. However, scaling these approaches to multi-node (i.e. multi-machine) distributed GPU topologies has been a challenge. We measured the synthesis time for ALLGATHER and ALLTOALL collectives on topologies of two Azure NDv2 nodes and two Nvidia DGX2 nodes (Figure 5) using SCCL [9, 30]. We modified the codebase to include both topologies and attempted to synthesize the collectives with a 24-hour time limit set for each synthesis query. Given a 24-hour time limit, SCCL’s `pareto-optimal` solver strategy did not finish synthesis for any combination of collective and topology. The only algorithm that SCCL could synthesize within the time limit was a latency optimal algorithm for ALLGATHER on two NDv2 nodes.

Low-effort inputs from algorithm designers. The search space of possible algorithms to implement a collective is intractably large and cannot be explored via brute-force. Deciding whether or not to route data chunks from n GPUs over l links in a topology has $O(2^{n \times l})$ combinations. As we scale to multi-node topologies, n as well as l will also scale, increasing the exponent quadratically. The search space explodes further if we consider the problem of ordering data sends at each link along with deciding routing for the data. We argue that high-level inputs from a human algorithm designer help reduce the search space to make algorithm synthesis more tractable. In the most extreme case, the designer would hand-write the entire algorithm. However, handcrafting data routing and scheduling over links to implement a collective is complex and requires many design choices. Instead, designers only provide input in the form of a communication sketch around which TACCL synthesizes an algorithm. Our goal is to ensure that providing inputs is a low-effort activity, but can discard large parts of the search space to achieve improvements in running-time of the synthesis engine.

Synthesis technique. TACCL synthesizes a collective algorithm by deciding the route that each data chunk in the collective should take in the topology as well as the ordering of chunks at every link. Even with communication sketches which reduces the search space for the synthesizer, this decision problem is NP-hard and the complexity increases exponentially with number of GPUs. To make the problem more tractable, we first relax the synthesis problem to solve just the routing of all data chunks and then heuristically order chunks sent over the same links according to bandwidth constraints. TACCL’s synthesizer design along with communication sketches help TACCL synthesize efficient collectives for multi-node topologies.

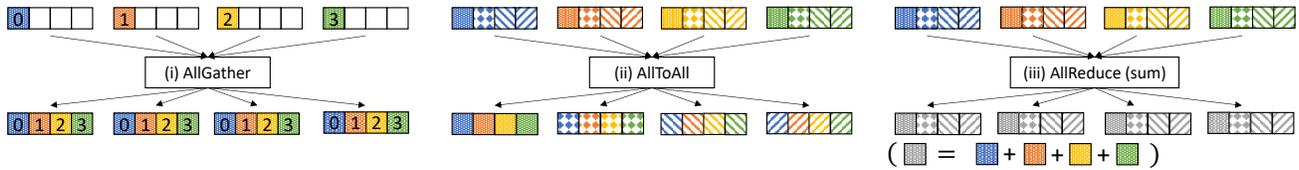

Figure 2: The initial and final data buffers on four GPUs participating in different collectives.

3 Communication Sketches

This paper proposes a new form of sketching [47] as an effective tool for users to communicate interesting aspects of collective communication algorithms to synthesis backends. Sketching approaches must strike a balance between allowing users to omit implementation details while still providing enough direction for the synthesis to scale. In our experience, *routing* is an aspect of collective communication that we often have intuitions about, while reasoning about *scheduling* tends to be tedious and better left to synthesis. Moreover, properties about scheduling are routing dependent since the order of operations is only relevant when routes intersect, which makes them harder to express. Meanwhile, interesting properties about routing are expressible globally, e.g., “never send over the InfiniBand NIC from this GPU”. Therefore, we ask the algorithm designer (user) for four low-effort inputs as a part of the communication sketch:

- Specify the *logical topology* as a subset of the actual physical topology that the algorithm will operate on. This constrains the routes chosen by the communication algorithm and alleviates over-subscription of low-bandwidth links. For example, the outgoing links of all but one GPU can be removed in the logical topology to force all data going to remote GPUs to be relayed through one GPU.
- The logical topology abstracts away switches (e.g., NVSwitches, IBSwitches) in the GPU network. Users can annotate switches in the topology for the synthesizer to use certain *switch-hyperedge policies*, enabling it to apply synthesis policies that help algorithms avoid contention.
- Provide *algorithm symmetry* based on the symmetries in the topology and the collective.
- Specify the expected *input size* of the data, which is used as a part of the synthesis engine’s built-in cost model.

We explain all parts of the communication sketch and provide an example sketch written for TACCL in Appendix A.

3.1 Logical Topology

The core of TACCL’s communication sketch is a *logical topology* consisting of a subset of the physical topology after excluding links that the user prefers TACCL to avoid. A logical topology has as many nodes as the physical topology and inherits the cost model produced by TACCL’s profiler

for the physical topology. Logical topologies omit NICs and switches and use switch-hyperedges (Section 3.2), abstracting them away into links between GPUs. The reason is two-fold: TACCL runtime is embedded in NCCL runtime and NCCL has no direct control over NIC or switch use, and it allows TACCL to reason over a smaller graph thus enhancing scalability. Section 3.2 discusses implications of this abstraction.

Example 3.1 (Sketching inside an NDv2). Consider the physical topology of an Azure NDv2, given by the union of Figure 5a and Figure 5b. While NCCL is able to communicate over both the NVLink and PCIe connections, the bandwidth offered by the NVLinks is much higher than that of PCIe, and thus it is reasonable to set the logical topology to just the NVLink subgraph in Figure 5a.

Example 3.2 (Distributed sketching for NDv2 clusters). It is essential to use PCIe connectivity for distributed collective communication with multiple NDv2 systems since the NIC is connected to GPUs over PCIe (Figure 5b). Due to lack of GPUDirect RDMA [1] on these systems, all communication over PCIe must pass through host memory. Therefore, care must be taken in choosing which links to use, as the PCIe links between PCIe switches and the CPU are oversubscribed. Obtaining maximum throughput communication requires a logical topology that avoids conflicting flows on the oversubscribed PCIe links. To build a logical topology for a cluster of NDv2 systems, a pair of receiver and sender GPUs is selected for each NDv2 such that the selected GPUs and the NIC are connected to the same PCIe switch.

3.2 Switch-Hyperedges

In a switched fabric with full bisectional-bandwidth, like the NVSwitch or IBSwitch fabrics in DGX-2 and NDv2 systems, nodes can simultaneously communicate at the full bandwidth of their ingress or egress links. However, as the number of connections through a switch, originating from a single GPU or NIC increases, the resulting queuing delays increase the latency. Figure 4 plots the accumulated ingress/egress bandwidth of exchanging varying volume of data (up-to 200-400 MB) for different number of connections over NVSwitches in a DGX2 node (left) and over IBSwitches among four DGX2 nodes (right). In both cases, the bandwidth drops as the number of connections increases despite the volume of data re-

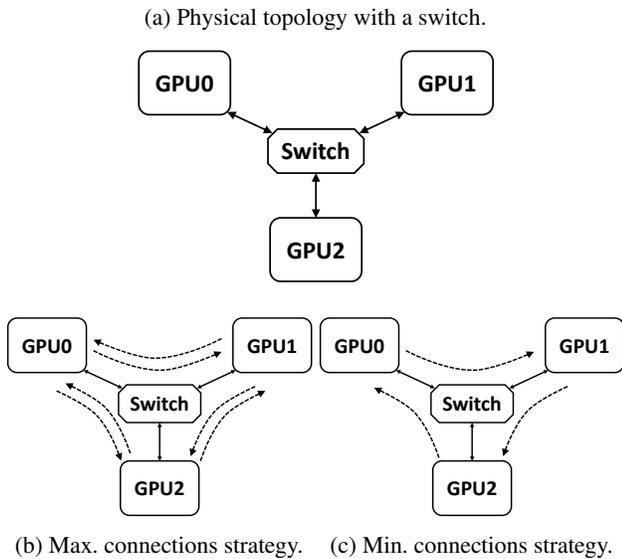

Figure 3: Effects of switch-hyperedge policies.

maintaining constant. However, for small input sizes, the difference for different number of connections is not significant. TACCL’s logical topology does not model switches and does not capture the effect of number of connections.

TACCL incorporates the effect of multiple connections using *switch-hyperedges* in the synthesizer to control the number of connections between GPUs and switches. A switch-hyperedge replaces a switch with a set of direct links in the logical topology for the entire runtime of an algorithm. The synthesizer still has the freedom to select which direct links are imposed. To control the number of direct links for each switch-hyperedge, TACCL provides three policies for a user: (1) *maximize* the number of links, (2) *minimize* the number of links, and (3) freely choose any number of links. These policies are enforced by adding the number of Connections to the objective function (see Appendix B.1 for details).

Example 3.3 (Sketching for congestion). Figure 3a shows a physical topology of three GPUs connected by a switch, where each GPU can communicate with any other GPU.

Figure 3b shows a logical topology with a switch-hyperedge that TACCL may choose with maximizing number of connections policy. This is desirable for small data sizes that result in low likelihood of congestion at the switch with large number of connections as shown in Figure 4.

In Figure 3c TACCL has minimized the number of connections, effectively resulting in a Ring topology. This is desirable for larger data sizes, as restricting the number of logical connections limits the congestion in the switch (Figure 4).

3.3 Algorithm Symmetry

Many collective communication algorithms are symmetric in a variety of ways. For example, ring algorithms follow a

ring symmetry or in hierarchical algorithms, the local phases inside all machines are symmetric to each other. Inspired by this, TACCL offers a generic way to enforce algorithms to be symmetric.

The user may enforce a symmetry by supplying an *automorphism* of the logical topology and collective, i.e., a permutation of the ranks and chunks that maintains the structure of the topology and the collective pre- and post-conditions, and a *partition* of the ranks such that the automorphism maps each subset of ranks to some subset of the partition. TACCL will then restrict synthesis to algorithms with the same symmetry for all chunk transfers.

Example 3.4. Consider a cluster of two NDv2 systems and the task of synthesizing an ALLGATHER. A hierarchical symmetry may be specified with an automorphism composed of a the permutation $[8, \dots, 15, 0, \dots, 7]$ for both chunks and ranks, and a partition $\{\{0, \dots, 7\}, \{8, \dots, 15\}\}$. Now if an algorithm performs a send of chunk 0 from rank 0 to rank 1, then it must also include a send of chunk 8 from rank 8 to rank 9. However, sends between GPUs in different NDv2s, e.g., between 0 and 8, are not affected by the symmetry.

Since the internal topologies of NDv2 systems are identical, enforcing this symmetry is reasonable and helps TACCL scale to larger distributed topologies. Meanwhile, TACCL still has the freedom to synthesize the top-level algorithm and connect the systems to each other as it best can.

4 Physical Topologies of GPU systems

ML engineers use a variety of multi-GPU systems to meet the scaling challenges posed by growing ML models. Before users can effectively sketch algorithms for TACCL to synthesize, they must understand the *physical topology* of the target multi-GPU system. However, the performance characteristics of their heterogeneous links are sparsely documented and for some cloud offerings [5] even the topology is not given. To address this, TACCL includes a *physical topology profiler* to measure performance characteristics of links (§4.1) and to disambiguate the topology of some multi-GPU systems (§4.2). This section also serves as a concrete introduction into two target systems: Azure NDv2 and Nvidia DGX-2.

4.1 α - β Cost Model and Link Profiling

In the well-known α - β [21] cost model, α is the latency of a link and β is the inverse of its bandwidth. The cost of sending a chunk of size s along a link is $\alpha + \beta \cdot s$. TACCL’s synthesizer adopts the α - β cost model for simplicity of encoding and tractability, but TACCL’s communication sketches expose features that provide users additional control to avoid excessive concurrency and congestion (see Section 3), which are not modeled by the α - β cost model. α and β are affected by both the interconnect hardware and the software stack running

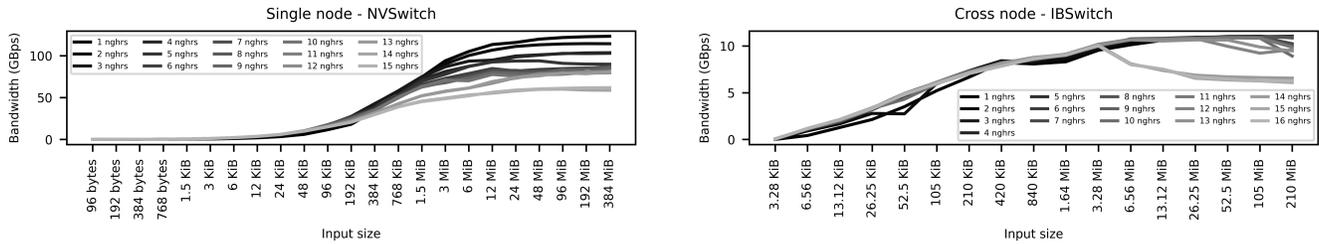

Figure 4: Multi-connection with varying number of GPU neighbors and data volume.

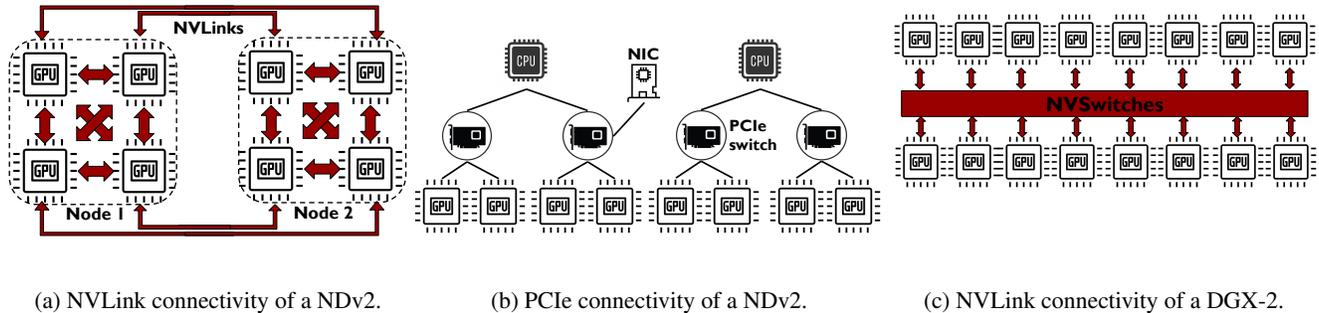

Figure 5: Aspects of physical topologies in various GPU systems.

the collective algorithm (for example software thread fences). TACCL’s topology profiler measures and infers the α and β costs of different types of links in a GPU system.

Modern GPU systems, e.g., Azure NDv2 (Figure 5a) and Nvidia DGX-2 (Figure 5c), have the following types of interconnects: (1) **Peripheral Component Interconnect Express (PCIe)**, (2) **NVLink** [38], (3) **Infiniband (IB)** NICs [36]. A PCIe bus connects GPUs to CPUs with limited shared bandwidth (PCIe Gen3 offers ≈ 13 GBps). PCIe connections often form a hierarchy with PCIe switches (Figure 5b). NVLink [38], however, is a GPU to GPU *intra-node* connection with dedicated bandwidth. NVLinks are either directly connected to other GPUs (NDv2 in Figure 5a) or they are connected to other GPUs via NVSwitches [39] (DGX2 in Figure 5c). NVSwitches enable fully-connected GPU-GPU communication through NVLinks. IB is an inter-node interconnect which allows GPUs to communicate with GPUs in other nodes like in the Azure NDv2 (Figure 5b). IB NICs are usually connected to PCIe switches and GPUs may communicate directly with the NICs through Remote Direct Memory Access (RDMA) or indirectly via host memory.

The profiler empirically derives the α and β parameters of different links in the network by performing peer-to-peer data transfers between GPUs. We send n chunks one after another on a link and measure the time to transfer. As per the $\alpha - \beta$ cost model, the time to transfer is $n \cdot (\alpha + \beta \cdot s)$. We then send n chunks all at once on the link and attribute that time to be $\alpha + n \cdot \beta \cdot s$. Using several measurements of time to transfer, we solve for α and β . Table 1 shows the α and β values for

Link	Azure NDv2		Nvidia DGX-2	
	α (us)	β (us/MB)	α (us)	β (us/MB)
NVLink	0.7	46	0.7	8
InfiniBand	1.7	106	1.7	106

Table 1: Experimentally obtained α and β costs for Azure NDv2 and Nvidia DGX-2 nodes.

NDv2 and DGX-2 systems. Using these values, we expect that for transfers between two Azure NDv2 nodes over InfiniBand (IB), a sending two 32 KB chunks together as a single 64 KB chunk will be 17% faster as compared to sending two 32 KB chunks one after the other. However, chunks sent together can only be forwarded once the last chunk is received. Based on the $\alpha - \beta$ values, TACCL’s synthesizer determines if and when to send chunks together on a link.

The $\alpha - \beta$ cost model causes TACCL’s synthesizer to formulate an MILP formulation as opposed to an LP since an algorithm has to be expressed in terms of discrete chunks.

4.2 Inferring Multi-GPU Topologies

For Azure NDv2 systems the physical topology was not fully documented: while the NVLink topology (Figure 5a) is known to match that of Nvidia DGX1, we did not know how GPUs and the one 12.5 GBps Infiniband NIC were connected with PCIe. PCIe peer-to-peer communication (and thus GPUDirect RDMA [1]) is not enabled on these machines, meaning that all communication happens through buffers in

CPU memory over potentially shared PCIe links. Further, virtualization obscures the true PCIe topology (all 8 GPUs and the NIC appear directly connected to one CPU) and NUMA node and GPU IDs are not assigned consistently from VM to VM. This means that, without additional information, software cannot avoid contention over shared PCIe links, creating interference and high variance in performance.

To determine the PCIe topology, TACCL’s profiler sends bandwidth and latency probes between the two CPUs, between pairs of GPUs, and between CPUs and the NIC. It answers the following questions:

- Which CPU is nearest to the NIC? We answer this using the latency of loopback operations between the NIC and each CPU.
- Which GPUs share a PCIe switch? We find all pairs of GPUs that get low bandwidth in a simultaneous copy to the CPU, indicating contention.
- Which GPUs share a PCIe switch with the NIC? We find which GPUs get low GPU to CPU bandwidth while the CPU is doing a loopback with the NIC. The CPU in this case is the one that is closer to the NIC.

With this profiling information we were able to deduce the PCIe topology (Figure 5b). Each CPU has two PCIe switches connecting to two GPUs each, and the Infiniband NIC is connected to one of these switches. Additionally, by running the profiler on every new NDv2 VM TACCL is able to select one of the NVLink topology’s four automorphisms and set the `CUDA_VISIBLE_DEVICES` environment variable such that the NIC is always placed close to GPU 0.

5 TACCL Synthesizer

Once the user has written a communication sketch, they are ready to call TACCL’s synthesizer. This section describes the synthesis process TACCL uses, as well as additional hyperparameters available to the user.

5.1 Problem Formulation

GPUs participating in a communication collective partition their initial data into C equal chunks where C is a hyperparameter selected by the user. TACCL’s synthesizer routes and schedules these chunks. Given a communication sketch and a collective, the synthesizer decides chunk transfer schedules across every link in the network, such that each chunk reaches its destination GPUs as specified by the collective.

TACCL encodes this problem as a mixed integer linear program (MILP) with binary and continuous decision variables. The encoding has a continuous variable called *start_time* for every chunk and GPU to indicate when a chunk is available at a GPU. A binary variable *is_sent* for all chunk and link pairs denotes if a chunk is sent over a link. Another continuous variable *send_time* indicates when a chunk is sent over a link.

The encoding has bandwidth and correctness constraints to ensure the correctness of a chunk transfer schedule. The objective of the MILP is to minimize *time* which is a continuous variable indicating the maximum time among all chunks that must reach their destination GPUs. Details of these variables and constraints are in Appendix B.

Additionally, TACCL’s synthesizer also decides if it should merge some chunks and transfer them contiguously as one large buffer over a link. Sending n chunks contiguously in one send instruction over a link requires paying only one α latency cost whereas sending n chunks one after the other requires paying $n \times \alpha$ latency costs. Note that this does not change the β bandwidth cost. However, sending n chunks separately over a link enables TACCL to order them such that subsequent dependent sends from the destination of the link could be scheduled earlier. TACCL’s synthesizer navigates this trade-off to minimize the time. TACCL uses this feature only for IB transfers due to their high α cost and ignores it for NVLinks due to their lower latency.

MILP problems in general are NP-hard. Luckily, there are solvers such as Gurobi [20] that apply heuristics to solve MILPs in a feasible way. However, this requires careful consideration regarding the number of variables and constraints in the formulation. In TACCL’s formulation, transferring chunks over a link cannot overlap and an ordering among them is required. Therefore, potentially a binary decision is needed for every pair of chunks that may traverse a link. If we assume there are C chunks for a collective problem, there are $O(C^2)$ such decisions per link. Moreover, as the number of nodes increase, the number of links increase linearly (larger topology) and the number of chunks for a collective increases linearly (ALLGATHER) or even quadratically (ALLTOALL). This large set of variables and constraints leads to infeasible solver time and memory requirements.

To solve this problem, we divide the synthesis into three parts. First, the synthesizer solves an optimization problem to determine the path used by every chunk without fixing any ordering among chunks, then it heuristically orders the chunks over every link, and finally, it solves another optimization problem to determine chunk contiguity. Complete formal descriptions of each step are in Appendix B.

Step 1: Routing solves a MILP for finding the path of each chunk independent of other chunks, allowing chunks sent over a link to overlap. The objective of this MILP is to minimize the time, which we constrain to be the maximum of two sets of variables. (1) for each link, the number of chunks that traverse that link multiplied by the transfer time of a chunk over that link. (2) for the path of each chunk, the summation of transfer times of the chunk along every link in the path. Note that this is only a lower bound on the time since we do not consider link contention or chunk ordering. TACCL also constrains each chunk’s path to be via GPU ranks that are on the shortest paths from their sources to their destinations using the links the user decided to include in the logical topology. If

the communication sketch specifies an algorithm symmetry, TACCL adds the constraints for the symmetric sends. Replacing switches with switch-hyperedges is also applied in this step. For each switch-hyperedge, a user-provided policy on the number of unique connections to/form a switch is applied (see Section 5.2).

TACCL uses Gurobi [20] to solve this MILP and the solution gives every chunk a `start_time` for each GPU along its path. Clearly this step solves chunk routing, but only partially solves the chunk scheduling and contiguity problem and requires follow-up steps (explained next) to account for ordering the chunks sent over a link as well as minimizing α costs of sends. However, by using this technique, TACCL’s synthesizer is able to reduce binary variables needed from $O(C^2)$ to $O(C)$ per link.

Step 2: Heuristic Ordering decides the chunk ordering sent on each link based on a heuristic. Note that this step is not an MILP and solely solved by a greedy algorithm. Regardless of when each chunk becomes available at a GPU, this step assigns a total order on the chunks sent over a link $l = (src, dst)$. This is decided by two heuristic functions. (1) chunks which need to traverse the longest path from `src` to their final GPU, have higher priority. (2) In case there is tie in (1), chunks which have traversed the shortest path from their initial GPU to `src`, have higher priority. This ordering will be used in Step 3 to assign the final schedules.

Step 3: Contiguity and Exact Scheduling solves an MILP problem to decide which chunks to send contiguously and gives the exact schedule. The path to be taken by chunks and their ordering over links have already been determined by the previous steps which are added as constraints to this MILP. The `start_time` and `send_time` variables are reassigned in this step by considering both the α and β costs for each transfer. In this step, the synthesizer allows either sending one chunk at a time or sending multiple chunks contiguously. This offers a trade-off between (1) sending the chunks that are available at the same time for a link according to the ordering in step 2 so that the subsequent sends can be scheduled earlier or (2) sending the chunks contiguously in one send instruction to save the latency cost. The objective of this MILP is to minimize the total time by enforcing all constraints which in TACCL solved by Gurobi [20]. The solution gives the exact schedule for each chunk. The details of these constraints and their formulation are in Appendix B.

5.2 Synthesizer Hyperparameters

TACCL’s synthesizer has some additional parameters that control the synthesis process. These are provided by the user to the synthesizer (see Figure 1) through the communication sketch. Details of each parameter is described in Appendix A.

Buffer Size. TACCL needs the size of input/output buffers of a collective for the α - β cost model. In ML workloads the input/output buffer size is a known fixed value.

Chunk Partitioning. The data buffer at each GPU at the start of the collective can be partitioned into multiple equal chunks. Each chunk is considered as an atomic scheduling unit by the synthesizer and different chunks of the same data buffer can be routed over different links. The semantics of a collective forces a minimum number of chunks such as ALLTOALL which needs at least as many chunks as the number of GPU for each buffer. On one hand, using the minimum number of chunks is often times ideal for finding latency-optimal algorithms. On the other hand, providing a higher number of chunks allows the synthesizer to better utilize the links that might be idle otherwise which is better for finding bandwidth-optimal algorithms.

Switch-Hyperedge Policy. TACCL can enforce policies for the number of connections established over a set of links in a switch-hyperedge by counting links utilized for data transfer and setting this count as a part of the MILP objective. The `uc-max` policy will maximize the number of connections, which performs best for small data sizes, while `uc-min` will minimize the number of connections, which works well when the data size is large and congestion is a concern.

5.3 Synthesizing combining collectives

TACCL synthesizes combining collectives (i.e., collectives that combine chunks like REDUCESCATTER and ALLREDUCE) by utilizing synthesis of non-combining collectives, similar to the technique used by SCCL [9]. REDUCESCATTER can be implemented as an “inverse” of ALLGATHER— a send from a source GPU in ALLGATHER is instead received and reduced on the source GPU. However, simply inverting the sends does not work — a GPU may simultaneous send on different links in an ALLGATHER, but it cannot reduce all receives together in the inverse case. We thus order the inverse sends using heuristic ordering followed by contiguity encoding in order to synthesize REDUCESCATTER. ALLREDUCE is synthesized directly by concatenating REDUCESCATTER with an ALLGATHER algorithm.

6 Backend

The synthesizer described above generates an abstract algorithm that specifies the order in which the nodes communicate the various chunks. The goal of the backend is to implement this abstract algorithm. To do so, we extend NCCL [37] with an *interpreter* which we call TACCL runtime. While any communication algorithm can be trivially implemented using NCCL’s point-to-point sends and receives, TACCL runtime enables us to execute the entire algorithm in a single kernel launch, eliminating multiple launch overheads. In addition, by reusing NCCL transport mechanisms, TACCL runtime is able to support all of NCCL’s communication backends such as IB, Ethernet, NVLink, and PCIe.

6.1 TACCL runtime

The input to TACCL runtime² is a TACCL-EF program, which is an XML format for representing collective algorithms. TACCL-EF programs operate on three buffers: input, output and scratch. For each buffer, the program specifies the number of chunks it will be sliced into such that all chunks are equal size. Every step of the algorithm is expressed in terms of these chunks.

The program is divided into a set of GPU programs made up of threadblocks. Each threadblock is made up of a series of steps that are executed sequentially, with each step specifying an instruction and operands as indices into the input/output/scratch buffers. The current instruction set includes sends, receives (with optional reduction), and local copies. To simplify the implementation of TACCL runtime, each threadblock can send to and receive from at most one GPU. Additionally, threadblocks within a GPU can synchronize by indicating that one step depends on another step, which will cause the interpreter to wait until the dependency has completed before executing the dependent step.

The TACCL runtime extends NCCL and it is backward compatible with its API. Therefore, integrating TACCL runtime into machine learning frameworks such as PyTorch is a single line change wherein that change swaps the third-party NCCL library for TACCL runtime. This allows TACCL to dynamically swap in collective algorithms generated for any training/inference workload using `torch.distributed`.

6.2 Lowering to TACCL runtime

To target TACCL-EF, abstract algorithms are lowered to the executable format. The sets of sends operating on abstract chunks that comprise the steps of the algorithm are transformed into pairs of send and receive operations operating on concrete buffer indices. Furthermore, these operations are placed sequentially into threadblocks and any necessary dependencies recorded between them.

Buffer allocation. Input and output buffers are preallocated by the user and passed to the collective. Scratch buffers are allocated by the TACCL runtime per TACCL-EF. Chunks are indices in the input, output and scratch buffers. For chunks that are common for both the input and the output buffers (e.g. as in `ALLGATHER`) a local copy from input to the output buffer is performed at the end.

Instruction generation. The operations of the abstract algorithm are split into two instructions for the sender and receiver GPU, and chunks are translated into buffer references and indices according to the buffer allocation.

Dependency insertion. TACCL transforms a synthesized algorithm into the asynchronous execution model of TACCL-EF and dependencies for each buffer index are inserted to

ensure that the data dependencies present in the abstract algorithm are honored.

Threadblock allocation. Instructions are grouped such that all of them are either sending to at most one GPU and/or receiving from at most another GPU (possibly different). Order of the instructions inside a group should follow the order of the abstract algorithm. TACCL allocates a threadblock for each group of instructions.

Instances. NCCL and consequently TACCL runtime cannot saturate the bandwidth of a link in a topology using a single threadblock. Thus, TACCL generates multiple instances of the algorithm to maximize the performance. This is done by subdividing each chunk into n subchunks that follow the same path as the parent chunk. All groups of instructions and their threadblocks are duplicated n times and executed in parallel. §7.2 explores the performance implications of choices of n .

7 Evaluation

We evaluate algorithms obtained with TACCL for `ALLGATHER`, `ALLTOALL`, and `ALLREDUCE` collectives on a cluster of 32 GPUs comprised of two Nvidia DGX-2 nodes or up to four Azure NDv2 nodes. To compare performances, algorithm bandwidth [33] measurement is used which is calculated by input buffer size divided by execution time. We synthesize TACCL algorithms by exploring different communication sketches and compare them against the popular Nvidia Collective Communication Library (NCCL) (v.2.8.4-1). This section analyzes how different communication sketches impact the performance of the algorithms synthesized by TACCL. In particular, we perform ablation studies by varying the inter-node connections in the logical topology, changing synthesizer hyperparameters, and changing the number of instances used when lowering to TACCL-EF. To evaluate how TACCL's speedups translate to end-to-end performance, we use algorithms generated by TACCL in two large language models, Transformer-XL and BERT. Finally, we discuss the synthesis time required by TACCL to generate these algorithms.

We believe our focus on up to 32 GPUs covers a large section of important use cases: in an internal cluster of DGX-2 nodes at Microsoft, the sum of GPUs in jobs of at most 32 was 93.7% of all jobs in the second half of 2021.

7.1 Standalone Experiments

All our communication sketches for DGX-2 and NDv2 use a hierarchical symmetry like the one in Example 3.4.

7.1.1 ALLGATHER

ALLGATHER on DGX-2. Figure 6(i) shows the algorithm bandwidth for TACCL's synthesized algorithms on two DGX-2 nodes for each output buffer size and plots it against that of

²Link to code: <https://github.com/microsoft/msccl>

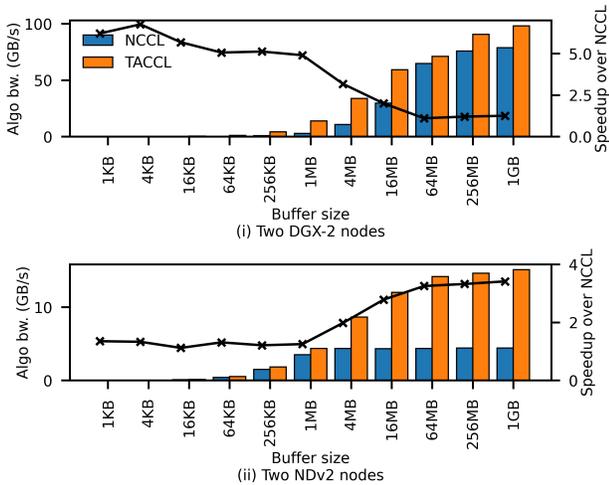

Figure 6: ALLGATHER comparisons of NCCL to TACCL’s best algorithm at each buffer size.

NCCL. We show the speedup of TACCL’s algorithms over NCCL on the right Y-axis of the plot. We used two different sketches for this topology which will be explained next.

A DGX-2 node has 16 V100 GPUs (Figure 5c) where each pair of GPUs share a PCIe switch with a NIC. This makes it natural to assign one GPU in a pair to be a receiver and the other to be a sender by eliminating outgoing and incoming links, respectively, in the logical topology. We design a sketch (*dgx2-sk-1*) that uses this logical topology, sets chunk size to 2MB, uses two chunk partitions for each buffer, and the sets switch-hyperedge policy to *uc-min*. With this sketch, TACCL synthesizes an ALLGATHER algorithm for two DGX-2 nodes. This algorithm almost saturates the inter-node bandwidth during the entire run of the algorithm and provides a 20% – 25% speedup over NCCL for large buffer sizes in the 256MB - 1GB range.

Next, we design a sketch (*dgx2-sk-2*) for smaller sizes. This sketch allows both GPUs in a pair to utilize the shared NIC. However, local GPU *i* on each node is only allowed to send/receive to/from local GPU *i* on the other node. Since the IB is shared, we double the β cost for each IB transfer to $2 * \beta_{IB}$ cost. In this sketch, chunk size is set to 1KB and the switch-hyperedge policy is *uc-max*. Using this sketch TACCL synthesizes an algorithm that is $4.9 \times - 6.7 \times$ faster than NCCL in the 1KB - 1MB range, and $10\% - 3.8 \times$ faster than NCCL in the 2MB - 64MB range. On inspecting this algorithm, we found that TACCL’s synthesized algorithm overlaps inter-node sends with intra-node all-pair ALLGATHER of node-local data chunks followed by an intra-node all-pair ALLGATHER of the node-external chunks received over IB.

Figure 6(i) shows the algorithm bandwidth and the speedup over NCCL baseline for the best of these two sketches for each output buffer size.

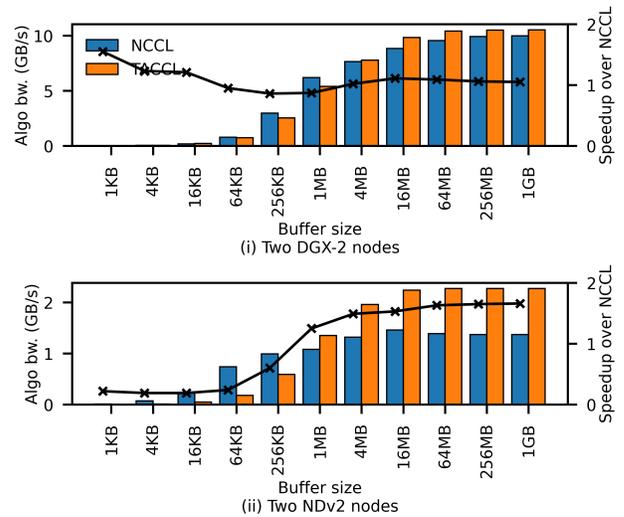

Figure 7: ALLTOALL comparisons of NCCL to TACCL’s best algorithm at each buffer size.

ALLGATHER on NDv2. The sketch we used, *ndv2-sk-1*, uses the logical topology discussed in Example 3.2, in which a sender and a receiver GPU were dedicated such that they are on the same PCIe switch as the NIC. We use a single instance when lowering algorithms into TACCL-EF for data sizes 1MB and below, and use 8 instances for larger data sizes. Figure 6(ii) compares the synthesized algorithms to NCCL on two Azure NDv2 nodes. TACCL’s synthesized algorithms are 12% – 35% faster than NCCL for buffer sizes of 1KB - 1MB, and $61\% - 3.4 \times$ faster than NCCL for sizes larger than 1MB. These algorithms better saturate the inter-node bandwidth thanks to the dedicated send/receiver GPUs.

We similarly synthesize ALLGATHER algorithms for four NDv2 nodes and present the results in Figure 11(i) in Appendix C. These algorithms are $10\% - 2.2 \times$ faster than NCCL depending on buffer size.

7.1.2 ALLTOALL

ALLTOALL on DGX-2. We explore the synthesis of ALLTOALL algorithms by reusing the *dgx2-sk-2* communication sketch designed in the previous section. Figure 7(i) compares the resulting algorithm on two DGX-2 nodes. The synthesized algorithm using this sketch performs up-to 15% faster than NCCL for batch sizes of 2MB and larger. For this sketch, TACCL’s synthesizer coalesces chunks sent in inter-node transfer in this algorithm, which reduces the latency of transfers over IB. TACCL also uses a communication sketch with chunk size set as 1KB and a logical topology where GPUs have links to all other GPUs connected via the NIC (*dgx2-sk-3*). This algorithm is up-to 55% faster than NCCL for small buffer sizes ranging from 1KB to 16KB.

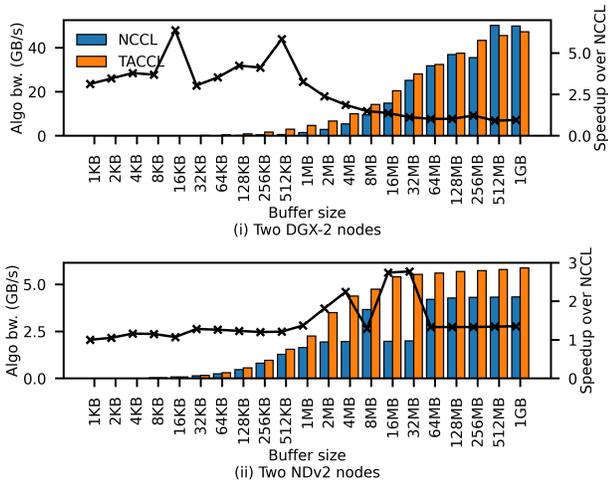

Figure 8: ALLREDUCE comparisons of NCCL to TACCL’s best algorithm at each buffer size.

ALLTOALL on NDv2. Figure 7(ii) shows a comparison of TACCL’s best algorithms for ALLTOALL on two Azure NDv2 nodes against NCCL. We reuse the communication sketch *ndv2-sk-1* and set the chunk size to 1MB. The generated algorithms run 53% – 66% faster than NCCL for buffer sizes between 16MB - 1GB. We explore another sketch (*ndv2-sk-2*) with a logical topology in which all GPUs in a node are fully-connected to all the GPUs in the other node and set chunk size as 1KB. The algorithm generated by TACCL using this sketch performs up-to 12% faster than NCCL for buffer sizes from 1KB to 128KB.

For four NDv2 nodes, TACCL’s synthesized algorithms uses communication sketch *ndv2-sk-1* and they are up-to 46% faster than NCCL for buffer size greater than 1MB, as shown in Figure 11(ii) in Appendix C.

7.1.3 ALLREDUCE

ALLREDUCE on DGX-2. As discussed in Section 5.3, TACCL composes REDUCESCATTER with ALLGATHER to implement ALLREDUCE and an algorithm for REDUCESCATTER can be constructed by inverting an ALLGATHER algorithm. Figure 8(i) shows the performance of TACCL algorithms on two DGX-2 nodes. The ALLREDUCE synthesized from the ALLGATHER using *dgx2-sk-2* is 49% – 6.4× faster than NCCL for buffer sizes ranging from 1KB - 4MB. TACCL’s generated algorithms by using other communication sketches like *dgx2-sk-1* are 2% – 37% faster than NCCL for buffer sizes ranging from 16MB - 256MB. For buffer sizes of 512MB and greater, our algorithms are at most 9% slower than NCCL. This is because NCCL uses the more optimized fused communication instructions (such as receive-reduce-copy-send) in its ALLREDUCE communication which

are unavailable in TACCL’s lowering. We leave these such further optimizations for future work.

ALLREDUCE on NDv2. These algorithms are based on the ALLGATHER synthesized from the *ndv2-sk-1* sketch and use two versions with 1 and 8 instances. Figure 8(ii) compares them to NCCL on two NDv2 nodes. The single instance TACCL algorithm outperforms NCCL’s ALLREDUCE by up to 28% for buffer sizes of up to 1MB, while the 8 instance algorithm outperforms NCCL by 28% – 2.7× for larger sizes.

On 4 NDv2 nodes, as shown in Figure 11(iii) in Appendix C, the TACCL algorithms are up to 34% faster than NCCL for small buffer sizes and 1.9 × – 2.1× faster than NCCL for larger buffer sizes.

7.2 Impact of Varying Synthesizer Inputs

In this section, we explore modifications to communication sketches, as well as the synthesizer hyperparameters and the instances for the lowering, in order to understand their impact on the performance of the synthesized algorithms. Our aim is to demonstrate that the controls offered by TACCL have intuitive effects on the resulting algorithms, which is necessary for effectively communicating user intuition to TACCL.

We present our analysis for the ALLGATHER collective on two Nvidia DGX-2 nodes. Unless mentioned otherwise, we use the following communication sketch as the baseline: same logical topology as *dgx2-sk-1*, chunk size set to 1MB, data partitioning set to 1, and the switch-hyperedge policy set to `uc-max`.

Changing logical topology. We create a logical topology with a dedicated sender and receiver GPU similar to *dgx-sk-1* except we allow a sender to be connected to n different receivers in the other node. Figure 9a shows the algorithm bandwidth of ALLGATHER obtained by varying n , the number of IB connections per GPU, for a fixed chunk size of 1KB, 32KB, and 1MB. For a 1KB chunk size, we found the algorithm that uses 8 IB connections per NIC performs better than algorithms using fewer connections. As the chunk size increases to 32KB and 1MB, the optimal number of IB connections per NIC reduces to 4 and 1, respectively. The benefits of link sharing shrink as the chunk size increases and β -cost starts dominating over the α -cost.

Changing transfer cost using chunk size. We analyze the sensitivity of TACCL’s synthesizer to the data size provided in the communication sketch when its algorithms are applied on a communication using a different data size. Figure 9b shows the performance of ALLGATHER algorithm for three different chunk sizes (1KB, 32KB, and 1MB). Algorithms generally perform well for a range of data sizes close to what they have been synthesized for. We recommend trying a small set of nearby sizes to ensure the best performance.

Changing data partitioning. Figure 9c shows the algorithm bandwidth of algorithms generated by partitioning data on

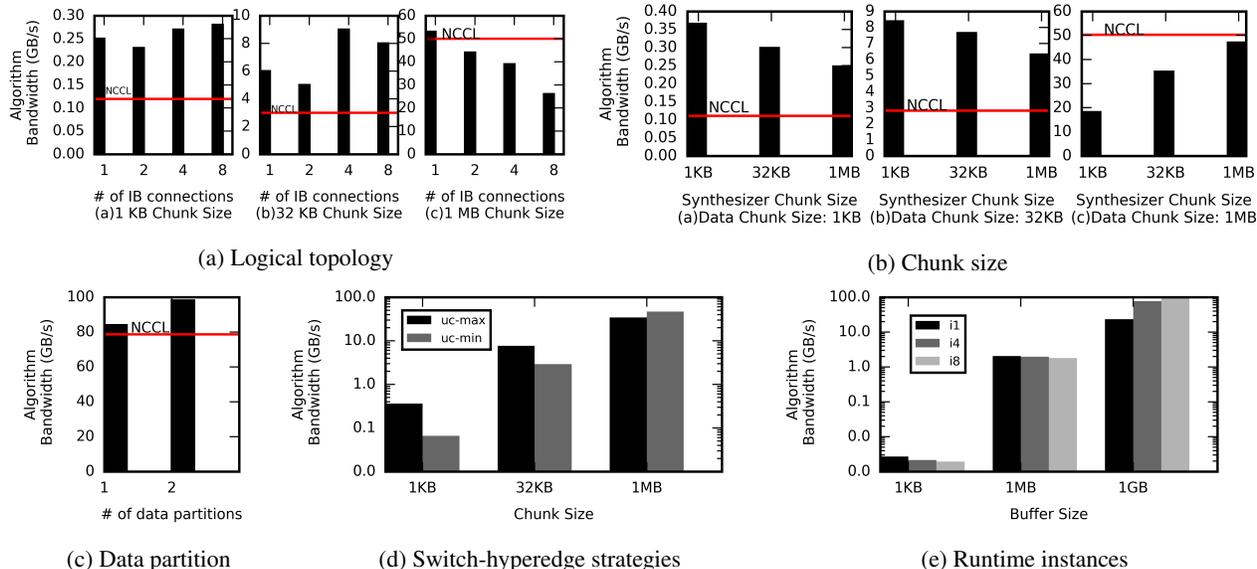

Figure 9: Algorithm bandwidth of ALLGATHER algorithms on DGX-2 by varying different inputs to TACCL

each GPU into a single or two chunks. We set the switch-hyperedge policy to `uc-min` and fix number of instances to 8. At a large buffer size of 1GB, the algorithm generated for two data chunks utilizes bandwidth better as compared to the algorithm generated for a single data chunk per GPU.

Changing switch-hyperedge policy. Figure 9d shows the algorithm bandwidth for algorithms generated and evaluated for 1KB, 32KB, and 1MB chunks. The algorithm bandwidth is displayed in log-scale. We vary the switch-hyperedge policy between `uc-max` and `uc-min`. For smaller buffer sizes, the `uc-max` configuration performs better than `uc-min`, whereas for larger buffer sizes, `uc-min` performs better than `uc-max`.

Changing number of instances. Figure 9e shows algorithm bandwidth with instances ranging from 1 to 8. The switch-hyperedge policy for these algorithms is set to `uc-min`. Increasing the number of instances improves bandwidth utilization — multiple threadblocks seem to be needed to keep the six NVLinks in a V100 busy. However, a larger number of threadblocks also increases latency, which we suspect is due to unfavorable scheduling of synchronization related memory operations onto the NVLinks at the start of each send. Since latency cost dominates for small buffer sizes, using a large number of instances only increases the latency cost. As the buffer size increases, the bandwidth improvements due to more instances become predominant. Since switch-hyperedge policy and number of instances have a similar relation with chunk sizes, we always run `uc-max` algorithms with a single instance and `uc-min` algorithms with 8 instances.

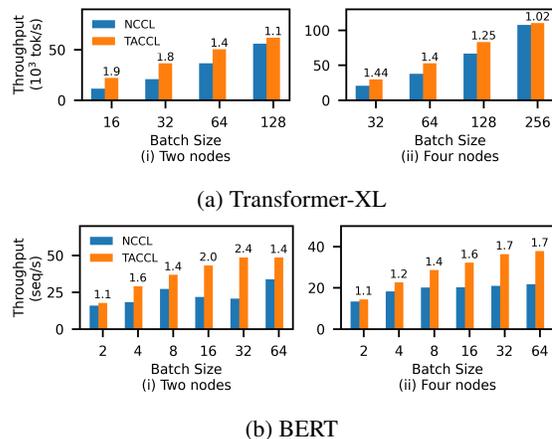

Figure 10: Training throughput using TACCL's collective algorithms on Transformer-XL and BERT compared against NCCL on 2 and 4 Azure NDv2 nodes. Speedup over NCCL is mentioned on top of the bars.

7.3 End-to-End Training.

We evaluate TACCL on distributed training of two large language models, Transformer-XL [4, 13] and BERT [3, 15], on two (and four) Azure NDv2 nodes, i.e. 16 (and 32) GPUs. Transformer-XL uses data parallelism and whereas BERT uses model parallelism. The typical transfer sizes for ALLREDUCE in Transformer-XL is in the 20 - 40MB range, and for BERT it is about 2MB. Both models communicate with `torch.distributed` and, as explained in Section 6, using TACCL algorithms in them is quite straightforward.

We lower the algorithm synthesized by the synthesizer

AllGather		AlltoAll		AllReduce	
Sketch	Time(s)	Sketch	Time(s)	Sketch	Time(s)
<i>dgx2-sk-1</i>	35.8	<i>dgx2-sk-2</i>	92.5	<i>dgx2-sk-1</i>	6.1
<i>dgx2-sk-2</i>	11.3	<i>ndv2-sk-1</i>	1809.8	<i>dgx2-sk-2</i>	127.8
<i>ndv2-sk-1</i>	2.6	<i>ndv2-sk-2</i>	8.4	<i>ndv2-sk-1</i>	0.3

Table 2: Synthesis time for TACCL algorithms for different collectives using different communication sketches.

into TACCL-EF with 1 and 8 instances, and show the performance of both against NCCL. Figure 10a and Figure 10b show the training throughput obtained by using TACCL’s collective algorithms for communication instead of NCCL for Transformer-XL and BERT respectively for different batch sizes. TACCL speeds up training of Transformer-XL by 11% – 1.94× on 2 nodes and by 2% – 1.44× on 4 nodes. The speedup for BERT is 12% – 2.36× on 2 nodes and 7% – 1.74× on 4 nodes. Depending on the memory available per GPU and on how the batch size affects model accuracy, any of these batch sizes might be chosen for use in practice.

We also use algorithms synthesized by TACCL for ALLTOALL and ALLREDUCE collectives for training an internal Microsoft’s mixture-of-experts workload on two NDv2 nodes. The ALLTOALL and ALLREDUCE sizes required for this model are ≈ 6MB and ≈ 256MB, respectively. TACCL improves the end-to-end throughput of this model by 17%.

7.4 Synthesis Time

Table 2 shows the total time it takes for TACCL to synthesize algorithms for different collectives using some of the communication sketches mentioned in Section 7.1. In most cases synthesis takes from seconds to a few minutes, making it amenable to a human-in-the-loop approach. When synthesizing an ALLTOALL collective using some communication sketches, TACCL’s contiguity encoding may take more time in proving the optimality of a feasible solution. We put a time limit of 30 minutes on the contiguity encoding in these cases. The contiguity encoding for sketch *ndv2-sk-1* reaches this timeout, but a feasible solution was already found in 4min 14s. We have also been able to synthesize an ALLGATHER for 80 GPUs (10 NDv2 nodes) in under 8 minutes.

8 Related Work

The MPI standard provides a set of collective communication algorithms that enable efficient distributed computations of interconnected nodes [16]. The HPC community has focused on the efficient implementation of these MPI collective algorithms [40, 50] and demonstrated how to build optimized algorithms for specific interconnects, like mesh, hypercube, or fat-tree [7, 8, 41]. In contrast to TACCL, these prior works assume homogeneous interconnects and are often only focused on bandwidth optimality. Hybrid algorithms [7, 10] combine

bandwidth- and latency-optimal algorithms based on input sizes, but only qfor mesh networks.

NCCL [37] is a GPU implementation of a subset of the standard MPI collectives, optimized for NVLINK and Infini-band interconnects. While NCCL uses the topology of GPU connections and NIC placement along with buffer size to decide between two main types of communication algorithms — Ring and Tree, it is agnostic to the exact performance profile of the links, and thus (as we show) is often multiple times slower than TACCL’s topology aware collectives.

Recent works like SCCL [9], Blink [51], and Plink [29] specialize algorithms for the underlying topology. SCCL solves an integer programming encoding based on discrete-time values in the form of steps and rounds of the algorithm in order to achieve the pareto-frontier of latency- and bandwidth-optimal algorithms. SCCL is able to synthesize a novel pareto-optimal ALLGATHER algorithm for an Nvidia DGX1 node, but its restrictive formulation constrains it to only synthesize algorithms for single-node topologies. TACCL on the other hand synthesizes collective algorithms for multi-node topologies. Blink uses a heuristic spanning-tree packing algorithm to maximize bandwidth utilization within a node and a hierarchical approach across. Blink has good performance over NCCL in the case when NCCL cannot create rings spanning all GPUs inside a node. TACCL, on the other hand, outperforms NCCL when using the entire node of GPUs. Plink constructs a logical topology based on bandwidth and latency probes of the physical topology to avoid oversubscribed and congested links and searches for a reasonable clustering of nodes for a two-level hierarchical reduction strategy. Plink builds that hierarchical reduction from known primitives and does not search over the space of possible algorithms.

There are also hierarchical approaches to implement collectives [12, 29, 42, 51]. For example, Horovod [42] implements an ALLREDUCE by a local ReduceScatter, a global ALLREDUCE, and then a local ALLGATHER. These methods do not search over possible algorithms, but instead pick from a known set of decompositions. Concurrent to our work, Ningning et al. [52] use syntax guided synthesis to combine base MPI primitives among a subset of nodes to hierarchically generate larger MPI primitives for the entire network. In contrast, TACCL uses a fine grained approach for algorithm synthesis while using communication sketches for scalability. Combining these two complementary approaches is an interesting opportunity for future work.

Program sketching [24, 47, 49] is a popular technique that has been applied to a variety of problems from synthesizing stencil computations [48], converting hand drawings to images [17] to social media recommendations [11]. Our work builds on this body of work to use sketching to effectively search a large space of communication algorithms.

Lastly, network flow problems have used linear programming to solve routing and scheduling problems for traffic engineering [22, 23, 25, 44, 46] and topology engineering [45].

These techniques, however, cannot be used for generating collective algorithms since communication collectives do not follow all flow properties. Non-source GPUs in a collective can send the same chunk over different links in parallel while having received that chunk only once, which violates an important flow-conservation property used extensively in network flow problem literature. TACCL on the other hand makes use of communication sketches and an encoding relaxation technique to solve a continuous-time integer linear programming that faithfully models communication collectives.

9 Conclusion and Future Work

TACCL is a topology and input-size aware collective communication library for multi-node distributed machine learning training and inference. TACCL uses user-provided communication sketches to guide synthesis of collective algorithms. Using a three-step technique of relaxed routing, heuristic ordering, and contiguity and exact scheduling, TACCL generates efficient collectives for multi-node topologies. We also make some brief observations about TACCL below:

Scalability. TACCL can synthesize algorithms for large-scale nodes - we have been able to synthesize an ALLGATHER algorithm for 8 Azure NDv2 nodes using TACCL in under 5 minutes. As compared to NCCL, this algorithm has up-to $1.7\times$ higher algorithm bandwidth for different data sizes. We also evaluated TACCL's synthesis for 8 Nvidia DGX-2 nodes (128 GPUs) and found a solution in around 11 hours. While TACCL scales to multi-node topologies, the synthesis technique is still based on solving an NP-hard problem that grows exponentially with a quadratic power with scale. As a future work, we would like to scale TACCL further by hierarchically composing synthesized algorithms.

Generality across different topologies. Apart from hierarchical topologies like Nvidia DGX-2 and Azure NDv2, TACCL can also be applied to non-hierarchical topologies like a 2D-Torus. We were able to synthesize an ALLGATHER algorithm for a 2D 6×8 Torus using TACCL. We made use of the symmetry attribute in communication sketches to explore synthesis for this topology. However, the amount of exploration we can do with different communication sketches may be more limited in these cases than for hierarchical topologies.

Exploring communication sketches. Communication sketches have proven effective in narrowing the search space of algorithms. Interestingly, different communication sketches can optimize different ranges of input sizes. Communication sketches reflect the intuition of developers, and by intelligently exploring the space of communication sketches we can obtain a range of collective algorithms with different performance characteristics. Learning an automated controller for exploring communication sketches is an interesting direction for collective algorithm synthesis in the future.

To conclude, TACCL uses the abstraction of communication sketches and a novel problem formulation to generate efficient algorithms for collectives like ALLGATHER, ALLTOALL, and ALLREDUCE. The algorithms thus generated are up-to $6.7\times$ faster than the state-of-the-art NCCL and result in $11\% - 2.4\times$ faster end-to-end training time.

A Communication Sketch Input

TACCL adopts a user-in-the-loop approach where algorithm designers provide a communication sketch to guide communication algorithm synthesis by TACCL. TACCL’s synthesizer takes in a profiled topology provided by TACCL profiler along with a communication sketch provided by a human-in-the-loop. A communication sketch comprises of a logical topology, switch-hyperedge strategy, symmetry information, input size, and other hyperparameters. Listing 1 gives an example of how users can provide a communication sketch input to the TACCL synthesizer. Here, we show an example of the communication sketch *dgx2-sk-1* used in the evaluation to synthesize an ALLGATHER algorithm for 2 Nvidia DGX-2 nodes (each node has 16 GPUs and 8 NICs, every two GPUs in the node share a NIC).

The sketch annotates the NVSwitch in each node and sets a `uc-min` switch-hyperedge strategy. Further, the inter-node sketch fixes the sender and receiver GPUs in a node for inter-node data transfers. In our example, the odd-numbered GPUs sharing a NIC are chosen as senders and the even-numbered GPUs are chosen as receivers for inter-node communication. The user also annotates how the inter-node relay GPUs would split the inter-node bandwidth using a `beta_split` attribute. Since only a single GPU per NIC is chosen in our example to perform inter-node send and similarly receive, the bandwidth is not split. Optionally, the user can also map chunks to sender GPUs so that only mapped GPUs are used for inter-node transfers for the chunk. The `chunk_to_relay_map` attribute defines the parameters for the mapping function. The communication sketch also allows users to play with rotational symmetry for data routing. Given a symmetry offset and a group size, a chunk transfer over a link is set to be equivalent to a rotationally symmetric chunk over a rotationally symmetric link. In our example of the `symmetry_offset` attribute, using `[2, 16]` fixes an intra-node symmetry with an offset of two, and using `[16, 32]` fixes a symmetric data transfer pattern between the two DGX-2 nodes. Hyperparameters like input data partitioning and input size can also be provided via the communication sketch.

B TACCL Synthesizer in Detail

As explained in Section 5, TACCL’s synthesizer has routing, heuristic ordering, and contiguity and exact scheduling stages. We provide a detailed description of each of these stages in this section. We first formally introduce some terms that we will use later. Let \mathcal{C} denote the set of chunks that are required to be routed in the algorithm for collective *coll*. Let \mathcal{R} denote the set of GPU ranks involved in *coll*. Let *coll.precondition* and *coll.postcondition* denote the precondition and post-condition of the collective respectively. The tuple $(c, r) \in \text{coll.precondition}$, $c \in \mathcal{C}$, $r \in \mathcal{R}$, if chunk *c* is present at rank *r* at the start of the collective. Similarly, the

$(c, r) \in coll.postcondition$ if chunk c has to be present at rank r at the end of the collective. Further, let \mathcal{L} denote the set of links, such that $(r1, r2) \in \mathcal{L}, r1 \in \mathcal{R}, r2 \in \mathcal{R}$ if there exists a link from rank $r1$ to rank $r2$ in the logical topology determined by the topology and communication sketch. Let \mathcal{S}_r^{send} denote the set of switched destinations for rank r , such that $dst \in \mathcal{S}_r^{send}$ if link (r, dst) is a part of a switch-hyperedge. Similarly, \mathcal{S}_r^{recv} denotes the set of switched sources for rank r , such that $src \in \mathcal{S}_r^{recv}$ if link (src, r) is a part of a switch-hyperedge. $\alpha(r1, r2), \beta(r1, r2)$ are the alpha and beta costs respectively of the link $(r1, r2) \in \mathcal{L}$. The term $lat(r1, r2)$ is the sum of $\alpha(r1, r2)$ and $\beta(r1, r2)$ cost of the link, which denotes the total transfer cost of a single chunk over link $(r1, r2)$. Table 3 lists the variables that the TACCL’s synthesizer solves for. We will describe each variable in detail in this section.

B.1 Routing

The main aim of the routing stage is to give us the path that every chunk takes in the collective. Our objective is to minimize the time (denoted by continuous variable $time$) it takes to reach the post-condition of the collective.

$$\text{Minimize } time \quad (1)$$

The time taken for the collective algorithm is the latest time at which a chunk becomes available on a rank that is in the post-condition of the collective. We use a continuous variable $start[c, r]$ to denote the time that chunk c becomes available on rank r , and end up with the following constraints for $time$

$$time \geq start[c, r] \quad \forall (c, r) \in coll.postcondition \quad (2)$$

For chunks on ranks that belong to the collective’s precondition, we set the start time to zero.

$$start[c, r] = 0 \quad \forall (c, r) \in coll.precondition \quad (3)$$

We also add correctness constraints in our formulation for routing - chunks are sent from a GPU rank only after they have been received on that rank. We introduce a continuous variable $send[c, src, r]$ to denote the time of sending chunk c from rank src to rank r and add the following constraint to our formulation:

$$send[c, src, r] \geq start[c, src] \quad \forall c \in \mathcal{C} \quad \forall (src, r) \in \mathcal{L} \quad (4)$$

We use a binary variable $is_sent[c, src, r]$ to indicate if chunk c is sent over the link (src, r) in our algorithm. We note that the routing stage does not strictly respect bandwidth constraints of any link - the generated solution may send two chunks simultaneously over a link at the time cost of one chunk. The chunk start time on a rank will be determined only by the chunk send time on the source, independent of other chunk transfers on the link (eq. 5). LHS→RHS in the

equation signifies an indicator constraint, i.e., if LHS is 1, RHS will hold.

$$is_sent[c, src, r] \rightarrow start[c, r] = send[c, src, r] + lat(src, r) \quad \forall c \in \mathcal{C} \quad \forall (src, r) \in \mathcal{L} \quad (5)$$

Instead of bandwidth constraints, this encoding uses *relaxed bandwidth constraints*. They are expressed by aggregating the link transfer time of all chunks sent over a link and using it to lower bound the total time of the algorithm (eq. 6). For switched connections, the total time is lower bounded by the sum of link transfer times of all chunks sent over all switched outgoing links from a source, and also by the sum of link transfer times for chunks received from all incoming links to a destination (eq. 7 and eq. 8).

$$time \geq \sum_{c \in \mathcal{C}} (lat(src, r) * is_sent[c, src, r]) \quad \forall (src, r) \in \mathcal{L} \quad (6)$$

$$time \geq \sum_{c \in \mathcal{C}} \sum_{dst \in \mathcal{S}_r^{send}} (lat(r, dst) * is_sent[c, r, dst]) \quad \forall r \in \mathcal{S}_{send} \quad (7)$$

$$time \geq \sum_{c \in \mathcal{C}} \sum_{src \in \mathcal{S}_r^{recv}} (lat(src, r) * is_sent[c, src, r]) \quad \forall r \in \mathcal{S}_{recv} \quad (8)$$

Based on the communication sketch, we also add constraints for `uc-max` and `uc-min` strategies for switch-hyperedges to maximize and minimize the number of links utilized in a switch respectively. We introduce a new binary variable $is_util[src, r]$ for links (src, r) that are a part of a switch-hyperedge. This variable is 1 if any chunk is sent over link (src, r) , and 0 otherwise.(eq. 9 and eq. 10). According to the switch-hyperedge strategy, we add this variable, weighted with a small constant γ , to the objective function (eq. 11). γ is negative for `uc-max` and positive for `uc-min`.

$$is_util[src, r] \geq is_sent[c, src, r] \quad \forall c \in \mathcal{C} \forall (src, r) \in \mathcal{L} \quad (9)$$

$$is_util[src, r] \leq \sum_{c \in \mathcal{C}} is_sent[c, src, r] \quad \forall (src, r) \in \mathcal{L} \quad (10)$$

$$\text{Minimize } time + \gamma \times \left(\sum_{(src, r): \text{switched links}} is_util[src, r] \right) \quad (11)$$

We also add symmetry constraints according to the symmetry offsets provided by user in the communication sketch. For a chunk c and link (src, r) , we identify a rotationally symmetric chunk \hat{c} and link $(s\hat{r}c, \hat{r})$ and add the following constraints:

$$start[c, r] = start[\hat{c}, \hat{r}] \quad (12)$$

$$send[c, src, r] = send[\hat{c}, s\hat{r}c, \hat{r}] \quad (13)$$

$$is_sent[c, src, r] = is_sent[\hat{c}, s\hat{r}c, \hat{r}] \quad (14)$$

MILP Variables	Explanation
Routing	
<i>time</i>	time spent in the collective algorithm
$start[c, r]$	time at which chunk c becomes available at GPU r
$send[c, src, r]$	time at which chunk c is sent from GPU src to GPU r
$is_sent[c, src, r]$	indicates if chunk c is sent from GPU src to GPU r
$is_util[src, r]$	indicates if any chunk is sent from GPU src to GPU r
Contiguity	
$is_together[c, o, r]$	indicates if chunks c and o are sent to GPU r together from the same source, thus sharing the bandwidth and reducing the latency cost of transfer

Table 3: Variables used in TACCL’s MILP formulation. Variables with prefix *is_* are binary variables and others are continuous variables.

Further, for chunks that start on one node and have a final destination on another node, we add inter-node transfer constraints which specify that at least one inter-node link will be used to transfer that chunk.

$$\sum_{(r_1, r_2) \in \mathcal{L}: r_1 \in \text{node}_1, r_2 \in \text{node}_2} is_sent[c, r_1, r_2] \geq 1 \quad (15)$$

B.2 Ordering Heuristics

We start the heuristic ordering by determining the paths each chunk takes using the solution of the path encoding. We then consider the first link in every path as a candidate for scheduling a chunk transfer. Using heuristics like *chunk-with-shortest-path-until-now-first* and *chunk-with-longest-path-from-now-first*, we select a path (and thus a chunk) which should be scheduled in this round. We keep a running estimate of link time, which is the earliest time at which a chunk can be scheduled over the link. We also keep a running estimate of chunk time, which is the earliest time at which the next link transfer can be scheduled for a chunk. At the start, the link time for every link is 0 and the chunk time for every chunk is 0. When a path is chosen in the first round, the chunk associated with the path is scheduled to traverse the first link in the path. The link time of that link increases by link latency and chunk time of that chunk increases by link latency. The link candidate from the selected path is also updated to be the next link in the path. For the next rounds, we decide which path’s candidate link to schedule next using the tracked link and chunk times along with the scheduling heuristics. This keeps going until we have scheduled a data transfer over all the links in all the paths. We find that the best heuristics differ for architectures with NVLinks and those with NVSwitches, in terms of whether to start selecting links to schedule in the same order as the paths or in the opposite order of the paths. The heuristic ordering has the following three outputs:

- $chunk_order(r_1, r_2)$, an ordered list of chunks transferred along each link (r_1, r_2) . If chunk c_1 is present

before chunk c_2 in $chunk_order(r_1, r_2)$, it denotes that c_1 is scheduled to be sent before c_2 over link (r_1, r_2) .

- $switch_send_order(r)$, an ordering on the chunks sent from a switch source r to any of the switch destinations $dsts$. If (c_1, dst_1) is present before tuple (c_2, dst_2) in $switch_send_order(r)$, it means that a send of c_1 over link (r, dst_1) should be scheduled before a send of chunk c_2 over link (r, dst_2) .
- $switch_recv_order(r)$, an ordering on the chunks received on a switch destination r from any of the switch sources $srcs$. If (c_1, src_1) is present before tuple (c_2, src_2) in $switch_recv_order(r)$, it means that a receive of c_1 over link (src_1, r) should be scheduled before a receive of chunk c_2 over link (src_2, r) .

B.3 Contiguity and Exact Scheduling

Finally, we describe the formulation for the contiguity and exact scheduling stage. Given the link and switch ordering from the heuristic ordering stage, the aim of this stage is to find the sweet spot in the trade-off between lower link latency by sending multiple data chunks contiguously as a big data chunk and reduced pipelining benefits due to the big data-chunk transfer. We provide the main set of constraints in our formulation below, leaving out other less important constraints.

Our objective is still to minimize the time of the collective and constraints eq. 1–eq. 4 must still hold in this formulation. We add a new binary variable $is_together(c_1, c_2, r)$ for all chunks c_1 and c_2 that are sent over the same link to rank r . If $is_together(c_1, c_2, r)$ is 1, chunks c_1 and c_2 are sent as a single data-chunk over a link to rank r .

$$is_together[c, o, r] \rightarrow send[c, src, r] = send[o, src, r] \quad \forall c, o \in chunk_order(src, r) \quad \forall (src, r) \in \mathcal{L} \quad (16)$$

The transfer time of a data chunk c along a link (src, r) will be determined by all other data chunks that it has to travel together with:

$$lat[c, src, r] = \alpha(src, r) + \beta(src, r) * \left(\sum_{o \in chunk_order(src, r)} is_together[c, o, r] \right) \quad \forall c \in chunk_order(src, r) \quad \forall (src, r) \in \mathcal{L} \quad (17)$$

$$start[c, r] = send[c, src, r] + lat[c, src, r] \quad \forall c \in chunk_order(src, r) \quad \forall (src, r) \in (\mathcal{L}) \quad (18)$$

We also add strict bandwidth constraints for this formulation, allowing only one data chunk per link transfer time

if the data chunks are not sent contiguously over the link. Let $pos(c, src, r)$ determine the position of chunk c in the $chunk_order(src, r)$, then

$$\begin{aligned} \neg is_together[c, o, r] \rightarrow & send[o, src, r] \geq send[c, src, r] \\ & + lat[c, src, r] \quad \forall c \in chunk_order(src, r) \\ & \quad \forall o \in chunk_order(src, r) \end{aligned} \quad (19)$$

if $pos(o, src, r) \geq pos(c, src, r) \quad \forall (src, r) \in \mathcal{L}$

Similarly, we add bandwidth constraints for switch, allowing a source to send data to only one switched destination at a time, and a receiver to receive data from only one switched sender at a time. Let $sw - pos - send(c, r, dst)$ determine the position of tuple (c, dst) in the $switch_send_order(r)$, and let $sw - pos - recv(c, src, r)$ determine the position of tuple (c, src) in the $switch_recv_order(r)$, then,

$$\begin{aligned} send[o, r, dst_o] \geq & send[c, r, dst_c] + lat[c, r, dst_c] \\ & \forall (c, dst_c) \in switch_send_order(r) \\ & \forall (o, dst_o) \in switch_send_order(r) \end{aligned} \quad (20)$$

if $sw - pos - send(o, r, dst_o) \geq sw - pos - send(c, r, dst_c)$
 $\forall r \in \mathcal{S}^{send}$

$$\begin{aligned} send[o, src_o, r] \geq & send[c, src_c, r] + lat[c, src_c, r] \\ & \forall (c, src_c) \in switch_recv_order(r) \\ & \forall (o, src_o) \in switch_recv_order(r) \end{aligned} \quad (21)$$

if $sw - pos - recv(o, src_o, r) \geq sw - pos - recv(c, src_c, r)$
 $\forall r \in \mathcal{S}^{recv}$

C Standalone Experiments on Four Azure NDv2 Nodes

Figure 11 shows additional algorithm bandwidth and the speedup over NCCL graphs of TACCL for ALLGATHER, ALLTOALL, and ALLREDUCE on 4-node NDv2 cluster. We synthesize all collectives using the *ndv2-sk-1* communication sketch (see Section 7.1 for details), and lower them using 1 or 8 instances. We plot the best of the two algorithms over different buffer sizes.

TACCL’s ALLGATHER algorithms are $10\% - 2.2\times$ faster than NCCL across all buffer sizes. For ALLTOALL, the *ndv2-sk-1* sketch is most effective for large buffer sizes, and helps generate algorithms that are up-to 46% faster than NCCL for buffer size greater than 1MB. TACCL ALLREDUCE algorithms are up-to 34% faster than NCCL for small buffer sizes and $1.9\times - 2.1\times$ faster than NCCL for larger buffer sizes.

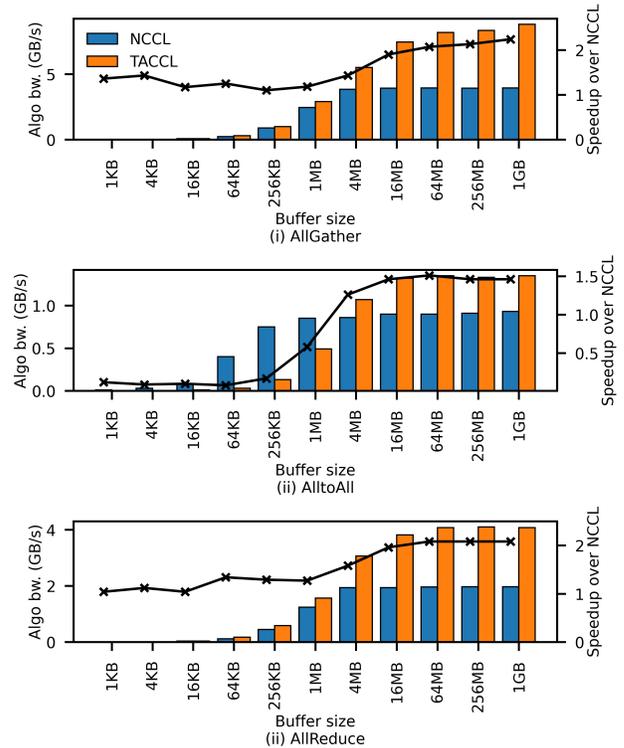

Figure 11: Algorithm bandwidth of TACCL algorithms compared against NCCL (left Y-axis) and their speedup over NCCL (right Y-axis) for ALLGATHER, ALLTOALL, and ALLREDUCE collectives on four NDv2 nodes.

Synthesizing Runtime Programmable Switch Updates

Yiming Qiu Ryan Beckett[†] Ang Chen

Rice University [†]Microsoft

Abstract

We have witnessed a rapid growth of programmable switch applications, ranging from monitoring to security and offloading. Meanwhile, to safeguard the diverse network behaviors, researchers have developed formal verification techniques for high assurance. As a recent advance, network devices have become runtime programmable, supporting live program changes via partial reconfiguration. However, computing a runtime update plan that provides safety guarantees is a challenging task. FlexPlan is a tool that identifies step-by-step runtime update plans using program synthesis, guaranteeing that each transition state is correct with regard to a user specification and feasible within switch memory constraints. It develops novel, domain-specific techniques for this task, which scale to large, real-world programs with sizable changes.

1 Introduction

Programmable switches accelerate the velocity of change and facilitate innovation [11, 12, 14]. The community’s ideal is to develop and deploy new features quickly in the network, without upgrading switch hardware. This has led to two synergistic lines of pursuit. On one hand, researchers have seized this opportunity to develop a slew of *switch applications*, such as monitoring [24, 48], security [31, 54, 55, 58], advanced routing [25, 33, 41], and offloading [27, 28]. On the other hand, to mitigate the potential risks of frequent changes, *formal verification* of switch programs promises to eliminate network bugs and provide high assurance [13, 18, 38, 51]. Combined, the two lines of work pave the way toward a featureful and reliable network infrastructure.

As of late, network programmability is at a new inflection point. Whereas traditional P4 programmable switches [10] require offline procedures for program updates (e.g., draining user traffic, reflashing the data plane with a new program, and undraining traffic), *runtime programmable switches* [4, 19, 52, 53] increase the benefits of programmability even further by supporting live program changes. Upon an update request (e.g., due to tenant requirements or infrastructure upgrades), the switch program is modified online to effect the change, by incrementally adding and removing match/action tables in a running program based on the “delta” [19, 53]. Compared to the approach of recompiling the changed program and reflashing the data plane from scratch, runtime updates enable rapid deployment of new features. Runtime programmability has become available in a variety of targets [19, 52, 53], including commercial off-the-shelf switch ASICs [3, 5, 9].

However, runtime programmability introduces another

layer of correctness concerns. It is known that live network updates come with risks—they result in intermediate states with different behaviors from the initial and final networks [29, 44, 45]. Even in a traditional network, updates must be carefully staged to ensure that the transition is free of error [36]. This risk and the challenges it raises are only magnified in programmable switch updates. A step-by-step update to a deployed P4 program, while the switch is in use, could expose partial and potentially unsafe program snapshots to user traffic. For instance, if not careful, an old ACL table may have been removed before the updated ACL is installed, leading to a transient program snapshot without access control. Although we could attempt to make all changes in a single step and avoid intermediate states, in practice, this is only feasible for minuscule updates. The “delta” corresponding to the update needs to be prepared in the switch scratch memory before activated [6, 53]; thus, this leads to a resource utilization peak that may exceed the available memory. A large delta often needs to be broken down into smaller steps, where each step prepares and applies only a fraction of the change [53].

To safeguard runtime network updates, we must again rely on formal reasoning techniques. Existing work in runtime programmability either asks the user to prescribe step-by-step updates [19] or employs algorithms that do not provide semantic guarantees [53]; thus, they do not offer the same level of assurance. Existing verification work, on the other hand, focuses on certifying the correctness of a single P4 program [18, 38, 51], but cannot help *identify a correct-by-construction sequence* for program transition. Thus, these verification techniques cannot guarantee the correctness of intermediate program snapshots during a transition, and bugs could be unwittingly introduced into the network. We believe that customizing *program synthesis* techniques to this new problem domain will bear much fruit. If we can formally synthesize a *safe* (i.e., conforming to a specification) and *feasible* (i.e., within switch resource limits) transition plan, then we can be confident about its effect on the network.

We develop such a tool called FlexPlan. It takes in a P4 program with annotated changes and a user specification, and produces such a transition plan. FlexPlan draws inspirations from a powerful approach to program synthesis—CEGIS, or counterexample-guided inductive synthesis [47]—and develops a variety of domain-specific techniques for our problem at hand. At a high level, the CEGIS algorithm navigates the search space by iterating between a “proposal” phase, which suggests potentially correct programs (e.g., transition plans), and a “verification” phase, which proves or disproves the

proposals. The verification phase also produces counterexamples (i.e., packets) upon failure, which are learned by the next proposal to guide the search. CEGIS has found success in many synthesis problems [17] and more recently, in networking [13, 22, 59]. However, runtime programmable switch updates raise distinct challenges that require novel designs.

The first challenge stems from the fact that FlexPlan needs to synthesize not just one single program but a *sequence* of program snapshots; further, each snapshot must successively modify the previous one safely and stay within the resource constraints. To cast this into a CEGIS framework, we develop two concise encodings that articulate the essence of this synthesis. A *version sketch* is derived from the switch program with annotated changes, adding version variables at change sites to represent the change progress. This building block provides a uniform representation for any intermediate program state that could appear in the transition. Further, a *sequence sketch* concatenates multiple version sketches, while constraining them to modify each other and make progress toward the final program. The synthesis target, therefore, is correct assignments to the version variables across snapshots—these are the program “holes” in the verbiage of the *program sketching* [47] synthesis framework.

The scalability bottlenecks of this synthesis represent the second challenge. Existing verification efforts are already challenged by the large SMT formulas produced by complex switch programs [38, 50, 51], but FlexPlan needs to reason about stacks of these formulas in each proposal/verification phase. To accelerate the synthesis, we develop two domain-specific techniques to shrink the problem sizes whenever possible—to as close as that of single program snapshots. *Snapshot learning* extracts insights about the synthesis from a single snapshot, and generalizes that knowledge to all subsequent snapshots. *Snapshot verification* shatters a proposed transition sequence into individual snapshots for divide-and-conquer. We arrange these techniques carefully to ensure that reasoning about the safety of a sequence from snapshot-based properties still produces a sound analysis.

Finally, we also leverage a unique property in the FlexPlan synthesis problem—its *diagnosability*—to perform introspection into the synthesis process. For a traditional CEGIS problem, the synthesis tool cannot know beforehand whether or not a correct solution exists. FlexPlan, however, can check the initial and final programs against the safety specification to see whether or not some safe transitions exist. If both programs are correct, then a safe transition must exist; a safe transition may not be feasible, however, due to resource constraints. To check feasibility, FlexPlan incrementally grows the transition sequence length—so that each step in the transition sequence makes smaller and smaller changes to approach feasibility—while performing another introspection to decide when to stop trying longer sequences. Finally, when FlexPlan concludes that no safe transition is feasible under the current switch headroom, it introspects on how much resource release

is needed for feasibility, as another assistance to the operator.

We prototype FlexPlan [2] and show that it scales to real-world switch programs and sizable changes, and supports a rich set of safety properties including but going beyond those in existing work [53]. With FlexPlan, operators can synthesize transition plans quickly and automatically (e.g., within a few minutes for sizable changes to switch.p4), while being assured of the correctness of the transition process.

2 Motivation

Analogues of our motivation can be found in existing work on OpenFlow network updates, summarized as follows: Network changes are a constant [23], but they often come with risks [36] due to intermediate states during transition [21, 45]. Rigorous approaches are needed to safeguard against transient disruption [44] to satisfy security requirements and stringent service-level objectives [16]. Ensuring transactional updates at each step [44], and formally guaranteeing the correctness of an update plan [39] is essential. These arguments hold true still, and are further amplified, for P4 programmable networks.

2.1 Runtime programmable switch updates

Programmable switches enable new network features to be quickly developed in-the-field [24, 27, 28, 35, 48, 56]; however, in earlier designs, *deploying* new features to the switch was an intrusive process. To update the switch program (e.g., add, remove, or modify a feature), the traditional approach was to completely recompile the changed program and reflash the data plane [60]. This results in device disruption, so program updates had to be conducted offline—user traffic is drained from the device and diverted elsewhere in the network, after which the switch is re-imaged, and finally, reactivated again.

Recognizing its cumbersomeness and risk for downtime, researchers and practitioners have made a concerted effort toward *runtime programmability* [4, 19, 52, 53, 57]. That is, switch programs are updated using partial reconfiguration without taking down the device for maintenance. Since P4 programs have modular table boundaries, runtime reconfigurations on specific match/action tables and their control flow logic need not disrupt other parts of the program. A feature update can be decomposed into a series of table and branch changes to transform a deployed program to a desired state.

Runtime programmability is not just an academic ideal. In response to the perennial call for both “feature velocity and cloud availability” [16], major switch vendors have embraced this trend with ASIC support. Nvidia’s Spectrum switches [53] and Broadcom’s Trident [9] and Jericho [3] switches are commercially available off-the-shelf, and academic prototypes [19, 52] are also exploring this design. Use cases of runtime programmable switches include real-time security defense [53], multi-tenancy [52], adaptive telemetry [19], where live switch updates afford higher flexibility not found in earlier programmable switches.

2.2 A motivating example

We will consider a simple example to illustrate the flexibility of runtime switch updates as well as the challenges they raise. The following program snippet uses `@add` and `@del` annotations to demarcate change boundaries in a control block:

```
1 /* Ex1: ipv4_ipv6 */
2 control ingress {
3     apply {
4         if (ipv4.isValid()) {
5             @del acl_v4.apply();
6             @add nat_acl_v4.apply();
7         } else if (ipv6.isValid()) {
8             @del acl_v6.apply();
9             @add nat_acl_v6.apply();
10        }
11        @add stats.apply();
12    }}

```

We remove two older versions of ACL tables for both IPv4 and IPv6 (Lines 5+8), and add two new tables that perform both NAT and ACL (Lines 6+9); we also add a statistics table for monitoring (Line 11). Since P4 is a target-independent language, operators can specify a desired change with such annotations without worrying about hardware details. Indeed, the mechanisms for implementing a live update depend upon the underlying switch platforms [19, 53]:

- FlexCore [53] relies on pointer swaps to achieve transactions, adding and removing a group of tables atomically. In our example above, we can first add `nat_acl_v4`, `nat_acl_v6`, and `stats` to scratch memory, and then use a transaction to make them visible to network traffic, while deleting the two older tables `acl_v4` and `acl_v6`.
- rP4 [19] also adds and removes MA tables leveraging scratch memory, but it relies on temporarily pausing traffic to achieve transactional effects. Before making the update, packets are paused and stored in a front buffer, and the respective tables are modified to effect the change. Buffered packets are then let out into the pipeline.

The careful reader may have noticed that this update appears to have completed within a single transaction, so no intermediate states are exposed. However, this is because we have yet to consider the resource constraints of the switch hardware. Switches have severe memory capacity bottlenecks, and they are easily packed to the brim with large MA tables [32, 53]. Thus, this logically simple update may be physically infeasible if the switch memory has high utilization.

The potentially infeasible operation is preparing the three new tables (`nat_acl_v4`, `nat_acl_v6`, and `stats`) in scratch memory before their old counterparts have been deleted. Assume without loss of generality that every MA table has the same size (say, of U , one unit of table entries), then the net resource increase after the change is only U . However, preparing the transaction causes a resource peak of $5 \times U$, which might exceed the available switch headroom. One workaround is to

ensure that the switch always has a low utilization [6], but this is obviously undesirable. Thus, recent work [53] proposes to break a larger update into multiple smaller batches to reduce the resource peak. For instance, if we first add `nat_acl_v4` and delete `acl_v4` in a transaction, it only requires $3 \times U$ headroom; the second transaction adds `nat_acl_v6` and deletes `acl_v6`, also within $3 \times U$ headroom; a final transaction adds the `stats` table, again within $3 \times U$ headroom. As tradeoff, after the first transaction, IPv4 traffic is processed with new tables for NAT and ACL, whereas IPv6 traffic is still processed with the old, and it only encounters new tables after the second transaction; further, the statistics table is only applied after the third transaction completes. Nevertheless, this may still be a reasonable sacrifice in order to achieve a feasible update, as long as the intermediate states are “well-behaved.”

2.3 Computing a safe and feasible transition

It is far from clear, however, how to conjure up a transition plan for a desired change. rP4 [19] relies on the user to supply this plan, and FlexCore [53] algorithms only analyze whether changes are “reachable” to each other in the table graph. Neither represents a formal approach that can provide semantic guarantees on the transitional behavior. In general, the notion of correctness is scenario-specific and should be encoded in a user specification in a granular manner, going beyond the three fixed definitions in FlexCore [53], summarized below:

- *Program consistency*: Only one-step updates without intermediate states are allowed.
- *Element consistency*: Intermediate states are acceptable as long as reachable regions (e.g., changes that eventually reach the same table) are changed together atomically.
- *Execution consistency*: Reachable tables can be changed independently as long as no packets will mix them.

This cannot, for instance, capture user intention on “traffic classes” (e.g., IPv4 vs. IPv6); nor can it support more granular correctness definitions (e.g., for any intermediate state, packets must go through an ACL table, or packets must be sent to the same outgoing port). For some cases, the three fixed consistency definitions conflate into the same. For the above change, execution and element consistency will find the same plan as program consistency, because all changes eventually reach the `stats` table, forcing a $5 \times U$ peak despite the desire to relax the requirements for a feasible update.

2.4 FlexPlan: A program synthesis perspective

We believe that a principled solution should instead rest upon a firmer foundation, grounded in formal synthesis. Such a solution would satisfy three key goals:

- *Automated*: Beyond expressing a desired property, human reasoning is not required to identify a plan.
- *Completeness*: If a safe and feasible transition exists, we will guarantee to find it.

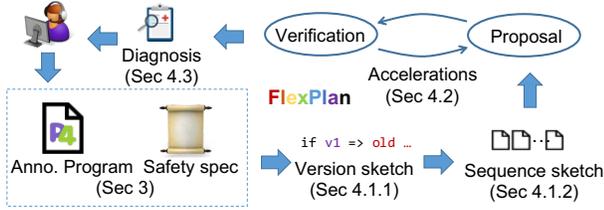

Figure 1: FlexPlan and its key techniques.

- *Soundness*: Once we output a transition, it is guaranteed to be safe and feasible.

The FlexPlan approach. We formulate this problem as follows. Given a P4 program p with a set of change annotations A , a safety specification ϕ , and resource headroom δ , identify a transition sequence $\{p_1 \rightarrow p_2 \rightarrow \dots \rightarrow p_i\}$, where p_i 's are the intermediate program snapshots, and at the end of the sequence, all changes in A have been applied. Further, we require that a) each p_i satisfies ϕ , and b) each transition step $p_i \rightarrow p_{i+1}$ makes positive progress and stays within the resource headroom, initialized to δ . Our synthesis relies on a CEGIS approach (cf. [46, 47] for more background): In each iteration, the proposal phase generates a candidate transition sequence that satisfies ϕ and δ on the current set of counterexamples (that is, packets), which is initialized to the empty set. The verification phase will try to extract a new counterexample packet that causes violation, which will be consumed by the proposal phase in the next iteration, and so on. This continues until no counterexample packets can be generated—in which case we have a correct sequence—or until no candidate sequences can be generated—in which case no update plan exists. Figure 1 illustrates the workflow of FlexPlan, with several key milestones in Sections 3 and 4.

3 Specifying Safe Updates

Users provide a P4 program with annotated changes, as well as a specification to constrain intermediate states.

Update annotations. FlexPlan provides three intuitive annotation primitives for users to express a desired update: `@add`, `@del`, and `@mod`. A source P4 program can be annotated with these primitives, where each annotation site captures a set of changes. In Section 2.2, we have already provided an annotated program in this syntax, and here we used another example to describe several other aspects of the annotations.

```

1 /* Ex2: acl_ecmp_flowlet */
2 control ingress {
3   apply {
4     //modify acl into nat_acl
5     if (ipv4.isValid()) {
6       @mod acl.apply(), nat_acl.apply();
7     }
8     //add ECMP, delete flowlet switching
9     @del { if (ipv6.isValid()) flowlet.apply(); }
10    @add ecmp.apply();
11  }

```

First, the syntax is similar to “P4 annotations” [7] in the P4 language standard. Our annotations target the common intersection of the reconfiguration primitives in existing work [19, 53]—an annotation may specify individual table updates (e.g., Line 10) or a code block update (e.g., tables with their control flow, as in Line 9). The hardware mechanisms are abstracted away from the annotations, but are assumed to provide atomicity for each change annotation, as in recent switches [19, 53]. The `@mod` primitive achieves similar effects as `@del+@add`, but `@mod` must complete in a single atomic step whereas the latter could occur in two separate steps. The entire update finishes when all annotations have been applied.

Specification language. Specifying resource constraints is as simple as providing a number δ that denotes the current switch headroom. Thus, our specification language focuses on the *consistency* properties, which constrain the relation between a program snapshot and the initial and final programs. FlexPlan refines the fixed consistency levels in existing work [53] in two ways: (1) a consistency property may refer to specific *traffic classes*, and (2) new consistency levels can be *programmatically* defined. Consider the following examples.

S1: Execution consistency for IPv4 traffic that hits ACL.

Any IPv4 packet that hits the `acl` table must not mix old and new code blocks in any intermediate state. However, two IPv4 packets traversing different execution paths in the program do not need to use the same program version—e.g., TCP traffic may be processed by old code blocks, but UDP traffic by the new. We do not constrain the behaviors of other traffic classes.

```

1 specification {
2   // create new ghost variables for the program
3   // these are used for verification only
4   ghost bit<1> sawOld = false;
5   ghost bit<1> sawNew = false;
6   ghost bit<1> acl_hit = false;
7   // update ghost state when tables are applied
8   @old => { sawOld = true; }
9   @new => { sawNew = true; }
10  @hit('acl') => { acl_hit = true; }
11  // define: no path mixes old and new nodes
12  // $cur: the current/transitional program state
13  execution_consistency_ipv4 = {
14    $cur.in.ipv4.isValid() & $cur.eg.acl_hit =>
15    !($cur.eg.sawOld && $cur.eg.sawNew);
16  }
17  assert execution_consistency_ipv4;
18 }

```

Lines 4-6 define “ghost variables” that track meta-level properties of a program execution—specifically, whether a packet has encountered an old code block, a new block, or the ACL table, respectively. Lines 8-10 describe how ghost variables should be updated for an execution: whenever a packet triggers an old code block, a new block, or a table named `acl`, assign the respective ghost variable to be true. Lines 13-17 are the consistency assertion, where `$cur` represents a packet traversing the current program snapshot. If such a packet contains a valid IPv4 header when it arrives at the ingress, and

if it has hit the ACL table before it exits the egress, then we assert that it should not be processed by a mix of code blocks.

S2: Field consistency for egress_spec. We define a new consistency level that only constrains the processing outcomes of specific header fields. The following example specifies that any intermediate states should preserve the processing outcome for the packet’s egress port—i.e., a packet should either go to the same port as the old program or as the new one. The `$new` and `$old` variables denote two packets traversing the old and new programs, respectively.

```

1 specification {
2   // preserve processing outcome of egress_spec
3   field_consistency_espec = {
4     $cur.in == $old.in == $new.in =>
5     ($cur.eg.espec == $new.eg.espec ||
6     $cur.eg.espec == $old.eg.espec);
7   }
8   assert field_consistency_espec;
9 }

```

S3: Program consistency for TCP traffic: We require that TCP packets must not encounter any intermediate state. The `all_old` assertion states that if at the ingress a packet carries a valid TCP header, then at the egress it must only have been processed by old tables. Analogously, the `all_new` assertion states the opposite. Their disjunction implies that TCP traffic will only be processed by one version of the program. The primary difference between this specification and S1 is that execution consistency only constrains the behaviors of each individual packet, whereas program consistency constrains the behaviors across all packets of a certain kind (e.g., TCP).

```

1 specification {
2   // same ghost variables as before
3   ghost bit<1> sawOld = false;
4   ghost bit<1> sawNew = false;
5   @old => { sawOld = true; }
6   @new => { sawNew = true; }
7   // define whether all packets use the old program
8   all_old = {
9     $cur.in.tcp.isValid => !$cur.eg.sawNew;
10  }
11  // define whether all packets use the new program
12  all_new = {
13    $cur.in.tcp.isValid => !$cur.eg.sawOld;
14  }
15  // all packets use old program or all use new
16  assert all_old || all_new;
17 }

```

These granular consistency levels require program semantic analysis and cannot be captured by fixed definitions [53]. We describe several more examples in Appendix 9.1 and summarize them in Table 1. Figure 2 presents the grammar of the specification language. Like existing work [18, 50, 51], the specifications are eventually translated into assertions in the source P4 program. Appendix 9.2 shows one such translation.

<code>spec</code>	::=	specification { <code>stmt</code> *}	Specification
<code>stmt</code>	::=	<code>gvar</code> *	Ghost vars
		<code>instr</code> *	Instrumentation
		<code>property</code> *	Property
		<code>assert</code> *	Assertion
<code>gvar</code>	::=	ghost bit < <code>n</code> > <code>gv</code>	Ghost vars
<code>gexpr</code>	::=	\$cur \$old \$new	Network version
		<code>gexpr.field</code>	Field dereference
		<code>gexpr + gexpr</code>	Addition
		...	Other expr
<code>instr</code>	::=	<code>label => assignment</code> *	Ghost update
<code>assignment</code>	::=	<code>gv = gexpr</code>	Assignment
<code>label</code>	::=	@new @old @hit	Annotation
<code>property</code>	::=	<code>name = {gexpr*}</code>	Consistency
<code>assert</code>	::=	assert <code>name</code>	Assertion

Figure 2: FlexPlan specification language grammar.

Specifications	LoC
S1. Execution consistency for IPv4 [53]	13
S2. Field consistency for egress_spec	8
S3. Program consistency for TCP [53]	13
S4. Element consistency for ACL [53]	15
S5. Table consistency for ECMP	10
S6. VLAN table access [51]	8
S7. Correct TTL decrement [51]	6

Table 1: FlexPlan supports granular consistency specifications that go beyond existing work [53] (e.g., S1-S5). Although our primary focus is consistency, FlexPlan can also support general program snapshot correctness (e.g., S6-S7) guarantees addressed by existing verification work [18, 51].

4 Update Plan Synthesis

Next, we describe how FlexPlan synthesizes an update plan from the annotated program and specification. We denote these inputs as $\langle p_{[A]}, \phi, \delta \rangle$, where $p_{[A]}$ is an annotated P4 program with a set of change sites $A = \{a_1, \dots, a_k\}$, and ϕ and δ are the safety and resource constraints, respectively. FlexPlan outputs an update sequence $s = \{p_{old} = p_1 \rightarrow p_2 \rightarrow \dots \rightarrow p_t = p_{new}\}$, where two special states p_{old} and p_{new} represent the initial and final programs, respectively. We ask that each intermediate state p_i must be safe (i.e., satisfying ϕ) and each transition from $p_i \rightarrow p_{i+1}$ is feasible (i.e., the resource spike for this transition stays within δ_i , as computed from the initial headroom δ after applying transitions before p_i). If no such s can be found, FlexPlan outputs diagnostic information on whether the safety or feasibility constraints have caused the failure, and in the latter case, it analyzes how much resource release would enable a feasible synthesis.

4.1 Synthesizing a program sequence

Our CEGIS formulation uses *program sketching* [47], a classic framework for synthesis. This formulation views the synthesis task as filling “holes” in an incomplete program (i.e., a “sketch”), and it has been successfully applied to network

```

1  control ingress {
2      apply {
3          /* annotation site 1: acl->nat_acl */
4          if(ipv4.isValid()) {
5              if (! vsk.v1) { // @mod
6                  acl.apply();
7              } else {
8                  nat_acl.apply();
9              }
10         }
11         /* annotation site 2: delete flowlet */
12         if(! vsk.v2) { // @del
13             if (ipv6.isValid())
14                 flowlet.apply();
15         }
16         /* annotation site 3: add ecmp */
17         if(vsk.v3) { // @add
18             ecmp.apply();
19         }
20     }}

```

Figure 3: A version sketch that is derived from the `acl_ecmp_flowlet` example in Section 3. Version variables `vsk.v` are the sketch holes. The safety specification will also be instrumented into the version sketch (cf. Appendix 9.2)

programs [13, 22]. However, the objective in FlexPlan differs from existing work as it must identify a correct *sequence* of program snapshots that successively build upon each other toward the final program. To cast this into the CEGIS framework, we develop two novel encodings: a *version sketch* to represent any valid program snapshot during transition, and a *sequence sketch* to string together multiple version sketches and constrain them to make progress toward our final state.

4.1.1 Version sketch: Encoding program snapshots

The version sketch is a uniform and expressive encoding that can capture any transitional program snapshots derived from $p_{[A]}$. As its name suggests, it introduces a “version variable” v_i at the annotation site $a_i \in A$. The annotation is then substituted with two version control branches guarded by v_i . Without loss of generality, consider $a_i = \{\text{@mod } s_i \rightarrow t_i\}$, a modification from s_i to t_i . It will be transformed into `if (v_i) then $\{t_i\}$ else $\{s_i\}$` , or simply `ite(v_i, t_i, s_i)`. That is, a version sketch with v_i turned on encodes a program snapshot where annotation a_i has been applied; on the other hand, a version sketch with v_i turned off represents a snapshot where the change a_i is yet to be applied. The `@add` and `@del` annotations are handled analogously, with one of the branches controlling an empty statement: `ite($v_i, t_i, noop$)` for adding t_i and `ite($v_i, noop, s_i$)` for deleting s_i . Across all annotation sites, by turning version variables on or off, the resulting snapshot seamlessly reflects any combination of applied changes.

Figure 3 shows the version sketch for `acl_ecmp_flowlet`, where version variables are added to the input program as instrumentations. From this instrumented program, FlexPlan derives an SMT formula, where ξ represents the unchanged components without annotations, and the i -th `ite` formula

represents annotation a_i . Constraining the version sketch with the safety specification would give an SMT encoding:

$$\text{vsk}(\xi, \bigwedge_{i=0}^k \text{ite}(v_i, t_i, s_i)) \wedge \phi$$

FlexPlan obtains SMT formulas in a similar way as existing work [18]. ϕ is instrumented into the version sketch. Then, FlexPlan converts all statements into static single assignment form and SMT formulas. It then computes the weakest preconditions based on the control flow logic.

The version sketch is expressive enough to encode any intermediate snapshot and constrain its safety with ϕ . However, it cannot capture the resource constraint δ , because it is a *sequence* property defined over a series of snapshots and their relations. As a version sketch only represents an individual snapshot, it cannot easily reason about end-to-end feasibility for a snapshot sequence. By itself, it only enables an awkward workaround—start with an empty version sketch, synthesize a safe snapshot as its immediate next step, and iterate based on the new snapshot. More concretely, one could ask that the next snapshot must fill more holes than the current one, while staying safe with respect to ϕ and within the current headroom δ . This would result in a new snapshot where a subset (but likely not all) of version variables have been turned on. This serves as the new “initial” state for another synthesis, until the final state has been reached. However, this results in a difficult search process, as it can only be guided with some greedy heuristics—e.g., maximizing the progress for each step by filling as many holes as possible, or minimizing the resource spike for each step while ensuring some progress. Either way, the lack of a global view could corner the search into a difficult or infeasible state (e.g., no more headroom), where it must backtrack and probe again in the very large search space—all possible permutations of change annotations, together with all possible combinations of adjacent changes in each permutation. This greedy synthesis also cannot easily conclude that no feasible solution exists.

4.1.2 Zooming in on resource constraints

Thus, resource constraints must be encoded explicitly to enable a cross-snapshot, end-to-end synthesis. Recall that δ denotes the initial switch headroom, which is obtained by subtracting the total table sizes of p_{old} from the overall switch memory. From there, each transition from one snapshot to the next `vsk'` adds and removes some tables—thus, we must keep track of the changes to δ and two metrics “spike” and “release” at each transition. Consider the version variable v_1 in Figure 3, which modifies an `acl` table (2Mb) into a `nat_acl` table (3Mb). To achieve atomicity, this is done by first adding `nat_acl` in switch memory, resulting in a transient resource spike of 3Mb, and then deleting `acl` and freeing 2Mb in the same transaction. We record this as `add1 = 3` and `del1 = 2` for turning on v_1 . Thus, across all v_i we define the *spike*:

$$\text{vsk}'.\text{spike} = \sum_i \text{ite}(\text{vsk}'.\text{v}_i \wedge \neg \text{vsk}.\text{v}_i, \text{add}_i, 0)$$

That is, if the transition from vsk to vsk' has turned on v_i , then the transient resource spike increases by add_i ; otherwise, if v_i is not changed in this step, it does not contribute to the spike. We can therefore define the resource *release* after the transaction completes and the spike comes down:

$$vsk'.rel = \sum_i \text{ite}(vsk'.v_i \wedge \neg vsk.v_i, del_i - add_i, 0)$$

In our example, the net release is $del_1 - add_1 = -1$. This reflects in the overall headroom update to δ after this step:

$$vsk'.headroom = vsk.headroom + vsk'.rel$$

The feasibility constraint can therefore be stated as $vsk.headroom \geq vsk'.spike$ for any two adjacent snapshots, across the entire transition sequence from p_{old} to p_{new} .

4.1.3 Sequence sketch: Encoding a transition plan

Based on the above resource constraint analysis, we develop a sequence sketch encoding that enables an end-to-end CEGIS. A sequence sketch ssk is the conjunction of t version sketches $\{vsk_1, vsk_2, \dots, vsk_t\}$ as well as their sequential relations to each other. vsk_1 and vsk_t encode the initial and final programs, respectively, and other states represent the transitions.

$$\begin{aligned} \forall i \neg vsk_1.v_i & \quad ; \text{initial program } p_{old} \\ \forall i vsk_t.v_i & \quad ; \text{final program } p_{new} \\ \forall j (\forall i vsk_{j-1}.v_i \implies vsk_j.v_i) & \quad ; \text{progress} \\ \forall j \text{SpikeAndHeadroom}(vsk_{j-1}, vsk_j) & \quad ; \text{feasibility} \end{aligned}$$

That is, all version variables in the initial sketch are turned off, equating it to p_{old} ; all variables in the final sketch are turned on, resulting in p_{new} . A later sketch in the sequence must monotonically advance the version variables to make progress toward the final state. Furthermore, each transition's spike must be feasible within its current headroom (Section 4.1.2).

Sequence synthesis. This encoding enables an end-to-end CEGIS by filling the ssk holes (i.e., all v variables in all version sketches vsk) in a way that satisfies ϕ for all snapshots and δ across all adjacent snapshots. The sketch holes are $H \in \mathbb{B}^{k \times t}$, a two-dimensional matrix of binary variables.

$$H_{k \times t} = \begin{bmatrix} vsk_1.v_1 & vsk_1.v_2 & \cdots & vsk_1.v_k \\ vsk_2.v_1 & vsk_2.v_2 & \cdots & vsk_2.v_k \\ \vdots & \vdots & \vdots & \vdots \\ vsk_t.v_1 & vsk_t.v_2 & \cdots & vsk_t.v_k \end{bmatrix}$$

In this matrix, k is the number of annotations, and t is the number of transitional states; and we will synthesize all holes in an end-to-end CEGIS, as shown in Figure 4. The proposal phase (Lines 7-11) identifies a potentially correct program (i.e., values in H) by solving for H that exhibits correct behaviors on all counterexamples collected so far (Line 9). The verification phase strengthens the check to test against the full specification (Lines 12-17). If no further violations are

```

1: function SEQUENCECEGIS(ssk,  $\phi$ ,  $\delta$ )
2:   for  $t = 1..k$  do //Iteratively increase seq length  $\triangleleft$  Opt-Diag
3:     ssk.H  $\leftarrow$  RAND( $\mathbb{B}^{k \times t}$ ) //Init w/ random H
4:     ce_set  $\leftarrow$   $\emptyset$  //No counterexample so far
5:     // Next, enter main CEGIS loop  $\triangleleft$  Opt-SnapL
6:     while  $\neg$  Timeout do
7:       // Proposal: Identify candidate  $H=h$ 
8:       ssk.H  $\leftarrow$  SYMBOLIC( $\mathbb{X}^{k \times t}$ )
9:       {ssk.H := h}  $\leftarrow$  SMTSOLVE(ssk,  $\phi$ ,  $\delta$ , ce_set)
10:      if ssk.H ==  $\emptyset$  then // No solution exists, t++
11:        break
12:      // Verification: Verify  $H=h$ 
13:      ce  $\leftarrow$  SMTVERIFY(ssk.H,  $\phi$ ,  $\delta$ )  $\triangleleft$  Opt-SnapV
14:      if ce  $\neq$   $\emptyset$  then // Obtain counterexample
15:        ce_set  $\leftarrow$  ce_set  $\cup$  {ce}
16:      else // Verifies, solution found!
17:        return ssk.H

```

Figure 4: The end-to-end CEGIS algorithm on the sequence sketch. Later subsections will further develop three optimization techniques, labeled as ‘Opt-’, to scale this analysis.

found, we have obtained a correct solution; otherwise, counterexamples are added to ce_set and we continue with a new proposal. The power of CEGIS lies in the fact that with more counterexamples, SMT solvers learn from violations and eliminate entire classes of proposals in the search. Notice also that at Line 2, we iteratively deepen the search based on the sequence sketch length, so it does not need to reason about a larger problem instance unless absolutely necessary.

In the `acl_ecmp_flowlet` example (Figure 3), suppose that we require program consistency for IPv4 and that the current headroom is 1Mb. A correct ssk could give a two-step transition denoted by:

$$H_{3 \times 3} = \begin{bmatrix} F & F & F \\ F & T & F \\ T & T & T \end{bmatrix}$$

The first transition deletes `flowlet` (3Mb) for IPv6 traffic. This causes a resource spike of 0Mb and a release of 3Mb; and the headroom becomes 4Mb after this transaction. Next, the second transition modifies `acl` (2Mb) into `nat_acl` (3Mb) and adds `ecmp` (1Mb) for IPv4 traffic, which causes a resource spike of 4Mb and a release of -2Mb.

4.2 Accelerating the CEGIS loop

We have now obtained a sequence CEGIS algorithm that is guaranteed to be sound (i.e., a synthesized transition is correct) and complete (i.e., if a correct transition exists, it will be found); it also produces the shortest transition due to the iterative deepening search. (More discussions in Section 4.4) However, in terms of performance, this algorithm has a series of scalability bottlenecks. A traditional CEGIS problem only has to reason about SMT formulas generated from a single program, but FlexPlan produces formulas many times larger as they are derived from program sequences. Thus, we develop

two domain-specific optimizations to accelerate the proposal and verification phases, respectively, based upon a divide-and-conquer approach. Our observation is that, for specific CEGIS steps, we can avoid reasoning about ssk directly but instead reason about its comprising vsk instances individually. Since SMT algorithms tend to grow exponentially with the formula size, dividing a large instance (i.e., ssk) into many smaller ones (i.e., vsk) and reasoning about the smaller formulas individually is more efficient than reasoning about the larger instance in a single shot.

Snapshot learning and generalization. We extract insights from a single snapshot before entering the main CEGIS loop (Line 5, ‘Opt-SnapL’; Figure 4). This algorithm learns what a “bad” snapshot might look like, and then generalizes the knowledge for the entire sequence. We observe that, if a snapshot vsk violates the safety property ϕ , then no matter where this snapshot appears in the transition sequence ssk , it still constitute a violation. Thus, there is much to learn from an individual vsk before we have to stitch many such snapshots together. Stated in another way, resource constraints δ force us to perform end-to-end reasoning in general, but the safety aspect of the reasoning is still decomposable to individual snapshots.

This is achieved by operating a loop that extracts as many unsat cores as possible (within timeout threshold) from a single snapshot vsk , but only asserting safety properties ϕ and ignoring resource concerns δ . Each iteration produces one counterexample that witnesses a specific violation for *any* snapshot in the sequence. For instance, a counterexample might say that $\{v1(T), v2(T), v3(F)\}$ violates IPv4 execution consistency, so this snapshot should never appear anywhere in the sequence. After producing many counterexamples, we aggregate and feed such knowledge into the main CEGIS loop, so that the proposal phase will not err in the same way on the larger sequence sketches. Further, for efficiency, FlexPlan distills counterexamples into “minimum unsatisfiable cores” (unsat cores) [20], which is a subset of assignments to $vsk.v$ as the root cause. In our running example, the unsat core $\{v1(T), v3(F)\}$ articulates the essence of the violation—the two IPv4 related blocks are not updated together. The main CEGIS loop ingests this condensed knowledge, avoiding the larger formulas from full-blown counterexamples.

Snapshot verification. The ‘Opt-SnapV’ optimization reduces the task of verifying a proposed ssk against ϕ into smaller tasks of verifying each individual vsk in it. The intuition still stems from the fact that ϕ can be reasoned per snapshot, whereas δ is a sequential property and needs to be synthesized end-to-end. The proposal phase (Line 9; Figure 4) must already ensure end-to-end feasibility in its proposal; so a subsequent verification may only fail due to violation of ϕ . Thus, when verifying ssk , we check individual vsk snapshots separately. If any snapshot produces a violation, its counterexample is used in the next round of synthesis.

Figure 5 shows the pseudocode for both optimizations.

```

1: function SNAPSHOTLEARN( $vsk, \phi$ )
2:    $uc\_set \leftarrow \emptyset$  // Aim to learn unsat cores from  $vsk$ 
3:   while  $\neg$  Timeout do
4:     // Solve for a new violation by negating  $\phi$ 
5:      $\{vsk.v, pkt\} \leftarrow \text{SYMBOLIC}(\mathbb{B}^k, \text{Packet})$ 
6:      $\{vsk.v := v, pkt := p\} \leftarrow \text{SMTSOLVE}(vsk, uc\_set, \neg\phi)$ 
7:     if  $\{v, p\} == \emptyset$  then // Exhausted all  $ce$ 's
8:       return  $uc\_set$ 
9:     else // New violation, extract unsat core
10:       $uc\_set \leftarrow uc\_set \cup \text{EXTRACTUC}(v, p, \phi)$ 
11:   return  $uc\_set$ 
12: function SNAPSHOTVERIFY( $ssk, \phi$ ) // Verify a proposed  $ssk$ .
13:    $ce\_set \leftarrow \emptyset$  // Counterexample set
14:   for  $vsk \in ssk$  do
15:      $ce \leftarrow \text{SMTVERIFY}(vsk, \phi)$ 
16:     if  $ce \neq \emptyset$  then
17:        $ce\_set \leftarrow ce\_set \cup \{ce\}$ 
18:     return false
19:   return true // All snapshots verify!

```

Figure 5: The snapshot learning (Opt-SnapL) and snapshot verification (Opt-SnapV) algorithms. Note that the snapshot learning algorithm does not need to enumerate all counterexamples or unsat cores, as it serves as an optimization for the main CEGIS loop. If the learning times out (Line 3), the collected uc_set is still useful in the main CEGIS.

4.3 Diagnosing the synthesis

Another domain-specific property of our synthesis lies in its *diagnosability*. In traditional synthesis, even if the tool struggles to find a solution, it may not mean that a valid solution does not exist—unless it has exhausted the search space. Thus, the search in the worst-case scenario may spend a significant amount of time only to conclude at the end with a failure. In contrast, we observe that FlexPlan can obtain three types of conclusive proof early in the game. This helps us to determine whether or not a continued search will be fruitful, and enables further optimizations. We call these techniques *introspection*.

Existence? A basic type of introspection is to determine whether or not a safe transition exists at all, regardless of the resource headroom. We observe that FlexPlan can determine this by checking p_{old} and p_{new} against the safety specification ϕ . If both programs are correct, then some safe transition must exist—the degenerate case is to make a one-step transition $\{p_{old} \rightarrow p_{new}\}$, exposing no intermediate state (but potentially causing a very large resource spike and thus may not be feasible). However, if even this check fails, FlexPlan aborts with the conclusion that no solution exists.

Deepening the search? Once we pass this smell test, we are faced with a harder introspection task—what should be the upperbound of t , the length of the sequence sketch? The algorithm in Figure 4 uses a naïve upperbound, where t iteratively deepens from one to k , the total number of change annotations. It first searches through all possible t -step transitions; if no such transition is both feasible and safe, it attempts

a longer transition sequence with $t + 1$ steps. Failures are only conclusive at $t = k$, where each transition only applies one change thus no further breakdown is possible. However, this deepening search gets significantly more expensive with every increment to t —at each t , we need to perform a full round of CEGIS with a sequence of t sketches. Thus, it is beneficial to reflect on the usefulness of a larger t before we deepen the search, potentially stopping far earlier than the naïve bound. This introspection relies on the following property:

Introspection theorem. *Assume that the switch has infinite resources. Without resource constraints, if there does not exist a t -step safe transition plan, then there cannot exist any safe transition plan with more than t steps.*

Proof sketch: The intuition is that, if a t -step transition exists that satisfies ϕ but not δ , we can potentially make more granular changes in a longer transition sequence to stay within δ ; thus, attempting a $(t + 1)$ -step transition could be fruitful. On the other hand, if a t -step transition that satisfies ϕ does not exist to begin with, then any t' -step transition where $t' > t$ cannot exist either. We can prove this by contradiction: if a t' -step transition exists, repeatedly combine any adjacent transitions into a larger transition until it becomes a t -step transition. This resulting transition must satisfy ϕ as it exposes strictly a subset of the states in the t' -step transition. \square

Thus, when FlexPlan concludes that no t -step transitions exist, before it attempts a $(t + 1)$ -step CEGIS, it performs the above introspection. The introspection may conclude that a) some safe solution exists but b) no safe solution is feasible under the current resource constraints. This may be disappointing, but all is not lost—runtime programmable switches make it possible to deallocate resources to make extra room (e.g., by deleting certain tables or table entries).

Resource release? Whether to deallocate resources and which tables to delete are up to the network operator, but FlexPlan performs a third introspection to diagnose *how much* resource release would be sufficient for a t -step transition (where the search has stopped). This relies on an SMT optimization primitive `max-smt`, which can maximize an objective function while solving for a solution. Recall that each step causes a resource spike during the transition, and a headroom change after it. We track the the minimum headroom across a t -step transition, and ask for a solution that maximizes it:

$$\begin{aligned} \text{min_headroom} &= \min_{\forall j} \text{vsk}_j.\text{headroom} \\ \delta^* &= \text{max-smt}(\text{min_headroom}) \text{ s.t. } \text{ssk} \wedge \phi \end{aligned}$$

δ^* will be the smallest headroom possible to maneuver a t -step transition, and $\delta^* - \delta$ is the amount of resource release that is required to achieve a feasible update.

4.4 Remarks

We discuss several properties of the synthesis techniques.

Introspection. An important property of the introspection algorithms is that they work with sequence sketches of the

current length of the search (i.e., t steps). Thus, they do not lead to new scalability bottlenecks. Furthermore, the combination of the second and third introspection techniques also enables a synthesis goal of identifying a safe transition plan with minimized resource spikes—first determine the sequence length upperbound for a safe transition (with the second introspection), and then synthesize a transition while minimizing resource spikes at this length (with the third introspection).

Guarantees. The completeness of the synthesis is derived from the fact that the candidate solution space is finite and that CEGIS will eventually finish an exhaustive search [26]. Concretely, the solution space is defined by the two-dimensional matrix $\mathbb{H}_{k \times t}$. k is the number of annotations, and therefore finite. t is the sequence length, initially undetermined, but we know that it is upperbounded by k , because applying one annotation per step will result in the longest possible sequence. This is because we ask that each transition step makes positive progress, so no reverts are allowed once a change has been made. The synthesis is also sound, because FlexPlan always verifies the correctness of a proposed candidate plan.

5 Discussions and Limitations

P4 intermediate states. Intermediate states when the data plane is under change have been considered in the P4Runtime standard (cf. `DATAPLANEATOMICS`) [6]. However, the current standard focuses on the atomicity and intermediate states when adding or removing a batch of *table entries* for existing MA tables. Runtime table additions and removals, as a recent development, have not yet been captured in P4Runtime. Nevertheless, for table entry changes, P4Runtime describes how atomic pointer swaps can be used for transactional changes (when available in the target), and discusses the headroom requirement for preparing the changes in scratch area. This results in a similar range of considerations as recent designs for runtime programmable switches [19, 53]. We hope that FlexPlan will further the research in handling data plane intermediate states and the standardization process in P4Runtime.

Change annotation primitives. In the spirit of target-independence, our change annotations capture the intersection of hardware reconfiguration primitives between FlexCore [53] and rP4 [19]. Reconfiguration primitives that are not yet fully supported across platforms (e.g., parser changes [19] and table swap operations [53]) are considered out of scope for the current paper. These are interesting avenues for future work.

Switch architectures. Recent designs of runtime programmable switches [19, 53] employ disaggregation to split memory from compute. Thus, FlexPlan models memory resources as a global constraint—e.g., when a table is removed, the released resources can be used anywhere. However, future runtime programmable switches might adopt alternative architectures—e.g., RMT switches [12] with fixed stage boundaries would require a different model on memory reusability. Similarly, for SmartNIC targets with software and hardware pipelines [1], atomic transactions may become

Programs	LoC	Tables	Synthesis results		Programs (α)	Specification	Headroom	# Steps	Time(s)	Greedy

Table 2: FlexPlan scales to real-world programs. The left-hand side uses a range of popular programs, ranked by the number of MA tables they contain. It uses an update ratio of 20% with 50% resource headroom. The right-hand side focuses on case studies with switch.p4, including synthetic and realistic changes. For each change, we denote resource peak needed to atomically update the entire program in a single step as S, and set the headroom to $\beta \times S$ ($\beta = 20\%, 50\%, 80\%$). The greedy synthesis times out in 5 out of 10 cases, and it is much slower than FlexPlan for the rest of the cases.

harder due to the need to synchronize across pipelines. Thus, as alternative architectures become available in the future, FlexPlan may need to incorporate a new set of constraints.

Safety properties. The FlexPlan consistency specifications capture safety (but not liveness) properties that are defined over multiple program executions, or k-safety hyperproperties [15, 49]—specifically, 3-safety, as FlexPlan reasons about the old, new, and current snapshots. Among safety properties, it does not analyze stateful packet processing, where program behaviors may mutate based on the input packets [30]. Further, FlexPlan only reasons about a single network device, so extending it for network-wide updates is future work.

Resource utilization. FlexPlan considers switch memory constraints as the main bottleneck resource. In a P4 program, each MA table has a ‘size’ field that specifies the maximum number of entries it could contain. This provides coarse-grained information as input to FlexPlan. However, the number of entries in a table is not the same as physical memory consumption, which further depends on the match types and their target-specific implementation (e.g., TCAM vs. SRAM). To obtain exact information, FlexPlan would need the compiler to produce such data for the old and new programs. Modeling other types of resource constraints is left to future work.

Synthesis delay. Requiring each runtime update to go through a formal synthesis phase will incur delay to the change. As we will show, the latency is a few minutes across our evaluation. We believe that reliability gains outweigh the resulting delay.

6 Evaluation

Prototype. We have built FlexPlan in ~ 5000 lines of code (available at [2]). Our prototype consists of two components: (1) a frontend translator building upon an existing tool [18], which takes in the annotated P4 program and the specification, and converts them into an instrumented sequence sketch and SMT formulas; and (2) the main CEGIS backend which searches for a transition and performs introspection whenever needed. We use Z3 [8] as the SMT solver.

Methodology. Our program corpus is based upon popular

programmable switch applications, representing use cases in monitoring, security, offloading—similar as recent P4 verification projects [18, 38, 50]. It contains real-world P4 programs, with sizes ranging from 200+ to 5000+ LoC. Further, FlexPlan uses two methods to generate program changes. Synthetic changes are generated using a similar strategy as existing work [53], which controls the number of changes with a parameter α . If a program has M tables, an update ratio α will generate $M \times \alpha$ table additions, deletions, or modifications. To test realistic changes, we use switch.p4 as the basis to perform manual modifications based on its control block boundaries (e.g., remove or add back the egress statistics control block `process_egress_bd_stats()`), mimicking feature changes in realistic deployments. To analyze headroom, we assume that each table has the same size, denoted as U .

Evaluation objectives. Our evaluation primarily focuses on various dimensions of scalability: (1) How well does FlexPlan scale to real-world programs and sizable changes? (2) How well do the granular consistency levels work? and (3) How effective are the FlexPlan optimization and introspection techniques? We note that existing P4 verification projects [18, 38] analyze the correctness of single program snapshots, so they are not suitable as baseline solutions for comparison. Thus, we have created several FlexPlan variants as baseline solutions, where specific optimization techniques are disabled.

6.1 Macrobenchmarks

We start with the macrobenchmarks summarized in Table 2.

Scalability. The first macrobenchmark (left four columns) tests the scalability of FlexPlan with popular switch programs. We use “L2/L3 field consistency” (i.e., intermediate snapshots should preserve the same L2/L3 processing outcome) with a fixed update ratio of 20%. Further, we set the headroom to 50% of what would be required for the most straightforward plan that updates the entire program in a single step, which in turn would lead to the highest possible resource peak. There are two high-level takeaways. First, as the program size increases from 200+ to 5000+ LoC, synthesis time also grows

significantly, as larger programs produce bigger SMT formulas. However, even for the largest program, FlexPlan was able to finish within 3.4 minutes. Second, the number of learned counterexamples (‘ce’) also grows with the program size, and FlexPlan effectively learned from a relatively few number of counterexamples (varying from 0 for the smallest programs to 27 for the largest) before finding a correct transition. We further break it down by showing the number of counterexamples learned from a single snapshot (i.e., in the process of enumerating unsat cores with SnapL, labeled as ‘uc’). Except for switch.p4, FlexPlan enumerated all unsat cores in the SnapL phase, so the main CEGIS loop identified a correct solution in the first attempt. For switch.p4, FlexPlan performs 3 CEGIS iterations in the main loop to identify the transition.

Synthesized switch.p4 changes. The second macrobenchmark (right-hand side) zooms in on modifications to switch.p4, a datacenter switch implementation. We first test six synthesized changes with different control parameters—resource headrooms (rows 1-3), update ratios (rows 2+4), specification types (rows 5-6)—and examine their influence on the transition sequence lengths and synthesis time. As we can see, more severe headroom constraints lead to longer synthesis time (rows 1-3). FlexPlan had to try longer transition sequences to find a solution or conclude that no solution exists (shown as ×). Larger update ratios also lead to longer synthesis time (e.g., 23% increase when changing from $\alpha = 20\%$ to $\alpha = 40\%$ in rows 2 and 4). Moreover, the specification type also has a direct influence on synthesis. Field consistency on egress_spec is easier to check compared to L2/L3 header checks. FlexPlan took 1.8-7.3 minutes across all cases.

Hand-crafted switch.p4 changes. Next, we analyze a set of hand-crafted changes to switch.p4, by adding, removing, or modifying well-defined control blocks. We also vary the specifications across data points. The switch+meter-stat case removes all statistics tables (5 tables overall) in switch.p4, and adds in meter related tables (4 tables). For L2/L3 field consistency, FlexPlan identifies an update plan with 2 transitions. A closer look at the update plan shows that FlexPlan first removes all statistics tables, then adds meter tables—this is possible because statistics tables do not manipulate L2/L3 packet headers. On the other hand, IPv4 execution consistency fails to generate a update plan because most of the modified tables share some execution paths, which means they must be updated together. The required headroom goes beyond the available resources (20%). The switch+ipv4-ipv6 update removes IPv6 processing tables (10 tables in total) and adds IPv4 processing tables (8 tables). IPv4 execution consistency, on the other hand, could find a update plan with 20% headroom. This is because IPv4 and IPv6 tables can be updated separately as they do not share execution paths. All experiments with realistic changes finished within 4.2 minutes.

FlexPlan vs. greedy synthesis. We also test the greedy synthesis algorithm (Section 4.1.1), which either maximizes progress (‘Greedy MinSeq’) or minimizes resource spikes

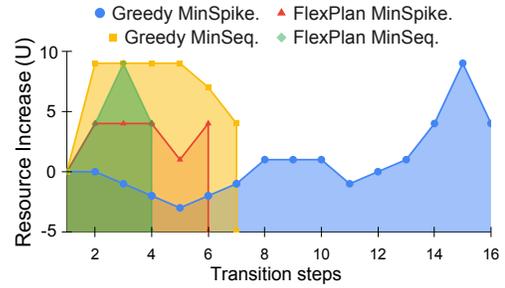

Figure 6: A NetCache case study showing step-by-step transitions and the headroom changes. The greedy synthesis produces suboptimal transitions when it is able to finish; it times out under more severe resource constraints.

(‘Greedy MinSpike’) for each step locally. As Table 2 shows, it times out after 30 minutes for five out of ten cases. When it is able to produce a transition, it only finds suboptimal solutions. Figure 6 visualizes a case study on NetCache, where greedily maximizing per-step progress results in a transition in seven steps with 80% headroom, whereas FlexPlan produces a much shorter transition in four steps (‘FlexPlan MinSeq’). Similarly, FlexPlan when minimizing resource usage (cf. Section 4.4) leads to much lower peak usage than greedily minimizing resource spikes per step. This demonstrates the benefits of the sequence sketch encoding for end-to-end synthesis.

6.2 Consistency levels vs. headroom

Next, we show that the granular consistency specifications in FlexPlan can lead to lower resource requirements when rolling out an update. We use “program consistency” and “execution consistency” as baselines, which are the strongest and weakest guarantees developed in existing work, respectively [53]. We chose three large switch programs (NetHCF, NetCache, switch.p4), and generated 50 changes with α ranging from 5% to 40%. For each change, we ask FlexPlan to find the transition sequence that minimizes the peak resource usage under each specification. We then averaged across all changes with the same α and show the results in Figure 7.

Our first takeaway is the inflexibility of heuristic-based definitions in FlexCore [53]. Although “execution consistency” is a weaker requirement than “program consistency,” it unfortunately does not reduce the resource peak by much and the two corresponding curves are closely coupled together (i.e., ‘FC-Prog’ vs. ‘FC-Exec’). It can reduce the resource peaks for specific cases, but aggregating over all cases the reduction is only 5%. We found that this is highly correlated to the program shapes and where the changes are made. A common root cause can be attributed to the *bottleneck table* problem. If a change modifies some tables that are shared by many or all execution paths, then it forces all changes to be made in the same step, equating “execution consistency” to “program consistency.” Since FlexCore [53] only relies on “reachability” information at table level and does not ana-

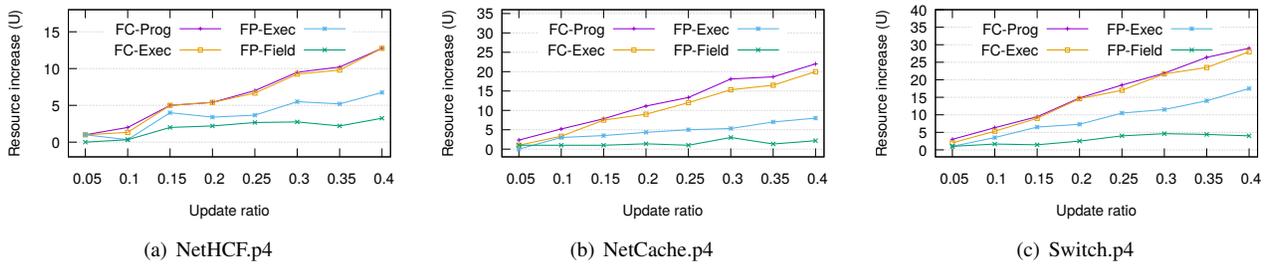

Figure 7: The granular consistency specifications in FlexPlan can effectively reduce peak resource usage. FC-Prog and FC-Exec represent program consistency and execution consistency properties as defined in FlexCore [53], which only analyzes reachability across tables without considering program semantics. FP-Exec refines execution consistency to consider specific traffic classes in FlexPlan. FP-Field is a new consistency definition in FlexPlan that constrains the processing outcomes of specific header fields.

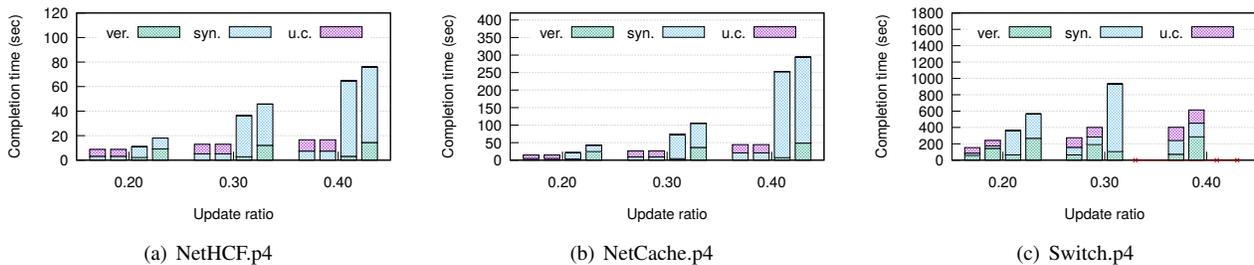

Figure 8: The snapshot-based optimizations are effective. Each group of bars plots the turnaround times, from left to right, for FlexPlan, NoSnapV (no snapshot verification), NoSnapL (no snapshot learning), and NoSnapVL (disabling both optimizations), respectively. On switch.p4, both techniques are necessary for sizable changes; otherwise the analysis will time out after 30 minutes. We further break down each bar by the time the solution spends in verification, synthesis, and unsat core extraction.

lyze program semantics, it cannot distinguish whether or not a change actually affects a particular traffic class, conflating the two guarantees whenever bottleneck tables are modified.

In contrast, the granular consistency levels in FlexPlan are effective in reducing the peak resource usage by capturing program semantics. First, FlexPlan refines “execution consistency” even further by defining it over traffic classes of interest. Specifically, we have tested three variants of “execution consistency” defined over traffic classes (shown as ‘FP-Exec’). For switch.p4, we specify it only for IPv4 traffic without tunneling; for NetCache, only for read requests to the cache data structure; and for NetHCF, only packets that establish TCP sessions. Thus, if a table change does not affect how these traffic classes are processed—even at a bottleneck table—FlexPlan is still able to produce granular transitions with lower peak resource usage. The reductions for NetHCF, NetCache, and switch.p4 are 47%, 64%, and 45%, respectively, compared to the fixed execution consistency in FlexCore. Further, we have also tested “field consistency,” to showcase FlexPlan’s ability to define new consistency levels beyond tuning traffic classes (shown as ‘FP-Field’). This states that L2/L3 headers and standard metadata must be processed with the same outcome during transition. This leads to even lower peak usage: the reduction is 46%, 67%, and 68%, respectively, compared to the granular execution consistency levels above. This is because it allows a mix of old and new

tables to co-exist on execution paths, as long as this does not change the processing behaviors for specific header fields.

6.3 Snapshot learning and verification

Next, we evaluate the effectiveness of the snapshot learning (SnapL) and verification (SnapV) optimizations. We create three baseline solutions from FlexPlan where one or both optimizations are turned off: NoSnapV, NoSnapL, and NoSnapVL. Figure 8 compares the four solutions with different update ratios and programs. Across all data points, FlexPlan outperforms NoSnapVL in terms of completion time by 70% on average, demonstrating the effectiveness of the two snapshot-based optimizations. On switch.p4, the NoSnapVL baseline times out when $\alpha > 20\%$. Further decomposition shows that the SnapL and SnapV optimizations lead to 58% and 37% improvements on average, respectively.

Both SnapL and SnapV are more effective with larger programs (which lead to larger SMT formulas per snapshot) and higher update ratios (which lead to a larger update plan search space). For instance, at $\alpha = 40\%$, SnapL reduces the completion time by up to 81% for NetCache. With smaller update ratios, the number of possible update sequences is already small, so the time spent in learning unsat cores with SnapL does not afford as much improvement. The trend for SnapV is similar. For smaller formulas (e.g., NetHCF and NetCache), it is possible for FlexPlan to iterate through all unsat cores,

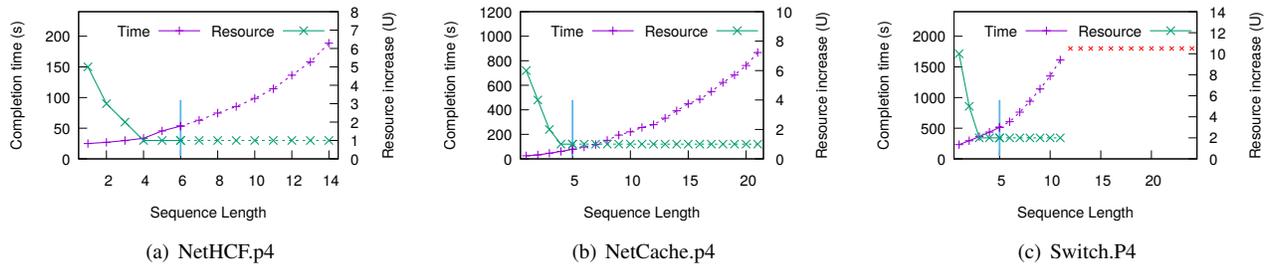

Figure 9: The FlexPlan introspection technique is effective in determining whether the synthesis should continue to try longer sequences. The vertical lines denote the stopping points for FlexPlan, which significantly outperforms a solution with introspection turned off, which naïvely increases the sequence length beyond the vertical lines until the maximal upper bound or timeout.

so the main CEGIS phase could bypass the verification completely since the first proposal attempt will identify a correct plan. Its impact is stronger on larger programs like switch.p4.

6.4 Introspection and diagnosis

We now evaluate the three CEGIS introspection techniques.

Existence. We first generate a set of program modifications that are guaranteed to violate the safety specification. For instance, if the specification requires that `egress_spec` processing outcomes should be preserved, we ensure that it is modified in a different way. For all cases, FlexPlan correctly rejects the annotated change as unsafe within 90 seconds.

Sequence length. Figure 9 evaluates the FlexPlan introspection for determining whether to attempt a longer sequence. We create cases where the resource constraints will guarantee an eventual failure, and test how soon FlexPlan can detect this inevitability. We also compare against a version of FlexPlan without this introspection. For NetHCF ($\alpha=40\%$), NetCache ($\alpha=20\%$), and switch.p4 ($\alpha=20\%$), FlexPlan concludes that the synthesis will fail when the sequence lengths are six, five, and five, respectively, within several minutes. However, the solution without introspection will keep increasing the sequence lengths (and running time) until the maximal upper bound (i.e., the total number of changes) or timeout, without being able to decrease resource usage further. It took $3\times$ and $12\times$ more time to conclude that the resources are insufficient for NetHCF and NetCache, respectively; for switch.p4, it times out before producing any useful results. Thus, the introspection technique helps determine failures efficiently.

Resource release. After each failure, we further ask FlexPlan to produce diagnostic results on the least amount of resource release that will enable a safe and feasible transition. This is achieved by introspecting the sequence upper bound for a safe transition, and then solving for a transition with minimized resource peak. This diagnosis took less than ten minutes across all update ratios and programs—the longer completion time is due to the need for trying the longest possible safe transition. We then emulated the release by increasing the switch headroom by the suggested amount, and re-attempted another synthesis and verified that it succeeded.

7 Related Work

Runtime programmability. Network switches have become programmable at runtime [3, 4, 9, 19, 52, 53], where switch programs can be modified with partial reconfiguration without downtime. Runtime programmability has also been studied in host networking [40, 42]. FlexPlan develops a formal approach to synthesizing runtime programmable switch updates.

Safe network updates. Ensuring the safety of network updates [34, 43] is a key goal in cloud datacenters [37]. In the context of OpenFlow-based SDN, consistent update algorithms have been extensively studied [21, 44, 45]. FlexPlan considers an analogous problem for programmable data planes, with new definitions on correctness and intermediate states, and uses program synthesis to achieve this goal.

Synthesis and verification. Program synthesis has found many applications in the networking domain [13, 22, 59], including for identifying safe configuration updates in OpenFlow SDN [39]. For programmable switches, existing projects have developed many formal verification techniques for P4 programs [18, 38, 50, 51, 61]. Compared to these lines of work, FlexPlan aims at synthesizing a correct-by-construction update sequence, which in turn requires new techniques.

8 Conclusion

Programmable networks enable the *development* of new features “in the field,” without relying on slow-paced vendors. To safeguard network behaviors, formal verification has proven essential. Runtime programmable networks [57], in contrast, emphasize that the *deployment* of these features must also be seamless and “in the field”—without requiring slow-paced maintenance operations. However, live program modifications necessitate new techniques for providing formal assurance. FlexPlan is a synthesis tool that can identify a safe and feasible program transition sequence automatically. It introduces domain-specific techniques for synthesizing switch program updates. With comprehensive evaluation, we demonstrate the scalability of FlexPlan on real-world programs.

9 Appendix

This appendix includes more details on the safety specifications as summarized in Table 1 in the main paper.

9.1 Specifications

S4: Element consistency for ACL. This specification is similar as program consistency, but only constrains traffic that goes through a particular ACL table. For all packets that have been processed by the ACL table, their execution paths must be of the same version (i.e., either old or new).

```

1  specification {
2    ghost bit<1> sawOld = false;
3    ghost bit<1> sawNew = false;
4    ghost bit<1> acl_hit = false;
5    @old => { sawOld = true; }
6    @new => { sawNew = true; }
7    @hit('acl') => { acl_hit = true; }
8    all_old = {
9      $cur.in.acl_hit => !$cur.eg.sawNew;
10   }
11   all_new = {
12     $cur.in.acl_hit => !$cur.eg.sawOld;
13   }
14   assert all_old || all_new;
15 }

```

S5: Table consistency for ECMP. We introduce a new consistency definition that is not available from existing

work [53], which we call “table consistency.” It states that for each packet, the table (in this case ECMP) hit/miss behavior in the intermediate state should be either the same with the old or the new processing logic.

```

1 specification {
2   ghost bit<1> ecmp_hit = false;
3   @hit('ecmp') => { ecmp_hit = true; }
4   // preserve processing behavior across states
5   table_consistency_ecmp = {
6     $cur.in == $old.in == $new.in =>
7     ($cur.eg.ecmp_hit == $new.eg.ecmp_hit ||
8     $cur.eg.ecmp_hit == $old.eg.ecmp_hit);
9   }
10  assert table_consistency_ecmp;
11 }

```

Although FlexPlan’s primary focus is consistency guarantees during the program transition, its specification language can naturally support general program correctness properties that are used in P4 program verification [18, 38]. We showcase two of them below. At a high level, general program correctness properties are expressed by constraining a single snapshot using $\$cur$, without referring to $\$old$ or $\$new$.

S6: VLAN table access. Packets should go through VLAN table during any intermediate state.

```

1 specification {
2   ghost bit<1> vlan_hit = false;
3   @hit('vlan') => { vlan_hit = true; }
4   table_access_vlan = {
5     $cur.eg.vlan_hit == true;
6   }
7   assert table_access_vlan;
8 }

```

S7: Modification on ipv4.ttl. Any intermediate program snapshot should always decrement the ipv4.ttl header by one when the packet leaves the egress.

```

1 specification {
2   decrement_ipv4_ttl = {
3     $cur.eg.ipv4.ttl == $cur.in.ipv4.ttl - 1;
4   }
5   assert decrement_ipv4_ttl;
6 }

```

9.2 Instrumentations

Figure 10 includes an illustrative example that shows how a specification is translated into instrumentations in the input P4 program. This uses our running example `acl_flowlet_ecmp`, building upon the version sketch in Figure 3 and adding the instrumentations from the specification S1.

As we can see, the `sawOld`, `sawNew` and `acl_hit` variables are directly inserted into source program. We then add instrumentation that checks whether there exists a packet that violates the execution consistency after going through execution path. We then compute the weakest preconditions for

```

1 control ingress {
2   apply {
3     ghost_ipv4_valid = ipv4.isValid();
4     /* annotation site 1: acl->nat_acl */
5     if(ipv4.isValid()) {
6       if (! vsk.v1) { // @mod
7         acl.apply(); ghost_saw_old = 1;
8         ghost_acl_hit = 1;
9       } else {
10        nat_acl.apply(); ghost_saw_new = 1;
11        ghost_acl_hit = 1;
12      }
13    }
14    /* annotation site 2: delete flowlet */
15    if(! vsk.v2) { // @del
16      if (ipv6.isValid())
17        flowlet.apply(); ghost_saw_old = 1;
18    }
19    /* annotation site 3: add ecmp */
20    if(vsk.v3) { // @add
21      ecmp.apply(); ghost_saw_new = 1;
22    }
23    if (ghost_ipv4_valid && ghost_acl_hit) {
24      if (ghost_saw_old && ghost_saw_new){
25        violation();
26      }
27    }
28  }
29 }

```

Figure 10: Instrumenting the version sketch in Figure 3 with safety specification, and also adding statements that check the safety properties.

the reachability of the violation nodes. This is achieved by iterating through CFG nodes and propagating stronger conditions to all their neighbors based on the transition relation. We then check whether the predicate is valid using the Z3 theorem prover. In the example, the combined program and safety formula to check would be derived as:

$$\begin{aligned}
gso &= (ipv4.isValid \wedge \neg vsk.v1) \vee (\neg vsk.v2 \wedge ipv6.isValid) \\
gsn &= (ipv4.isValid \wedge vsk.v1) \vee vsk.v3 \\
gah &= ipv4.isValid \\
check &= \neg(ipv4.isValid \wedge gah \wedge gso \wedge gsn)
\end{aligned}$$

where gso represents the logical formula for when `ghost_saw_old` is assigned true, and similarly for gsn as `ghost_saw_new` and gah for `ghost_acl_hit`. The logical variable gso , for example, captures the path conditions required to set the ghost variable to true as well as any intermediate assignments on the path to variables that might affect these path conditions/branches.

Practical Intent-driven Routing Configuration Synthesis

Abstract

Configuration of production datacenters is challenging due to their scale (many switches), complexity (specific policy requirements), and dynamism (need for many configuration changes). This paper introduces Aura, a production-level synthesis system for datacenter routing policies. It consists of a high-level language, called RPL, that expresses the desired behavior and a compiler that automatically generates switch configurations. Unlike existing approaches, which generate full network configuration for a static policy, Aura is built to support frequent policy and network changes. It generates and deploys multiple parallel policy collections, in a way that supports smooth transitions between them without disrupting live production traffic. Aura has been deployed for over two years in Meta datacenters and has greatly improved our management efficiency. We also share our operational requirements and experiences, which can potentially inspire future research.

1 Introduction

Stable and efficient routing in large data centers is crucial for many online service providers. Routing misconfiguration can lead to packet drops, traffic black holes, performance degradation, and service downtime [2, 3, 9, 22]. Traditionally at Meta datacenters, routing configuration relied on human operator expertise to manually translate high-level routing policies into low-level switch configurations. This approach has two key problems.

First, manual generation of policies is often error-prone, especially with the enormous increase in scale (thousands of switches across multiple data centers), complexity (policies that describe specifications unique to a network), and dynamism (configuration changes to accommodate failures or maintenance of switches) of modern datacenters [10, 14].

Second, manually crafting configurations for datacenters is a time-consuming process. Earlier data centers at Meta were uniform and the similar configurations could be used to provision new data centers. However, there is a need to

support diverse topologies required for various AI applications or existing topologies that are modified to accommodate resource shortages caused by supply chain bottlenecks. With the need to support diverse topologies, existing configurations can no longer be reused and each new topology implies a long process of manual configuration.

Recently, researchers have proposed configuration synthesis [7, 8, 12], which automatically generates switch configurations based on high-level policies. These systems usually provide a declarative language for operators to define the intended routing policies and then automatically synthesize low-level routing configurations, which implement these policies. While these solutions work well in principle, there are still a few challenges that are not handled by one-shot automated configuration synthesis.

Challenge 1: Handling dynamic configurations. Configuration changes are frequent in networks, because of many dynamic events. The dynamism is driven by different business objectives (shifting services from one data center to another), making network operations more efficient (e.g., smarter load balancing or more redundancy to failure), safely testing new protocols, or even performing regular routine maintenance of switches. Configuration synthesis should be able to generate configurations that natively handle dynamism.

Challenge 2: Expressing conditional policies. Current declarative languages express routing policies in a way that is not aligned with the realities of a production network. First, they treat each switch as live and ready to serve traffic. Yet, in large-scale data centers, switches can be in different operational states at the same time, and thus we need to be able to express routing policies that depend on these states. Second, current declarative languages specify all switches at a fixed granularity (e.g., one specific switch [7] or all switches in the specific role [8]). However, operational needs require specifications at a flexible granularity. Some intents in high-level policies may require specific switch or set of switches in one location, while others may require all switches in a given role.

Challenge 3: Reconfigurations at scale. Existing brown-field migration systems, plan out the configuration change

without disrupting production traffic by creating intermediate configurations that would help transitioning the network from old configuration to a new one [18, 23]. Although such techniques provide a safe, non-disruptive mechanism to change configurations, they can be expensive to carry out migrations. Our experiences show that deploying a new configuration in switches often takes a much longer time (minutes to hours) than computing the configuration (e.g., seconds), primarily because of the scale of the network. Given this constraint, migrating configurations via transitioning would take a very long time, hindering network operations.

In this paper, we introduce our configuration synthesis system *Aura*¹, which supports flexible granularity of policy intents, conditional intents and scalable synthesis to BGP configurations, to smoothly aid network dynamics. Our contributions are as follows:

- We propose a novel configuration synthesis approach, which pre-compiles a set of possible paths for the datacenter, called “base paths”, given a set of high-level policies. Our insight is that given datacenter regularity and symmetry, any path can be expressed as one of a small set of base paths. Network operators can use these base paths to support dynamic configuration.
- We define a new declarative language called RPL (routing policy language), which allows operators to define policy intents with flexible switch granularities and activation conditions, based on switch states.
- *Aura* leverages configuration staging and uses labels to activate them. When there is a need to change configurations, routes are announced with appropriate labels (e.g., BGP community tags). Switches on receiving the labels, check the appropriate configuration that match the conditions and activate the configuration. This minimizes the need to re-configure the network every time there is a need to change the configuration.

In addition to our contributions, *Aura* has been partially deployed in Meta datacenters for over two years, compiling all policies on hundreds of thousands of switches daily. To the best of our knowledge, we are the first to share operational experiences in building and deploying a configuration synthesis system. Our work unveils a unique set of challenges to academia, which we hope may inspire future research.

2 Background and Challenges

As discussed earlier, large-scale datacenters need automated configuration synthesis. Even with fully automated configuration synthesis, carrying out a data center-wide policy change still requires careful planning at every step, to ensure that the network remains operational throughout the change. We need to gradually roll out a policy change, with minimum

¹We chose the name *Aura*, because it represents the essence (of an individual).

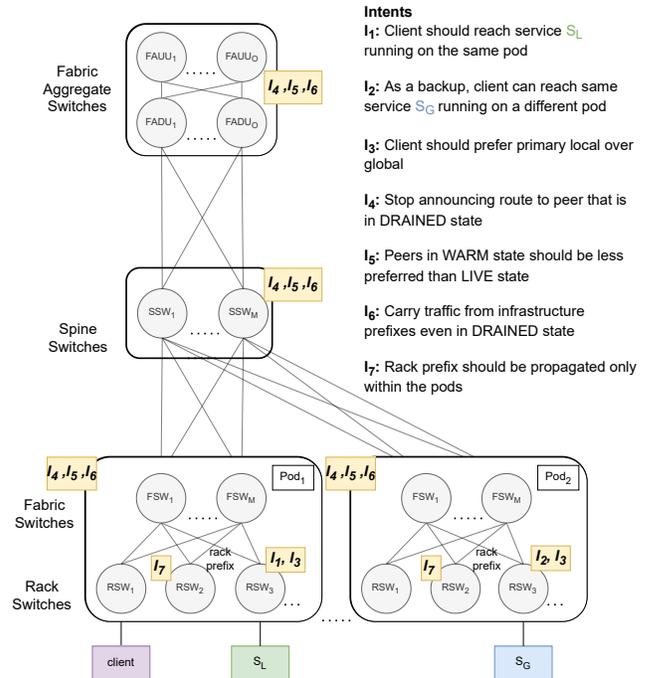

Figure 1: Data center topology with sample intents.

disruptions and safe fallback mechanisms. And we need to support such rollout across hundreds of thousands of switches, in different states of readiness. In this work, we stress one overlooked goal of configuration synthesis: producing configuration changes that lead to the shortest time to complete the reconfiguration, and making the process automated, non-disruptive to production traffic and with minimal operator burden. In this section, we start by describing our data center topology and routing intents. We then discuss the operational challenges of configuration synthesis in large data centers.

2.1 Background

We use Figure 1 to illustrate our production network topology [6, 29], a few sample intents (I_1 to I_7) used in our network, and the remaining open challenges, which our work addresses. **Data Center Topology:** It consists of a hierarchy of four layers with thousands of switches at each layer. Switches at the same layer share the same *switch role*. The servers are connected to leaf rack switches (RSW). RSWs are connected to fabric switches (FSW). RSWs and FSWs are grouped into pods. Spine switches (SSW) connect the pods and provide several disjoint paths between pods. Data centers are distributed over multiple buildings and are interconnected via the Fabric Aggregation (FA) layer. The FA consists of two layers: FAUU (uplink) and FADU (downlink). FAUU connects to data-center-external networks (i.e., the backbone planes), while FADU aggregates downstream-data-center networks by connecting to SSWs. In this work, we limit our scope of configuration synthesis till the FAUU layer, and leave the con-

figuration synthesis of external switches for future work. This topology enables several disjoint end-to-end paths between any two server racks for failure resilience. Other topologies in Meta datacenters share the same properties with different numbers of layers and switch roles. Other large production data centers exhibit similar symmetry of roles and hierarchy of switch roles [24], and likely face similar challenges to configuration synthesis.

Routing: We use the Border Gateway Protocol (BGP) to disseminate routing information through the network and provide connectivity to end servers [5]. BGP is a highly scalable routing protocol that can support large topologies with many prefixes. BGP is also commonly supported many network switch vendors, and network operators are typically familiar with BGP operation. We configure BGP policies to manage how routing information is shared across the network and to control traffic flow objectives, such as traffic load-balancing, redundancy, and path preference. At Meta, BGP configurations within network tiers are homogeneous. We configure BGP to use Equal Cost Multipath (ECMP), where each switch forwards traffic equally to its neighboring peers based on the routing policy. Meta data centers are also experimenting with our own routing protocols such as OpenR [15] that is being rolled out into parts of the data center. OpenR policies can coexist with BGP policies. Currently, we use OpenR policies for infrastructure prefixes (those prefixes belonging to the management plane) and BGP for traffic prefixes.

Intents, policies, and configurations: We define an *intent* as a high-level description of a routing goal, e.g., all rack prefixes should be propagated within pods. Intents are closely tied to our operational needs of service reachability, maintainability and reliability. [5]. Figure 1 shows seven intent examples to achieve our needs in traffic control. I_1 , I_2 and I_3 define reachability goals for a client to a service, that is, a service should be reachable even when an instance of the service is added, removed or migrated. Intents I_4 and I_5 help in managing networks during such events without disrupting production traffic, as switches often undergo maintenance when they fail, reboot, or even crash. I_6 is an exception to I_4 that aims to provide reliability under failure, and I_7 confines the propagation scope of a route. We will elaborate more about these intents from §2.2 to §2.4. We define a *policy* to be a collection of intents, e.g., a combination of intents I_1 to I_7 . At Meta, there are many data centers, and we define a collection of policies known as *configurations* for every data center. For example, the datacenter in Utah (EAG) has 53 policies with each policy containing upto 5 intents. The synthesis process starts with a policy specified by a domain-specific language and produces a set of switch configurations.

2.2 Handling Dynamic Configurations

Configuration changes are frequent in production and often impose a high operational burden to ensure live production

traffic is not affected. Previous synthesis systems focus on generating one snapshot of the entire network’s configurations [7, 8]. When changes happen, they have to rerun the entire synthesis and generate another snapshot. There are three common scenarios that necessitate configuration changes:

Intent changes: Intents describe high-level objectives of reachability, aggregation, and route propagation (see [5] for routing objectives). They can change due to various operational needs – a service migrating from one data center to another, a better load balancing strategy (e.g., adding new paths to a destination in the ECMP pool), a more resilient failure recovery (e.g., adding a new backup path) or changing preference strategy (e.g., when we would move from location-based path selection to client-based preference, where the client can themselves set a preference of which server they would like to reach). The underlying routing configuration should reflect these intent changes. To support changes between existing intent collections, we need a synthesis approach that can generate multiple configurations in a switch and control when each would activate. The same approach can add new policies by enriching existing switches with new, inactive configurations. New configurations can then be activated gradually throughout the production network.

Policy implementation changes: We can implement intents expressed by operators in different ways, by using different protocols, or different mechanisms in one protocol. For example, in BGP, one can carefully set MED values, IGP values, or local preference values to achieve the same intents. In our data centers, we are exploring alternative routing protocols for better scalability, e.g. our home-grown intra-domain routing OpenR [15]. Thus, the same network-wide intents can be supported in OpenR with a completely different set of configurations compared to BGP. To facilitate testing, we need to gracefully roll out OpenR configurations and replace old BGP configurations. Such evolution requires a large amount of changes to configurations on all switches. To minimize impact to business, we need a way to gracefully migrate between configurations, and even roll back changes should they prove inefficient.

Switch state changes: Switches constantly undergo changes due to failures, new builds, and regular maintenance. In all of these scenarios, we need to gracefully remove the impacted switches from serving traffic, to minimize disruptions to services. Switch state changes are common in our production network. In the month of August 2022, there were about 745K drain events with about 8K drain events on average per day.

2.3 Expressing Conditional Policies

Conditional policies require different configurations for a given switch, depending on network conditions. There are three common classes of network conditions:

Intents that apply to a subset of switches: Operators need

the flexibility to specify the groups of switches *where* a policy intent is applied. Some intents should be applied globally, while others may be relevant only for a specific service in a particular region to have customized routing solution. It is often needed during migration or deployment to accommodate the changing capacity. For example, intents I_1 to I_3 specify preference for local service S_L over global service S_G only for RSWs in Pod_1 and Pod_2 , whereas intent I_7 applies to all RSWs and restricts rack prefixes to pods. This means our intent specification and synthesis should support conditions that define groups of switches at different topological granularity.

Intents that apply to switches in a certain state: Data center topologies support multiple paths between any pair of server racks. Path selection depends on switch states. We define three operational states for each switch: LIVE, DRAINED, and WARM. A LIVE switch is in operation; it allows all traffic and announcements to go through. Conversely, a DRAINED switch is brought down for maintenance; it should not carry any live production traffic. A switch being drained goes through an intermediate WARM state when prefixes are gradually removed from its announcements. In this state, the switch could carry traffic for any prefix if the prefix does not have other paths involving only LIVE switches. Switch configurations should suppress announcements from DRAINED switches (reflected in intent I_4), and favor announcements from LIVE switches over those from WARM switches (reflected in intent I_5). To keep the production network operational with these requirements, one method is to synthesize, which generates multiple configurations, for different switch states. Only one configuration is active at the time at a given switch, depending on the current state of the switch. For instance, intent I_4 specifies to stop announcing a route to peers in DRAINED states and intent I_5 specifies that we prefer peers in LIVE states than those in WARM states.

Exceptions to policies: Network operators need to specify exceptions to their policies for failure resilience. For instance, as per intent I_4 , DRAINED switches do not carry any live traffic. However, an exception to this intent is I_6 , which requires DRAINED switches to carry traffic towards infrastructure prefixes. Intent specification language needs to support exceptions for critical prefixes (e.g., infrastructure prefixes), and our synthesis process must generate corresponding configurations that treat those specific prefixes differently from others.

2.4 Reconfigurations At Scale

It is challenging to support dynamic policies and conditional policies at production scale. Switch reconfiguration in a live production network is expensive, because it typically requires transferring away all the services that use the network and draining all routes from the switch. After these actions, we can bring down the switch, change the configurations, and then bring up the switch again. Finally, the switch would be tested before reintroducing the routes that it carried before

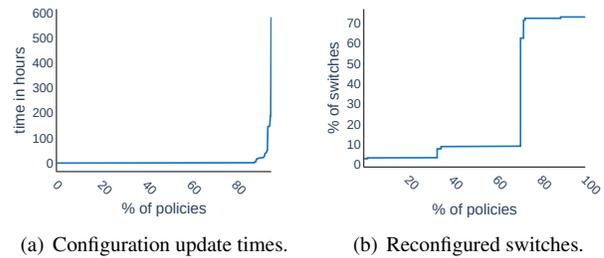

Figure 2: Switch reconfiguration metrics.

reconfiguration. Typically, not all switches in the data center are reconfigured at the same time. Instead, reconfiguration is achieved in a phased manner, where only a portion of the network is reconfigured at a time. This process could take many weeks to update all switches, given the scale of a production network, as well as the complexity of the phased deployment [10]. Figure 2(a), shows the configuration update times for policies that were changed at Meta in the last three months of 2021. On average, switches can take upto 4.5 hours to update. Most of the switches are updated immediately, but some switches take very long to configure. The 95th percentile of configuration update can take as much as 20 hours. This is mainly caused due to switch failures that require additional time to make them operational again.

Changing policies (e.g., switching between collections of intents) can also have a large footprint, that is, it involves the configuration of many switches. For instance, configuring backbone policies typically involves changing configurations for a few FA switches. On the other hand, introducing a new technique to handle infrastructure prefixes (such as I_6), would involve a lot more switches, as they can go into a DRAIN state. Figure 2(b) shows the percentage of switches in our network that required configuration update for different policy changes. An average policy change requires configuration of at least 25.6% of switches. Reconfigurations are only going to get longer as we typically double the number of switches every five years [10]. Moreover, the time and complexity taken for configuring switches differ depending on a switch's role. On one hand, FSW switches carry only a small portion of traffic in our network. Given the redundancies of our network, a failure in a FSW switch usually does not cause issues in the network. On the other hand, aggregate switches, such as fabric aggregators, carry a larger portion of traffic, so their changes should be planned more carefully. Failures during reconfiguration of these aggregator switches can be of a higher consequence as they can disconnect buildings within datacenters.

3 Aura Design

To address the outlined challenges, we present Aura in Figure 3. The goal of Aura is to allow network operators to

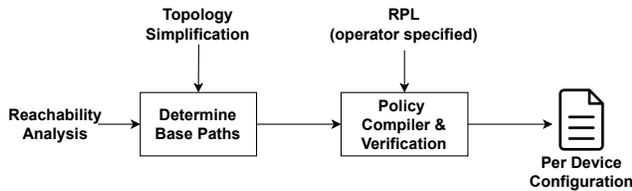

Figure 3: Aura architecture.

express flexible policies that are capable of handling various network reconfiguration scenarios at scale while minimizing disruption to production traffic. Aura handles the challenges outlined in §2 as follows:

- To support multiple configurations in a switch (as seen in § 2.2), Aura uses a set of base paths to pre-configure the network. Base paths are a collection of paths across different types of switches, which have the property that any propagation path in the network can be expressed as the base path or a sub-path of the base path. In §3.1, we explain how Aura uses topological features such as symmetry and hierarchy, along with reachability requirements to determine the set of base paths.
- To handle dynamic policies (as seen in § 2.2), Aura uses a labeling mechanism. If we are synthesizing into BGP configurations, Aura generates configurations that match on dedicated community tags and maps them to a corresponding policy. This results in multiple configurations defined in a single configuration file. In §3.2, Aura uses dedicated community tags that are attached by every switch to indicate its current state. Together with staging, this behaves as if there is a change between an old and a new configuration without the need for switch reconfiguration. Minimizing reconfigurations helps in supporting changes in policies at scale (as seen in §2.4).
- To express conditional policies (as seen in § 2.3), we introduce conditions that depend on switch state.
- We design a routing policy language (RPL) for Aura (§4), which uses base paths, switch conditions, route propagation conditions, and route preferences to express a set of policies.
- Finally, a compiler generates BGP configurations from RPL and tests configurations in the network (§5).

3.1 Base Paths: Minimizing Reconfiguration

Aura minimizes reconfiguration of large production networks by pre-compiling the network with a set of paths known as the *base paths*. Base paths are similar to pathlets, which are fragments of paths representing nodes that are willing to route [13]. The base path concept stems from the following two insights.

- *Policies can be defined on abstract paths:* Modern data center topologies are usually hierarchical, symmetric, and

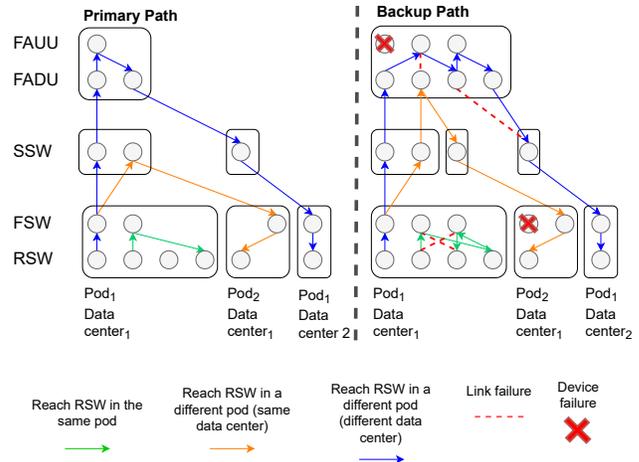

Figure 4: Extracting base paths.

uniform. To be resilient to failures and ease the operation, most data centers classify switches into different roles according to their layers in the FAT-tree like topology [24]. For example, every switch in the lowest layer (RSW in our topology) has a south bound connection to servers in a rack, and a north bound interface up to the aggregate switches (FSW in our topology). Switches of the same role are functionally equivalent. Thus, base paths can be defined as abstract paths using these abstract switch roles. In turn, policy intents can be expressed by using the base path or a sub-path of the base path.

- *Staging policies for dynamic scenarios:* Our base path set contains not only the preferred paths under a regular, static scenario, but also alternative paths under many dynamic scenarios, such as failures, migration, or maintenance as discussed in §2.2. When these changes occur, we simply need to select configurations that correspond to a different subset of base paths. Aura’s synthesis has already deployed all configurations in the individual switches, and we just need to deactivate one configuration and activate the other. We identify base paths by first *simplifying datacenter topology* and then *performing comprehensive reachability analysis* on that topology.

Topology simplification. We simplify a datacenter topology by abstracting multiple switches that share some given characteristic as a single switch. We can make abstractions at different granularities. For example, we can abstract all RSWs into a single node, or abstract all RSWs *in the same pod* into a single node. It is important to find the right granularity to maintain reachability without jeopardizing scale. Abstractions at too fine granularity create many paths and jeopardize synthesis scalability and operational maintainability. Abstractions at too coarse granularity (e.g., single role – single switch [7]) do not allow us to stage paths at different scenarios, such as intents I_1 and I_2 , which requires traversing through specific switches in the network. Moreover, role-based abstraction can

express these policies, but configuring switches to support them is a challenge. For example, intent I_2 requires visiting the same switch role multiple times. Aura’s compiler needs a way to keep track of propagating the announcement through such paths (see §5).

Reachability analysis. We find a balanced abstraction by performing a primary reachability analysis between RSW switches on the minimal topology. We then extend these paths to support alternative paths, to accommodate cases when nodes on a primary path fail. Any duplicate paths will be collapsed into a single path. Figure 4 illustrates this process. We start with three primary paths: one between two RSWs in the same pod, the second between two RSWs in different pods, and the third between two RSWs in different datacenters. Then we consider the failure of the direct FSW, direct SSW, or direct FA switch (or links connecting them) on the primary paths. For each failure we add nodes to express the backup path. Note that we first consider single switch or link failures on each primary path. Further, we consider larger failure scenarios such as regional failures and disasters. For example, we consider backbone failure and craft the paths to provide intra-region paths by traversing the FA layer. Currently, we generate base paths according to our reachability objective, which is, providing reachability of intents in the presence of at most two failures (either link or device or both)². Note that the process of generating base paths is not unique to Meta’s network. Any datacenter network can exploit its symmetry and hierarchical nature to derive its base paths.

3.2 Staging and Labeling: Supporting Dynamic Configurations

We support network changes, while minimizing reconfiguration via staging and labeling. These mechanisms help us support parallel configurations in switches (with only one configuration being active) and to support conditional intents.

- *Staging configuration snippets and activating them with labels* are the two key techniques to allow coexistence of multiple policies. Each policy is implemented as a set of configurations and loaded onto the switches. A policy may have a condition expressed as a combination of labels. Only when the conditions are satisfied, the policy will be activated.
- *Propagating label with routes* is the way we achieve conditional policies. The labels are translated into BGP community tags in our synthesis process, and are attached to routes and propagated through switches. Each switch can match the conditions based on the current switch state, attach its own state as community tags, and announce it to downstream switches.

²We determined any failures beyond that would degrade capacity, thus this would no longer be a reachability problem. We deploy other measures to handle such large-scale failures, which are beyond the scope of this work.

We provide two examples to show how staging and labeling support dynamic scenarios.

Supporting OpenR deployment. In our data centers, we are developing an alternative routing protocol known as OpenR [15] for better scalability. One challenge of applying Aura to production is how to gracefully migrate the switch configurations from an old to a new set of configurations. BGP and OpenR configurations are completely different and switching between them requires drastic changes to the fleet. We use Aura to support this process with no disruptions, as illustrated in Figure 5.

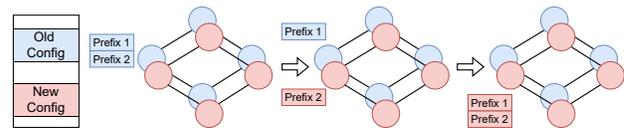

Figure 5: Staging and subscription used for migration.

Both versions of configurations are staged on all switches³, each snippet starts with an activating condition, mapped into different BGP community tags. In Figure 5, we illustrate this as red and blue tags. Network operators can then attach tags to prefixes (prefix 1 or 2) to implement the policy for that particular prefix. By this, Aura simultaneously supports both the old and new policy. This technique also gives the network operator the flexibility to shift traffic in any order they like, and it also offers the fallback opportunity, should the new policy have some unforeseen effects on traffic when it is deployed.

Initially, all prefixes (prefix 1 and 2) use the old configuration (blue). We start with prefixes of less critical services first to avoid business disruptions. At the origin, *Prefix₂* is announced with the red tag, so when the announcement arrives at intermediate switches, the corresponding red configuration is activated and the blue configuration becomes inactive. Other prefixes are gradually on-boarded to the new configuration by switching their tags in announcements. If the new configuration has any issue, we can safely switch back to the old version by controlling community tags at the origin.

Handling switch maintenance. As explained in §2.2, routes from LIVE switches are preferred over those from WARM switches (intent I_5), and routes from DRAINED switches should not be used (intent I_4). To reflect this policy, we stage parallel configurations on each switch⁴ Each configuration describes actions for a given state of this switch and a given

³FBOSS (Facebook Open Switching System [10]) supports concurrent deployment of BGP and OpenR configurations.

⁴FBOSS supports parallel configurations for each device state via instances. Each FBOSS instance contains a local control plane and communicates with the central network management system via thrift based service. Although there can be several instances, only the active instance uses the switch’s hardware resources [10]. We believe any other switch could also achieve this by pushing necessary configurations from the control plane.

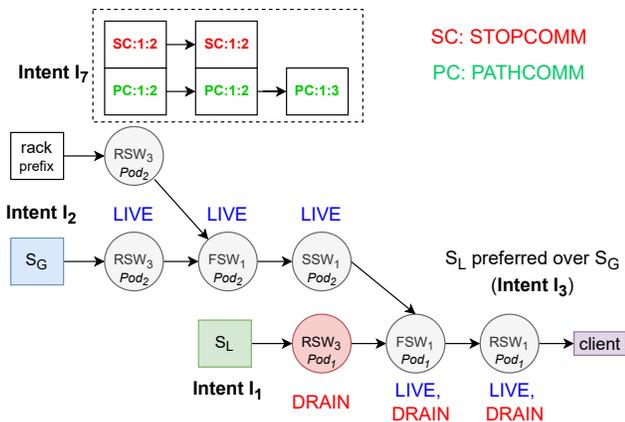

Figure 6: Supporting conditional policies.

state of the neighboring switch sending announcements to this switch. The actions could be adding/removing community tags, setting preferences, and accepting/rejecting routes. Taking intent I_1 and I_2 as an example, as shown in Figure 6, there are two paths to the client to reach the local service S_L and the global service S_G . Intent I_3 specifies that I_1 (primary) is preferred over I_2 (backup). The RSW switch along the primary path is going through a DRAINED state, therefore it attaches the DRAINED tag to its announcement. On the other hand, the backup path contains all live switches and the announcement only contains the LIVE tag. The downstream switches on receiving both the announcements would prefer the backup path to global prefix over the primary path to the local prefix. To support this, switches in both primary and backup paths should be configured to match the DRAINED tag and allocate a lower preference to the primary path. In §5, we show how to implement it with concrete BGP attributes.

4 RPL: Expressing Conditional Policies

Our routing policy language – RPL – allows a network operator to express high-level routing intents, by defining paths and path preferences. We had two choices while designing RPL – to make it a domain specific language (DSL), that is, its syntax is designed from scratch or to make it an embedded language based on Python. Embedded languages typically benefit from existing IDE, debugger, type ahead assistant and error messages, which allows for quick adoption by network operators. However, embedded languages are hard to verify. For instance, in Python, users can override basic operators making it hard to verify a program without running it. On the other hand, with DSL, the language itself can be defined in a way that it can reject wrong programs and enforce invariants we care about. We could also apply any number of static analysis techniques to determine the effect without running the program. Therefore, we traded-off the flexibility provided by embedded languages for correctness and verifiability of DSL.

Table 1: RPL block and leaf statements.

RPL’s syntax is designed from scratch and is based on ANTLR [1] – an engine that provides basic syntax parsing. ANTLR also allows us to easily extend the support of RPL as and when our operational needs change. Table 1 shows the collection of statements supported by RPL. Statements are used to identify base paths, location of switches, describe tags and define policies with their preferences and conditions. Groups of these statements, known as “blocks,” are used to describe different components of the policy. For example, the topology block (B_{top}), describes the topology containing the locations of switches, tags and base paths. The RPL program required to support all policies discussed in Figure 1 is shown in Figure 7. To handle the challenges of expressing flexible policies (§2.3), RPL supports the following features.

Minimizing reconfigurations: RPL allows network operators to specify topology block (shown in lines 1–23) that helps in pre-compiling the network. Specifically, in the topology block, the operator can specify scopes of devices (§3.2), tags (§3.2) and base paths (§3.1) that could be used by policies. For example, to support intents I_1 to I_7 , topology block f16 is sufficient. As described in §3.1, network operators are free

to specify any number of intents that could be supported by this topology block. If operators want to support other intents, they could always extend the topology block, but would require reconfiguration. From our operational experience, we show in §6 that these changes configure much lesser number of switches than competing approaches.

Supporting dynamic configurations: Network operators can specify different policy in the `policies` block of an RPL configuration file. This allows them to dynamically change policy over time. Each policy block, contains the name of the policy (e.g., `RSW_REACHABILITY`), routing (topology block used by the policy), origin (origination location of routes), propagation (set of paths used by the policy) and preference (preference among paths or tags). In Figure 7, policy `RSW_REACHABILITY` implements the intents I_1 to I_5 , policy `ALLOW_INFRA` implements intent I_6 and policy `LIMIT_RACK_PREFIX` implements intent I_7 . A network operator may choose to apply any one of these policies for appropriate prefixes. For instance, as described in an example in §3.2, network operators may apply `RSW_REACHABILITY` for services S_L and S_G and apply `ALLOW_INFRA` for infrastructure prefixes.

Expressing conditions with scopes: To support flexible granularity of intents, RPL introduces the notion of a *locations*, i.e., one can define a switch in RPL at different levels of granularity, such as switch role, switch ID, switch plane, fabric, region, and the datacenter. A location can be defined in the topology block (as shown in lines 3–12 in Figure 7). Location definition consists of the switch role, followed by switch number, pod number, fabric number, and datacenter name. Some elements can also be replaced by wildcards. The naming convention for our production network leverages the symmetry of the network to keep it simple and uniform. For example, the first spine plane in every data center would have the same identification number [5]. Network operators can leverage these naming conventions to define a scope. For example, I_1 requires the route to propagate through the first RSW present in Pod_1 , present in the first fabric in the Altoona (ATN) datacenter, scope `RSW.3.2.1.1.ATN` can be used.

Expressing different switch states: RPL introduces the `tags` block to indicate tags that will be used to identify switches in a given state. An example of the tags block is shown from lines 13–17 in Figure 7, which defines tags `LIVE`, `DRAINED` and `WARM`. These tags will eventually be mapped in the synthesis process into BGP community tags, which would be attached from every switch to communicate the state of the switch to its neighbors (see §5 for implementation details). RPL also allows network operators to limit the propagation of a route announcement by using `prop-condition` statement. In Figure 7, we limit the propagation of announcements based on the switch state to only `LIVE` and `WARM` switches (line 29).

Handling exceptions: As per I_6 , `DRAINED` state switches

are required to carry traffic for infrastructure prefixes. Network operators can define a new policy `ALLOW_INFRA`, that allows `DRAINED` switches to propagate routes. Network operators can use the `ALLOW_INFRA` policy for applicable prefixes (as described in §3.2).

Figure 7: RPL configuration describing policies.

5 Compiler Implementation

In this section, we discuss how Aura takes RPL specification and synthesizes BGP configurations for various switches. Aura uses properties of BGP to flexibly map the RPL specification to switch configurations.

5.1 Supporting Base Paths

The production network would need to be pre-compiled to support the base paths (specified in the topology block in RPL). To achieve this, Aura utilizes reserved community tags and generates rules to match these community tags. The key idea of using community tags is similar to that of source routing [26]. To implement a policy for a prefix, appropriate community tags are attached to the prefix while announcing it. On receiving the announcement, switches match on the community tags and take appropriate action of allowing or denying the route or modifying the tags. Although the idea seems straightforward, the challenge is how to come up with *systematic community assignment that can be interpretable and maintainable at scale*. Our key idea is an easy to interpret and debug encoding scheme that translates the base paths and other intents directly into different bits in the community attribute.

Encoding paths: Aura encodes the base paths into a structure called *path community tags* (PathComm for short). Depending on the number of base paths, Aura allocates a unique PathComm with a format of *PATHCOMM:P(1-10):H(1-6)*, where numbers in parentheses denote the bit sizes of the fields. The 10 most significant bits denote the unique base path ID P and the least significant 6 bits denote the hop number H . Some paths have switch roles that occur multiple times, e.g., intent I_2 , where switch roles RSW and FSW occur twice. For such paths, the hop count field is used to keep track of where the announcement is on the path. Aura configures the switches to support intent I_2 as follows. At RSW on the first hop, the switch matches announcements that contain the *PATHCOMM:1:1*, modifies the community tag to *PATHCOMM:1:2*, (i.e., increments the hop count), and allows the announcement to be advertised to FSW. Similarly, Aura configures FSW to match, modify and advertise the announcement to the corresponding next-hop, that is RSW. When the announcement reaches RSW again at the last hop, the switch matches *PATHCOMM:1:3*, it stops announcing the announcement further. Therefore at RSW, there are two sets of rules, one that matches the announcement on the first hop (*PATHCOMM:1:1*) and the other that matches the announcement on the third hop (*PATHCOMM:1:3*). The use of the community tag ensures the abstraction of the switch role is maintained without needing to split roles of switches further to support multiple hops over the same switch type on the same path.

Containing announcements: Some intents require announcements to be contained to a specific location. For instance, intent I_7 limits rack prefix to pods (Figure 6). To support this, Aura uses a dedicated community tag known as *stop community* (StopComm for short). Similar to PathComm, StopComm follows the format of *STOPCOMM:P(1-10):H(1-6)*, where P and H are used to denote the path ID and the hop number to stop announcement respectively. For intent I_7 , Aura appropriately configures RSW to stop propagating

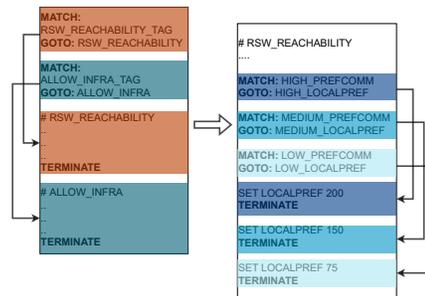

Figure 8: Aura generated configuration.

the announcement when it receives *STOPCOMM:1:2* and restricts the announcement to pods.

During configuration synthesis, Aura generates appropriate match action rules to match on the corresponding communities and take appropriate action. That is, for *PATHCOMM*, the action would be to modify the *PATHCOMM* to reflect the hop changes and for *STOPCOMM*, it would remove the community tags and prevent the forwarding of the announcement.

5.2 Supporting Dynamic Network

Staging: Aura has reserved community tags to accommodate different policies. Aura’s compiler incrementally allocates the community tags based on the order in which they are specified in RPL. For instance, from Figure 7, a dedicated community tag known as policy community (PolComm) will be allocated for *RSW_REACHABILITY* and *ALLOW_INFRA* policies. Similar to PathComm and StopComm, PolComm follows the format of *POLCOMM:POL(1-16)*, where POL denotes the policy ID. Figure 8, illustrates how the staged community tags are used as a pointer to different segments of the BGP configuration file. BGP configurations are processed sequentially by switches. At the beginning of the configuration are match statements, matching the staged community tags. The corresponding action on a match is a *GOTO* statement pointing to the section of the configuration implementing the policy. At the end of the section is the *TERMINATE* command that terminates the processing of the configuration. We discuss consistency guarantee from a practical perspective in §7.

Supporting preferences among paths: Within each policy, network operators may specify preferences among intents (see §4). To accommodate this, Aura uses preference community (PrefComm) with a format of *PREFCOMM:X*, where X denotes the preference value. For every X value there is a one-to-one mapping to a local preference value. Currently, at every switch, there are twelve preferences matching twelve local preference values. If a switch receives an announcement with PrefComm, the configuration generated by the compiler contains a rule that matches on X and the action is a *GOTO* statement that implements the appropriate localpref. This is

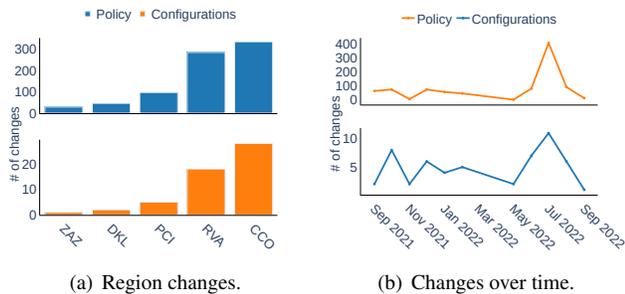

Figure 9: Intents/policies generated by Aura.

also illustrated in Figure 8, where there are match statements for setting high, medium, and low local preference values.

5.3 Validating Configuration

To verify the correctness of the BGP compiler output, Aura uses an emulation-based, routing policy validation framework. We run a container-based high-fidelity emulation of FBOSS switch [10], which constructs an overlay network among containers emulating a small-scale data center without relying on hardware switches. The topology contains multiple switches of the same role to mimic cross-POD and cross-DC route propagation. We load the configurations generated by Aura to the BGP agent on the emulation switches. The switches exchange routes according to the rules in the BGP policy and broadcast End-of-Rib (EoR) messages on convergence. On receiving all EoR messages, the verification framework collects Routing Information Base (RIB) from all switches for validation. The validation algorithm verifies whether the routing status is identical to the RPL policy. Here, the basic idea is to traverse the switch network graph as specified in the RPL propagation path, and check whether all routing paths are correctly present as specified in RPL (Algorithm in Appendix §A). First, the algorithm checks whether the prefixes are originated as intended. It mines the originated prefixes from the first hop switches of the RPL propagation path and inserts the found switch and prefix information into a queue for Breadth-First Search (BFS) traversal. Then, it pops data from the queue, looks up the given switch and prefix and collects the RIBs from the switches. From the next switches' RIBs, the algorithm searches for the matching prefix and community tag and checks if the next hop of the path is the current switch. If so, it marks the routing path as *visited* and pushes the next path information into the queue to continue traversal. This procedure is repeated until the algorithm traverses all propagation paths in RPL. We also perform additional verification on the RPL (described in Appendix C).

6 Evaluation

We first measure the configuration changes made in our production data center, and use these measurements to evaluate Aura by showing how it minimizes switch re-configurations (§5.1), has a flexible language to express policies (§4) and overall reduces operator burden. Aura's compiler is implemented in Python, and has around 13.8 K lines of code. The routing policy verification is developed in Python with around 1,200 lines of code.

We capture the intent changes made by network operators for a year from Sept, 2021 to Sept, 2022. During this time, Aura supported five different data center regions, where each region has a separate configuration. Figure 9(a) shows the number of configuration and policy versions generated by network operators across all Aura-supported regions. We introduced Aura to CCO and RVA datacenter regions in September 2021 and thus these two regions have the highest number of changes. We eventually rolled it out to the remaining regions this year, with ZAZ being the most recent data center running Aura. Over time, across these data center regions, there were 54 different versions of configurations and 840K different policies. On average, there were 10.8 versions of the configurations and 168 versions of policies per region. There are fewer configuration changes than policy changes as not all policy change would require reconfiguration. Many policies would have already been pre-compiled by Aura in the network (as seen in §3.1 and §3.2).

Figure 9(b) shows a timeline of the policy and configuration changes that occurred across all Aura-supported data center regions every month. Every month on average, we changed 5 configurations and 87.3 policies. The largest frequency of updates was observed in July 2022, where we made several updates to introduce a new propagation path from the backbone network to our data centers. We discuss our experience of this roll-out in Section 7.

6.1 Minimize Switch Changes

To show the benefits of pre-compiling the network, we compare Aura with Propane [7]. Aura creates snapshots of policies and configures the network to support multiple common policies in parallel, as opposed to Propane, which compiles the configuration as and when there is a policy that needs to be supported in the network. A key drawback of Propane is that a change in policy may lead to reconfiguration of a large number of switches. We use simulation to quantify the benefit of our base path design in practice. We simulate a scenario where we replay all the policy changes made by network operators as shown in Figure 9(b). That is, whenever a policy is changed, we determine the switches that require re-configuring in case when Aura is run versus the case when Propane is run, to synthesize switch configurations.

Propane involves too many switch re-configurations: Fig-

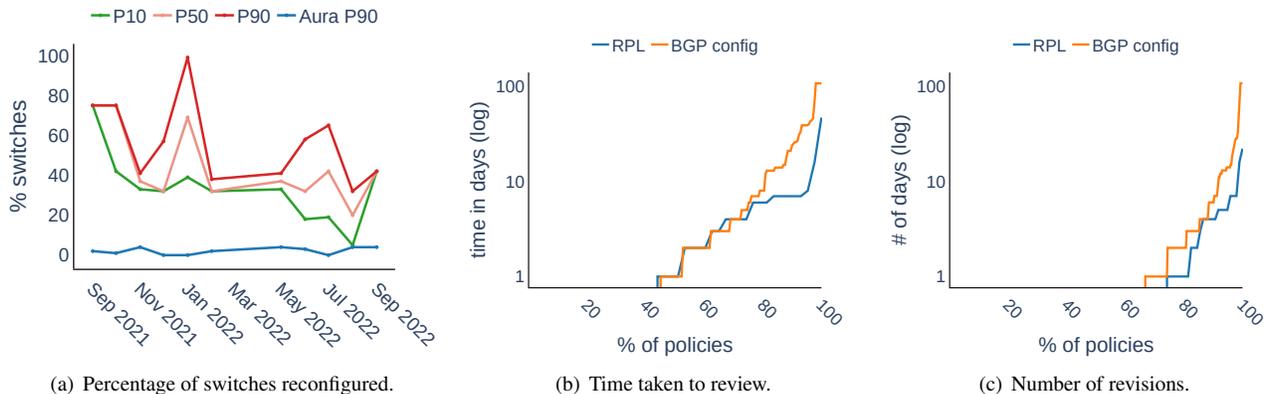

Figure 10: Aura performance.

Figure 10(a), shows the number of switches in all datacenter regions supported by Aura that are reconfigured by Propane. For every month, we show the 10th, 50th and 90th percentile of switch re-configurations that are needed. As described in §2.4, this is time-consuming and disruptive to production traffic. Even the median number of policy changes on average can reconfigure 46.8% of all switches. Given the size of our networks, this could be in order of tens of thousands of switches. On the other hand, Aura reconfigures the network only when new policies cannot be supported by the pre-compiled configurations. Even for the 90th percentile of cases, Aura only reconfigures 2.1% of the switches on average.

6.2 Aura Reduces Operational Burden

During policy generation, Meta adopts a peer review process, where network operators generate a configuration and ask other operators to review the changes. In case of non-Aura-supported regions, network operators send the new BGP configuration for review. On the other hand, for Aura-supported regions, network operators send the new RPL configuration for review.

Non-Aura regions take longer to evaluate: Figure 10(b) shows the time (log scale) taken in peer review for Aura and non-Aura regions. On average, we find that non-Aura regions take 8 days per policy and Aura-regions take 3.6 days per policy. Some policies can take much longer to review than others. For instance, the most amount of review time taken for a policy by non-Aura-region was about 108 days. This policy introduced a new fairness goal in the fabric aggregation layer, which was carried out in phases where multiple policies in non-Aura-regions had to be implemented before the given policy. On the other hand, for Aura-generated policies, the maximum review time was about 47 days. Similar to the non-Aura case, this specific policy involved introducing new backup paths and had to be extensively tested along with other Aura-generated policies.

Non-Aura regions generate many more code revisions:

One key factor for reviewing configurations from non-Aura-supported regions are code revisions. Once the reviewer gives feedback via code review, the author addresses the comments and gets back to the reviewer. This process goes on until the author has addressed all the comments and the reviewer has no other feedback. Since the raw BGP configurations are much harder to understand than RPL, revision process tends to be error prone. Figure 10(c) shows the number of days taken to generate a revision for Aura and non-Aura regions. On average, Aura-supported regions take 1.1 day per revision and non-Aura-supported regions have 3.2 days per revision. This difference is pronounced at the tail, where the maximum time taken for a revision was 22 days for Aura-supported region. However, for non-Aura-supported region, the maximum number of revisions was 107 days.

6.3 Aura Configuration Properties

Breakdown of RPL policies. All policy versions were encoded in 83.2 K lines of RPL by network operators. The most common statements used to define the policies include the propagation condition, propagation policy, origin and routing – this constitutes 1.9K–2.5K lines of code. There are also 382 preference statements. A large number of origin (2.5K), routing (2.5K) and path (2.3K) statements reflect the support for multiple backup paths in the network. Similarly, a large number of prop-condition statements, reflects the frequent need to restrict the scope of propagation in the network. Other statements including location, signature, base path, routing protocols and device states are used only once per configuration, and there were only 54 such statements.

Aura’s Performance. Aura can be broken down into three stages: time taken to process and validate RPL, compiler execution time and the per-switch configuration generation time. On average, RPL processing and validation takes 4.3 seconds and the compiler contributes 2.9 seconds, both of

which are negligible in the entire process. The majority of the time is taken by BGP configuration generation, which takes about 88 seconds on average. This is expected, as the complexity of Aura mainly lies in the BGP compiler, which must synthesize BGP configurations for every switch in the network. Before Aura, network operators manually encoded intents into switch configurations. Based on our interviews with network operators, these configurations took about 26 weeks to generate, validate and safely deploy. Aura also scales when the number of policies increases, which typically occurs as the network grows. We artificially increase the number of policies to test the configuration synthesis times. We find that the synthesis times are about the same (about 90 seconds) for 50, 100 and 150 policies.

7 Operational Experience

RPL supporting verification for non-Aura regions. During Aura deployment, for the regions that are not Aura ready, i.e., those using legacy BGP configurations, operators still craft the intent in RPL. In this case, although RPL-based intent is not used to generate BGP policies, it is used for verification. The existing verification tool uses RPL as the source of truth and verifies it against manually generated BGP configuration. From this experience, RPL enables global verification before and during Aura deployment, which guarantees the correctness of the policy migration. There are other tools which uses RPL as an input. For instance, after the policy has been deployed, we constantly verify the routes in the production network and alert when unintended behaviors are observed. This tool uses RPL as the source of truth for verifying the intents.

Identifying latent failures. The verification approach helped identifying several errors during the Aura deployment, such as intent specification errors, faulty compiler logic, BGP agent bugs, etc. We summarize the identified issues in Table 2 in Appendix B. We now look into two issues. First, when we configured multiple backup paths to reach RSW within the same pod – a primary path ($RSW \rightarrow FSW \rightarrow RSW$), a backup path via a different FSW, and a second longer backup path ($RSW \rightarrow FSW \rightarrow RSW \rightarrow FSW \rightarrow RSW$). When the primary path fails, the wrong configuration was used, resulting in using the longer backup path, instead of the shorter one, causing performance degradation. The second issue was a drained FSW switch, which did not announce the infrastructure prefixes to the connected RSWs. When another FSW switch failed, the external world lost connectivity to the RSW’s management plane, which should have existed through the drained FSW switch. Such latent failures are hard to detect in production as they only manifest themselves during certain scenarios and the verification helped fix these errors before deployment.

The verification approach is not perfect and has failed to prevent some issues. In one instance, a operator created a policy to inject a route to server using virtual IPs. The verification

framework verified the propagation of the path to the server, but did not check the IP address usage. It turned out that the operator specified an incorrect IP address which actually belonged to a switch. This resulted in traffic destined towards the switch to be wrongly routed to the server. To prevent this, the verification approach is now planning to validate the IP address usage along before validating route propagation.

Consistency guarantee in practice: One concern for policy update is the consistency during convergence. Aura tackles the problem in a practical manner with three steps. First, we always drain a switch by moving the live traffic away, which is also called *disruptive config update* [10]. This prevents packet loss during transient state. Second, after the new path is enabled, we wait for a time period that is long enough for BGP convergence at a DC level. We conducted experiments to evaluate the convergence time scaling with the size of the network and chose the window to be tens of minutes. Finally, we use BMP monitoring to guarantee that the new routes are propagated in place before removing the drain configuration. The convergence time depends on the amount of traffic a switch carries. On one hand, switches that carry less traffic such as FSWs can take upto 6 seconds, but on the other hand, switches that carry more traffic such as FAUU can take 92 seconds.

Ease of operation: After implementing Aura in some data-center regions, we see significant improvement in experiences of network operators. For instance, after the last year’s outage [3], we wanted to provide additional backup paths which included allowing routes over DRAINED switches with a lower preference. In Aura, we can support it with only 4 lines of RPL code change (details shown in Appendix D, Figure 11). This change took less than an hour to implement. On the other hand, we still had to support this change for non-Aura-supported regions, and it took three experienced engineers 30 days to make manual changes. During this time, the policy went through 6 rounds of review with over 40 comments for changes in the peer review process.

Supporting new networks: Our data center topology is constantly evolving to react to various deployment constraints and to new business requirements. For example, the recent global supply chain shortage pressed us to have a more condensed topology to reuse available ports. To accommodate the growing AI workload, we are developing a new AI backend topology. Adapting routing policy to a new topology is not trivial. Before Aura’s deployment, it took network engineers up to 6 months to support a new topology. As an anecdotal example, in a recent deployment topology with Aura in June 2022 (ZAZ) took only 3 weeks by a single engineer.

Unsupported policies: Aura currently does not support UCMP (Unequal Cost Multi-Paths). Typically, UCMP is used in traffic migration scenarios, where we add additional planes to the backbone layer. Under regular operations, the FAUU uses ECMP to equally distribute traffic to available backbone

planes. During migration, we would like to test the newly introduced backbone planes, before running them in full capacity. In such cases, we make use of UCMP to manipulate the amount of traffic going towards the backbone planes. This is an area of potential future work for Aura to support UCMP.

Coordination with non-routing policies: Aura focuses on specification and validation of routing policies. However, there are other policies that impact forwarding decisions. First, there are policies that are specific to services. Services have their own policies about the use of network resources (e.g., load balancing, replication) and can create varying traffic patterns that could lead to a routing policy adjustment. Future research is needed to streamline and coordinate intent changes between service and network layers. Second, there are the access control lists (ACLs) that restrict the flow of traffic across different network domains at Meta, which in turn affects routing policies. These ACLs also have a policy specification that is maintained by a different team. Detecting conflict and maintaining consistency across different intent management systems is an unsolved problem. Finally, while Aura manages all the data center routing policies, there are outside domains such as backbone and edge networks at Meta. These networks run different routing protocols and have their own policy intents. One of the extension of Aura is to support backbone routing intent using RPL, so that we can perform end-to-end verification. In the future, we plan to explore how to adapt Aura to other non-routing policies.

8 Related Works

Configuration synthesis: Propane [7], Propane/AT [8] and SyNet [11] use their own DSL or existing techniques to express intents. Then the intents are synthesized into low level configurations. Alternatively, rather than specifying intents, operators can partially specify the BGP configuration, and the synthesis approach can fill in the holes. Although these techniques help reduce operational burden, they cannot handle dynamic changes at scale without requiring constant re-configurations. Propane [7] and Propane/AT [8] are also limited to BGP protocol, while Aura supports multiple routing protocols (BGP and OpenR). Finally, some configuration synthesis systems like SyNet [11] and ConfigAsure [21] are hard to scale to the size of large datacenter networks, like Meta. Beyond BGP configuration synthesis, Robotron [25] uses high-level intents to low-level device configurations with minimal human intervention. This involves, designing a network, generating appropriate switch configurations for the network and monitoring them. Aura also uses some Robotron components such as FBNet, and extends the flexibility of BGP configuration generation via synthesis.

Supporting dynamic configurations: Typically, systems focus on supporting dynamic configurations by switching from one configuration to the other. For instance, zUpdate [18] and Snowcap [23] determine a transition plan from one con-

figuration to the other. However, these techniques involve shifting from one configuration to the other via several intermediate configurations. As seen in § 2.4, configuration updates to switches in a large network can take a lot of time, and transitioning across different configuration would only exacerbate this issue. Our technique of supporting multiple policies is similar to fast failover [17] and MPLS reroute [4] techniques, where backup options are pre-configured without the need of operator intervention. Alternatively, support for parallel configuration can be done via virtual routers such as VROOM [28] which is similar to FBOSS instances where each instance has its own control plane. However, the key difference is that only the active instance in FBOSS use the switch hardware resources, whereas all VROOM instances use the switch hardware resources.

There have been several other works in SDN [16, 19, 20], that help in transitioning from one configuration to the other. However, re-configuring in SDN context is different, than switch reconfiguration, as forwarding state is changed directly from a centralized controller, avoiding the challenges of a large distributed network. Moreover, there are problems unique to a SDN setting which are not applicable to BGP. For instance, planning rule updates [19] in SDN is crucial to avoid packet drops and unintended network behavior. However, in our setting, configuration change happens a phased manner, where traffic is drained from switches before a configuration update. This ensures that the transition between configuration do not interfere with traffic.

Expressing intents: In recent years, there have been many efforts to raise the level of abstraction for low level configurations. Jinjing [27] introduces LAI to express ACL update synthesis and Propane [7] introduces RIR to express constraints on policy. Propane's RIR cannot express intents across different scopes, whereas both LAI and RIR do not support device state specifications and preferences based on these specifications (e.g., I_4 , I_5 and I_6).

9 Conclusion

Providing stable and efficient routing in large data centers is crucial. Existing synthesis systems generate configuration only once, but production networks require multiple reconfiguration to support their scale and dynamics. We present Aura, that enables network operators to express high-level intents to be automatically configured into the switch policy implementation with minimal reconfiguration.

Acknowledgment We would like to thank many of Meta colleagues who have contributed to this work over the years and toward this paper. These include Jason Wilson, Yan Cai, Maaz Mohiuddin, Hyojeong Kim, Jingyi Yang, Michael Liu and many others. We also thank our shepherd Dr. Soudeh Ghorbani and the anonymous reviewers to help making a better version of this paper. A Routing Policy Validation Algorithm

Algorithm 1 shows the algorithm used during emulation to verify Aura generated configuration.

Algorithm 1 RPL-based routing policy validation

```

1: procedure traverse(path, tag)
2:   ▷ path: a propagation path from RPL
3:   ▷ tag: a community tag that identifies policy
4:   ▷ Enqueue the originated prefixes into BFS queue
5:   Q = Queue()
6:   for sw in get_switches(path[0], all) do
7:     for R in RIB(sw) do
8:       if tag in R.tag then
9:         visited_sw = [sw]
10:        L = 0
11:        N = node(sw, route.prefix, L, visited_sw)
12:        Q.enqueue(N)
13:   ▷ Check if the prefix exists in RIBs
14:   while !Q.isEmpty() do
15:     N = Q.pop()
16:     L = N.L + 1
17:     for sw in get_switches(path[L], N.sw) do
18:       if sw in N.visited_sw then continue
19:       route_found = False
20:       for R in RIB(sw) do
21:         if R.prefix == N.prefix
22:            and tag in R.tag
23:            and R.nextHop == N.sw then
24:           route_found = True
25:           R.visited = True
26:           if L < length(path) then
27:             visited_sw.append(sw)
28:             N_new = node(sw, R.prefix, L, visited_sw)
29:             Q.enqueue(N_new)
30:           assert route_found == True
31: procedure routing_policy_validation(tag)
32:   prop_paths = get_propagation_paths_from_rpl(tag)
33:   for path in prop_paths do
34:     traverse(path, tag)
35:   ▷ Verify if there is any prefix leakage
36:   for sw in get_switches(all, all) do
37:     for R in RIB(sw) do
38:       if tag not in R.tag then continue
39:       assert R.visited == True

```

B Issues detected via emulation

We show the issues detected during emulation in Table 2. Broadly, they are categorized into compiler errors and BGP agent errors.

C Detecting Ambiguous Statements

Once RPL specification is complete, we use it as input into a compiler, which generates switch configurations. To avoid ambiguity, Aura compiler performs certain verification steps on the RPL specification.

Rule 1: Explicitly specify preference across all paths. It is possible that an operator designing a policy does not specify preferences across all the paths. For example, if there were four paths, P1–P4, and the preference rule stated $P_1 > P_2 > P_4$, preference for P3 is unspecified. One possible approach would be to assign a default preference value. However, depending on the preference values assigned to the other three paths, the total ordering of paths is unpredictable. For instance, if the default preference value is 100, there could exist two sets of ordering, $P_1(100) = P_3(100) > P_2(50) > P_4(25)$ or $P_1(200) >$

Category	Identified Issues
Compiler	Leaked intra-fabric prefix to FA Announced FA loopback address to unwanted scope VIP prefixes not withdrawn from drained devices VIP priority misconfigured Prefix originated from SSWs in one DC was not propagated to another DC Drained SSW did not forward default route to FSWs Prefixes from backbone not propagated to FADUs Drained FAUU does not withdraw default route FA loopback addresses leaked to RSW
BGP agent	Unsupported BGP action Config parsing crash in switches

Table 2: Identified issues by emulation.

$P_2(100) = P_3(100) > P_4(50)$. This non-determinism could make debugging routing behavior more challenging, and even worse, result in a hidden intent violation. Our solution is to detect underspecified preferences during verification and prompt the operator to explicitly define each preference.

A similar issue arises when the operator specifies two parallel preferences: $P_1 > P_2, P_3 > P_4$. The order between paths in these different preferences can be interpreted as $P_1 > P_2 > P_3 > P_4$ or $P_3 > P_4 > P_1 > P_2$, and in several other ways. When verifying a RPL specification, Aura notifies operators to define ordering between all paths.

Rule 2: Detect hidden conditions. RPL supports adding a condition to a preference (Section 4). For example, the preference $P_1(BB_DEFAULT_ROUTE) > P_2 > P_3 > P_4$ means that for an announcement containing a community $BB_DEFAULT_ROUTE$, P_1 should have higher preference than other paths. However, there is an ambiguity. If the $(BB_DEFAULT_ROUTE)$ community is not attached, then the preference for P_1 is not specified, and the order of P_1 ($\neg BB_DEFAULT_ROUTE$) and the rest of paths is unspecified as well. During verification, the operator is prompted to clear this ambiguity by explicitly specifying the preference for P_1 with and without the attached condition, and ensuring that the partial ordering is maintained.

D RPL changes to change intent

Figure 11 shows the RPL change done by network operators to allow DRAINED switches to propagate routes with a lower preference.

Abstract

Accurate and thorough analysis of network performance is challenging. Network simulations and emulations can only cover a subset of the continuously evolving set of workloads networks can experience, leaving room for unexplored corner cases and bugs that can cause sub-optimal performance on live traffic. Techniques from queuing theory and network calculus can provide rigorous bounds on performance metrics, but typically require the behavior of network components and the arrival pattern of traffic to be approximated with concise and well-behaved mathematical functions. As such, they are not immediately applicable to emerging workloads and the new algorithms and protocols developed for handling them.

We explore a different approach: using formal methods to analyze network performance. We show that it is possible to accurately model network components and their queues in logic, and use techniques from program synthesis to automatically generate concise interpretable workloads as answers to queries about performance metrics. Our approach offers a new point in the space of existing tools for analyzing network performance: it is more exhaustive than simulation and emulation, and can be readily applied to algorithms and protocols that are expressible in first-order logic. We demonstrate the effectiveness of our approach by analyzing packet scheduling algorithms and a small leaf-spine network and generating concise workloads that can cause throughput, fairness, starvation, and latency problems.

1 Introduction

New network functionality is often analyzed, both empirically and analytically, to predict how it would perform under different kinds of input traffic. However, it is growing increasingly difficult to do such analysis in a manner that is reasonably *exhaustive*, i.e., does not miss traffic patterns that are probable to occur in production, and *general*, i.e., is not only applicable to a limited set of network functionality.

To see why, consider the existing empirical approaches, i.e., using simulators, emulators, and testbeds [1–3]. These approaches allow operators to realize a model of their network in software and/or hardware, push a concrete sequences of packets through it, and measure how well the network performs for that specific input traffic pattern. As such, operators have to pick and choose which input traffic patterns to try. This

leaves room for unexplored traffic patterns that may experience poor performance because of overlooked corner cases and bugs. The problem is only exacerbated as new networked applications emerge, expanding the set of traffic patterns that a network may face in production.

On the analytical side, there is a substantial body of work that applies techniques from queuing theory and network calculus to derive bounds on performance metrics such as throughput, delay, and loss [4–9]. However, to obtain tight and useful bounds, the network functionality and the arrival pattern of traffic need to be closely approximated with concise and well-behaved mathematical functions. This limits the set of network functionality and traffic patterns that can be reasoned about using these frameworks [10], a problem that is, again, aggravated with the continuous evolution of networked applications and the network functionality that supports them.

This paper explores an alternative approach: *using formal methods to analyze network performance*. That is, we would like to use logical formulas to model packets, how packets are processed by each piece of network functionality as they traverse the network, and how performance metrics such as throughput and delay change over time. We can then use verification and synthesis techniques from the formal methods community to exhaustively explore the space of all possible traffic patterns and find those for which the network cannot provide satisfactory performance.

Why use formal methods? Because they can nicely complement existing empirical and analytical approaches for performance analysis. Unlike empirical approaches, they do not need to explicitly try out every single traffic pattern to find ones that experience performance problems. Moreover, they enable us to reason about network functionalities that are expressible in logical formulas, many of which may be not feasible to approximate in a way that is suitable for existing analytical approaches. Finally, past efforts in using formal methods to solve networking problems have proven quite successful. Over the past decade, researchers and practitioners in both academia and industry have coupled advances in formal methods tools and techniques with domain-specific optimizations to rigorously reason about the functional correctness of various aspects of networks [11–28]. This provides further encouragement that formal methods could bring similar benefits to reasoning about *performance*.

Realizing this vision is not without its own unique challenges. First, performance metrics (e.g., throughput and delay) are statistics over packet streams and are affected by the order and the time at which packets from competing traffic enter and exit network components. As such, reasoning about performance requires reasoning about the enormous space of possible packet-level interactions and finding those that can lead to unsatisfactory performance. For that, we have found efficient ways to encode interactions that can significantly affect performance, e.g., interactions across network queues, in Satisfiability Modulo Theories (SMT) formulas and over a bounded number of time steps.

Second, when it comes to performance analysis, finding a single counter-example is not always useful. In this case, a counter-example is an assignment to the model's logical variables that leads to poor performance, where the model variables describe packets and the order and time at which they enter the network. Such a detailed packet trace is not easily interpretable. Moreover, unlike counter-examples for correctness properties, it may not even point to a bug, but an extremely rare scenario where providing sub-optimal performance does not have tangible consequences.

We argue that a more useful output (also a more challenging one to produce) is a traffic pattern or *workload* that can succinctly capture the commonality between a whole *set* of packet traces that can experience poor performance. To generate such workloads efficiently, our main insight is to use syntax-guided synthesis (SyGuS) [29]. That is, we define a language for specifying workloads. Then, we systematically search through the space of all workloads to find one such that *all* packet traces represented by it experience poor performance. The search algorithm, inspired by prior work on invariant synthesis [30], is based on Markov Chain Monte Carlo (MCMC), with a cost function that guides the algorithm towards the parts of the search space where there is a higher chance of finding an answer.

To demonstrate the effectiveness of our approach, we apply it to packet scheduling algorithms as well as a small leaf-spine network and ask queries about throughput, fairness, latency, and starvation. The fact that packet sequences are bounded, as well as other optimizations in our SMT encoding, enables our framework to analyze each workload in $< 1s$ on average. Moreover, our search algorithm can successfully find workloads that convey high-level insights about traffic classes that can experience transient or persistent performance problems in 6-18 minutes.

These results provide an encouraging indication that using formal methods to analyze network performance has the potential to grow into a valuable tool for understanding network behavior and making networks more robust. Our proof-of-concept prototype can analyze compositions of a few tens of network components, modeling small-scale networks or host-based scenarios where flows from different applications or VMs contend for end-host resources across a few layers of

classifiers and packet schedulers. That said, we recognize that, similar to data and control-plane verification tools that have matured over a decade to scale to large-scale networks [31], much work needs to be done to improve the scalability of formal methods tools for network performance analysis. We discuss potential future research directions in §9.

2 Overview and Motivation

In this section, we use a buggy packet scheduler to demonstrate our approach in using formal methods to reason about performance.

The scheduler. FQ-CoDel [32] is the default queuing discipline in Linux. It is a hybrid packet scheduler and active queue management (AQM) algorithm. Flows are classified into queues which are managed by the CoDel AQM algorithm. The scheduler decides which queue gets to transmit next. It prioritizes the transmission of the first few packets of new flows so that short latency-sensitive flows with a few packets are not blocked by longer flows.

Our motivating example is inspired by the scheduler in FQ-CoDel. When a packet comes in, it is first classified (e.g., based on its 5-tuple) and assigned to a queue. For simplicity, let's assume hash collisions are rare and each queue is holding packets of one flow at any point in time. The scheduler maintains a list of pointers to queues with potential short flows called *new_queues*, and another list called *old_queues* with pointers to all the other queues with outstanding packets. At a high level, queues in *new_queues* are prioritized over those in *old_queues*, and the queues in the same list are serviced using a deficit-round-robin (DRR)-like algorithm [33].

How does the scheduler determine which list each queue belongs to? Suppose the incoming packet is assigned to q_i . If q_i is in neither of the lists, it means it has not received packets recently and this could be the start of a short flow. So, the scheduler will add a pointer to q_i to the end of *new_queues*. Otherwise, the queue will remain in its current list. In both cases, the packet is enqueued in q_i .

On dequeue, the scheduler first looks at *new_queues*. Suppose q_h is the queue at the head of the list. It will be selected to send a packet unless (1) it is empty, in which case it is removed from the *new_queues* and marked as inactive, or (2) it has packets but has already sent at least a (configurable) quantum of bytes, in which case it is not considered a short flow, is removed from *new_queues* and is inserted at the end of *old_queues*. If q_h is not eligible, the scheduler moves on to the next queue in *new_queues*.

The bug. When a queue in *new_queues* is empty, it is immediately deactivated. When it receives another packet, it is placed in *new_queues* and gets priority over the queues in *old_queues*. This can potentially cause starvation for queue in *old_queues*. When proposing the separation between new and old queues, the FQ-CoDel RFC [32] warns against this bug: “the queue could reappear (the next time a packet arrives for it) before the list of old queues is visited; this can go on indefinitely,

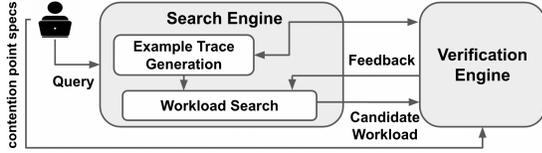

Figure 1: Overview of workload synthesis.

even with a small number of active flows, if the flow providing packets to the queue in question transmits at just the right rate.” To avoid this problem, the RFC suggests that when a queue in *new_queues* becomes empty, it should be first demoted to the *old_queues*, and only deactivated if it still stays empty after all the old queues are visited on subsequent dequeues.

This is a subtle bug that is difficult to catch with existing approaches for performance analysis. The traffic pattern that reveals the bug consists of a flow sending packets at a very specific rate, which could depend on the number and traffic pattern of other active flows that traverse the scheduler. As such, it is not likely to be part of the common traffic patterns that are tried out in simulation and emulation and can be overlooked in empirical experiments. Similarly, approaches based on queuing theory and network calculus focus on schedulers and arrival patterns that have concise and well-defined mathematical approximations and cannot be readily applied to this specific variation of DRR scheduler or this traffic pattern.

2.1 Using Synthesis to Analyze Performance

Figure 1 shows an overview of our approach using formal methods and workload synthesis to reason about the performance of network components like our example scheduler.

Modeling contention points (§3). First, the users specify which network component(s) they are interested in, and if there are more than one, how those components are connected together. Given this input, the verification engine generates logical variables and constraints that model the network components and their interactions. Each component is modeled as one or more *queuing modules*, each with n input queues, m output queues, and a processing block in the middle. The processing block takes packets from input queues, processes them, and puts the resulting packets into output queues.

Here, we model the scheduler as a queuing module with five input queues and one output queue (Figure 2). Specifically, in the verification engine, we generate SMT formulas that model these queues and their content for T consecutive time steps, where time advances on every dequeue operation. Every time step, each input queue receives a bounded number of packets. Moreover, the processing block selects one input queue according to the scheduler’s dequeue logic, dequeues a packet from it, and places the packet into the scheduler’s output queue. The formulas describe how the scheduler state, e.g., *new_queues* and *old_queues* lists, and queue contents at time t connects with those at time $t + 1$.

Performance queries (§4). Next, the user asks a query about a performance metric of interest such as throughput, latency, or fairness. Since the FQ-CoDel scheduler is supposed to

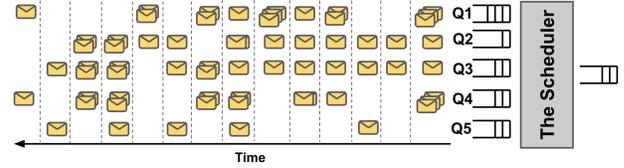

Figure 2: An example trace.

provide fairness, suppose the user asks whether or not one queue can take more than its share of the bandwidth:

$$\left(\bigwedge_{i=1}^4 \forall t \in [1, T], \text{cenq}(Q_i, t) \geq t \right) \rightarrow \underbrace{\text{cdeq}(Q_5, T) > 2 \lfloor T/5 \rfloor}_{\text{can } Q_5 \text{ get more than its fair share?}}$$

assuming other queues are backlogged

where $\text{cenq}(q, t)$ and $\text{cdeq}(q, t)$ are the number of packets respectively enqueued into and dequeued from queue q by the end of time step t . The query can be read as “if queues Q_1 to Q_4 are backlogged the entire T time steps, is it possible for Q_5 to dequeue more than twice its fair share (i.e., $\lfloor T/5 \rfloor$)?”. Note that we use lower case letters for variables and upper case letters for literals and constants.

Introducing workloads (§5). At this point, we can ask the verification engine to use an SMT solver like Z3 [34] to find an input packet *trace* that satisfies the query. A packet trace is simply an assignment to the variables that represent how many packets enter each queue in every time step. Figure 2 shows an example trace, found by the verification engine, that satisfies the query. While the trace does provide a concrete scenario in which Q_5 receives more than its fair share of the bandwidth, it is not easy to interpret as it specifies the ordering and timing of the entry of every single packet: is the fact that three packets entered Q_1 in the same time step in the beginning crucial to Q_5 getting a larger share of the bandwidth or is it just an arbitrary choice? Would the query still be satisfied if instead Q_2 had received three packets in the first time step? Even if these details actually do matter, it is not clear if the trace is actually pointing to a subtle but prominent performance problem, or just an extremely rare and uninteresting scenario.

Rather than output a single packet trace, our search engine synthesizes a *workload* that can concisely describe a set of packet traces that can cause performance problems:

$$\begin{aligned} & \forall t \in [1, 6] : \text{cenq}(Q_5, t) \leq 1 \\ & \wedge \forall t \in [7, 14] : \text{aipg}(Q_5, t) \geq 2 \\ & \wedge \forall t \in [13, 14] : \text{cenq}(Q_5, t) \geq 5 \\ & \wedge \underbrace{\left(\bigwedge_{i=1}^4 \forall t \in [1, 14], \text{cenq}(Q_i, t) \geq t \right)}_{\text{backlog assumption from the query}} \end{aligned}$$

$\text{cenq}(q, t)$ is the total number of packets that enter q by $t + 1$, and $\text{aipg}(q, t)$ is the inter-packet gap between the last two packets entering q by $t + 1$. Such an answer is more interpretable as it captures the commonality of a set of traces that satisfy the query. Moreover, the fact that a set of similar packet traces all cause the same performance problem is a preliminary indication that it represents more than just a rare scenario.

We define workloads as a conjunction of constraints, each specifying a traffic pattern for one or a subset of queues over

a period of time. For $T = 14$, the above workload specifies a traffic pattern that will always satisfy the query, i.e., cause Q_5 to dequeue at least five packets when it should not have dequeued more than three. The first constraint states that at most one packet enters Q_5 in the first 6 timesteps, so that unlike the other four queues, Q_5 is not demoted to the list of old queues. After that, the second constraint ensures that Q_5 receives traffic at a specific rate, at most one packet every other time step. This ensures Q_5 becomes empty and gets deactivated after dequeuing each packet (the bug). So, it is activated as a new queue when it receives its next packet and is prioritized over others for dequeue. The third constraint ensures that Q_5 receives at least five packets by $T = 14$, so it has enough packets to dequeue and satisfy the query. The final constraint ensures that the other queues are always backlogged, which comes from the assumption specified in the query.

Synthesizing workloads (§6). The search engine is responsible for generating a workload that satisfies the query. It first uses the verification engine to generate a set of example traces that can guide the search towards finding a suitable workload. Next, inspired by prior work on program and invariant synthesis [30, 35], it starts a stochastic search process based on Markov Chain Monte Carlo (MCMC) that synthesizes a candidate workload and asks the verification engine to verify if all traces in that workload satisfy the query. If not, the violating trace is returned to the search engine and added to the example traces to help guide finding the next candidate workload. This process repeats until an answer is found and returned to the user, who can either terminate the analysis or ask for other workloads that satisfy the query.

User Interface. Similar to many other existing work that use formal methods for networks, our queries and workloads are specified as logical expressions. Moreover, the encoding of packet processing algorithms and protocols into logic is done manually. To enable widespread adaptation of formal approaches, it is important to develop front ends that interface with these “logical backends”, abstract away the details of logical expressions and formulas, and enable users to interact with them using higher-level and more familiar interfaces. In fact, there are several ongoing efforts for providing higher level query interfaces and automated generation of logical models and SMT formulas from implementations [36–40]. With the right interface in the middle, the front-end and the logical back-end can evolve independently. As such, for our case study in §8, we create a simple front-end to demonstrate an example of one such interface, and leave the design of a more general front-end for future work.

3 Modeling Contention Points

Queues are an integral part of networks. In fact, networks can be viewed as multiple layers of queues with well-defined functionality in between that describes how to deliver data from one layer to the next. From source to destination, packets go from socket buffers, to queues in packet schedulers

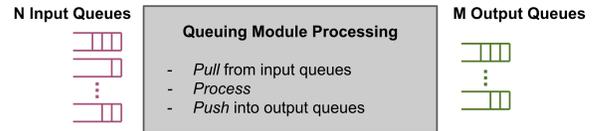

Figure 3: A queuing module.

in the end-host stack (e.g., Linux qdiscs), to NIC transmit queues on the sender. Then, they traverse switch input and output queues in the network, and the NIC, qdisc, and socket buffers on the receiving end. Network contention points, e.g., switches, NICs, and network stacks, heavily rely on queues to decide how to allocate network resources to competing traffic streams. Indeed, performance metrics of a packet stream are significantly affected by the queues it traverses and the frequency at which those queues are selected to pass on their traffic. As such, queues are a fundamental part of our model.

Figure 3 shows a simple yet expressive building block for modeling layers of queues: a *queuing module* with $n \geq 1$ input queues, $m \geq 1$ output queues, and a processing block in the middle. Every timestep, the processing block takes a batch of packets from the input queues, processes them, and puts the resulting packets into the output queues. To keep track of performance metrics, we designate extra variables per queue for each metric that get updated as packets enter and exit queues, and ask queries about their values for different queues (see §4 for examples).

Composition. Queuing modules can be easily composed by feeding the output queues of one module to the input queues of another (e.g., figures 6 and 9). So, one could start by modeling a single bottleneck, e.g., a qdisc, or a NIC/switch scheduler, and compose them together to reason about segments or paths in the network (§7 and §8). We can even close the loop by designating a queuing module for congestion control algorithms, with one input queue receiving acks and other control packets and one output queue transmitting data packets. While we have not explored this last direction in this paper, we believe it is a very interesting avenue for future work.

Modeling Time. We define a time step as the time between the dequeue operations of the slowest output queue. That is, time advances when a new dequeue happens. Modeling time based on dequeues is a natural choice. It is coarser-grained than wall-clock time, and since our verification engine performs bounded model checking over time, this helps performance problems manifest over fewer time steps. It is also fine-grained enough for capturing the arrival order of packets within and across time steps. To capture the arrival order within a time step, we put an upper bound K on the number of packets that can enter a queue between dequeues. This bound allows us to create K variables p_{t_1}, \dots, p_{t_K} to capture the order at which those K packets enter the queue at time t (p_{t_i} comes before p_{t_j} if $i < j$). It also helps us avoid finding “trivial” workloads that simply flood the queuing module every time step with an unrealistically large number of packets.

Modeling Packets. We model packets as tuples consisting

of multiple “metadata” variables. Depending on the query, these variables can include the arrival and departure time of the packet into and out of different queues of interest, flow id, application id, or packet size.

Modeling Queues. A queue is specified with two parameters, its size S and the maximum number of enqueues K allowed at every time step. We define three sets of variables for each queue for every time step t : (1) $enqs[t][1 : K]$ consists of K tuples to capture the packets that are sent to the queue at time t , (2) $elems[t][1 : S]$, consists of S tuples to capture the packets that are inside the queue at time t , and (3) an integer variable $deq_cnt[t]$ that captures how many packets will be dequeued from this queue at time t . We constrain these variables such that they collectively behave like a FIFO. Finding the right constraints to model FIFOs in a scalable manner is not straightforward, especially when there are multiple enqueues and dequeues per time step. We describe our encoding of FIFOs in SMT in Appendix A.

When two modules are composed, we need extra constraints to move packets from the output queue of one to the input queue of the other. Suppose the first output queue of module A ($A.out_1$) is connected to the first input queue of module B ($B.in_1$). B decides how many packets to dequeue from $A.out_1$ at time t and sets its $deq_cnt[t]$ to, say, k . We add constraints to enqueue the first k packets in $A.out_1$ into $B.in_1$. We provide two different kinds of composition. In *sequential* composition, $B.in_1.enqs[t][1 : k] = A.out_1.elems[t][1 : k]$, that is, packets from $A.out_1$ will appear in $B.in_1$ at time $t + 1$. In contrast, in *immediate* composition, packets leaving $A.out_1$ at time t will be visible in $B.in_1$ in the same time step. We discuss examples of different kinds of composition and their implications in our case studies in §7 and §8.

Modeling packet-processing algorithms. The packet-processing algorithm in a queuing module sets the $deq_cnt[t]$ variables of the module’s input queues to denote how many packets will be dequeued from each input queue at time t . It also decides which one of those packets to move to the $enqs[t]$ of which of the output queues, potentially changing, dropping, or cloning some packets in the process. As long as an algorithm’s logic can be expressed in SMT, we can plug it into our framework.

4 Performance Queries

Performance queries are logical formulas over one or more performance metric. Users can define their metrics of interest to be tracked for all or a subset of queues in the queuing modules. They can then ask queries about the value of a certain metric for one queue or a set of queues, or compare the values of metrics between different queues.

Performance metrics. A performance metric $m(q, t)$ is a function that computes a value over the packets that have entered or departed the queue q until the end of time step t . Most metrics can be defined as recursive functions over time. For instance, metric d that tracks the maximum delay experienced

$$\begin{array}{l|l} \text{qry} := \text{wl} \rightarrow \text{tr} : \text{qlhs} \oplus \text{rhs} & \text{wl} := \text{true} \mid \text{con} \wedge \text{wl} \\ \text{tr} := \{\forall \mid \exists\} t \in [T_1, T_2] & \text{con} := \forall t \in [T_1, T_2] : \text{lhs} \oplus \text{rhs} \\ \text{qlhs} := \text{lhs} \mid m(Q_1, t) - m(Q_2, t) & \text{lhs} := m(Q, t) \mid \sum_{q \in S} m(q, t) \\ & \text{rhs} := C \cdot t \mid C \end{array}$$

Figure 4: Syntax for queries (§4) and workloads (§5).

by packets in a queue, can be defined in the following way:

$$\begin{aligned} d(q, 0) &= 0 \\ d(q, t) &= \max(t - a, d(q, t - 1)) \\ &\text{where } a = \min_{p \in \text{depart}(q, t)} \text{arrival}(p, q) \end{aligned}$$

where $\text{depart}(q, t)$ is the set of packets that depart from queue q at time t , and $\text{arrival}(p, q)$ is packet p ’s arrival time into q . In defining metrics, one can use simple operations such as addition, subtraction, multiplication with a constant, and taking the maximum and minimum between values.

Queries. Queries are logical formulas over performance metrics. As shown in Figure 4, they ask questions about the values of metrics for one queue or a set of queues, or compare the values of metrics for two queues, over a certain period of time.

For instance, using the metric d defined above, we can ask if packets could face significant delay in queue Q with the following query: $\exists t \in [1, T] : d(Q, t) > D$. Moreover, as part of the query, users can specify base_wl , a workload (formally defined in Figure 4 and §5) that constrains the space of traces the user is interested in. That is, the final workload returned by the search algorithm should be a subset of base_wl . For instance, suppose we want to know, assuming a minimum input rate R for a queue Q , whether it will transmit fewer than K packets during T time steps. For that, we can use the following query:

$$\underbrace{\forall t \in [1, T] : \text{ceng}(Q, t) \geq R \cdot t}_{\text{base_wl}} \rightarrow \exists t \in [T, T] : \text{cdeq}(Q, t) < K$$

where $\text{ceng}(q, t)$ and $\text{cdeq}(q, t)$ track the total number of packets that have entered and exited q by end of t .

Similarly, we can investigate fairness between two queues by assuming minimum input rates for both in base_wl and comparing the number of packets they transmit:

$$\begin{aligned} \text{base_wl} &= \forall t \in [1, T] : \text{ceng}(Q_1, t) \geq R_1 \cdot t \\ &\quad \wedge \forall t \in [1, T] : \text{ceng}(Q_2, t) \geq R_2 \cdot t \\ \text{base_wl} &\rightarrow \exists t \in [T, T] : \text{cdeq}(Q_1, t) - \text{cdeq}(Q_2, t) \geq T/2 \end{aligned}$$

Thus, queries can ask about many performance metrics, including latency, throughput, fairness, and starvation.

5 The Workload Language

Workloads are also specified as logical formulas over a set of metrics. A workload is a set of constraints, each specifying the traffic pattern for a subset of queues over a period of time. Workloads only constrain *input queues*, i.e., queues that receive packets from “outside” as opposed to another queuing module. This can help users analyze how a contention point will perform under different classes of external traffic.

More formally, as shown in Figure 4, a workload wl is a conjunction of constraints (con). Each con is of the form

Algorithm 1: Workload synthesis search.

Input: User query (qry) from Figure 4.**Output:** Workload formula (wl) from Figure 4.

```
1 Procedure Search(qry)
2   if (not feasibleBaseWorkload(qry)) return BadQuery
3   wl = true; G = goodSet(qry); B = badSet(qry)
4   c1 = cost(wl, G, B)
5   while (true) do
6     (found, bad_trace) = verify(wl, qry)
7     if (found) break else B.insert(bad_trace)
8     op = randomOperation()
9     next_wl = wl.apply(op)
10    c2 = cost(next_wl, G, B)
11    if (c1 > c2) then wl = next_wl; c1 = c2
12    else if (e-λ·(c2-c1) > rand()) wl = next_wl; c1 = c2
13  shrink(wl); broaden(wl); return wl
```

$\forall t \in [T_1, T_2] : \text{lhs} \oplus \text{rhs}$, where T_1 and T_2 are integers denoting the interval of time over which con constrains the input traffic, lhs is either a metric for one queue, or the aggregate of a metric over a set of queues, and \oplus is a comparison operator ($>, \geq, <, \leq, =$) that shows how the lhs will be constrained by the rhs, which is time, or a constant.

Workloads can describe sets of traces in a concise and intuitive manner. Consider the single-constraint workload: $\forall t \in [1, 10] : \text{cenq}(Q_1, t) \geq t$. Any trace that satisfies this constraint, that is, sends at least t packets into Q_1 by time t and, as a result, does not leave the queue idle, is part of this workload. It does not matter if the traffic enters one packet at a time, or if 10 packets all come in at time step 1, or if 5 packets enter in the beginning, and 5 more at time step 5. That is, workloads can abstract away small details of packet traces as long as a higher-level property, as specified with a metric, is satisfied.

Workload metrics. The search algorithm explores the space of all workloads to find one that satisfies the query. When synthesizing candidate workloads, it decides how many constraints to include in the workload, and what metrics and queues to include in each constraint (§6).

While we leave the metrics that can be used in queries unconstrained, deciding the set of metrics that are used in synthesizing workloads requires careful consideration. We want the set to be small to keep the search space tractable but expressive to enable specifying common workloads in a concise and intuitive manner. We define our workloads over two metrics: (1) cumulative enqueues ($\text{cenq}(q, t)$), the total number of packets that enter q by the end of time step t , and (2) arrival inter-packet gap ($\text{aipg}(q, t)$), the inter-packet gap between the last two packets that enter q by time t .

While small, this is a quite expressive set. cenq constrains the total number of packets entering the queue, independent of the exact time they arrive. So, it can abstract away the timing details of traces when they are not important for the query. aipg , on the other hand, constrains the gap between packets and their arrival pace. So, it can capture low-level timing details if necessary in answering the query. Together, they create a good balance in capturing the commonalities

of traces that satisfy a query, abstracting away unnecessary details and including necessary ones.

Our experience in the case studies has shown that this set is capable of expressing a variety of workloads. But, we view this as a suitable starting point and not necessarily the final answer. We hope that as using formal methods, and specifically workload synthesis, for performance analysis evolves, the set of metrics will mature as well. In fact, our search algorithm is parametrized over the set of metrics and, if needed, any metric that can be encoded in SMT can be easily added to our search algorithm (see §8 for examples).

6 Synthesizing Answers

The search engine uses a guided randomized search over the space of workloads to find one that satisfies the query. The search algorithm (Algorithm 1) is based on the Metropolis Hastings Markov Chain Monte Carlo (MCMC) sampler, which combines random walks with hill climbing and has been successfully used for synthesizing optimized programs and loop invariants [20, 30, 35]. Starting from an initial workload $\text{wl} = \text{true}$ (line 3), which imposes no constraints on the input queues, the search algorithm asks the verification engine to verify the workload, i.e., check if all the traces in the workload satisfy the query (line 6). If yes, the search engine returns the workload as the answer to the query (line 7). If not, using the feedback from the verification engine, the search algorithm moves on to synthesize and try another candidate workload until a suitable workload is found (lines 8-12).

6.1 Verifying workloads

Given a workload wl , and a query $\text{base_wl} \rightarrow \text{qry}$, the verification engine uses an SMT solver [34] to check if the following formula is satisfiable

$$\text{model} \wedge \text{base_wl} \wedge \text{wl} \wedge \neg \text{qry}$$

where model is the logical encoding of the queueing modules the user is interested in (§3).

If the formula is satisfiable, there is at least one trace that is (1) valid, i.e., satisfies the constraints specified in model such as the maximum number of packets that are allowed to enter a queue between dequeues, (2) satisfies both base_wl (the space of traces in which user is interested (§4)) and wl , and (3) does not satisfy the query. This means that our current candidate workload, wl , is not a suitable answer to the query. So, this trace is returned to the search algorithm to guide the synthesis of the next candidate workload.

If the formula is not satisfiable, either (1) base_wl or wl or their combination with respect to model is *infeasible*, meaning that no valid trace can satisfy their constraints and they actually represent the empty set, or (2) there are no valid traces in $\text{base_wl} \wedge \text{wl}$ that do not satisfy the query. Only in the second case wl is a valid and non-trivial answer to the query.

To distinguish between these two cases, the search engine asks the verification engine if $\text{model} \wedge \text{base_wl}$ is satisfiable (line 2). If not, the set of valid traces specified by base_wl is

empty. So, the search engine does not start the search and notifies the user to modify `base_wl`. Moreover, when verifying a candidate workload `wl` (verify on line 6), the verification engine checks whether `model ∧ base_wl ∧ wl` is satisfiable. If not, the fact that `wl` is infeasible is also returned as feedback to guide the selection of the next candidate.

6.2 Generating the next candidate

If a candidate workload is not the final answer, the search algorithm synthesizes another workload to try. The next candidate workload, `next_wl`, is a mutation of the previous one, `wl`. Suppose the previous candidate is $wl = \bigwedge_{i=1}^k \text{con}_i$. The search algorithm chooses one of the following operations at random (line 8), and applies it to `wl` (line 9), to obtain `next_wl`:

- **Add** a new random constraint `con`, so $\text{next_wl} = \text{con} \wedge \text{wl}$.
- **Remove** a random constraint `conj` from `wl`. That is, $\text{next_wl} = (\bigwedge_{i=1}^{j-1} \text{con}_i) \wedge (\bigwedge_{i=j+1}^k \text{con}_i)$.
- **Modify** a random constraint `conj`. Suppose $\text{con}_j = \forall t \in [T_{1j}, T_{2j}] : \text{lhs}_j \oplus_j \text{rhs}_j$. The search algorithm randomly picks whether to change one of T_{1j} , T_{2j} , lhs_j , \oplus_j , or rhs_j to obtain `con'j`, so that $\text{next_wl} = (\bigwedge_{i=1}^{j-1} \text{con}_i) \wedge \text{con}'_j \wedge (\bigwedge_{i=j+1}^k \text{con}_i)$.

These operations are motivated by prior work that has empirically shown MCMC to work well with a mixture of major (add and remove) and minor (modify) changes to the current candidate to obtain the next one [30, 35].

Next, the search algorithm uses a cost function (§6.3) to decide whether it is “worth” transitioning to `next_wl` and try it out. If `next_wl` has a lower cost compared to `wl`, `next_wl` becomes the current candidate (line 11). If `next_wl` has a higher cost, to avoid getting stuck in local minima, the algorithm may still choose to make the transition with a probability proportional to the difference in `next_wl` and `wl`’s costs (line 12). The algorithm repeats this process until it finds the next candidate workload.

6.3 The Cost Function

Intuitively, a good cost function should (1) favor workloads when they include a large number of packet traces that satisfy the query, and (2) penalize those that include traces that do not satisfy the query. Inspired by prior work [30], we quantify these criteria into a cost function using *example traces*.

We create two sets of traces before starting the search (line 3): a set of *good* example traces (G), all of which satisfy the query, and a set of *bad* examples (B), none of which satisfy the query. Suppose $\text{match}(\text{wl}, E)$ is the number of traces in E that are also in `wl`. The cost function is then defined as:

$$\text{cost}_E(\text{wl}, G, B) = \text{match}(\text{wl}, B) - \text{match}(\text{wl}, G).$$

Recall that if a workload is feasible but does not satisfy the query, the verification engine returns a trace in that workload that does not satisfy the query as feedback. These traces are added to B as the search goes on, further refining the cost function (line 7).

In our experience, cost_E can effectively guide the search toward workloads that satisfy the query. But there could be multiple such workloads. So, we define another function $\text{cost}_S(\text{wl})$ that favors *concise* workloads, i.e., those with fewer constraints that constrain fewer queues over longer, less fragmented periods of time (details in Appendix B). We define our final cost function as $\text{cost}(\text{wl}) = C_E \cdot \text{cost}_E(\text{wl}) + C_S \cdot \text{cost}_S(\text{wl})$. We set $C_E > C_S$ so that in the beginning, the search algorithm probes the space of workloads for *any* answer that satisfies many good examples and no bad ones. Once the algorithm has reduced $\text{cost}_E(\text{wl})$ and is in the “right” part of the space, $\text{cost}_S(\text{wl})$ helps direct it towards a more concise answer.

Note that even if a workload matches some bad examples, it can still have a low cost and get selected as the next candidate. This is acceptable because the search algorithm may need to go through “obviously” bad workloads to explore different regions of the search space and find the answer. Also, example traces are used only to guide the search; each candidate workload is *verified* in the verification engine to ensure that every trace represented by the workload satisfies the query.

6.4 Generating The Example Sets

Before the search starts, the search engine asks the verification engine to generate traces for G and B. A trace *eg* is a 2D array that concretely specifies how many packets enter each queue at each time step. For example, if $\text{eg}[Q_1][5] = 3$, it means that in this trace, Q_1 receives 3 packets at time 5.

The bad examples set (B). The *i*th bad example is a trace that satisfies the following formula:

$$\text{model} \wedge \text{base_wl} \wedge \neg \text{qry} \wedge \neg (\bigvee_{j=1}^{i-1} \text{eg}_i \neq \text{eg}_j) \wedge \text{local_mods}_i.$$

Having $\neg (\bigvee_{j=1}^{i-1} \text{eg}_i \neq \text{eg}_j)$ ensures that the trace is different from the previous $i - 1$ traces. local_mods_i ensures that there is variety across the traces in B so that the search algorithm can prune the search space faster. For that, we pick P random points $(q_1, t_1), \dots, (q_P, t_P)$ in the $(i - 1)$ th trace and P random integers v_1, \dots, v_P such that $\text{eg}_{i-1}[q_j][t_j] \neq v_j$. Then, we define $\text{local_mods}_i = \bigwedge_{j=0}^P \text{eg}_i[q_j][t_j] = v_j$. This way, the *i*th trace is different from the previous one in at least P points. If no such trace could be found after two tries, we decrement P and retry until a new trace is found.

The good examples set (G). Generating G is more complicated. To see why, consider the diagram in Figure 5 and an arbitrary workload `ans` that satisfies the query. No matter how we choose B, `ans` cannot not include any of its traces. So, by minimizing $\text{match}(\text{wl}, B)$ in the cost function, the search algorithm is always moving in the direction of an answer. However, depending on how we pick G, `ans` may include all (`ans1` in Figure 5), a subset (`ans2`), or none (`ans3`) of G’s traces. There may not even exist a workload like `ans1` that can express all the traces in G without including any bad traces. So, if we do not pick G’s traces carefully, by maximizing $\text{match}(\text{wl}, G)$, the algorithm may repeatedly be directed towards a part of the search space where there are no suitable answers.

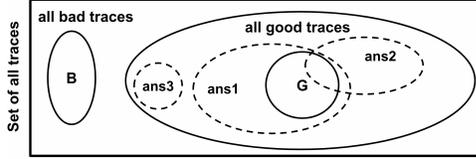

Figure 5: Relationship between answer workloads and G and B.

Intuitively, we want to pick traces for G that are (1) not radically different from each other, so that the majority of them can be represented with a single workload, and (2) not too similar, so that the workload found by the search algorithm is sufficiently general. To do so, the search engine asks the verification engine to create a *base* trace that it will use as the basis of generating the rest. Specifically, it asks for a trace eg_0 that satisfies $\text{model} \wedge \text{base_wl} \wedge \text{qry}$ while using Max-SMT to minimize the following criteria in the specified order:

1. **Total number of queues with traffic**, i.e., $\sum_q I_q$, where $I_q = 1$ if $\sum_t eg_0[q][t] = 0$, and is zero otherwise. This helps keep the search focused. To see why, suppose we find an eg_0 that satisfies the query and in which only Q_1 , Q_2 , and Q_3 have traffic. When generating the rest of G, we add constraints that make sure the queues that have no traffic in eg_0 stay empty in the rest of the traces as well. So if there is another set of traces with traffic in, say, Q_2 , Q_4 , and Q_5 , that satisfy the query, they will not be included in G, making sure G’s traces are not radically different from each other.
2. **Total number of time steps queues do not receive traffic**, i.e., $\sum_{q,t} I_{q,t}$, where $I_{q,t} = 1$ if $eg_0[q][t] = 0$ and is zero otherwise. This means that in the base trace, every queue receives at least one packet every time step as long as it is “harmless”, i.e., it does not stop the trace from satisfying the query. This smooth background traffic in the base trace can be randomly changed in the rest of the traces to ensure diversity in the good examples set.
3. **Total traffic in the trace**, i.e., $\sum_{q,t} eg_0[q][t]$. Given the above optimization criteria, this ensures that the background traffic is not flooding the contention point with too many packets and only allows more than one packet per time step in the base trace if necessary for satisfying the query.

The rest of G’s traces are generated from eg_0 . Similar to generating B, the search engine asks for a trace that satisfies the query, is not any of the previous traces, and is different from the previous trace in at least P random places. There are two differences: for the i th trace eg_i , we add extra constraints so that queues that have no traffic in eg_0 (see optimization criteria 1) have no traffic in eg_i either, and we minimize the “distance” between eg_i and eg_0 , i.e., minimize $\sum_{q,t} d_{q,t}$, where $d_{q,t} = 1$ if $eg_i[q][t] \neq eg_0[q][t]$ and zero otherwise.

6.5 Optimizations

We have employed several optimizations to improve the synthesis process and the final answer. We discuss some of the major ones here and the rest in Appendix C.

Reducing the search space. If a queue q has no traffic in

our base trace eg_0 (§6.4), it means that as long as the other “non-idle” queues have traffic, its traffic is either not important or has to be zero for satisfying the query. So, we temporarily add $\forall t \in [1, T] : \text{cenq}(q, t) = 0$ to base_wl and only look for workloads that constrain the rest of the queues during search. This reduces the space of workloads the search algorithm needs to explore. These constraints will be removed in post-processing if not necessary.

Post-processing. Once the search engine finds a workload wl that satisfies the query, it creates a new workload ans that includes all the constraints from wl and base_wl . It then performs “workload shrinking” (Algorithm 1, line 13) by removing the constraints in ans one at a time and checking if ans still satisfies the query. This helps remove any constraint that is added to base_wl during example generation or to wl during search but is not necessary for satisfying the query. Next, we try “workload broadening”. For a queue Q_i that is not in ans and a constraint con in ans , if con ’s left hand side is $m(Q_i, t)$, it is changed to $\sum_{q \in \{Q_i, Q_j\}} m(q, t)$, and if it is $\sum_{q \in S} m(q, t)$, it is changed to $\sum_{q \in S \cup \{Q_i\}} m(q, t)$. If the workload still satisfies the query, this helps include even more traces in the workload.

Reducing calls to the verification engine. Each call to the verification engine can be expensive as it checks the satisfiability of non-trivial formulas. So, if the search algorithm selects a candidate workload that matches a trace in B, it moves on to finding the next candidate without consulting with the verification engine, as it already knows that the current candidate includes a trace that does not satisfy the query.

Escaping local minima. To avoid getting stuck in local minima, the search algorithm keeps track of its progress, i.e., the difference between the cost of the previous candidate workload and the next one. If the progress is below a threshold for a number of rounds, it “looks ahead” a couple of hops when generating the next candidate by applying a sequence of moves in §6.2 to generate the next workload. If it still cannot make enough progress in another several rounds, it restarts the search from a workload with no constraints.

7 Case Study: Packet Scheduling

We have prototyped our techniques in a tool we call FPerf in $\sim 10K$ lines of C++ code, which is publicly available [41]. We use Z3 [34] in the verification engine for checking the satisfiability of SMT formulas. In this section, we describe our experience in using FPerf to analyze packet scheduling algorithms. Our goal is to explore *expressiveness*, i.e., whether our workload language can express a wide range of workloads in answering queries, *interpretability*, i.e., whether the final workloads are concise, intuitive, and interpretable, and *tractability*, i.e., whether workloads are generated in reasonable human timescales (i.e., minutes).

7.1 Stand-alone Schedulers

The priority scheduler is a single queuing module with four input queues and one output queue. Q_i has a higher prior-

ity than Q_j if $i < j$. Every time step, the scheduler picks the highest-priority non-empty input queue, dequeues a packet from it, and puts the packet in the output queue. In a strict priority scheduler, lower priority queues may get starved, which we quantify with the metric $blocked(q, t)$ defined as the number of consecutive time steps that q has packets but is not chosen for transmission. We then ask $\exists t \in [1, T] : blocked(Q_3, t) > 5$.

Starting from $T = 5$, we increment T until the verification engine finds a satisfying trace in the example generation phase at $T = 7$. Then, the search algorithm finds $\forall t \in [1, 7] : \sum_{q \in \{Q_1, Q_2\}} ceng(q, t) \geq t \wedge \forall t \in [1, 7] : ceng(Q_3, t) \geq 1$. That is, to satisfy the query, Q_1 and Q_2 , which have higher priorities than Q_3 , should collectively receive a consistent flow of traffic (constraint 1), and Q_3 should at least have one packet to be considered blocked (constraint 2). While the answer is not surprising, it demonstrates FPerf’s ability to abstract away the details of which higher priority queue receives packets at exactly what time step, only capturing the necessary details.

The round-robin scheduler is a single queuing module with five input queues and one output queue. The input queues are serviced in a round-robin fashion (independent of packet size, see §9). If every queue receives steady traffic over a time period T , each should be selected for dequeue at least $T/5$ times. So, when we ask if Q_3 can dequeue more packets than Q_2 with query $\forall t \in [10, 10] : cdeq(Q_3, t) - cdeq(Q_2, t) \geq 3$ and base workload $\bigwedge_{i=1}^5 \forall t \in [1, 10] : ceng(Q_i, t) \geq t$, the verification engine cannot find any traces that satisfy the query.

Now suppose we relax `base_wl` to restrict the average rate of traffic every 5 time steps as opposed to every time step, i.e., have the queues receive at least 4 packets every 5 time steps: $base_wl = (\bigwedge_{i=1}^5 \forall t \in [5, 5] : ceng(Q_i, t) \geq 4) \wedge (\bigwedge_{i=1}^5 \forall t \in [10, 10] : ceng(Q_i, t) \geq 8)$. FPerf finds $\forall t \in [1, 4] : \sum_{q \in \{Q_1, Q_2, Q_4, Q_5\}} ceng(q, t) \leq 0 \wedge \forall t \in [1, 4] : ceng(Q_3, t) \geq t \wedge base_wl$, which describes a workload where all queues except Q_3 receive no packets in the first four time steps and receive a burst of at least 4 packets at time 5, while Q_3 continuously receives traffic. So, while the average input rate of all queues is the same, other queues temporarily fall behind Q_3 in terms of dequeues due to the burstiness of their traffic.

FQ-Codel. This case study analyzes the buggy scheduler inspired from the FQ-Codel qdisc [32]. The scheduler’s logic, the query, and the workload are described in §2 as our motivating example. Here, we only report that the same workload was overwhelmingly returned as the answer across all runs.

7.2 Composing Host and NIC Schedulers

Modern NICs expose multiple transmit queues to the host, so that CPU cores can concurrently send traffic to the NIC, each through a dedicated transmit queue [42–44]. This provides significant performance benefits but makes it difficult to enforce policies about how applications on the same host should share network resources. Prior work [44] demonstrates this using an example, which we analyze in this case study.

Suppose two tenants reside on a server with multiple CPU

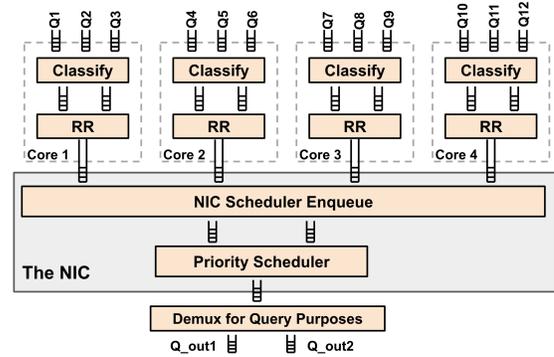

Figure 6: Setup for the case study in §7.2.

cores. Tenant 1 runs spark [45], and tenant 2 runs both spark and memcached [46]. All applications are multi-threaded and can use all the cores. We want to ensure that the two tenants fairly share the network bandwidth, and tenant 2’s memcached traffic is prioritized over its own spark traffic. One option, described in [44], is to use software packet schedulers (e.g., Linux qdiscs) to enforce fair sharing between the tenants on the host, and a priority scheduler on the NIC to enforce prioritization of memcached traffic. Note that to avoid overhead, software schedulers enforce policies per core not across cores.

Figure 6 shows how we model this in FPerf for 4 CPU cores. There is one input queue for traffic from each application on each core. That is, $Q_{3(i-1)+1}$, where i is the core number, are for tenant 1’s spark, $Q_{3(i-1)+2}$ for tenant 2’s spark, and Q_{3i} for tenant 2’s memcached traffic. For each core, a queuing module first classifies traffic from that core’s input queues into two output queues, one for each tenant. Then, a round-robin scheduler shares bandwidth between the two tenants into the NIC’s transmit queue. On the NIC, a module classifies traffic from the cores into two output queues, one for spark and one for memcached traffic. Finally, a priority scheduler that prioritizes memcached traffic decides what packet to send out of the NIC. We add a “dummy” module that takes the output from the NIC and “demultiplexes” it into Q_{out1} queue for tenant 1 and Q_{out2} for tenant 2 to use in our queries.

Since the final scheduler always prioritizes memcached traffic over spark, it is easy to see how the second half of the policy is always enforced. So, we ask whether tenant 1 and tenant 2 will get equal access to the NIC output link:

$$base_wl \rightarrow \forall t \in [10, 10] : cdeq(Q_{out2}, t) - cdeq(Q_{out1}, t) \geq 3$$

$$base_wl = (\forall t \in [1, 10] : \sum_{q \in S_{tenant1}} ceng(q, t) \geq t) \wedge$$

$$(\forall t \in [1, 10] : \sum_{q \in S_{tenant2}} ceng(q, t) \geq t)$$

$S_{tenant1}$ are $Q_{3(i-1)+1}$ ($1 \leq i \leq 4$), which carry tenant 1’s spark traffic, and the rest of the queues are in $S_{tenant2}$. That is, in `base_wl`, we ensure that both tenants receive a steady stream of packets. For this query, FPerf finds the workload

$$\forall t \in [1, 10] : ceng(Q_4, t) \geq t \wedge \forall t \in [1, 10] : ceng(Q_9, t) \geq t$$

$$\wedge (\bigwedge_{i \in S_{rest}} \forall t \in [1, 10] : ceng(Q_i, t) \leq 0),$$

where S_{rest} is $\{1, \dots, 3, 5, \dots, 8, 10, \dots, 12\}$. That is, if tenant 2’s memcached runs on core 3 and tenant 1’s spark on core 2, they

(a) Statistics from running FPerf 10 times for each case study. **Parameters:** Queue parameters are $S = 10$ and $K = 4$ packets. For example sets, $|G| = |B| = 50$, and $P = \min(10, \frac{\text{trace_size}}{5})$. During search, the maximum number of constraints in the workload is set to twice the number of input queues, threshold for slow progress is $0.03 \cdot \max(\text{cost}_E, \frac{C_E}{C_S} = 10)$, and number of rounds of slow progress tolerated before look-ahead and restart is 10 and 20 respectively.

Figure 7: Case study statistics and results (§7 and §8).

will only compete in the priority scheduler in the NIC, where memcached traffic is prioritized over spark traffic, and tenant 2 is favored to access the link. The same phenomena can happen as long as tenant 2's memcached traffic and tenant 1's spark traffic come from two different cores.

Next, we modify the base workload to see if the problem still exists if there is no memcached traffic. We add $\bigwedge_{i \in \{3,6,9\}} \text{cenq}(Q_i, t) = 0$ to the base workload and repeat the query. This time, we get the following workload as answer:

$$\begin{aligned} & \forall t \in [1, 10] : \text{cenq}(Q_8, t) \geq t \wedge \forall t \in [1, 10] : \text{cenq}(Q_{11}, t) \geq t \\ & \wedge \forall t \in [1, 10] : \sum_{q \in \{Q_2, Q_5\}} \text{cenq}(q, t) \geq t \\ & \wedge \forall t \in [1, 10] : \text{cenq}(Q_{10}, t) \geq t \\ & \wedge (\bigwedge_{i \in \text{rest}} \forall t \in [1, 10] : \text{cenq}(Q_i, t) \leq 0). \end{aligned}$$

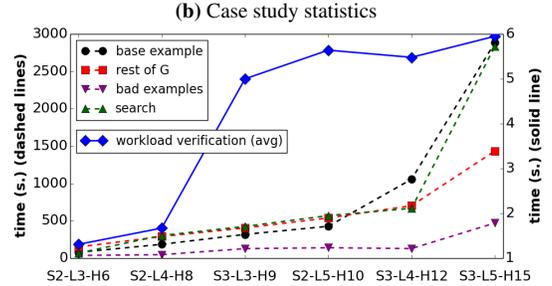

where $\text{rest} = \{1, 3, 4, 6, 7, 9, 12\}$. Here tenant 2's spark runs on all cores and tenant 1's spark only on core 4. The first three constraints ensure that there are three different concurrent streams of traffic from tenant 2's spark. Since there is only one stream of spark traffic for tenant 1, that is, because the spark flows are not uniformly spread across cores, tenant 1 gets access to the link less frequently than tenant 2. Both workloads are consistent with the empirical results in [44].

7.3 Tractability

Tables 7a and 7b summarize statistic about different phases involved in workload synthesis for the packet scheduling case studies across 10 runs. We use a server with 4-socket NUMA-enabled Intel Xeon Gold 6128 3.4GHz CPU with 6 cores per socket. For Comp, we only include the results for the second query as, compared to the first query, its analysis is more involved in all synthesis phases.

Generating G is expensive. This is not surprising: when generating trace eg_i , we constrain it to have different randomly

(c) Workload synthesis statistics for the latency query on leaf-spine networks of increasing size. $S_i-L_j-H_k$ has i spines, j leaves, and k hosts per leaf to avoid oversubscription ($k = i \times j$). Parameters are same as figure 7a except $|G| = |B| = 25$ (see §9).

chosen values from eg_{i-1} in $p = P$ random places. If no trace is found in two tries, we decrement p and try again. Each time, we also ask the verification engine to minimize the distance between eg_i and the base trace (§6.4). The more such calls, either due to the sheer size of G , or because we have to retry a lot for each trace, the longer generating G will take.

Compared to Prio and Comp, it takes more tries to find a trace for RR and FQ-Codel (average of 16 and 6 tries, respectively). This is because the answers to their queries are more sensitive to the timing of packets in the trace: RR needs a specific kind of burstiness and FQ-CoDel needs a specific rate. So, making p random modifications to eg_{i-1} for larger values of p makes it improbable to satisfy the query for eg_i , increasing the number of retries. By default, $P = \min(10, \frac{\text{trace_size}}{5})$, which is 10 for RR and FQ-CoDel, translating to a maximum of 20 tries per example trace. Instead, we can potentially set P to the moving average of the p that has worked for the previous traces and reduce the number of retries, and consequently, the total time for generating G .

Another option is to reduce $|G|$, potentially increasing search time as shown in Figure 10 (Appendix). For all but FQ-Codel, the decrease in example generation time outweighs the increase in search time, and workload synthesis is fastest for $|G| = 25$. For FQ-CoDel the sweetspot is $|G| = 50$. One could execute workload synthesis in parallel for different values of $|G|$ and use the results from whichever finishes first. Moreover, once we have the base trace ego , we can potentially parallelize the generation of G into x threads, each generating $\frac{|G|}{x}$ traces. Our randomized changes from one trace to the next reduces the risk of getting duplicate traces across threads, and even if there are a few, it will not affect the correctness of the search. **The verification engine is efficient.** The verification engine can verify a workload in $< 1\text{sec}$ on average. The worst case

is $\sim 10sec.$ for Comp, and $< 1sec.$ in other case studies. The efficiency of the verification engine is thanks to the advances in SMT solvers [34], our efficient encoding of queues (Appendix), and our choice to use immediate composition.

In *immediate* composition, packets leaving output queues at time t are visible in the input queues of the next module at time t , as opposed to $t + 1$ in sequential composition (§3). So, if we have a chain of L queuing modules, a packet arriving at time t is processed by all the queuing modules one-by-one but in the same time step and appears in the final output queue at $t + 1$, as opposed to $t + 1 + L$. In Comp, all the paths from input to output queues through the queuing modules have the same length. So, if we use immediate composition across *all* modules, it will not change the relative ordering of packets across queuing modules and allows us to analyze the model in 10 as opposed to 15 time steps and get the same output.

Optimizations (§6.5) are effective. For instance, when a candidate workload matches one of the bad example traces, we can move on to the next candidate without calling the verification engine. Using this optimization, we avoided calling the verification engine in ~ 40 to 70% of the rounds, which translates to saving ~ 113 and 192 seconds in FQ-CoDel and Comp that are more complex. Moreover, The “look-ahead” strategy is used in 5% of the rounds, helping the search algorithm to avoid local minima and plateaus.

8 Case Study: A Small Leaf-Spine Network

In this section, we use FPerf to analyze a small leaf-spine network (Figure 8). Our goal is to demonstrate the expressiveness of our model and the generality of our techniques.

Modeling switches. We model our switches after input-queued switches with virtual output queues (VOQs). Suppose the switch has P ports. Each input port i has P VOQs, where the j th VOQ stores packets that are destined for output port j . The switch crossbar decides which input ports can simultaneously send packets to which output ports without interfering with each other, and delivers packets from the corresponding VOQs at those input ports to their destination output ports.

Figure 9 shows how we model this in FPerf. A switch with P ports is a composition of $P + 1$ queuing modules. There are P forwarding modules, one for each input port. The i th forwarding module takes a packet from input port i , decides the destination port j it should be forwarded to, and places the packet in the j th VOQ for port i . The crossbar queuing module models the switch crossbar. In each time step, using the iSlip algorithm [47], it matches input ports and output ports such that each input port is matched with at most one output port and vice versa. If an input port i is matched with an output port j , the crossbar moves a packet from the j th VOQ at port i to the output queue for port j . iSlip and its variants are widely used in switching fabrics as they provide high throughput in the crossbar and fairness across inputs.

Packet metadata and workload metrics. The per-packet metadata variables include dst , a variable representing the fi-

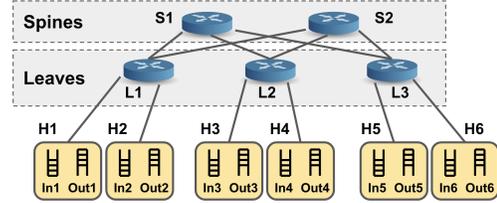

Figure 8: A small leaf-spine network as case study (§8).

nal destination of the packet, and $ecmp$, a variable with values in $[0, S]$ where S is the number of spine switches, representing the result of the ECMP hash of the packet’s flow id modulo the number of spines. We extend example traces and our algorithms for generating them (§6.4) to include packet metadata (details are in Appendix D.1). Moreover, we add two corresponding metrics, $dst(q, t)$ and $ecmp(q, t)$, to our workload language to track the values of these variables for packets entering q at time t . These metrics, together with $cenq(q, t)$ and $aipg(q, t)$, can be used in the synthesized workloads to describe a range of traffic patterns and flows.

User Interface. To create a model of a network of switches, the users need to specify the topology (switches and links) and the forwarding rules (mapping per-packet metadata to an output port) for each switch. For a leaf-spine network, FPerf provides a special interface that only requires specifying the number of leaves and spines. For the base workload, the users can provide a list of constraints using an interface that abstracts away the logical operators and expressions in Figure 4. Each constraint is either (1) $[t1, t2] q.m \oplus c$, constraining metric m for queue q against a constant (\oplus is any comparison operator), (2) $[t1, t2] (q1.m + \dots + qn.m) \oplus c$, (3) $[t1, t2] q1.m \oplus q2.m$, or (4) $[t1, t2] (q1.m + \dots + qn.m)/t \oplus c$, constraining a metric’s value for one or more queues over time. Queues are identified by switch id and port number.

For queries, the users provide a list of questions with a similar interface, asking if the value of a metric over a time period for one or more queues can go above or below a threshold. There are two special shorthands for common queries: $q.avg_rate$ is the average input rate for queue q , which translates to $q.cenq/t$, and $lat(s1, \dots, sn)$ is the latency through the specified sequence of switches, which translates to sum of queue sizes ($q1.qsize + \dots + qn.qsize$) along the path. Appendix D.2 includes more details on the translation between this interface and the syntax in Figure 4.

The throughput query (LS-T). Since there is no oversubscription in our leaf-spine network, we first ask whether the throughput between hosts 1 and 6 can drop below line-rate:

$$\begin{aligned} \text{base_wl} &\rightarrow \forall t \in [10, 10] : cenq(Out_6, t) < 5 \\ \text{base_wl} &= (\forall t \in [1, 10] : dst(In_1, t) = 6) \wedge \\ &(\wedge_{i,j \in [1,6], i \neq j} \forall t \in [1, 10] : dst(In_i, t) \neq dst(In_j, t)) \end{aligned}$$

In_i and Out_i are the queues host i uses to send traffic into and receive traffic from the network, respectively. The query asks whether the total number of packets received by host i at time 10 is less than half of what it should have received at line rate. The base workload ensures that host 1 sends a steady stream

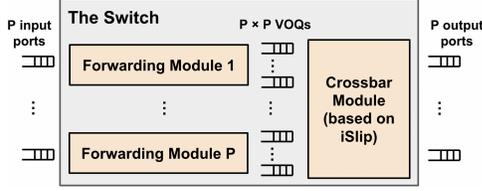

Figure 9: Modeling an input-queued switch with VOQs in FPerf.

of traffic to host 6 (at least 1 packet per time step), and no two hosts send traffic to the same destination so there is no traffic concentration at the hosts. For this query, FPerf finds the following workload:

$$\begin{aligned} \forall t \in [1, 10] : dst(In_3, t) \geq 5 \wedge \forall t \in [1, 7] : ecmp(In_1, t) = 1 \\ \wedge \forall t \in [1, 7] : ecmp(In_3, t) = 1 \wedge \forall t \in [1, 10] : cenq(In_4, t) \leq 0. \end{aligned}$$

That is, if there is another flow from host 3 to the third pod (constraint 1) with the same *ecmp* as the flow from host 1 to 6 (constraints 2 and 3), the two flows have to compete for bandwidth on the link from S_1 to L_3 (Figure 8) and host 6 will not receive traffic from host 1 at line rate. The last constraint ensures that the flow from host 3 has all the bandwidth from the second pod to itself to compete with the flow from host 1.

The latency query (LS-L). In the absence of queuing delay, it takes packets three time steps to go from a host in one pod to a host in a different pod. We want to know if it can take much longer, say, 13 time steps, for packets to go from host 1 to 6. To do so, we ask if it is possible to have a queue build up of at least 10 packets along the path of the flow:

$$\begin{aligned} base_wl \rightarrow \forall t \in [10, 10] : \Sigma_{q \in path} qsize(q, t) \geq 10 \\ base_wl = (\forall t \in [1, 10] : dst(In_1, t) = 6) \wedge \\ (\forall t \in [1, 10] : ecmp(In_1, t) = 1) \wedge (\forall t \in [1, 10] : cenq(In_1, t) \leq t) \end{aligned}$$

Here, the base workload ensures there is a flow from host 1 to 6 (constraints 1 and 2), and that the flow sends at most at line rate (constraint 3), so that there is no artificial queue build up from the flow’s own packets. *path* is the set of queues the flow visits as it traverses L_1 , S_1 (since in *base_wl*, $ecmp(In_t, t) = 1$), and L_3 (see Figure 8).

For this query, FPerf finds the following workload:

$$\begin{aligned} \forall t \in [1, 8] : dst(In_3, t) = 6 \wedge \forall t \in [1, 8] : ecmp(In_3, t) = 1 \\ \wedge \forall t \in [1, 10] : ecmp(In_5, t) = 6 \wedge \forall t \in [1, 10] : cenq(In_4, t) \leq 0. \end{aligned}$$

That is, if hosts 3 and 5 (from pods 2 and 3) send traffic to host 6 at the same time (constraints 1 to 3), there will be a queue build up of at least 10 packets along the path of the flow and its packets will experience high latency. Similar to the throughput query, the last constraint ensures that the flow from host 3 has all the bandwidth from the second pod to itself to contribute to quickly building up the queues.

Tractability. Tables 7b and 7a summarize statistics about different phases of workload synthesis for the queries about the leaf-spine network. The results are consistent with our observations in §7.3. Generating the good example set is expensive but there are opportunities for parallelization and further optimizations. The verification engine is efficient, verifying

workloads in $< 1.7sec.$ on average and $\sim 4sec.$ in the worst case. Beyond what is described in §7.3, we employ other optimizations that contribute to this efficiency. Specifically, we use the forwarding rules in the leaf-spine topology to (1) remove certain VOQs from the switch crossbar if their corresponding input and output ports are not expected to communicate (e.g., a packet entering a leaf from a spine is expected to go to one of the output ports connected to the hosts and not other spines), and (2) constrain the values of the per-packet metadata to reduce the search space (e.g., all packets going into S_1 have *ecmp* set to 1). Finally, our search optimizations remain effective, avoiding calls to the verification engine in ~ 55 to 89% of the rounds, and the example traces effectively guide the search towards workloads that satisfy the query.

Takeaways. Queuing modules and their composition are expressive enough to model a variety of network components, from packet schedulers and classifiers to a network of switches. We did not need to make any changes to how we model contention points (§3) to model the leaf-spine network. Similarly, our workload synthesis techniques generalize beyond packet scheduling. Our example generation strategy and workload metrics need only minor changes to include the packet metadata needed for forwarding over the network, and our search algorithm can find workloads for the queries as effectively without any modifications.

9 Discussion and Future Directions

Scaling to large networks. Figure 7c shows how example generation, search, and workload verification times increase for the latency query on leaf-spine networks of increasing size. As the network size increases, the number of variables and constraints go from 45k and 46k to 182k and 181k, and automated theorem provers (e.g., Max-SMT and SMT solvers) which we use in example generation and workload verification, can take exponentially longer as the problem size increases. For our largest evaluated network (not shown in the figure) with 4 spines, 4 leaves, and 16 servers (56 modules and 288 queues), it takes 224 minutes to find an answer.

There is room for more optimizations, some of which we have implemented for this experiment and discuss in Appendix D.3. But, as with any other approach that relies on similar formal methods tools, there is a limit to how many variables and constraints we can jointly reason about within a reasonable amount of time. As such, similar to data and control-plane verification tools that have matured over a decade to scale to large-scale networks, much work needs to be done to improve the scalability of formal methods tools for network performance analysis.

For example, we may need to develop new techniques, e.g., domain-specific algorithms for reasoning about network properties to replace SAT/SMT solvers [12, 48] or decompose global properties into local properties for modular analysis [15, 31]. Specifically, given that performance queries and properties such as latency lend themselves well to decomposi-

tion over regions and paths, we believe modular analysis to be key in scaling automated formal reasoning about performance and an important direction for future work.

Bounded Time. We model queuing modules for a bounded number of time steps, starting with empty queues and every module in its initial state. Nevertheless, the workloads in our case studies often include “repeatable” patterns. For instance, in FQ-CoDel, Q_5 can continue causing fairness problems after 14 timesteps if it keeps sending at the rate specified in the workload. Prior work explores how to find periodic adversarial input patterns for P4 programs [49], and it would be interesting to explore similar ideas in our context. Moreover, to cover different portions of the time horizon, we can explore ways to compute a subset set of reachable states in queuing modules and start from those as opposed to the initial state. Finally, exploring verification techniques for reasoning about unbounded time [50] is an interesting avenue for future work.

Packets vs. bits. In our prototype, metrics, and therefore, queries and workloads, are defined in terms of packets rather than bits. We plan to extend FPerf to include packet sizes as extra variables, so they can be used in defining metrics and potentially reveal even more interesting workloads.

Generating traces from workloads. We can use the verification engine to generate example traces from the final workloads. Transforming these traces or the traces in G to concrete packets that can be injected into real-world networks (e.g., see Adapters in [37]) is an interesting future direction.

10 Related Work

Network Calculus. Network Calculus [6, 51] offers a uniform mathematical framework for analyzing performance guarantees. To use network calculus, one needs to model the input workload as an “arrival curve”, which bounds the arrival pattern of bits into a network component, and the network component as a “service curve”, which bounds the number of serviced bits. Using these curves and $(\min, +)$ algebra, one can then derive bounds on performance metrics such as throughput, latency, jitter, and loss [4, 52–54]. However, these curves need to be reasonably concise and provide tight bounds on the behavior of the network component and the input traffic pattern for the final bounds to be tight and useful. Deriving arrival and service curves is challenging, particularly for today’s complex network functionality and traffic patterns [10].

Quantitative Reasoning. There is a line of work for reasoning about quantitative network properties: Some extend dataplane verifiers to reason about quantities such as link loads and hop counts [55–57]. Others reason about probabilistic aspects of networks (e.g., weighted ECMP) and answer probabilistic questions (e.g., the probability that packets reach a destination) [58, 59]. Our work is similar in that performance properties are quantitative. However, these tools focus on *verification*, whereas, we propose to use *synthesis* to automatically generate not just one counter-example, but a workload that violates user-defined performance-related properties. Moreover,

these tools abstract away many low level network details as nondeterministic, which we are able to model more precisely in SMT in our queuing modules.

Automated protocol analysis. Recent work uses techniques such as bounded model checking and guided search to check if congestion control algorithms can be driven into undesirable states or underutilize the network [60–62]. Khan et al. propose to train Markov models that capture the temporal behavior and throughput and delay distributions of delay-based congestion control protocols [63]. Gilad et al. use reinforcement learning (RL) to train agents that generate adversarial traces for protocols and use it to demonstrate sub-optimal performance in some RL-driven protocols [64]. We propose generating workloads describing sets of traces in response to user-defined queries about performance problems.

Synthesis. Syntax-Guided Synthesis (SyGuS) is a general approach to program synthesis that uses a verifier together with a candidate program grammar. There are various ways to do SyGuS; there are enumerative [65, 66], stochastic [20, 30, 35], and logical approaches [67]. Our work is based on stochastic search. Moreover, recent work explores using synthesis in networking to generate packet processing code [19, 20], network configuration [21–23], configuration updates [24], or control-plane repairs [25, 26]. We use synthesis to generate workloads to reason about network performance.

11 Conclusion

Over the past decade, a large body of academic and industry work has demonstrated the feasibility and benefits of using formal methods to reason about the functional correctness of networks. Inspired by their success, we set out to bring the same benefits to analyzing network performance.

Along the way, we have developed efficient encodings of packet-level interactions that affect network performance. We have also found that when it comes to performance analysis, returning isolated packet traces that violate performance properties is not always useful. Instead, we argue that a more useful output is a workload that can concisely describe the commonality of a set of traces that can experience performance problems. We have shown how to apply existing synthesis techniques to generating such workloads and demonstrated the tractability of our approach using case studies.

This is only the start; as with other applications of formal methods to systems and networking, much work needs to be done to make such formal performance analysis approaches suitable for analyzing real-world networks, some of which we have outlined in this paper as future research directions.

A Efficient Encoding of FIFOs in SMT

A queue is specified with two parameters, its size S and the maximum number of enqueues K allowed at every time step. We define the following variables for each queue for every time step t :

1. $enqs[t][1 : K]$ consists of K tuples, where each tuple represents a packet. This captures the packets that are sent to the queue at time t . These packets will enter that queue at time $t + 1$,
2. $elems[t][1 : S]$, consists of S tuples, where each tuple represents a packet. This captures the packets that are inside the queue at time t , and
3. an integer variable $deq_cnt[t]$ that captures how many packets will be dequeued from this queue at time t .

We also define a set of helper boolean variables $val_elem[t][i]$. $val_elem[t][i]$ is true if there is a packet in $elems[t][1 : S]$ and is false if $elems[t][i]$ is empty. $val_enq[t][1 : K]$ is defined similarly.

Our queues can have up to K enqueues and up to S dequeues in every time step. To model that, we take care of the dequeues first. We define an extra set of helper variables $tmp_val[t][1 : S]$ to denote which indexes in the queue would still have packets and which ones would become empty at $t + 1$ if we were to only do $deq_cnt(t)$ number of dequeues and not any enqueues. Specifically, $tmp_val[t][i]$ is true if the i th element of the queue will still contain a packet after the dequeues in that time step assuming no enqueues happen.

To capture that, for every $1 \leq i \leq S$ and $1 \leq d \leq S$, if $i + d \leq S$, we add

$$(deq_cnt[t] = d) \rightarrow (tmp_valid[t][i] = val_elem[t][i + d])$$

Otherwise, we add

$$(deq_cnt[t] = d) \rightarrow (\neg tmp_val[t][i]).$$

We also have some standard constraints to shift the packets in $elem$ forward depending on the $deq_cnt(t)$.

The next set of constraints handle the enqueues in a “sliding window” fashion. That is, starting from the head of the queue, we consider all possible $K + 1$ consecutive positions in the queue to find a window where the first element has a packet and the next K are empty. This will be the tail of the queue and where we will be enqueueing the new packets.

Specifically, for every $1 \leq i \leq S - K$ and $1 \leq j \leq K$, we add the following constraint:

$$tmp_val[t][i] \wedge \neg tmp_val[t][i + 1] \rightarrow elem[t][i + j] = enqs[t - 1][j]$$

We add extra constraints for the start and end of the queue and when there is not enough space for K packets.

Finally, we add constraints to make sure there is no “hole” in the queue. That is, suppose the queue has a packet at index i and no packets at index $i + 1$. Then, there is a packet at any index $j \leq i$ queue. Moreover, at any index $j > i$, the queue is empty. Specifically, for every $1 \leq i < S$, we add:

$$val_elem[t][i] \vee \neg val_elem[t][i]$$

B Definition of costs

Consider a workload $wl = \bigwedge_{i=1}^k con_i$, where $con_i = \forall t \in [T_{1_i}, T_{2_i}] : lhs_i \oplus_i rhs_i$. $cost_S(wl)$ is defined in the following way:

$$cost_S(wl) = \sum_{i=1}^k queue_cnt(spec_i) + interval_cnt(wl)$$

where $queue_cnt(spec_i)$ is the number of queues constrained by con_i , which is equal to the number of queues specified in lhs_i . $interval_cnt(wl)$ captures the degree of time fragmentation in the workload and is defined as the number of non-overlapping time intervals with unique sets of constraints.

As an example, suppose wl has three constraints, $\forall t \in [1, 15] : cenq(Q1, t) \geq 2$, $\forall t \in [3, 7] : cenq(Q2, t) \leq 5$, and $\forall t \in [5, 10] : aipg(Q5, t) = 3$. These three constraints are specifying a traffic pattern over five non-overlapping time intervals $([1, 2], [3, 4], [5, 7], [8, 10], [11, 15])$ each with a unique set of constraints. So, $interval_cnt$ is equal to five in this example. We favor workloads that cause less time fragmentation as they are less likely to overfit to the example sets, more concise, and more interpretable.

C Details on Search Engine Optimizations

Reducing the search space. We have described one of our optimizations to reduce the search space in §6.5. Another optimization is detecting and ignoring “duplicate” workloads. Our workload language allows for easy mutation of workloads with simple operations during search to generate new candidates. So, it is possible for a workload’s mutation to represent the same set of traces while being syntactically different. We perform several checks to detect such workloads and avoid generating them as candidates, reducing the space of workloads the search algorithm needs to explore.

Reducing calls to the verification engine. As we describe in §6.5, if the search algorithm selects a candidate workload that matches a trace in B , it can move on to finding the next candidate without consulting with the verification engine, as it already knows that the current candidate includes a trace that does not satisfy the query. Note that the search algorithm selects these candidates despite that fact that they match traces in B as they could help it explore different regions of the search space. Similarly, if a workload is rejected because it is infeasible (§6.1), the search engine will keep track of it and avoid a potentially expensive call to the verification engine if that workload comes up in the future.

Other optimizations. Instead of only applying one of the operations in §6.2 and generating one candidate workload, we apply all of them one at a time, generate a set of candidates, and pick one randomly from the ones with the lowest cost. This helps the algorithm explore the lower-cost regions of the search space earlier. Moreover, we introduce a new operation, *replace*, which replaces a randomly-chosen constraint in the workload with a new random constraint. *Replace* is equivalent to a *remove* followed by an *add*, but it helps the algorithm to generate a more diverse set of candidates faster. Finally,

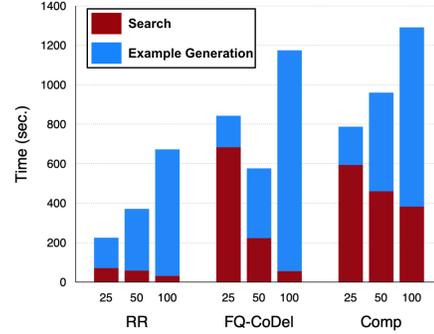

Figure 10: Search and example generations times for $|G| = |B| = 25, 50, \text{ and } 100$. Prio results are not shown as the total time was less than 20s for Prio and would not be visible in the plot.

if the search algorithm selects a candidate workload that is infeasible, adding or modifying constraints in the workload to generate the next one are likely to yield another infeasible candidate. So, the algorithm backtracks to the last known feasible candidate and continues from that point.

D More Details on the Leaf-Spine Case Study

D.1 Introducing New Packet Metadata

In the leaf-spine case study §8, packets have two metadata variables: *dst*, representing the final destination of the packet, and *ecmp*, with values in $[0, S]$ where S is the number of spines switches, representing the result of the ECMP hash of the packet’s flow id modulo the number of spines.

We define the metrics $dst(q, t)$ as the destination of packets that enter q at time t and $ecmp(q, t)$ as the ECMP hash modulo number of spines for those packets. So, our workloads describe traffic patterns in which packets entering a queue at the same time have the same *dst* and *ecmp*.

For generating the base example, we add another optimization criteria, to maximize the “smoothness” of flows. That is, for the traffic entering from the hosts, the trace should not introduce new flows or go back and forth between flows with different *dst* and *ecmp* if not needed for satisfying the query. When generating the rest of the good examples, we maintain the same “smoothness” criteria, and when minimizing the distance between eg_0 and eg_i , we include the difference in per-packet metadata in the computing the distance.

D.2 From User Interface to Logical Formulas

In the user interface described in §8, for the base workload, the users can provide a list of constraints using an interface that abstracts away the logical operators and expressions in Figure 4. Here, we describe how these constraints are translated to the logical formulas in Figure 4.

- $[t_1, t_2] q.m \oplus c$ becomes $\forall t \in [t_1, t_2] : m(q, t) \oplus c$.
- $[t_1, t_2] (q_1.m + \dots + q_n.m) \oplus c$ becomes $\forall t \in [t_1, t_2] : \sum_{q \in \{q_1, \dots, q_n\}} m(q, t) \oplus c$.
- $[t_1, t_2] q_1.m \oplus q_2.m$ becomes $\forall t \in [t_1, t_2] : m(q_1, t) \oplus m(q_2, t)$

- $[t_1, t_2] (q_1.m + \dots + q_n.m)/t \oplus c$ becomes $\forall t \in [t_1, t_2] : \sum_{q \in \{q_1, \dots, q_m\}} m(q, t) \oplus c \cdot t$

For queries, the users provide a list of questions with a similar interface, asking if the value of a metric over a time period for one or more queues can go above or below a threshold. A single question $[t_1, t_2] lhs \oplus rhs$ becomes $\exists t \in [t_1, t_2] : \text{trans}(qlhs \oplus rhs)$, where $\text{trans}(qlhs \oplus rhs)$ is the translation of the left hand side similar to what is described above. A list of questions will translate to the conjunction of their equivalent logical formulas. Note that queries in the form of $\forall t \in [t_1, t_2] lhs \oplus rhs$ are still possible in the user interface by creating a separate question for each time step between t_1 and t_2 . It is also possible to extend the user interface to directly specify \forall queries.

D.3 Example Generation Optimizations

For our scalability experiments in Figure 7c, we started with the default $|G| = |B| = 50$. However, example generation is expensive, and automated theorem provers (e.g., Max-SMT and SMT solvers) which we use in example generation and workload verification, can take exponentially longer as the problem size increases. So, to be able to observe the trends for larger networks, we used $|G| = |B| = 25$

We also employed extra optimizations when generating G . Recall that when generating the base example, we minimize the number of queues that have traffic in them. If a queue does not receive any traffic in the base example trace eg_0 , it will stay empty in the rest of the traces in G . So, once eg_0 is generated, we create a “reduced” model in which remove the input queues that are marked as empty in eg_0 as they would be empty in the rest of the examples anyway. This helps reduce the number of variables and constraints, specifically in the crossbar modules of the leaf switches.

Moreover, recall that when generating trace eg_i , we constrain it to have different randomly chosen values from eg_{i-1} in $p = P$ random places. If no trace is found in two tries, we decrement p and try again. Instead of fixing the starting point to $p = P$, we set it to the moving average of the p s the worked when generating the last K examples.

Flattened Clos: Designing High-performance Deadlock-free Expander Data Center Networks Using Graph Contraction

Shizhen Zhao^{1,*}, Qizhou Zhang^{1,*}, Peirui Cao¹, Xiao Zhang¹, Xinbing Wang¹, Chenghu Zhou^{1,2}
¹Shanghai Jiao Tong University, ²Chinese Academy of Sciences

Abstract

Clos networks have witnessed the successful deployment of RoCE in production data centers. However, as DCN bandwidth keeps increasing, building Clos networks is becoming cost-prohibitive and thus the more cost-efficient expander graph has received much attention in recent literature. Unfortunately, the existing expander graphs' topology and routing designs may contain Cyclic Buffer Dependency (CBD) and incur deadlocks in PFC-enabled RoCE networks.

We propose Flattened Clos (FC), a topology/routing co-designed approach, to eliminate the PFC-induced deadlocks in expander networks. FC's topology and routing are designed in three steps: 1) logically divide each ToR switch into k virtual layers and establish connections only between adjacent virtual layers; 2) generate *virtual up-down* paths for routing; 3) flatten the virtual multi-layered network and the virtual up-down paths using graph contraction. We rigorously prove that FC's design is deadlock-free and validate this property using a real testbed and packet-level simulation. Compared to expander graphs with the edge-disjoint-spanning-tree (EDST) based routing (a state-of-art CBD-free routing algorithm for expander graphs), FC reduces the average hop count by at least 50% and improves network throughput by $2 - 10\times$ or more. Compared to Clos networks with up-down routing, FC increases network throughput by $1.1 - 2\times$ under all-to-all and uniform random traffic patterns.

1 Introduction

Driven by the need of low latency, high throughput and low CPU overhead, large Internet service providers such as Microsoft and Alibaba have deployed RDMA over Commodity Ethernet (RoCE) [14, 20] in their Clos data centers. RoCE requires a lossless network for optimal performance. To avoid packet loss in Ethernet, Priority-based Flow Control (PFC) is usually enabled to perform a hop-by-hop flow control to avoid exhausting switch buffers by upstreaming flows. However,

enabling PFC introduces the risk of deadlocks, especially for the large-scale deployment of RoCEv2. Thanks to the layered structure of Clos data centers, the up-down routing in Clos networks can prevent deadlocks with proper safety mechanisms under normal operations [20] and failure scenarios [24].

However, as the data center traffic and the network bandwidth keep increasing, building Clos topologies is becoming cost-prohibitive [4]. In order to reduce the network cost, flatter expander graphs, such as Jellyfish [46], SlimFly [5], Xpander [50], FatClique [54], etc., have been proposed to build data centers. A recent study [36] shows that a full throughput expander uses 25% fewer switches than a full throughput Clos. Note that the throughput values of expander graphs are attained using a multi-commodity flow formulation based on the K-Shortest Path (KSP) routing [53]. Unfortunately, the KSP routing in expander graphs may contain Cyclic Buffer Dependency (CBD), and thus could incur severe PFC deadlocks. Therefore, the performance-gain or cost-reduction of expander graphs over Clos becomes questionable for RoCEv2 traffic.

The key to supporting RoCE in expander graphs is to eliminate CBD. Approaches to eliminate CBD can be generally grouped into three classes. The first approach is to assign different lossless priorities for packets at different hops [12, 15, 27]. This approach has been widely adopted in HPCs, in which the underlying Infiniband network supports 15 lossless priorities (*a.k.a.* Virtual Channel). However, due to the limited switch buffer space, data center switches can support at most two or three lossless priorities [20]. The second approach is to disable PFC and redesign RoCE to work with lossy networks, e.g., NDP [21], IRN [35], FatPaths [6], etc. However, lossy RoCE requires hardware support. For example, Mellanox ConnectX-4 onwards NICs support lossy RoCE, but Mellanox ConnectX-3 NICs do not. In addition, lossy RoCE may incur higher latency for mice flows, especially when a sender has to rely on a timeout to retransmit a lost packet. iWarp [41] is another RDMA technology that runs on lossy networks. However, its performance is poor because it relies on TCP to guarantee lossless delivery.

*These authors contribute equally to this work.

The third approach is to design a routing solution that is fundamentally free of CBD, just as the up-down routing in Clos. Along this direction, TCP Bolt [48] and DF-EDST [47] were proposed, and the key idea is to find as many edge disjoint spanning trees (EDST) in an expander graph as possible and then route each packet in one of the spanning tree from its source to its destination. The EDST-based routing is CBD-free, but its throughput performance is poor. The key reason is that the EDST-based routing cannot effectively utilize all the network resources: 1) the average path length is usually large and increases quickly with network size; 2) some network links could remain idle as they do not belong to any EDST.

Our work called **Flattened Clos (FC)** offers a novel topology-routing co-design to eliminate CBDs in RoCE networks. FC's topology is essentially a random regular graph that is mappable to a multi-layered topology. We construct FC's topology in two steps: 1) virtually split each ToR switch into k virtual switches, each of which belongs to a virtual layer, and 2) randomly interconnect the layer- i ($i = 2, \dots, k - 1$) virtual switches to the layer- $(i - 1)$ and the layer- $(i + 1)$ virtual switches. The multi-layered virtual structure of FC allows performing up-down routing based on virtual layers. To this end, we propose the Edge-Disjoint Virtual Up-Down Routing for FC. For every source-destination pair, FC's routing transforms the path-finding problem into a min-cost-flow problem and then finds the maximum number of edge-disjoint paths. We analyze FC's design as follows to demonstrate its feasibility:

1. We offer a theoretical guidance for choosing the right number k of virtual layers when constructing FC's topology (see the strategy (*) in Section 3.2.3), and validate the strategy via numerical analysis.
2. We prove that FC's routing is CBD-free, and thus is deadlock-free. In fact, FC's topology and routing paths can be viewed as contracted graphs of a virtual multi-layered network and virtual up-down paths. This *graph contraction* operation preserves the CBD-free property.
3. We show that FC's cabling complexity can be dramatically reduced by introducing a layer of Patch Panels (PP) or Optical Circuit Switches (OCS) to interconnect all the ToR switches. Admittedly, having this PP/OCS layer increases cable length and cable cost. As network size becomes large, the overall network cost of FC is still lower than that of Clos under similar bisection bandwidth.
4. We demonstrate that FC outperforms expander graphs with EDST routing [47, 48] (the state-of-art CBD-free routing for expanders). Specifically, FC reduces the average hop count (AHC) by at least 50% and increases network throughput by $2 - 10\times$ or more.
5. We compare the throughput performance between FC and Clos networks with up-down routing, built using the same number of hosts and electrical switches. FC

achieves $1.1 - 2\times$ throughput for all-to-all and uniform random traffic patterns, but its near-worst throughput is lower. We argue that when OCSs are used to construct FC, vendors do not have to worry much about FC's near-worst throughput. By simply generating a different FC's topology, one can avoid matching an FC's topology with its near-worst traffic patterns.

6. We validate that FC is deadlock free using a small test bed and a packet-level simulator, even under extreme (but practical) cases where congestion control is disabled and switches are misconfigured with a very small PFC PAUSE threshold. In contrast, we see deadlocks triggered under shortest-path routing and thus ECMP&KSP routing is not safe.

2 Background & Motivation

2.1 Deploy RDMA over Ethernet in Clos

Clos network, a.k.a. fat-tree, was proposed for data center network (DCN) architecture in [3], and has become the de-facto standard for large service providers, such as Google [45], Microsoft [19], Facebook [44], etc. TCP/IP is the dominant transport/network stack in today's data centers. However, the traditional TCP/IP stack cannot offer high throughput ($> 40\text{Gbps}$ or more) and ultra-low latency ($< 10\mu\text{s}$ per hop) for modern data center applications such as cloud storage, deep learning framework and database [20, 30, 57]. Therefore, data center operators, e.g., Microsoft [20], Alibaba [30], etc., have started large-scale deployment of RDMA in Clos data centers to attain better network performance.

RDMA is a hardware offloading technology that offers several benefits such as high throughput, low latency and low CPU overhead by bypassing the host networking stack. HPC community has long used RDMA in special-purpose clusters, and deployed RDMA using Infiniband (IB) technology. However, modern data centers are built with IP and Ethernet technologies. For technical and economical reasons, RoCE was proposed for RDMA deployment in data centers.

The commonly used RoCE protocol is RoCEv2. RoCEv2 encapsulates an RDMA transport packet within a UDP packet to be compatible with the existing networking infrastructure of data centers. RoCEv2 was initially designed to run on a lossless network, which can be guaranteed by enabling the Priority-based Flow Control (PFC) [25]. Admittedly, there have been advanced RoCE designs, e.g., Resilient RoCE, IRN [35], etc., that could work with a lossy network. However, supporting RoCE in lossy networks requires handling packet retransmission using time out, selective ack, etc., which may not only complicate the NIC design, but also hurt network latency and throughput performance. As a result, lossy RDMA may not be able to substitute lossless RDMA in all cases. In this paper, we focus on lossless networks to support RoCEv2.

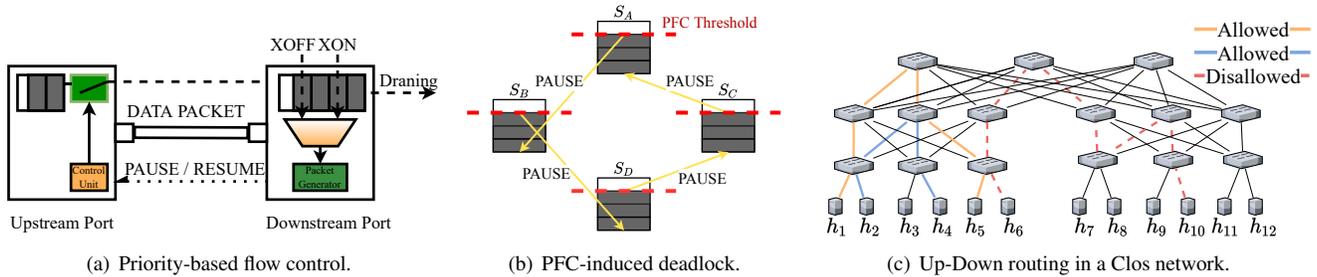

Figure 1: Key technologies of supporting RoCE in a lossless Clos network.

2.1.1 Priority-based Flow Control (PFC)

PFC is a hop-by-hop flow control approach to prevent switch buffer overflow, which is the primary cause of packet loss in data centers. As shown in Fig. 1(a), the downstream switch sends a PAUSE frame to its upstream switch when its ingress queue length exceeds a certain threshold (XOFF). The upstream switch stops transmission after receiving the PAUSE frame. A RESUME frame is sent when the downstream queue drains below another threshold (XON). It takes some time for the upstream switch to react to the PAUSE frame and stop transmission. So the downstream switch needs to reserve some buffer space to accommodate the packets sent by the upstream switch during this time. The buffer space is called *headroom*. PFC can guarantee zero packet loss when the headroom size is configured correctly. Typically, data center switches can support at most two or three lossless priorities [20] due to the buffer size limit. Although the switch buffers keep increasing, the data center link bandwidth has been increasing much faster and the buffer/bandwidth ratio is actually decreasing over time [18]. Hence, we believe that supporting more lossless priorities can be even more difficult for the foreseeable future.

2.1.2 PFC-induced Deadlocks

PFC can raise some performance issues such as unfairness, PFC storms and deadlocks [14, 20, 30, 57]. Specifically, the PFC-induced deadlocks may hinder the large-scale deployment of RoCEv2. When cyclic buffer dependency (CBD) exists, deadlocks can be triggered by PFC PAUSEs [23], causing packets to wait indefinitely for buffer resources [48]. As shown in Fig. 1(b), four switches S_A, S_B, S_C, S_D have reached the PFC threshold and start to send PAUSE frames; then the network is trapped into a deadlock and no switch can make any progress. Note that, the PFC-induced deadlock cannot go away once it occurs even if we restart all the servers.

Deadlock recovery is a common approach to combat deadlocks. It contains two steps: deadlock detection and deadlock resolution. Traditional approaches detect deadlocks in the control plane [34]. However, these solutions cannot react to deadlocks quickly enough due to the large communication

latency between data planes and control planes. A recent work, ITSY [51], could detect deadlocks in the data plane and achieve at least $3.2\times$ faster detection speed. However, ITSY requires programmable switch hardware (e.g., P4) support. As for deadlock resolution, temporary rerouting [34] is a common approach, but may create new congestion and deadlocks. ITSY [51] tried to resolve deadlocks completely in the data plane without rerouting, but the proposed solutions either incur packet loss or cannot efficiently handle concurrent deadlocks. To sum up, existing deadlock recovery mechanisms are not ideal. As a result, deadlock prevention has received much attention in the recent literature.

2.1.3 Avoiding Deadlocks in Clos Networks

Large vendors have gained years of experience in deploying RDMA in Clos data centers [20]. The following strategies are adopted to avoid deadlocks:

1. Perform up-down routing, which is CBD and deadlock-free under normal network conditions in Clos networks. (Note that containing a CBD is a necessary condition to have deadlocks.) As shown in Fig. 1(c), the paths of $h_1 \rightarrow h_5$ and $h_2 \rightarrow h_4$ obey the “up-down” rule and are allowed; but the path of $h_6 \rightarrow h_{10}$ contains a “down-up” segment and thus is not allowed.
2. Do not put multicast and broadcast packets into lossless classes. It was reported in [20] that ARP broadcasts+up-down routing can cause PFC deadlocks.
3. Use a different lossless class for rerouted packets upon network failures. [24] shows that packet rerouting may break the “up-down” rule and trigger PFC deadlocks.

2.2 From Clos to Expander

Despite of the success of deploying Clos data centers, however, a Clos network is inherently suboptimal in terms of bandwidth provision. As the Ethernet speed keeps increasing, the network cost, especially the power consumption of Clos networks, is becoming prohibitively high [4]. To reduce

the network cost, researchers have started seeking for more cost-effective network architectures.

One of the promising alternative for DCNs is expander graph. As shown in Fig. 2, expander graphs adopt a flat topology design: servers connect to ToR switches and these ToRs are directly interconnected without a layered structure. Examples of expander graphs include Jellyfish [46], SlimFly [5], Xpander [50], FatClique [54], etc. Expander graphs is more cost-effective for bandwidth provision than Clos networks. Using KSP routing, a full throughput expander uses 25% fewer switches than a full throughput Clos [36]. The network performance of expander graphs was also studied under other routing protocols, including ECMP, Valient Load Balancing (VLB) and a hybrid of the two [28]. However, none of these widely studied routing strategies is CBD-free.

2.2.1 ECMP/KSP are not CBD-free in Expanders

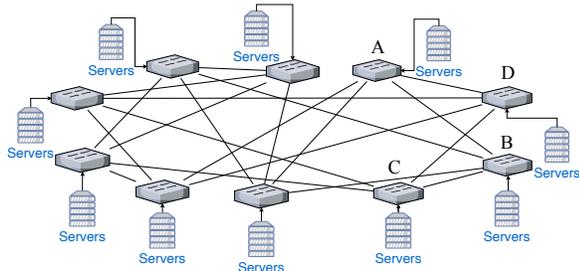

Figure 2: An expander graph.

Consider the expander graph in Fig. 2. This expander is a random regular graph with 4 inter-ToR links per ToR. Consider the four ToRs A, B, C, D and the shortest paths for $A \rightarrow C$, $B \rightarrow D$, $C \rightarrow A$, $D \rightarrow B$. Assume that there is a flow routed along the shortest path $A \rightarrow B \rightarrow C$. Then, if the egress port at link (B, C) is paused, the egress port at link (A, B) will be paused. If there is another flow routed along the shortest path $D \rightarrow A \rightarrow B$, since the egress port at link (A, B) is paused, the egress port at link (D, A) will also be paused. Similarly, if we have another two flows routed along the shortest paths $C \rightarrow D \rightarrow A$ and $B \rightarrow C \rightarrow D$, then the egress ports at link (C, D) and link (B, C) will be paused. Now, we find a CBD in this expander graph under shortest-path routing. To sum up, when there are 4 flows routed along the paths $A \rightarrow B \rightarrow C, D \rightarrow A \rightarrow B, C \rightarrow D \rightarrow A$ and $B \rightarrow C \rightarrow D$, if one of the egress ports $(A, B), (B, C), (C, D), (D, A)$ is paused for a sufficiently long time, a deadlock will be triggered.

The above analysis indicates that shortest-path routing is not CBD-free. Now we consider ECMP and KSP routings. ECMP uniformly split traffic among all the shortest paths, while KSP split traffic among the first K shortest paths. (To improve network performance under ECMP/KSP, one can also optimize the path weights using a multi-commodity flow formulation.) Under ECMP or KSP routing, it is still possible

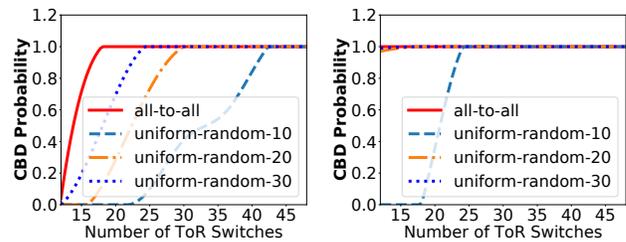

to have four flows taking the paths $A \rightarrow B \rightarrow C, D \rightarrow A \rightarrow B, C \rightarrow D \rightarrow A$ and $B \rightarrow C \rightarrow D$ in the above example. Therefore, both ECMP and KSP routings are not CBD-free. Using the same approach, we can prove that the VLB routing and the hybrid of ECMP&VLB in [28] are not CBD-free, either.

2.2.1.1 Probability of Containing CBDs

We further analyze the probability of an expander graph containing CBDs under different traffic patterns. We generate two classes of expander graphs, Jellyfish [46] and Xpander [50]. In each expander graph, each ToR switch has 5 ports connected to other ToRs. For each expander graph, we evaluate two classes of traffic patterns under shortest-path routing (the algorithm that determines if a set of paths is CBD free in a given topology is offered in Appendix A.2):

All to All: Every source-destination pair has an on-going flow. This represents the most-likely case of having CBDs.

Uniform Random- p : Every ToR randomly picks p fraction of ToRs to communicate. This represents practical DCN traffic patterns in which the majority of traffic of a server is often destined to a few racks [44].

(a) Jellyfish CBD probability.

(b) Xpander CBD probability.

Figure 3: Jellyfish and Xpander CBD analysis.

The results are depicted in Fig. 3. We can see that as the number of ToRs increases, the CBD probability quickly increases to one and Xpander graphs are more likely to encounter CBDs than Jellyfish graphs. Note that even under shortest-path routing (ECMP), the CBD probability becomes one with only tens of ToR switches. Other routing algorithms, including KSP, VLB, etc., contain even higher CBDs.

Remark on the necessity of eliminating CBDs: Even if the probability that the ECMP/KSP/VLB routing policies lead to CBDs is close to 1, the possibility that these CBDs eventually turn into deadlocks may not be that high. Nevertheless, eliminating CBDs can be still important. Some network applications requires five-nines availability, which means that the maximum downtime in a month must be less than 26.3 seconds. As long as the deadlock probability is non-zero, when a data center runs for a long time, a deadlock may be triggered eventually and hurts the overall system availability.

Remark on Tagger’s approach: Given any routing paths, Tagger [24] offered a generic approach to eliminate CBDs. The key idea is to break each path into several segments

and assign each segment a lossless priority. As long as the path segments belonging to the same lossless priority are CBD-free, the entire network is CBD-free. Unfortunately, this approach may require too many lossless priorities to eliminate CBDs in large expander networks.

3 Flattened Clos

We propose a new class of expander graphs, called **Flattened Clos (FC)**, for efficient deadlock prevention. Our design is motivated by the CBD-free up-down routing in Clos networks and the *flattened butterfly* topology [29]. FC is a topology built on top of ToR switches. The key idea of FC is to split each ToR switch into a few virtual switches, and assign each virtual switch a virtual layer id. By creating links only between virtual switches in adjacent virtual layers, FC can adopt virtual up-down routing to avoid deadlocks. The detailed topology and routing designs of FC are described below.

3.1 Topology

We study a data center network with N ToR (Top of Rack) switches $S = \{S_1, S_2, \dots, S_N\}$. Each switch has $p = s + h$ ports, h of which connected to the hosts and s of which connected to other ToRs. We construct an FC topology in two steps:

Step 1: Splitting Virtual Switches. To create an FC with k virtual layers, we logically split each switch $S_i, i = 1, 2, \dots, N$ into k virtual switches, and label these virtual switches as $S_i^1, S_i^2, \dots, S_i^k$. The virtual switch S_i^j belongs to the j -th layer, and has l_j number of links to connect to other switches. The total link count of the virtual switches $S_i^1, S_i^2, \dots, S_i^k$ is equal to the total link count of S_i that connect to other ToRs, i.e.,

$$\sum_{j=1}^k l_j = s. \quad (1)$$

Step 2: Random Wiring. For each $j = 1, 2, \dots, k - 1$, we randomly generate a bipartite graph between the virtual switches in layer j and the virtual switches in layer $j + 1$. Let $a_j, j = 1, 2, \dots, k - 1$ be the degree of each virtual switch in the j -th random bipartite graph. We must have

$$l_1 = a_1, l_2 = a_1 + a_2, \dots, l_{k-1} = a_{k-2} + a_{k-1}, l_k = a_{k-1}. \quad (2)$$

When we generate random bipartite graphs, we never create links between S_i^j and S_i^{j+1} for $i = 1, 2, \dots, N, j = 1, 2, \dots, k - 1$. The reason is that S_i^j and S_i^{j+1} actually belong to the same switch, and there is no need to create a link in between.

3.1.1 Theoretical Topology Properties of FC

In an FC's topology, each ToR switch has s links connected to other ToRs. Thus, FC falls into the category of random regular graphs (RRG). Here, we restate some useful theoretical results for RRGs in literature, which also applies to FC.

We represent a network by $G = (V, E)$, where V is the vertex set and E is the edge set. The bisection bandwidth of G can be characterized by *Edge Expansion*, which is defined as $EE(G) = \min_{|S| \leq \frac{N}{2}} \frac{|\partial S|}{|S|}$, where N is the number of vertices in V , S is a subset of V , $|S|$ is the size of S , ∂S is the set of edges leaving S . The Edge Expansion of an s -regular graph is upper bounded by $s/2$ [50]. The following theorem indicates that random regular graphs attain near-optimal edge expansion.

Theorem 1 (Near-optimal Edge Expansion [7]) For every $s \geq 3$ and $0 < \eta < 1$ satisfying $2^{4/s} < (1 - \eta)^{1-\eta} (1 + \eta)^{1+\eta}$, almost every s -regular graph G has its edge expansion

$$EE(G) \geq (1 - \eta)s/2.$$

Given a traffic matrix $T = [t_{uv}]$, where t_{uv} is the amount of requested flows from ToR switch u to ToR switch v . The throughput $\alpha(G, T)$ of a network G under the traffic matrix T is defined as the maximum value $\theta(T)$ for which $T \cdot \theta(T)$ is feasible in G . The following two theorems guarantee that random regular graphs achieve good throughput under both uniform and adversarial patterns.

Theorem 2 (High throughput under all-to-all pattern [50]): For the all-to-all traffic pattern $T_{all-to-all}$, almost every s -regular graph G achieves a throughput

$$\alpha(G, T_{all-to-all}) \geq \frac{1}{O(\log s)} \alpha(G^*, T_{all-to-all}),$$

where G^* is the s -regular graph that attains the optimal throughput under $T_{all-to-all}$.

Theorem 3 (Resilience to adversarial patterns [50]): For almost every s -regular graph G and every traffic pattern T , the throughput $\alpha(G, T) \geq \frac{1}{O(\log N)} \alpha(G^*, T)$, where G^* is the s -regular graph that attains the optimal throughput under T .

3.2 Routing

3.2.1 Edge-disjoint Virtual Up-down Routing

Although FC's topology exhibits high network throughput in theory, such a throughput may not be achievable in PFC-enabled RoCE networks due to the potential risk of deadlocks. To completely eliminate the risk of deadlocks, we propose the CBD-free **Edge-disjoint Virtual Up-down Routing**. This routing strategy computes paths in three steps:

Step 1: Construct a Multi-layered Virtual Topology. According to the construction of FC's topology, each FC's topology is mappable to a multi-layered topology. Consider the toy example in Fig. 4(a). While we construct this topology, we have virtually divided each ToR switch S_i into $k = 3$ sub-switches S_i^1, S_i^2 and S_i^3 . The first port of S_i belongs to S_i^1 ; the second and the third ports belong to S_i^2 ; the fourth port belongs to S_i^3 . It is easy to check that each edge in Fig. 4(a) corresponds to a solid line in Fig. 4(b). Note that the k sub-switches

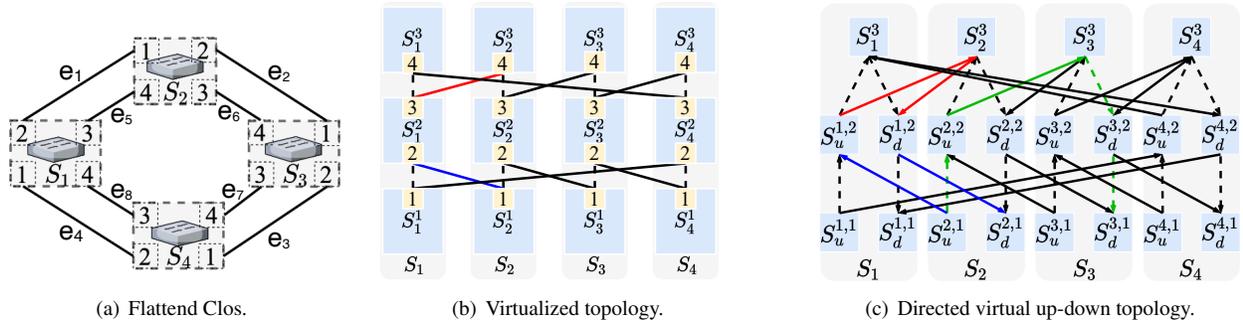

Figure 4: FC's topology and routing design.

$S_1^1, S_1^2, \dots, S_1^k$ can communicate with each other, because they belong to the same physical switch. Hence, we also create an edge between S_i^j and S_i^{j+1} for every $j = 1, 2, \dots, k-1$ (see the dashed lines) in Fig. 4(b).

Step 2: Construct a Directed Virtual Up-Down Topology.

Our objective is to find the maximum number of virtual up-down paths in the multi-layered virtual topology. To enforce this “up-down” constraint, we further convert the undirected multi-layered graph in Fig. 4(b) to a directed virtual up-down graph in Fig. 4(c). Specifically, we first split each virtual node S_i^j ($j < k$) into one “up node” $S_u^{i,j}$ and one “down node” $S_d^{i,j}$ in the directed up-down graph. (Note that we do not split the top layer virtual nodes S_i^k .) We then map each link in Fig. 4(b) to two directed links in Fig. 4(c): each undirected link ($S_{i_1}^{j_1}, S_{i_2}^{j_2}$) in the top layer (see the red line in Fig. 4(b) as an example) is mapped to two directed links ($S_u^{i_1, j_1}, S_d^{i_2, j_2}$) and ($S_d^{i_2, j_2}, S_u^{i_1, j_1}$); each undirected link ($S_{i_1}^{j_1}, S_{i_2}^{j_2}$) ($j = 2, \dots, k-1$) (see the blue line in Fig. 4(b) as an example) is mapped to two directed links ($S_u^{i_1, j_1}, S_u^{i_2, j_2}$) and ($S_d^{i_2, j_2}, S_d^{i_1, j_1}$).

Step 3: Compute CBD-free Paths. For every source-destination pair (S_i, S_j) , we first find a path set \mathcal{P}_{ij} with the maximum number of virtual up-down paths from the node $S_u^{i,1}$ to the node $S_d^{j,1}$ in the directed virtual up-down topology using min-cost max-flow (see Appendix A.1 for more details). In this set \mathcal{P}_{ij} of paths, each solid link is used at most once while each dashed link can be used multiple times. Then, for every path $P \in \mathcal{P}_{ij}$, we map it to a path in FC's topology (Fig. 4(a)). For example, as shown in Fig. 4(c), we find one up-down path $S_u^{2,1} \rightarrow S_u^{2,2} \rightarrow S_3^3 \rightarrow S_d^{3,2} \rightarrow S_d^{3,1}$ (marked with green) for the source-destination pair (S_1, S_2) . Since $S_u^{2,1}, S_u^{2,2}$ are from the ToR switch S_2 and $S_3^3, S_d^{3,2}, S_d^{3,1}$ are from the ToR switch S_3 , this path can be contracted to $S_2 \rightarrow S_3$ in the FC's topology. Since each solid link is used at most once in \mathcal{P}_{ij} , the resulting paths in the FC's topology must be edge-disjoint.

3.2.2 FC's Routing is CBD Free

In FC's edge-disjoint virtual up-down routing, we first compute an up-down path set \mathcal{P}_{ij} based on the directed virtual

up-down topology, and then contract all the paths in \mathcal{P}_{ij} to obtain the final paths for FC's topology. Let $\mathcal{P} = \cup_{i,j} \mathcal{P}_{ij}$ be the set of virtual up-down paths obtained from the directed virtual up-down topology. According to Theorem 8 in Appendix A.2, \mathcal{P} is CBD free. In order to prove that the final set of paths in FC's topology is CBD free, we need the following definition and lemma (see Appendix A.2.1 for the proof).

Definition 1 Given a set of nodes V , $\{V_1, V_2, \dots, V_m\}$ is called a partition of V , if the following conditions are met: 1) $V_{m_1} \cap V_{m_2} = \emptyset$ for every $m_1 \neq m_2$; 2) $V_1 \cup V_2 \cup \dots \cup V_m = V$.

Lemma 4 Given a graph $G(V, E)$, a path set \mathcal{P} and a partition $\{V_1, V_2, \dots, V_m\}$ of V , a graph and path set pair $(\hat{G}(\hat{V}, \hat{E}), \hat{\mathcal{P}})$ is called a contraction of $(G(V, E), \mathcal{P})$ if

1. every node in $\hat{v}_i \in \hat{V}$ corresponds to the vertex set V_i ;
2. the number of edges between \hat{v}_i and \hat{v}_j is the same as the total number of edges between V_i and V_j in $G(V, E)$;
3. each path $\hat{P} \in \hat{\mathcal{P}}$ is a contraction of a path $P \in \mathcal{P}$, i.e., \hat{P} is obtained by first replacing each vertex in P by a vertex in \hat{V} and then removing cycles and duplicated vertices.

Then, if the path set \mathcal{P} is CBD-free in $G(V, E)$, the path set $\hat{\mathcal{P}}$ must be CBD-free in $\hat{G}(\hat{V}, \hat{E})$.

Apparently, FC's topology and routing path set can be viewed as a contraction of the directed virtual up-down topology and the corresponding virtual up-down path set \mathcal{P} . Since the path set \mathcal{P} is CBD free in the directed virtual up-down topology, then according to Lemma 4, we immediately know that FC's routing path set is CBD free.

3.2.3 How Routing Affects FC's Topology Design?

We have described FC's routing and topology designs. Note that there is a critical parameter k in the design. If k is not properly chosen, FC's routing policy may not be able to find a path for some switch pair, thus hurting the connectivity of FC. In this section, we offer a theoretical guideline to determine the number of virtual layers in FC.

Number of Switches	Number of Servers	k_{min}	k	Average Number of Edge Disjoint Up-down Paths	Average Path Length of Edge Disjoint Up-down Paths	Minimum Number of Edge Disjoint Up-down Paths
500	12000	3	3	10.05	4.29	4.00
			4	16.08	4.57	12.00
1000	24000	3	3	7.10	4.43	1.00
			4	14.01	4.86	9.00
2000	48000	4	4	11.85	5.13	7.00
			5	15.77	5.36	11.00
3000	72000	4	4	10.63	5.30	6.00
			5	14.66	5.54	10.00
5000	120000	4	4	9.17	5.52	3.00
			5	13.28	5.75	9.00

Table 1: Choosing the right k for FC.

Lemma 5 Let x be the number of ancestors in the virtual layer k for each layer-1 virtual node. If $x > \sqrt{(2+\epsilon)N \ln N}$, where $\epsilon > 0$ is an infinitesimal value, then as $N \rightarrow +\infty$, with probability 1, every pair of layer-1 virtual nodes has a common ancestor in the virtual layer k .

Proof 1 We use A_{ij} to denote the event that the virtual nodes S_i^1 and S_j^1 have no common ancestor in the virtual layer k . Then, the probability that A_{ij} happens is

$$\begin{aligned}
P(A_{ij}) &= \frac{C_{N-x}^x}{C_N^x} \leq \left(1 - \frac{x}{N}\right)^x \\
&< \left(1 - \frac{\sqrt{(2+\epsilon)N \ln N}}{\sqrt{N}}\right)^{\sqrt{(2+\epsilon)N \ln N}} \\
&= \left(\left(1 - \frac{\sqrt{(2+\epsilon)N \ln N}}{\sqrt{N}}\right)^{\frac{\sqrt{N}}{\sqrt{(2+\epsilon)N \ln N}}}\right)^{(2+\epsilon) \ln N} \\
&< (1/e)^{(2+\epsilon) \ln N} = N^{-(2+\epsilon)}.
\end{aligned}$$

Let A be the event that at least one pair of virtual nodes in layer 1 has no common ancestor in layer k . Then,

$$\begin{aligned}
P(A) &= P(\cup_{i \neq j} A_{ij}) \leq \sum_{i \neq j} P(A_{ij}) \\
&= \frac{N(N-1)}{2} \times N^{-(2+\epsilon)} < \frac{1}{2} N^{-\epsilon}.
\end{aligned}$$

Then, $\lim_{N \rightarrow +\infty} P(A) = 0$. This completes the proof.

Based on FC's routing, it is easy to calculate that the number of distinct up-paths from a virtual node in layer 1 is $(a_1 + 1)(a_2 + 1) \cdots (a_{k-1} + 1)$, which is an upper bound of the number of ancestors in layer k . According to Lemma 5, we can choose a k such that

$$(a_1 + 1)(a_2 + 1) \cdots (a_{k-1} + 1) > \sqrt{(2+\epsilon)N \ln N}. \quad (3)$$

According to Equation (1) and (2), it is easy to obtain $\sum_{i=1}^{k-1} a_i = s/2$. We could choose a_1, a_2, \dots, a_{k-1} to maximize the left hand side of (3), and obtain

$$\left(1 + \frac{s}{2(k-1)}\right)^{k-1} > \sqrt{(2+\epsilon)N \ln N}. \quad (4)$$

Let k_{min} be the smallest integer solution of (4). We could choose a k value around k_{min} . As shown in Fig. 5, k_{min} does not grow fast with respect to N .

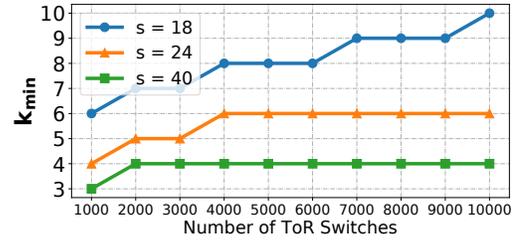

Figure 5: Relationship between k_{min} and network size N .

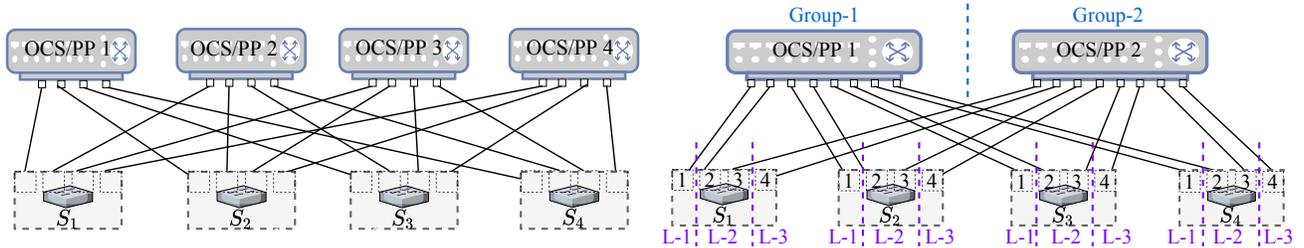

Numerical Verification: To verify the above theoretical result, we perform a numerical analysis using 64-port ToR switches. Each ToR switch has $h = 24$ ports connected to the hosts and $s = 40$ ports connected to other ToR switches. For different number of ToR switches ($N = 500/1000/2000/3000/5000$), we choose $k = k_{min}, k_{min} + 1$, generate an FC's topology and count the number of distinct virtual up-down paths. As shown in Table 1, as we increase k , more paths can be found for every source-destination ToR switch pairs. Note that the average path length increases with respect to k . Hence, it is better to choose a smaller k . On the other hand, if we choose k to be too small, some ToR switch pairs may not have sufficient number of distinct paths. Here we suggest a simple strategy that works well for FC:

Strategy (*): Try k_{min} first; if not working, try $k_{min} + 1$.

For example, in the case where $N = 1000, k = k_{min} = 3$, the minimum number of distinct paths between ToR pairs is 1. This creates a bottleneck in the network. Hence, $k = k_{min} + 1 = 4$ will be chosen instead.

3.2.4 Computational Complexity of FC's Routing

The main complexity comes from using the min-cost max-flow solver to find edge-disjoint virtual up-down paths. Given a graph $G = (V, E)$ with n vertices and m edges, the computational complexity of the min-cost max-flow algorithm

(a) Uniform cabling through OCSs/PPs. Any inter-ToR topology is realizable by properly configuring the s OCSs/PPs one by one. (b) Virtual-layered cabling through OCSs/PPs. There is 1 port for virtual layer-1 (L-1), 2 ports for L-2, and 1 port for L-3 in every switch. OCSs/PPs are divided into 2 groups.

Figure 6: Example of cabling with the help of optical circuit switches (OCS) / patch panels (PP).

implemented in Ortools is $O(m \cdot n^2 \cdot \log(n \cdot C))$, where C is the value of the largest link cost in the graph [1] (in our case, $C = 1$). If we choose the parameters k and a_1, a_2, \dots, a_{k-1} such that $(a_1 + 1)(a_2 + 1) \cdots (a_{k-1} + 1) = \Theta(\sqrt{N \log N})$, each virtual node in the first virtual layer will be able to reach at most $\Theta(k\sqrt{N \log N})$ virtual nodes through at most $\Theta(k\sqrt{N \log N})$ edges. When we compute edge disjoint paths from S_i to S_j , we only need to focus on a subgraph of the directed virtual up-down topology, which contains all the nodes reachable from $S_u^{i,1}$ and $S_d^{j,1}$. This subgraph has $\Theta(k\sqrt{N \log N})$ nodes and edges. Thus, the overall computational complexity is $\Theta((k\sqrt{N \log N})^3 \cdot \log(k\sqrt{N \log N})) = \Theta(k^3 N^{3/2} (\log N)^{5/2})$.

3.3 Cabling

FC adopts random wiring for its topology design. However, random wiring has long been criticized for its high cabling complexity [50, 54]. Indeed, if we directly connect different ToR switch pairs, the number of distinct fiber lengths would be in the order of $\Theta(N^2)$. Directly connecting ToR switches could also increase the management complexity when we perform data center expansion [56].

To reduce cabling complexity, motivated by TROD [9] and Google’s Jupiter data center [40], we propose to use a set of co-located optical circuit switches (OCS) or patch panels (PP) to interconnect different ToR pairs and form FC’s topology. Since these PPs/OCSs are co-located, the number of distinct fiber lengths reduces to $\Theta(N)$. Next, we offer two strategies to interconnect PPs/OCSs with ToR switches.

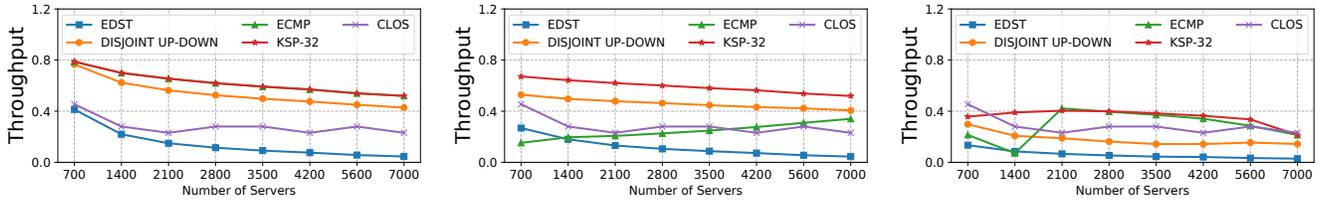

Uniform Cabling (see Figure 6(a)): Note that each ToR switch has s ports to be connected to other ToR switches. We use s OCSs/PPs, and construct a uniform bipartite graph between ToR switches and OCSs/PPs. Under this cabling strategy, it was proven in [55] (see Lemma 4 and Theorem 5 therein) that any inter-ToR topology is realizable by properly configuring the s OCSs/PPs one by one. According to this fact, we could first generate an FC topology without considering the layer of OCSs/PPs, and then decompose this topology into s sub-topologies that can be mapped to each

OCS/PP. This approach reduces cabling complexity. However, it encounters scalability challenge. Specifically, the port count of the commercially available OCSs/PPs is on the order of a few hundred. For example, a Calient s320 OCS [8] can offer 320 TX/RX ports. Thus, the number of ToR switches can be at most a few hundreds. Since each ToR switch typically connects to tens of servers, this uniform cabling strategy can support at most a few thousands of servers.

Virtual-Layered Cabling (see Figure 6(b)): Note that FC’s topology is designed based on the concept of virtual layers. Assume that there are a_1 ports for layer-1, $a_1 + a_2$ ports for layer-2, ..., $a_{k-1} + a_k$ ports for layer- $(k-1)$, and a_k ports for layer- k . We group all the OCSs/PPs into $k-1$ groups, and connect $2a_i$ ports of each ToR switch to the i -th OCS/PP group. In the i -th OCS/PP group, each OCS/PP have half of its ports connected to ToR switches’ layer- i ports and half of its ports connected to ToR switches’ layer- $(i+1)$ ports. If we enforce that every OCS/PP should connect to all the ToR switches, we will encounter the same scalability challenge as the uniform cabling strategy. In the virtual-layered cabling strategy, $2\eta a_i$ number of OCSs/PPs are used in the i -th group, and each ToR switch will randomly choose $2a_i$ OCSs/PPs in group- i to connect its layer- i and layer- $(i+1)$ ports. Under this cabling strategy, the total number of ToR switches that can be supported becomes “ $\eta \times$ port count of an OCS/PP”. This strategy scales well. For example, if we use 320-port OCSs, 64-port ToR switches (assume that each ToR connects to 24 servers), and choose $\eta = 20$, then the maximum number of servers would be $20 \times 320 \times 24 = 153600$, which can definitely support a large-scale data center.

Remark on the parameter η : When $\eta > 1$, a cabling constraint is imposed to FC when we generate the topology between adjacent virtual layers, i.e., not all topologies are realizable because the interconnection between ToRs and each group of OCSs/PPs is not uniform. Fortunately, Appendix A.5.1 shows that enabling this cabling constraint when generating FC’s topology has little impact on FC’s routing statistics.

Remark on the network cost: Compared to traditional expander graphs, having a layer of OCSs in FC reduces the

(a) Throughput of the all to all traffic matrix. (The ECMP and KSP curves overlap together.) (b) Throughput of uniform random traffic matrices (averaged over 10 runs). (c) Throughput of the near-worst permutation traffic matrix.

Figure 7: Throughput simulation results under ECMP, EDST, Edge-disjoint Virtual Up-down and 32-way KSP routing.

number of distinct cable lengths, but unfortunately increases the total cable length. We compare the total network cost between FC and Clos in Appendix A.4. To achieve similar bisection bandwidth, FC and Clos have similar network cost when the network size is small and FC’s cost becomes lower as the network size increases to a point where 4 switch layers are required to build a Clos. In addition, FC uses fewer number of electrical switches and thus its network power consumption is lower.

A potential future direction: Using OCSs introduces another interesting problem: how to design deadlock-free and traffic-aware topology & routing policies. As reconfiguring OCSs incurs non-negligible delay, it may not be possible to reconfigure OCSs for every traffic-pattern change. Google’s Jupiter data center [40] and our prior work [9, 49] both showed that low-frequency reconfiguration might be sufficient, because the traffic patterns in real data centers do not change arbitrarily. Low-frequency reconfiguration may also work for lossless RDMA networks, but requires further investigation.

4 Numerical Throughput Analysis

We numerically evaluate the throughput for FC in this section. We evaluate two scenarios. Due to space constraints, we only present one here and put the other one in Appendix A.5.2.

We generate FC’s topologies of different sizes using up to 500 32-port ToR switches. Each ToR switch has 18 ports connected to other switches and 14 ports connected to servers. The number of virtual layers k is chosen based on the strategy (*) in Section 3.2.3. For each FC’s topology, we evaluate four routing strategies: 1) FC’s edge-disjoint virtual up-down routing, 2) EDST routing, 3) ECMP or Shortest-Path routing, and 4) KSP routing. Given a traffic matrix T , we use a multi-commodity flow formulation to calculate the maximum throughput value $\theta(T)$ such that $T \cdot \theta(T)$ is feasible under the given topology and routing paths. (For ECMP, the throughput is also calculated based on the multi-commodity flow formulation. Evenly spreading traffic among all the shortest paths may yield very poor throughput.) In addition, for each FC’s topology, we also compare it with a Clos network generated using roughly the same number of switches with throughput

optimized (see Appendix A.3).

We compute throughput values under all-to-all traffic patterns, uniform random traffic patterns and near-worst traffic patterns. In an all-to-all pattern, each server sends an equal amount of traffic to all other servers. In a uniform random pattern, each ToR randomly picks 10% of ToRs to communicate. To generate near-worst patterns, we 1) first construct a complete bipartite graph B with N source nodes and N destination nodes, where the weight of the edge (s, d) is the length of the shortest path from ToR s to ToR d ; 2) and then find the permutation matrix with the maximum weight. This approach was also adopted in [26, 36] to generate near-worst patterns. We believe that the above three classes of traffic patterns offer an adequate coverage of real data center traffic patterns. The uniform random pattern is highly representative in real data centers. Indeed, Google’s data center traffic patterns are approximately uniform random [40]. The all-to-all pattern is widely used in MPI communication. The near-worst pattern allows us to understand network’s performance lower bound.

4.1 FC’s Routing vs EDST Routing

The EDST routing is CBD-free for expander graphs. A random s -regular graph has $s/2$ edge-disjoint spanning trees with high probability [38]. Thus, EDST is a direct competitor of the Edge-disjoint Virtual Up-down Routing for FC’s topology.

As shown in Fig. 7, FC’s edge-disjoint virtual up-down routing (denoted by “DISJOINT UP-DOWN”) performs consistently better than EDST for all the traffic patterns. When the network is small ($N = 50$), FC’s routing achieves $2\times$ throughput of the EDST routing. As the network size increases, the performance of the EDST routing deteriorates quickly. When $N = 500$, the performance gain of FC’s routing becomes $10\times$ and the gain keeps increasing with the network scale.

There are two reasons that lead to the poor performance of the EDST routing. First, existing edge-disjoint spanning tree (EDST) algorithms [42, 43] can find the maximum number of spanning trees, but there is no guarantee that the height of each spanning tree found is small. When we perform routing in a *tall* spanning tree, the average hop count would be large. This is also justified in the following routing-path analysis.

Number of Switches	Number of servers	k	Port Count of Virtual Switches	Routing	Average Number of Paths	Average Path Length	Average Shortest Path Length
50	700	4	[3, 6, 6, 3]	Edge Disjoint Up-down	8.02	3.86	2.68
				EDST	9.00	7.69	3.12
100	1400	4	[3, 6, 6, 3]	Edge Disjoint Up-down	6.43	4.22	3.04
				EDST	9.00	10.01	4.04
200	2800	4	[3, 6, 6, 3]	Edge Disjoint Up-down	4.99	4.56	3.44
				EDST	9.00	14.01	5.50
300	4200	4	[3, 6, 6, 3]	Edge Disjoint Up-down	4.24	4.75	3.70
				EDST	9.00	16.70	6.52
500	7000	5	[2, 4, 4, 5, 3]	Edge Disjoint Up-down	4.55	5.22	4.00
				EDST	9.00	21.96	8.14

Table 2: Edge-Disjoint Virtual Up-down Routing vs. the EDST Routing (32-port Switches are Used).

Second, some links remain unused in the EDST routing. In an expander graph with N ToR switches, each spanning tree contains $N - 1$ links. Note that the total number of ToR-to-ToR links is $Ns/2$. When $Ns/2$ is not divisible by $N - 1$, there must be links not used by any spanning tree.

Routing-Path Analysis: For several FC’s topologies of different sizes ($N = 50/100/200/300/500$), we analyze the routing paths under FC’s routing and the EDST routing. We calculate three metrics, including average number of paths, average length of paths and average length of the shortest paths. As shown in Table 2, although the EDST routing could find more paths than FC’s routing, its average path length is much higher. When $N = 50$, the average path length under FC’s routing is $1 - 3.86/7.69 \approx 50\%$ lower than that under the EDST routing. As N increases to 500, the reduction of average path length becomes $1 - 5.22/21.96 \approx 76\%$. We expect that this number will continue to increase for larger networks. The EDST routing cannot guarantee a small routing path length. In contrast, the parameter k restricts that FC’s routing path length cannot exceed $2k$ and k increases slowly with N .

4.2 FC’s Routing vs ECMP/KSP Routing

ECMP/KSP are widely-used routing protocols for expander graphs. In FC’s topology, ECMP’s throughput fluctuates significantly because ECMP cannot provide enough path diversity; KSP’s throughput is more stable under different traffic patterns. This coincides with the findings in Jellyfish [46].

Fig. 7 shows that KSP’s throughput is consistently higher than that of the FC’s edge-disjoint virtual up-down routing. However, deploying KSP routing in expander networks poses a deadlock risk. We have shown in Section 2.2.1.1 that the probability that ECMP/KSP routing contains CBDs is close to 1. Although containing CBDs is not sufficient to trigger deadlocks, we will show in Section 6.1 that ECMP/KSP could indeed trigger deadlocks in certain cases in a real testbed.

How to close the throughput gap: FC uses only one lossless queue, and its throughput performance is lower than that of the KSP routing. The reason is that FC’s routing has lower path diversity than the KSP routing. To improve path diversity, we could let FC use more than one lossless queues. We will explore this further in our future work.

4.3 FC vs Clos

Clos is the de facto standard topology for data centers and has witnessed the successful deployment of RDMA in production [20]. To ensure fair comparisons, given an FC’s topology with N ToR switches and H servers, we choose a Clos network that offers the maximum throughput to the H servers using roughly the same number of switches (Appendix A.3).

As shown in Fig. 7(a) and 7(b), FC attains $1.1 - 2 \times$ the throughput of Clos networks. Note that there is a decrease in throughput when the network size changes from 700 to 1400. The reason is that when the switch port count is 32, we can build a two-layered Clos to support 700 servers, but at least 3 layers are required in order for a Clos to support 1400 servers.

However, under near-worst traffic patterns, Fig. 7(c) shows that FC’s throughput can be $15\% - 50\%$ lower than that of the Clos networks. We argue that this issue can be resolved when a layer of OCSs is used to interconnect different ToRs. If the real traffic pattern is close to a near-worst pattern of the current topology, we can reconfigure the OCSs to generate a topology that matches this traffic pattern. Then, a natural question arises. How frequent should we reconfigure the topology? Certainly, the answer to this question depends on the traffic patterns. If the traffic patterns exhibit some long-term stability [40], occasional reconfiguration might be sufficient. We will study this problem further in our future work.

5 Packet-Level Simulation

We cross-validate our throughput analysis using a packet-level simulator [22]. We generate an FC’s topology using 144 32-port switches. Each switch has 8 ports connected to hosts and 24 ports connected to other switches. In total, there are 1152 hosts. On top of this topology, we run FC’s routing or the EDST routing. We also generate a Clos network using 148 32-port switches with throughput optimized. This Clos network has 64 ToR switches, 56 aggregation switches and 28 spine switches. Each ToR has 18 ports connected to hosts and 14 ports connected to the aggregation switches. The total number of hosts is still 1152. For this Clos topology, we use up-down routing. The port speed is set as 25Gbps.

We generate three sets of flows based on the all-to-all traffic pattern, a uniform random traffic pattern (each ToR choose 12.5% of ToRs to communicate) and the near-worst traffic pattern. In Facebook’s data centers, the median link utilization varies between 10% to 20% and the busiest 5% utilization of links is between 23% to 46% [44]. Here, we set the network load as 0.3, meaning that the maximum ingress/egress traffic of each ToR is $0.3 \times \text{Number of Hosts per ToR} \times 25\text{Gbps}$. For all the flows, we enable DCQCN for congestion control. We adopt dynamic PFC threshold such that the PFC is triggered when an ingress queue consumes more than 11% of the free switch buffer as suggested by HPCC [30]. We evaluate performance based on the flow completion time (FCT).

We summarize the FCT results in Table 3. FC attains higher throughput under the all-to-all pattern and the uniform random patterns. Correspondingly, FC achieves lower FCT in the packet-level simulation. FC’s near-worst-case throughput is lower than that of Clos. But Fortunately, FC has lower average hop count and thus its FCT performance is not much worse. More detailed results are available in Appendix A.5.4.

6 Formation and Impact of Deadlocks

We study how to trigger deadlocks and understand the impact of deadlocks via both testbed experiments and simulations. We will show that under extreme but practical cases, FC’s edge-disjoint virtual up-down routing is still deadlock-free; but ECMP/KSP could trigger deadlocks.

6.1 Trigger Deadlocks in a Real Testbed

We build a small testbed using four switches, each with 8 50Gbps ports. (The four switches are virtualized from a single CE12800 switch. The original port speed is 100Gbps and we limit the port speed as 50Gbps.) This testbed has 16 servers, each equipped with one Mellanox CX5 NIC with maximum rate configured as 50Gbps. (We use PCIE-3.0 \times 8 to connect to the NICs, and thus these NICs cannot run at a rate higher than 64Gbps.) Each switch in this testbed has four ports connected to other switches and four ports connected to four servers. We virtually split each switch into 3 virtual switches, with 1, 2, 1 number of ports respectively. The connections between FC’s virtual switches are shown in Fig. 4(b), and the resulting topology is shown in Fig. 4(a). This topology can be also viewed as a subgraph of a large expander graph (see switches A, B, C, D in Fig. 2). If a deadlock occurs in this subgraph, a PFC storm will quickly propagate to the entire network.

We implement ECMP, edge-disjoint virtual up-down and EDST routings using ACL rules in our testbed. We enable PFC to guarantee that the network is loss-free. The PFC-pause threshold *XOFF* is set to 50KB and the PFC-resume threshold *XON* is set to 47KB. Note that these PFC thresholds are lower than the recommended values. This allows the network to trigger more PFC pauses. As we will see shortly, the virtual

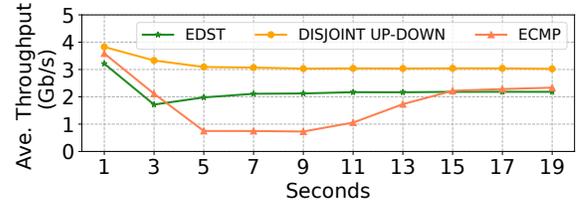

Figure 8: Average throughput of the testbed experiment.

up-down routing is deadlock-free even in this extreme situation. Note that this setup can be viewed as a misconfiguration of network switches. Microsoft reports that switch misconfiguration accounts for 38% of the high-impact failures in their data centers [52]. In a PFC-storm incident reported also by Microsoft [20], a switch parameter was misconfigured such that PFC PAUSE frames could be triggered more easily.

We generate RoCEv2 traffic using the “*ib_write_bw* [31]” command. For every NIC, we establish an RDMA connection with every NIC under a different ToR switch. For example, NIC1 under the first ToR switch sends traffic to NIC5, NIC6, ..., NIC16. In total, we establish $16 \times 12 = 192$ RDMA connections. We configure the “- *run_indefinitely*” parameter at the client side of each connection to run the test indefinitely until interrupted by external.

Results: In the first experiment, we apply ECMP routing. ECMP is not CBD-free in this testbed. We see a deadlock after running our testbed for just a few seconds. (KSP typically generates more paths than ECMP, and thus KSP could also trigger deadlocks.) When deadlock happens, a large number of RDMA connections are broken. We deep dive into the source code of “*ib_write_bw*” to understand why many connections are tear down abnormally. We found that the PFC-deadlocks cause the verbs API “*ibv_post_send*” to fail and return an error code to the main program of “*ib_write_bw*”. Once the main program catch the exception code, “*ib_write_bw*” will stop sending traffic and clean up the resources. Note that, if we use dynamic PFC thresholds or use the recommended values to set static PFC thresholds (*XOFF* = 800KB, *XON* = 797KB), we could not observe PFC deadlocks under ECMP routing. However, this does not eliminate the deadlock risk for ECMP.

In the second and third experiments, we set up the edge-disjoint virtual up-down and the EDST routing respectively to run the same test. In this case, we do not see any deadlock even under low PFC pause/resume thresholds and all RDMA connections can work continuously. This experiment demonstrate that both the virtual up-down routing and the EDST routing can avoid PFC-deadlock in lossless Ethernet.

Finally, we track the average throughput for all the 192 RDMA connections under different routing strategies over one minute, and plot the results in Fig. 8. The virtual up-down routing attains the highest average throughput, which is about 50% higher than that of the EDST routing. Under ECMP routing, the average throughput drops quickly at the

Network Setup	Num. of Hosts	Num. of Switches	Copper / Fiber Cable (km)	Num. of Transceivers	Network Cost (Million \$)	All-to-All (load=0.3)			Uniform Random (load=0.3)			Near-Worst (load=0.3)

Table 3: FCT Results vs. Throughput Analysis. (“Tput” is short for “Throughput”.)

first 5 seconds due to PFC deadlocks. Although the average throughput of ECMP increases after deadlock recovery, 66% of the RDMA connections have already failed.

6.2 Understanding Deadlocks via Simulation

We perform packet-level simulation to understand how a deadlock is triggered. We use the same testbed topology (Fig. 4(a)) in our simulation. We generate 192 flows at time 0, and set all the flow sizes as 100MB. For different flows, we either disable congestion control or enable DCQCN for congestion control. When DCQCN is enabled, we set the ECN-marking related parameters as $K_{min} = 5KB$, $K_{max} = 200KB$, $P_{max} = 0.01$ as suggested by the DCQCN paper [57]. To simulate the extreme cases where lots of PFC pauses are triggered, we set a small PFC-pause threshold and a small PFC-resume threshold ($XOFF = 50KB$, $XON = 47KB$).

We evaluate ECMP and FC’s edge-disjoint virtual up-down routing. For adjacent switch pairs, there are two paths under both ECMP and FC’s edge-disjoint virtual up-down routing. For non-adjacent switch pairs, there are 8 shortest paths (4 clock-wise paths and 4 counter-clock-wise paths) under ECMP routing and 2 edge-disjoint virtual up-down paths (1 clock-wise path and 1 counter-clock-wise path) under FC’s routing. We assign a path to each flow using two strategies:

Balanced Allocation: There are 16 flows generated between every switch pair and we assign the same number of flows to each path under both routing strategies. In this case, every link between adjacent switch pair is shared by exactly 16 flows.

Imbalanced Allocation: Flows between adjacent switch pairs are still equally assigned to all the paths; but flows between non-adjacent switch pairs are only assigned to the clock-wise paths. This situation could happen due to hashing imbalance. In this case, every clock-wise link is shared by 24 flows, which becomes the bottleneck of the network. Incast can thus happen at the 4 switches. In addition, under ECMP routing, the following paths $\{[e_1, e_2], [e_2, e_3], [e_3, e_4], [e_4, e_1]\}$ form a CBD (actually there are more CBDs), which makes ECMP prone to deadlocks.

Results: Under balanced allocation, we do not see deadlocks even if we use a small static PFC threshold and disable DCQCN. In Fig. 9, we compare the CDFs of the FCTs (Flow Completion Time) under both ECMP and FC’s edge-disjoint virtual up-down routing with and without DCQCN. Both routing strategies yield similar FCT performance.

Under imbalanced allocation, FC’s routing can still finish all the flows and the FCT performance is shown in Fig. 9.

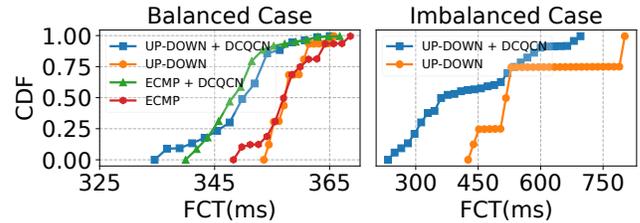

Figure 9: CDF of the FCTs of ECMP and FC’s routing under balanced/imbalanced allocation in the testbed topology.

In contrast, the ECMP routing triggers a deadlock even if we enable DCQCN. To rootcause this issue, we record all the PFC pauses and PFC resumes. We find 4 critical PAUSE signals that lead to the deadlock: 1) at time 531 us, S_1 sends a PAUSE to the link e_4 ; 2) at time 537 us, S_4 sends a PAUSE to the link e_3 ; 3) at time 543 us, S_3 sends a PAUSE to the link e_2 ; 4) at time 552 us, S_2 sends a PAUSE to the link e_1 . These events happen within just 21 us.

Takeaway: A DCN suffers from a high risk of deadlocks, when the following three conditions are met: 1) there exist CBDs in the network; 2) links in the CBDs are congested; 3) PFCs are triggered more frequently than usual. If we apply ECMP/KSP routing in an expander graph, we may have to constantly monitor the congested links and the abnormal switch behaviors. FC’s design completely eliminates CBDs, and thus could significantly simplify the RoCEv2 deployment.

7 Discussion

7.1 Handling Link/Node Failures

Link/node failures are common in practical data centers [16]. When a link/node fails, to avoid packet drop, local rerouting is performed to forward the affected packets along a different path to the destination [32]. Unfortunately, local rerouting may introduce CBDs and cause deadlocks even if the original network is CBD-free [24]. Consider the Clos network in Fig. 10(a). Initially, packets from ToR A to ToR E follow an up-down path $A \rightarrow B \rightarrow C \rightarrow D \rightarrow E$. When the link DE fails, packets that arrived at the switch D cannot find an alternative downstream path to E and thus are bounced back to F . Then, the path from A to E becomes $A \rightarrow B \rightarrow C \rightarrow D \rightarrow F \rightarrow G \rightarrow E$. This path contains a down-up bounce, which could introduce CBDs into Clos networks.

To avoid deadlocks in Clos networks under link/node fail-

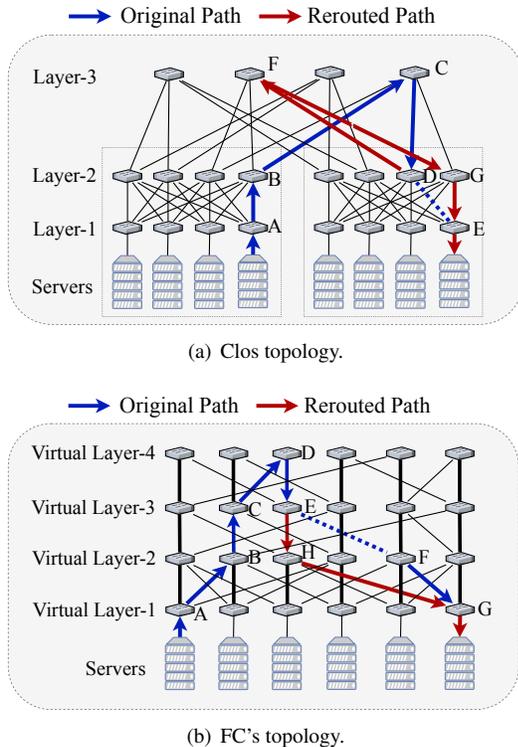

Figure 10: Rerouting under link failures.

ures, Tagger [24] adds a tag to all the packets, increases the tag on the bounce and puts packets with different tags into different lossless queues. This approach should also work for FC because we can treat FC as a virtual multi-layered network. Nevertheless, better approach may exist for FC. In Clos networks, every top-layer switch has a unique path to every ToR switch and thus every packet affected by a downstream link/node failure has to be bounced back to another top-layer switch. In contrast, every packet affected by a link/node failure in FC can freely choose any virtual layer as long as there is a link to forward this packet, because every virtual switch in the same column (see Fig. 10(b)) belongs to the same physical switch. For example, there is a flow from A to G in Fig. 10(b) and the original path is $A \rightarrow B \rightarrow C \rightarrow D \rightarrow E \rightarrow F \rightarrow G$. When the link EF fails, the affected packets can be rerouted to $A \rightarrow B \rightarrow C \rightarrow D \rightarrow E \rightarrow H \rightarrow G$. This new path is still an up-down path and thus tagging is not required. (Admittedly, if the rerouted path contains a down-up bounce, we still need to update the packet tags.) Based on the above analysis, we suspect that FC could be more efficient in handling link/node failures than a Clos network. We will explore this further in our future work.

7.2 Handling Route Reconfiguration

Route reconfiguration is common in data centers, which could happen when 1) new flows join/leave the network; 2) DCN

topology changes; 3) Traffic Engineering is enabled; 4) an SDN controller reoptimizes routing paths after link/node failures. FC's design makes it easy to handle route reconfiguration. FC performs virtual up-down routing. As long as the virtual layers remain unchanged (i.e., which ToR port belongs to which virtual layer), the combined set of the original paths and the post-reconfiguration paths is CBD-free. This could dramatically simplify the workflow of route reconfiguration, because any transient state during route reconfiguration is guaranteed to be deadlock-free.

In rare cases, e.g., after data center expansion, we may need to change the virtual layers because the original number of layers may not be able to support a larger-scale network. In this case, there could be a CBD in a transient state during route reconfiguration. Existing solutions on deadlock-free route reconfiguration [11, 24, 33, 39] can be applied here.

7.3 The Scalability of Routing Tables

Expander graphs, including FC, Jellyfish [46], Xpander [50], FatClique [54], etc., face a common scalability challenge in the switch routing tables. Unlike Clos, expander graphs cannot easily aggregate IP addresses in the switch routing tables due to the increased routing complexity. To resolve this challenge, one potential solution is to design a hierarchically routing strategy, e.g., divide ToRs into groups based on their IP prefixes and then perform intra-group and inter-group routing separately. This approach could increase the chance of IP aggregation in the switch routing tables, but may also hurt path diversity and load balancing efficiency. We will explore this tradeoff further in our future work.

8 Conclusion

We present FC, a topology-routing co-designed methodology to eliminate PFC-induced deadlocks, for cost-effective and safe deployment of RoCEv2 over expander networks. Motivated by the fact that the up-down routing paths of multi-layered Clos networks are CBD-free, we design FC's topology to exhibit a virtual layered structure, and propose an edge-disjoint virtual up-down routing for FC that is guaranteed to be CBD-free. We evaluate FC against several competitors using throughput analysis, testbed implementation and packet-level simulation. Our evaluation results demonstrate that 1) FC is deadlock-free while ECMP/KSP may trigger deadlocks; 2) FC significantly reduces average hop count and improves network throughput over the state-of-art EDST-based routing strategy; 3) FC attains higher throughput than Clos networks built using the same number of switches under all-to-all and uniform random patterns. These properties make FC a promising design for deadlock prevention in expander graphs.

A Appendix

A.1 Finding Edge-Disjoint Paths Using Min-Cost Max-Flow

Definition 2 (*Min-Cost Max-Flow Problem*) Given a flow network $G(V, E)$ with

- $u(v, w)$, upper bound on flow from node v to node w ;
- $c(v, w)$, cost of a unit of flow on (v, w) ,

and a source-destination pair (s, t) , $[f(v, w)]_{(v, w) \in E}$ is called a flow assignment from s to t if the following constraints are met:

1. Capacity constraints: $0 \leq f(v, w) \leq u(v, w)$;
2. Flow conservation constraints: $\sum_u f(u, v) = \sum_w f(v, w)$ for any node $v \neq s, t$ and $\sum_w f(s, w) = \sum_u f(u, t) = F$. Here F is called the total amount of flow from s to t .

The objective of the min-cost max-flow problem is to find a flow assignment $[f(v, w)]_{(v, w) \in E}$ with the maximum flow that minimizes

$$\sum_{(v, w)} c(v, w) \cdot f(v, w).$$

Note that the constant parameters $u(v, w)$ are all positive and $c(v, w)$ can be either positive or negative. In addition, the min-cost max-flow problem has a very nice property that guarantees integer solutions:

Theorem 6 (*Integral Flow Theorem*) Given a min-cost max-flow problem, if $u(v, w)$'s are all integers, then there exists an integer solution, i.e., $f(v, w)$'s are all integers, such that $[f(v, w)]_{(v, w) \in E}$ attains the maximum flow with minimum cost.

In fact, when we solve a min-cost max-flow problem with integer bounds using the Scaling Push-Relabel algorithm [1, 17], the resulting optimal solution is guaranteed to be an integer solution.

Finding Edge-Disjoint Paths: As a consequence of Theorem 6, we can find the maximum number of edge-disjoint paths from s to t using min-cost max-flow. Specifically, let E_0 be the set of links that can be used at most once (see the solid links in Fig. 4(c)), and $E \setminus E_0$ be the set of links that can be used multiple times (see the dashed links in Fig. 4(c)). If we set the upper bound as $u(v, w) = 1$ for all the links $(v, w) \in E_0$ and set the upper bound as $u(v, w) = \infty$ for all the links $(v, w) \in E \setminus E_0$, then the resulting min-cost max-flow solution $[f(v, w)]_{(v, w) \in E}$ can be decomposed into F (F is the maximum flow) paths where links in E_0 can be used at most once. The F paths can be found by performing Depth First Search F times (see Algorithm 1). Note that when we perform DFS in line 5 of Algorithm 1, we will never encounter a cycle. Otherwise, by removing this cycle we could obtain another flow assignment with lower cost. Having this observation could slightly simplify the DFS implementation. We do not need to track the set of visited nodes during the DFS search.

Algorithm 1: Find Edge-Disjoint Paths in the Directed Virtual Up-Down Graph

Input : A directed virtual up-down graph (see Fig. 4(c)) and a source-destination pair (s, t) .

Output : Maximum number of edge-disjoint up-down paths from s to t .

- 1 Let E_0 be the set of solid lines in the directed virtual up-down graph. Construct a flow graph by setting the link capacity and the link cost as 1 for all links in E_0 , and setting the link capacity as ∞ and the link cost as ϵ (an infinitesimal value) for all links not in E_0 .
 - 2 Solve the min-cost max-flow problem. Let $[f(v, w)]_{(v, w) \in E}$ be the optimal solution and let F be the maximum flow from s to t .
 - 3 Use \mathcal{P} to store the set of paths, and initialize $\mathcal{P} = \emptyset$.
 - 4 **for** i **in** $\{1, 2, \dots, F\}$ **do**
 - 5 Use Depth First Search to find a path P from s to t such that $f(e) \geq 1$ for every edge e in P .
 - 6 Store P in \mathcal{P} .
 - 7 For every edge e in P , decrement $f(e)$ by one.
 - 8 **end**
 - 9 Return \mathcal{P} .

A.2 A Sufficient and Necessary Condition for CBD-Free Routing

We first introduce the concept of *link dependency graph*.

Definition 3 Given a network $G(V, E)$ and a path set $\mathcal{P} = \{P_1, P_2, \dots, P_K\}$, a link dependency graph $G'(V', E')$ can be constructed as follows:

1. V' is the set of directed links used by at least one path $P \in \mathcal{P}$;
2. For any $e_1, e_2 \in V'$, there is a directed link from e_1 to e_2 in E' if and only if e_1 is the next hop of e_2 in one path $P \in \mathcal{P}$.

Then, the following theorem offers a sufficient and necessary condition for a set of paths to be CBD-free.

Theorem 7 Given a network $G(V, E)$, a path set $\mathcal{P} = \{P_1, P_2, \dots, P_K\}$ is CBD free if and only if the corresponding link dependency graph $G'(V', E')$ contains no loops.

Proof 2 Necessity \Rightarrow : If the path set \mathcal{P} is CBD free, we prove that $G'(V', E')$ contains no loops. We prove this by contradiction. Suppose that $G'(V', E')$ contains a loop $v'_1 \rightarrow v'_2 \rightarrow \dots \rightarrow v'_s \rightarrow v'_1$. Let e_i be the link in $G(V, E)$ that corresponds to v'_i . Since e_1 is the next hop of e_2 in a path, if e_1 is paused, e_2 will be paused. Based on the same argument, e_3, \dots, e_s will be paused. Since e_s is the next hop of e_1 in a path, the pause of e_s will in turn pause e_1 . Then, a CBD is formed, which contradicts the assumption that the path set \mathcal{P} is CBD-free.

Sufficiency \Leftarrow : If $G'(V', E')$ contains no loops, we prove that the path set \mathcal{P} is CBD free. We again prove this by contradiction. Suppose that \mathcal{P} contains a CBD. Then, there must exist a sequence of links e_1, e_2, \dots, e_s such that e_i is the next hop of e_{i+1} in a path and e_s is the next hop of e_1 in a path. Then, the corresponding vertices of e_1, e_2, \dots, e_s in $G'(V', E')$ forms a loop, which contradicts to the assumption that $G'(V', E')$ contains no loop.

According to Theorem 7, we design Algorithm 2 to check if a set of paths is deadlock-free.

Algorithm 2: Check if a set of paths is deadlock-free

Input : A set of paths $\mathcal{P} = \{P_1, P_2, \dots, P_K\}$ and a network $G(V, E)$.

Output : Whether \mathcal{P} is deadlock-free.

- 1 Construct a link dependency graph $G'(V', E')$ based on Definition 3.
 - 2 Use deep first search to check if $G'(V', E')$ has a loop.
 - 3 Return true if G' has no loop; return false otherwise.
-

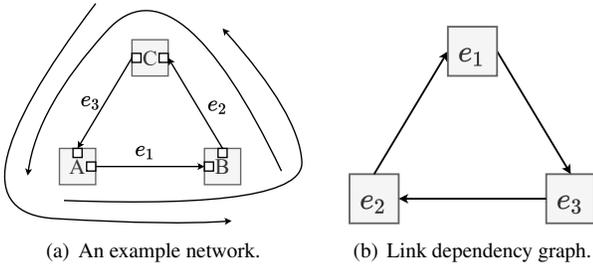

Figure 11: Deadlock detection with a link dependency graph.

We use the example in Fig. 11 to illustrate the idea of the deadlock detection algorithm. Given a path set $\mathcal{P} = \{A \rightarrow B \rightarrow C, B \rightarrow C \rightarrow A, C \rightarrow A \rightarrow B\}$, we can construct a link dependency graph with three vertices: $e_1(A \rightarrow B), e_2(B \rightarrow C), e_3(C \rightarrow A)$. It is easy to see that this link dependency graph contains a loop. Thus, the path set \mathcal{P} contains a CBD.

Using Theorem 7, we can prove that up-down routing is CBD-free in a multi-layered network.

Theorem 8 *In a multi-layered network, the path set generated by up-down routing is CBD-free.*

Proof 3 *For all the links in a multi-layered network, we can define a partial order as follows. A link e_1 is considered smaller than another link e_2 if either of the following three conditions is met:*

1. e_1 is an up link while e_2 is a down link;
2. e_1, e_2 are down links and e_1 is at a higher layer than e_2 ;
3. e_1, e_2 are up links and e_1 is at a lower layer than e_2 .

Then, when we construct a link dependency graph based on up-down paths, it is easy to verify the following fact: if there is a directed link from e_1 to e_2 , we must have $e_2 < e_1$. Therefore, the link dependency graph cannot contain a loop. As a result, the path set generated by up-down routing is CBD-free.

A.2.1 Proof of Lemma 4

Proof 4 *Since the path set \mathcal{P} is CBD free in $G(V, E)$, the corresponding link dependency graph $G'(V', E')$ must contain no loop. In this case, we could construct a new graph $G''(V', E'')$ by adding a link from $v_1 \in V'$ to $v_k \in V'$ whenever there exists a sequence of node $v_2, v_3, \dots, v_{k-1} \in V'$ such that $(v_i, v_{i+1}) \in E'$ for every $i = 1, 2, \dots, k - 1$. It is easy to check that $G''(V', E'')$ is also loop-free.*

Now we consider the contraction process. Let $\hat{G}'(\hat{V}', \hat{E}')$ be the link dependency graph of $(\hat{G}(\hat{V}, \hat{E}), \hat{\mathcal{P}})$. We can prove that $\hat{G}'(\hat{V}', \hat{E}')$ is a subgraph of $G''(V', E'')$. First, in $\hat{G}(\hat{V}, \hat{E})$, the edges within each vertex set $V_i (i=1, 2, \dots, m)$ are removed. Thus, $\hat{V}' \subseteq V'$. Second, for any edge $(e_1, e_2) \in \hat{E}'$, there must be a path $\hat{P} \in \hat{\mathcal{P}}$, such that e_1 is the next hop of e_2 in \hat{P} . Note that \hat{P} is obtained by contracting a path $P \in \mathcal{P}$. We must have e_1 as a down-streaming hop (not necessarily next hop) of e_2 in P . Based on the construction of $G''(V', E'')$, we know that $(e_1, e_2) \in V''$. Therefore, $\hat{E}' \subseteq V''$. Based on the above analysis, we immediately know that $\hat{G}'(\hat{V}', \hat{E}')$ is a subgraph of $G''(V', E'')$. Since $G''(V', E'')$ is loop-free, $\hat{G}'(\hat{V}', \hat{E}')$ must also be loop-free. Then, according to Theorem 7, we must have that the path set $\hat{\mathcal{P}}$ is CBD free in the topology $\hat{G}(\hat{V}, \hat{E})$.

A.3 Generating a Clos Network with H Hosts Using N p -Port Switches

Given N p -port switches and H hosts, we study how to construct a Clos network with the maximum throughput.

We first consider a 2-layered Clos Network. For each switch, let h be the number of ports connected to hosts. Then, the total number of switches in the first layer (i.e., the ToR layer) is $\lceil H/h \rceil$. As long as $\lceil H/h \rceil \leq p$, we can put $p - h$ switches in the second layer and create a complete bipartite graph between the ToR switches and the switches in the second layer. In total, $\lceil H/h \rceil + p - h$ switches are used. To maximize throughput, we only need to find the smallest h by solving the following optimization problem:

$$\min h \text{ such that } \lceil H/h \rceil \leq p, \lceil H/h \rceil + p - h \leq N. \quad (5)$$

In many cases, it may not be feasible to construct a 2-layered Clos network or a 2-layered Clos network may not be throughput optimal. Hence, we also need to study how to construct a multi-layered Clos network.

We adopt a trial-and-error approach to find the throughput optimal L -layered Clos network ($L = 3, 4, \dots$). Starting from $h = 1$, we try if it is possible to construct an L -layered Clos

			2m	5m	10m	15m	20m	30m	50m	100m	(100 + 50x)m	100m	500m	2000m
\$ 59099	\$ 60000	\$ 189	\$ 4.29	\$ 4.71	\$ 5.29	\$ 5.71	\$ 6.38	\$ 7.38	\$ 9.46	\$ 16.54	\$ (16.54 + 6.3x)	\$ 499	\$ 799	\$ 1099

Table 5: Unit Price of Different Network Components.

network using at most N switches. If it is possible, we obtain the optimal h for the L -layered Clos network; otherwise, we increase h by one and retry the construction.

Starting from $L = 2$, we could use the above approach to find the best $h(L)$ for every L ($h(L) = \infty$ if it is not feasible to construct an L -layered Clos network). $h(L)$ may decrease at the beginning, but will eventually increase with respect to L . Whenever we see $h(L) < h(L + 1)$, we can stop and return the minimum value of h , denoted by h^* . With h^* , the optimal throughput is $(p - h^*)/h^*$. When $h^* \leq \lfloor p/2 \rfloor$, the optimal throughput becomes larger than 1. In this case, the DCN offers abundant capacity while the access links between servers and ToRs become the bottleneck.

A.4 Network Cost Analysis

We offer a rough estimate about the total network cost for FC and Clos in this section. The network cost includes the electrical switch cost, the OCS cost and the cabling cost. Given an FC and a Clos with the same number of servers, we vary the number of servers per ToR switch and compute the number of required electrical switches and OCSs (only FC uses OCSs). To compute the cabling cost, we assume that intra-rack connections use direct attach copper cables, and inter-rack connections use optical fibers. An optical fiber requires an optical transceiver to connect to an electrical switch. The number of optical transceivers is easy to compute, which is equal to the total number of connected electrical switch ports

(some switch ports may be unused) minus the total number of hosts. In contrast, the copper/fiber cable length depends on the detailed network layouts.

A.4.1 FC's Layout

In order to estimate the cable length, we make the following assumptions about FC's layout. On a data center floor, all the servers, switches and OCSs are hosted in racks. We use 2d coordinates (x, y) to represent a rack location.

- The i -th ToR switch is located at $((-1)^{\lfloor i/N_r \rfloor} (\lfloor i/(2N_r) \rfloor + 1), i\%N_r)$, where N_r is the number of racks per column;
- A rack can host four OCSs, and the i -th OCS is located at $(0, \lfloor i/4 \rfloor)$.

Fig. 12(a) shows FC's layout. For FC, the server-ToR connections use 2-meter copper cables and the ToR-OCS connections use fiber cables. We use Manhattan distance to compute the cable length between two racks. We vary N_r so that the total fiber cable length is minimized.

A.4.2 Clos's Layout

We focus on 3-layered and 4-layered Clos networks below. Both the 3-layered and 4-layered Clos networks follow the ToR-Aggregation-Spine architecture. In a 3-layered Clos,

Number of Switches	Number of Servers	k	Port Count of Virtual Switches	η	Cabling Constraint	Average Number of Paths	Average Path Length	Minimum Number of Paths
500	12000	4	[7, 13, 13, 7]	4	N	16.08	4.57	12.00
					Y	16.10	4.57	12.00
1000	24000	4	[7, 13, 13, 7]	7	N	14.01	4.86	9.00
					Y	14.01	4.86	9.00
2000	48000	5	[5, 10, 10, 10, 5]	13	N	15.77	5.36	11.00
					Y	15.77	5.36	11.00
3000	72000	5	[5, 10, 10, 10, 5]	19	N	14.66	5.54	10.00
					Y	14.66	5.53	10.00
5000	120000	5	[5, 10, 10, 10, 5]	32	N	13.28	5.75	9.00
					Y	13.28	5.75	9.00

Table 6: Using virtual-layered cabling has little impact on FC’s routing statistics (64-port switches are used).

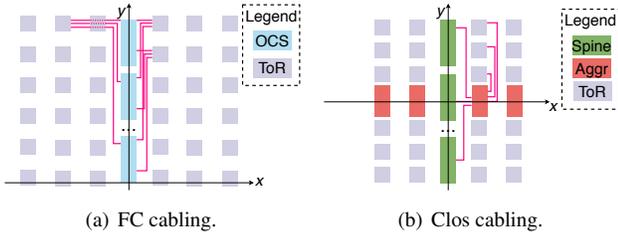

Figure 12: Layouts of FC and Clos. The red lines are the cable paths. To avoid visual clutter, most cable paths are omitted.

each spine is an electrical switch; in a 4-layered Clos, each spine is a 2-layered folded Clos built with electrical switches. We make the following assumptions about Clos’ layout.

- The aggregation switches in the i -th PoD are located at $((-1)^i(\lfloor i/2 \rfloor + 1), 0)$;
- The j -th ToR switch in the i -th PoD is located at $((-1)^i(\lfloor i/2 \rfloor + 1), (-1)^j(\lfloor j/2 \rfloor + 1))$;
- For a 3-layered Clos, a rack can host 24 spine switches, and the i -th spine is located at $(0, (-1)^{\lfloor i/24 \rfloor}(\lfloor (i + 24)/48 \rfloor))$. For a 4-layered Clos, we use 2 co-located racks to host a gigantic spine. Each gigantic spine is a folded Clos network, with 32 32-port switches in the first layer and 16 32-port switches in the second layer. The i -th gigantic spine is located at $(0, 2(-1)^i(\lfloor (i + 1)/2 \rfloor))$ and $(0, 2(-1)^i(\lfloor (i + 1)/2 \rfloor + 1))$. Note that the intra-spine links use copper cables.

Fig. 12(b) shows Clos Network’s layout. For Clos, the ToR-Aggregation and Aggregation-Spine connections use fiber cables. The Server-ToR connections use 2-meter copper cables. For 4-layered Clos, the intra-Spine connections also use 2-meter copper cables. Again, we use Manhattan distance to compute the cable length between two racks.

A.4.3 Comparison Results

Table 4 compares the number of electrical switches/optical transceivers/OCSs and the copper/fiber cable length for FC

and Clos networks. For each row, the number of servers per ToR in a Clos network has been carefully chosen such that its bisection bandwidth is equal to or slightly lower than that of FC. Generally speaking, given an FC and a Clos with the same number of hosts and similar bisection bandwidth, FC requires fewer number of electrical switches and optical transceivers, but it requires more fiber cables and additional OCSs.

Next, we offer a rough estimate on the total network cost for FC and Clos. The unit prices of different network components are summarized in Table 5. A 32×400 Gbps electrical switch costs about \$59000 [2] and a 320×320 optical circuit switch costs about \$60000 [8]. Intra-rack connections, including server-ToR connections and intra-spine connections, use 2-meter 400Gbps copper cables, which cost about \$189 [10]. The price of fiber cables increases sub-linearly with respect to the fiber length [13]. (The prices listed in [13] are the prices for 12-fiber bundles. We have divided the original price numbers by 12 in Table 5.) Hence, for each fiber cable used, we pick the shortest fiber in Table 5 that is longer than this fiber cable and use its price as the cost. The price of optical transceivers also varies depending on the transmission distance [37]. For FC, we use 2km optical transceivers because the adopted transceivers must have enough power budget to traverse an OCS. Note that traversing an OCS typically incurs about 1.5dB loss (at most 3dB) [8]. For Clos, we choose between 100m or 500m optical transceivers depending on the fiber cable length. We compare the total network cost in Table 4. When the network size is small (3-layered Clos is used), FC and Clos have similar network cost; when the network size is large (4-layered Clos is used), FC’s network cost is smaller. In addition, under similar bisection bandwidth, FC uses fewer number of electrical switches and thus its network power consumption is lower (the power consumption of an OCS is only 50watts [8], which is negligible).

A.5 Additional Results

A.5.1 Impact of Cabling on FC’s Routing

We generate FC’s topology of different sizes & η values and evaluate if the virtual-layered cabling strategy has any impact on FC’s routing. From Table 6, we cannot see clear difference

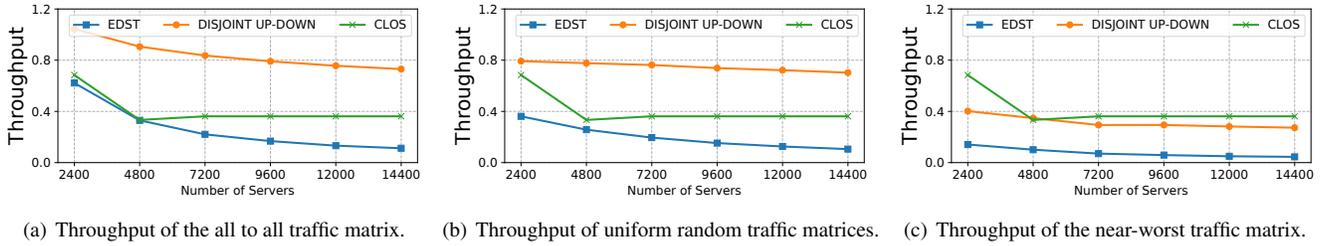

Figure 13: Throughput simulation results using 64-port switches.

Number of Switches	Number of servers	k	Port Count of Virtual Switches	Routing	Average Number of Paths	Average Path Length	Average Shortest Path Length
500	12000	4	[7, 13, 13, 7]	Edge Disjoint Up-down	16.08	4.57	3.20
				EDST	20	18.34	5.26
1000	24000	4	[7, 13, 13, 7]	Edge Disjoint Up-down	14.01	4.86	3.50
				EDST	20	26.52	6.99
2000	48000	4	[7, 13, 13, 7]	Edge Disjoint Up-down	11.85	5.13	7.00
				EDST	20	33.49	9.12
3000	72000	4	[7, 13, 13, 7]	Edge Disjoint Up-down	10.63	5.30	6.00
				EDST	20	39.82	10.45

Table 7: Edge-Disjoint Virtual Up-down Routing vs. the EDST Routing (64-port Switches are Used).

when we enable/disable the cabling constraints.

A.5.2 Throughput Analysis

Clos, FC and Expander+EDST are three network architectures that are guaranteed to be deadlock-free. For networks built using 32-port switches, we demonstrate in Section 4 that

1. FC consistently outperforms Expander+EDST;
2. FC achieves higher throughput than Clos networks under all-to-all and uniform random traffic patterns.

In this section, we generate FC’s topologies of different sizes using up to 600 64-port ToR switches. Each ToR switch has 40 ports connected to other switches and 24 ports connected to servers. The number of virtual layers k is chosen based on the strategy (*) in Section 3.2.3. We evaluate both FC’s edge-disjoint virtual up-down routing and the EDST routing. For each FC’s topology, we also compare it with a Clos network generated using roughly the same number of switches with throughput optimized. From Fig. 13, we can see that the above conclusions on FC’s throughput benefits also hold for networks built using 64-port switches.

A.5.3 Routing-Path Analysis

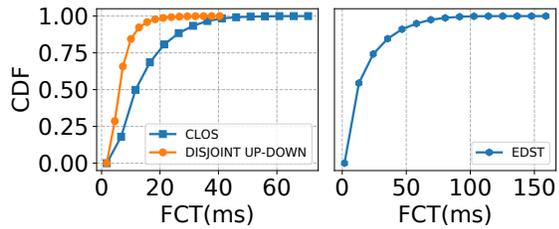

We then perform the same routing-path analysis for FC’s edge-disjoint virtual up-down routing and the EDST routing. We generate FC’s topologies of different sizes ($N = 500/1000/2000/3000$) using 64-port ToR switches with $s = 40$. As shown in Table 7, the average path length under FC’s routing is still much shorter than that under the EDST routing.

A.5.4 More Packet-Level Simulation Results

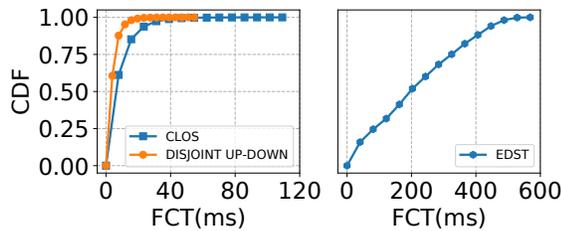

In Section 5, we perform packet-level simulation for three network setups: FC, FC+EDST, and Clos. Here, we present the detailed simulation results. We plot the CDFs for FCTs in Fig. 14. Apparently, the FCT performance under FC’s routing is much better than that under the EDST routing. Hence, we mainly focus on the comparison between FC and Clos.

Under the all-to-all traffic pattern and the uniform random traffic pattern, FC achieves clearly better FCT performance than Clos because it has higher throughput. This coincides with our throughput analysis in Section 4.3.

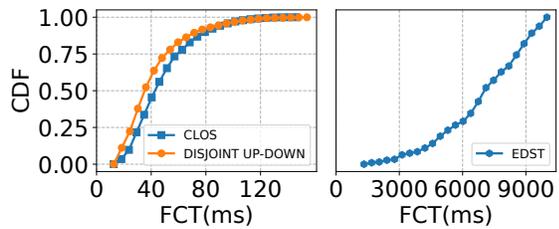

However, under the near-worst traffic pattern, we find that FC’s FCT performance is just slightly worse than the Clos network’s FCT performance. In contrast, our throughput analysis in Section 4.3 suggests that FC’s throughput is lower than the corresponding Clos network’s throughput. (In this case, FC’s throughput under the near-worst pattern is about 0.5, while the Clos network’s throughput is about 0.78.) The reason is that, the average hop count under FC is shorter than that under a Clos network; when the network is not congested, having a smaller average hop count compensates for the throughput gap between FC and Clos. Nevertheless, as network load increases, FC will encounter more severe congestion than Clos. We perform another simulation for the near-worst traffic pattern with network load increased from 0.3 to 0.7. (More specifically, we increase the size of each flow by 7/3 times.) As shown in Fig. 14(d), we can see that FC’s FCT performance is much worse than the Clos network’s FCT performance. In fact, we see a large amount of PFC PAUSE frames in FC’s network. But the good news is, there is no deadlock.

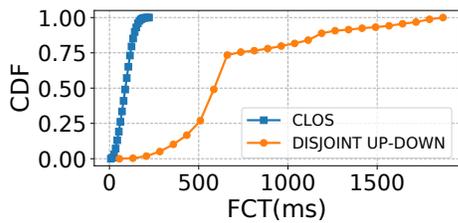

(a) All-to-all traffic pattern (Network Load=0.3).

(b) Uniform random traffic pattern (Network Load=0.3).

(c) Near-worst traffic pattern (Network Load=0.3).

(d) Near-worst traffic pattern (Network Load=0.7).

University of Washington

Abstract

In this paper, we consider how to provide fast estimates of flow-level tail latency performance for very large scale data center networks. Network tail latency is often a crucial metric for cloud application performance that can be affected by a wide variety of factors, including network load, inter-rack traffic skew, traffic burstiness, flow size distributions, oversubscription, and topology asymmetry. Network simulators such as ns-3 and OMNeT++ can provide accurate answers, but are very hard to parallelize, taking hours or days to answer what if questions for a single configuration at even moderate scale. Recent work with MimicNet has shown how to use machine learning to improve simulation performance, but at a cost of including a long training step per configuration, and with assumptions about workload and topology uniformity that typically do not hold in practice.

We address this gap by developing a set of techniques to provide fast performance estimates for large scale networks with general traffic matrices and topologies. A key step is to decompose the problem into a large number of parallel independent single-link simulations; we carefully combine these link-level simulations to produce accurate estimates of end-to-end flow level performance distributions for the entire network. Like MimicNet, we exploit symmetry where possible to gain additional speedups, but without relying on machine learning, so there is no training delay. On a large-scale network where ns-3 takes 11 to 27 hours to simulate five seconds of network behavior, our techniques run in one to two minutes with accuracy within 9% for tail flow completion times.

1 Introduction

Counterfactual simulation—to answer “what if” questions about the interaction of network protocols, workloads, topology, and switch behavior—has long been used by both researchers and practitioners as a way of quantifying the effect of design options and operational parameters [2, 16, 21, 23–26, 36]. As production data center networks have scaled up in bandwidth and scaled out in size [4, 29], however, network simulation has failed to keep pace. Although there is ample parallelism at a physical level in large scale data center networks, it has been difficult to realize significant speedup with packet-level network simulation [22, 30]. As packets flow through the network, the scheduling decisions at each switch affect the behavior of every flow traversing that switch, and therefore the scheduling decisions at every downstream switch, and—with congestion control—future flow behavior, in a cascading web of very fine-grained interaction. In our own experiments using ns-3 [23], for example, simulating a 384-rack, 6,144-host network on a single thread of a modern desktop CPU took 11

to 27 hours of wall-clock time to advance five seconds of simulated time. While parallel techniques for discrete event simulation exist [10], recent work has demonstrated their limited efficacy for speeding up simulations of highly interconnected data center networks [34]. As a result, packet-level network simulation today is mostly used for small scale studies.

The need for faster network simulation has spawned recent efforts to use machine learning to model how different parts of the network affect each other [32, 34]. While promising, these approaches have several limitations. MimicNet requires hours-long retraining for new workloads and network configurations, and it only accelerates simulations of uniform fat trees with uniform traffic among equally-sized clusters of machines [34]. DeepQueueNet relaxes some of MimicNet’s restrictions but does not model congestion control, which can be a first-order determiner of performance [32].

This paper aims to address this gap, to develop techniques for fast approximate simulation of large scale networks with arbitrary workloads and topologies. Our work involves no training step, aiming to produce near-real time results even at scale. In addition to reducing the cost of evaluating new protocols, another goal is to provide real-time decision support for network operators, such as warnings of SLO violations if links fail [17, 20], advice on task placement of communication-intensive jobs [7], and predicting the performance impact of planned partial network outages and upgrades [8, 35].

A key observation is that we could achieve high degrees of parallelism if we could somehow disentangle the interactions between switch queues, allowing us to study the behavior of the traffic on each link in isolation. Of course, switch queues are not in reality completely disentangled. The packets for any particular flow experience a very specific set of conditions at each switch, and those conditions are affected by the presence of upstream bottlenecks which can smooth packet arrivals for competing flows at downstream switches. The congestion response for a flow depends on the combination of conditions at every switch along the path.

However, large scale data center networks are typically managed with the goal of delivering consistent high performance to applications. While congestion events do occur, they are often chaotic rather than persistent, popping up and then disappearing in different spots due to the inherent burstiness and flow size distribution of applications, rather than due to some long-term mismatch between demand and capacity in some portion of the network [33]. Further, we are often interested in *aggregate* behavior, such as the frequency of poor flow performance, rather than the behavior of each individual packet or flow.

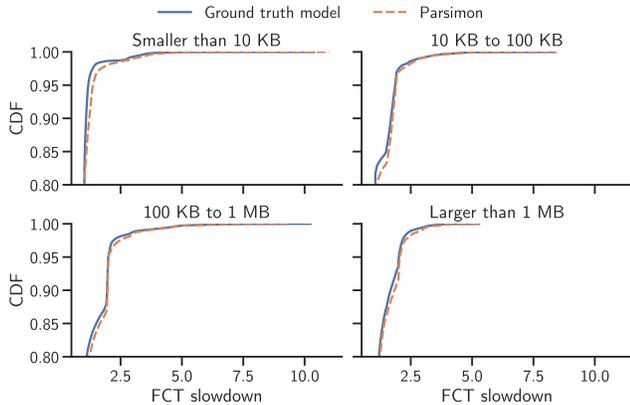

Figure 1. CDF of ns-3 versus Parsimon for flow completion time (FCT) slowdown across multiple flow size ranges, zoomed into the tail. While ns-3 took nearly 11 hours to produce these results, Parsimon took one minute and 19 seconds, end-to-end. Results were taken on a 6,144-host topology with an industry traffic matrix, 2-to-1 oversubscription, and bursty traffic.

To model aggregate behavior, our hypothesis is that we can approximate the distribution of end-to-end flow performance for a particular workload running on a large scale network by modeling the frequency and magnitude of local congestion events at each link along individual paths. A long flow will of course experience multiple congestion events during its lifetime, but most of these will occur at different points along the path *at different times*. Modeling the effect of simultaneous congestion events, and the response of the congestion algorithm to multiple simultaneous bottlenecks, is second order.

Our hypothesis is related to the concept of product-form solutions in queuing theory. For certain classes of queueing networks (e.g., Jackson [12] and BCMP networks [6]), the equilibrium distribution of queue lengths can be written in product form, i.e., the state of an individual queue is only dependent on the traffic it receives and not on the state of the rest of the network. These results generally require specific assumptions about job arrival processes (e.g., Poisson), service-time distributions (e.g., Exponential), and queueing/routing disciplines (e.g., FIFO or processor-sharing queues), and there has been much theoretical work on identifying classes of queueing networks that admit product-form solutions [13]. Although data center networks do not strictly conform to these conditions and the dynamics of each individual queue can be quite complex (e.g., due to congestion control), our hypothesis is that product-form solutions are approximately true in most realistic settings, and therefore we can analyze individual queues in isolation and combine the results to approximate end-to-end network behavior.

We built Parsimon to directly test this hypothesis. First, we deconstruct the network topology into a large number of simple and fast simulations where each can be run entirely in parallel by a single hyperthread. Each simulation aims to collect the distribution of delays that flows of a particular

size would experience through a single link, assuming that the rest of the network is benign. We then combine these simulated delay distributions to produce predictions of the end-to-end delay distribution, again for flows of a given size. At each step, we make conservative assumptions for how delays should be computed and combined. In many settings, researchers and operators are interested in keeping tail behavior well-managed, making a conservative assumption more appropriate than an optimistic one. Finally, Parsimon clusters links with common traffic characteristics, eliminating much of the overhead of simulating parallel links in the core of the network as well as edge links used by replicated or parallel applications, further improving simulation performance.

Because validation against detailed packet-level simulation at scale is so expensive, we focus our study on a single widely used transport protocol, DCTCP [2], with FIFO queues with ECN packet marking at each switch [27]. We also focus on queue dynamics rather than packet loss; most data center networks are provisioned and engineered for extremely low packet loss [28, 29]. We note that these assumptions are not fundamental to our approach. We show Parsimon generalizes to two other transport protocols, DCQCN [36] and the delay-based TIMELY [19]. Validation of other transport protocols [3, 14, 16, 21], switch queueing disciplines [1, 9, 11, 21], and packet loss remains future work. We note that modern data center transport layer protocols are adept at quickly adapting to the presence and absence of congestion, and so we caution our results may not extend to older transport protocols where convergence time is a large factor.

Parsimon speeds up simulations by reasoning about links independently, which enables massive parallelization, but at a cost in accuracy. As we will see in §3.6, anything that creates standing congestion both at the core and at the edge, or when cross traffic is correlated across multiple hops, will result in less accurate estimates. While our methods are designed to favor overestimating rather than underestimating tail latencies, this property is only evaluated experimentally (§5). In general there is no formal guarantee, since factors like congestion control can in theory behave in arbitrary ways that render less appropriate the approximation of considering links independently. We assume that we can simulate for long enough for the network to reach equilibrium; studies of short term transient behavior should not use our approach. We do not provide predictions at the level of an individual flow, but we are able to show that Parsimon is accurate for sub-classes of traffic for mixed workloads. We do not attempt to model end host scheduling delay of packet processing, even though that may have a large impact on network performance [14, 15]; we leave addressing that to future work.

To assess accuracy, we compare distributions of flow completion time (FCT) slowdown, defined as the observed FCT divided by the best achievable FCT on an unloaded network, and we say a flow is complete when all of its bytes have been delivered to its destination. Fig. 1 shows a sample of our results for

the 6,144 host network mentioned above, running a published industry traffic matrix [28] and flow size distribution [21], and with standard settings for burstiness and over-provisioning. We describe the details of this and other experiments later in the paper. Depicted are FCT slowdown distributions binned by flow size. While ns-3 took nearly 11 hours on this configuration, Parsimon was able to match flow-size specific performance of ns-3 in 79 seconds (a 492 times speedup) on a single 32-way multicore server with an error of 9% at the 99th percentile. Given a small cluster of simulation servers, we estimate a completion time of 21 seconds using our approach.

In our evaluation, we scan the parameter space to identify circumstances where our approximations are less accurate. Link clustering improves performance but hurts accuracy somewhat; this tradeoff can be avoided by using more simulation cores. Without clustering, accuracy suffers when there is high utilization of links in the core (above 50%), there are high levels of oversubscription, and a large fraction of network traffic is due to flows that finish within a single round trip. Generally, a combination of factors is required for poor accuracy. In 85% of the configurations we test, the error relative to ns-3 is under 10%.

Parsimon source code and evaluation scripts are publicly available at <https://github.com/netiken>.

2 Parsimon Overview

This paper describes a set of methods to quickly and scalably estimate distributions of flow performance in data center networks. These techniques are implemented in a prototype called Parsimon, designed to provide the following:

- **Fast, scalable estimates.** We aim to supply estimates two to three orders of magnitude faster than full-fidelity simulation. Given enough cores, execution time should remain bounded regardless of network size.
- **Tight latency bounds, including tail performance.** Our approximations bias slightly towards overestimation, but still provide close estimates even for the 95th or 99th percentile of the distribution for a given flow length.
- **Minimal restrictions on topology and workload.** Our methods are largely independent of both topology and workload, although some combinations of topology and workload will have lower accuracy.

Fig. 2 illustrates the intuition behind its core method, and Fig. 3 depicts its workflow. The user supplies 1) a description of the topology, as a set of nodes and links, and 2) the workload, as a set of flows and routes. In our implementation, we generate the flow list by sampling from the traffic matrix and the flow size distribution, with inter-arrival times determined by a burstiness parameter. Once inputs are supplied, Parsimon proceeds in several steps:

Decomposition. To start, flows are assigned to each link they traverse, e.g., for a fat tree using ECMP. Then, for each

link l , Parsimon generates a custom backend simulation with a topology selected to determine—as accurately as possible—the *contribution of l* to the end-to-end flow completion times (FCTs) of the flows passing through it. Each of these backend simulations can run in parallel.

Clustering. Depending on the size of the topology, there may be tens or hundreds of thousands (or more) of link-level simulations to perform. Fortunately, data center topologies exhibit notable symmetries, and industry has reported that the same is true for many of their workloads [28]. Parsimon can optionally cluster links with similar workloads together. Only one representative from each cluster need be simulated; the rest of the link-level simulations are pruned. Clustering is discussed in more detail in §4.2.

Simulation. The next step is to simulate all cluster representatives in parallel. The decomposition step resulted in a topology and a workload for each link-level simulation, and we can use any simulation backend. Our prototype supports two: ns-3 and a custom high-performance link-level simulator (§4.1). This allows us to directly validate our link-level simulator against ns-3. However, other efficient models, such as fluid flow [18] or machine learned models could be used here instead, for different tradeoffs of performance and accuracy. Each link-level simulation produces a distribution of the delay contributed by that link to the flow completion time (FCT), bucketed by flow size. Note this is not the link’s propagation delay—we calculate that contribution directly from the topology. These distributions—described in the next section (§3)—are organized according to the original input topology, as depicted in Fig. 2. Recall that only one representative from each cluster is simulated; every other link is populated with the distributions of its cluster representative.

Aggregation. The last step is to aggregate the link-level results into estimates for entire paths through the network. These estimates are also represented as delay distributions. Conceptually, Parsimon obtains a delay distribution for a path by convolving together the appropriate distributions from each of the path’s component links. Since there are multiple distributions per link and potentially many paths through the network, we do not compute convolutions up-front. Instead, convolution is done on-demand via Monte Carlo sampling; a by-product is that we can efficiently produce estimates for individual source-destination pairs, virtual networks, or classes of service (§A). To make a single point prediction for a flow taking some path through the network, Parsimon uses the flow size to find the appropriate distribution for each link, samples a value from each of them, and combines them together. This process is repeated for each flow.

At a bird’s-eye view, Parsimon’s method is simple: to accelerate FCT estimates, we estimate the effect of each link independently and in parallel. Then to make predictions about the whole network, we combine the results. However in our experience, the accuracy of the method hinges tightly on the

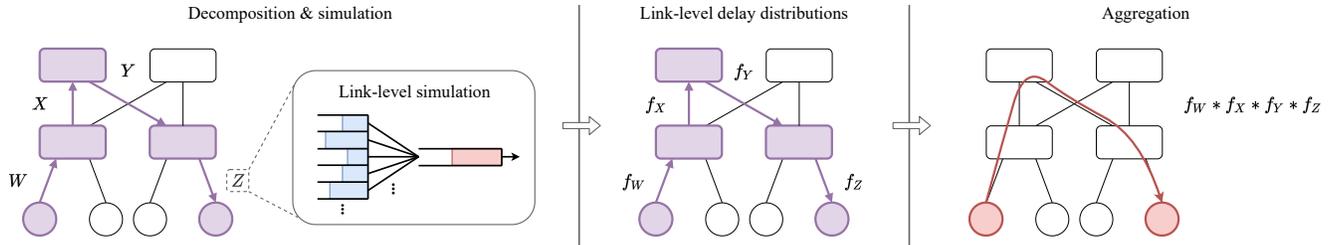

Figure 2. Overview of Parsimon. First, for any path, Parsimon estimates the contribution of each component link to delays in flow completion times, represented as a probability distribution. Parsimon then combines delays along the path using Monte Carlo simulation (see §3). Further, for added performance, link-level simulations are optimized and redundant simulations (due to e.g., ECMP or symmetries in workload patterns) are pruned (see §4).

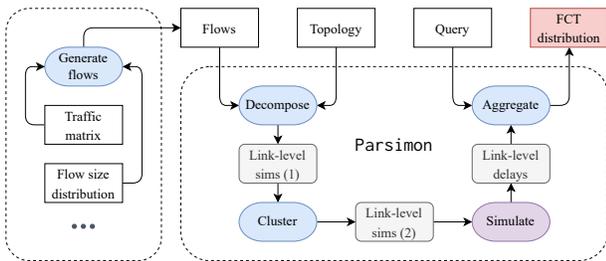

Figure 3. An illustration of Parsimon’s workflow. All inputs and outputs are shown in the top row. Rectangular boxes are inputs and outputs, rounded boxes are intermediate artifacts, and ovals are Parsimon’s actions.

quality of the link-level estimates and subsequent aggregation. For example, when generating the backend simulations, we have observed that failure to adequately capture pertinent features of the network severely degrades the quality of Parsimon’s estimates. Similarly, link-level results must be processed and aggregated with care to preserve accuracy across all flow sizes. §3 describes these techniques in detail.

3 Key Methods: Decompose and Aggregate

Together, the methods for decomposition and aggregation are what enables Parsimon’s scaling, and while we later engage additional techniques for further speed-up, they are a byproduct of—and not independent from—these more essential methods. Decisions made during this step are also the central determiners of accuracy. This section describes these processes in detail: how link-level topologies are generated, how the link-level data are post-processed and stored, and finally how they are aggregated to produce end-to-end estimates.

3.1 Generating Link-Level Workloads

To start, Parsimon associates each link with the flows passing through it. Since links are bidirectional, there are two sets of flows—and consequently two link-level simulations—per link. Parsimon populates links with flows using flows’ routes. Then for each link and in each direction, the associated flows constitute the input workload to the link-level simulation. The sizes and arrival times of the flows pass through unmodified.

3.2 Generating Link-Level Topologies

Once the link-level workloads are in place, we generate the link-level topologies. In this step, we think of each link as contributing some amount of delay to end-to-end FCTs. Any given flow will accrue these delays at each hop, depending on—for example—how much bandwidth is available and how much queuing is present. Highly-loaded links are expected to contribute more delay, while rarely utilized links will contribute relatively little.

For each link and in each direction, we generate a topology and perform a simulation using just the flows traversing that link. Once the simulation is finished, the delay caused by the link for a given flow is computed by taking the observed FCT and removing the ideal FCT for that flow size. (For a flow of size s traversing a link of speed C and propagation delay l , the ideal FCT is $s/C + l$.) This intuitively captures all delays incurred due to queuing, congestion control, bandwidth sharing, and so on at the target link.

In generating a per-link topology, our goal is to isolate and measure the expected delay contribution of the target link. A simple but inefficient strategy would be to use the original topology, but with only the traffic traversing the target link, without any cross traffic. This would be relatively accurate at measuring the delay contributed by the target link, albeit a bit conservative. Upstream cross traffic congestion will slightly smooth out downstream congestion at the target link, and so removing cross traffic would make the queue distribution at the target link slightly worse than in reality.

Although relatively accurate and parallelizable, simulating every link on the original network topology would still be inefficient, as packet-level simulation cost is roughly proportional to the number of packets simulated times the number of hops each packet takes through the network. Because we run the link simulation separately in each direction on every packet that passes through that link, this would inflate the aggregate computational cost of the simulation by a multiplicative factor of roughly half the average network path length—a significant factor for large-scale networks. Instead, we want to simulate only a small constant number of hops per target link.

An extreme alternative would be to simulate only the target switch queue. This is inaccurate for two reasons. First, we

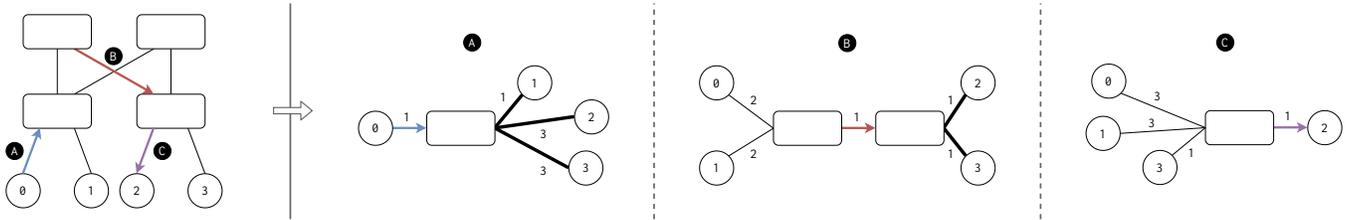

Figure 4. An illustration of how Parsimon generates link-level topologies. Simulations are unidirectional, and a different topology is used for (A) first-hop links, (B) switch-to-switch links, and (C) last-hop links. For illustration purposes, each link in the original topology has a propagation delay of one. To the left is the original topology; to the right are the corresponding link-level topologies, with new propagation delays annotated. Bold lines denote links whose bandwidths have been artificially increased during topology generation.

need to preserve end-to-end round trip delays, as these affect the speed of the congestion control adaptation to congestion or its absence; hosts closer to the target adapt faster than those farther away. Second, we need to preserve the spacing of packets induced by the original topology—a large flow does not immediately dump all of its data into the queue for the target link; instead, those packets arrive spaced apart by the edge link capacity. Ignoring this effect would lead to larger queues and more delay at the simulated link than would occur at that link in the original network.

Thus, we construct a topology for each link-level simulation that reflects a performance-accuracy tradeoff, attempting to capture the most important effects for computing the delay contributed by the target link. Fig. 4 shows how topologies are minimized. The generated topology takes one of three shapes, depending on the location and direction of the target link: (i) a first-hop up-link from a host to a ToR, (ii) a switch-to-switch link in the middle of the network, or (iii) a last-hop downlink from a ToR to a host.

Suppose the traffic through the target link originates from sources S and terminates in destinations T . In case A of Fig. 4, we connect the target link directly to each host in T via a dedicated link. If the target link is a switch-to-switch link (case B), we remove intermediate hops and connect the hosts in S directly to the input, and the output directly to the hosts in T . Lastly, if the target link is a last hop (case C), then the hosts in S are connected directly to the input. Rewriting the topology in this manner ensures that packets can traverse at most three hops, regardless of the size of the original topology.

Modeling round-trip delay. Next, we set the link delays in each constructed topology to match the round trip delays in the original network. For example, in case A of Fig. 4, the round-trip time between host 0 and host 2 is 8 in both the original topology and the generated topology, even though Parsimon has removed intermediate hops between the switch and host 2. Fig. 4 is meant as illustrative; as with ns-3, Parsimon can model arbitrary round-trip delays.

In data center networks, congestion controllers play a large role in determining the extent to which longer flows yield throughput to benefit the latency of short flows. Most algorithms such as DCTCP [2], DCQCN [36], and TIMELY [19]

are *end-to-end* in the sense that sources adjust their sending rates based on feedback echoed from destinations [11]. With an end-to-end control loop, a source must wait an entire round-trip time (RTT) before being able to adapt its sending rate based on congestion feedback, resulting in longer queue lengths with higher RTTs. Thus, correctly modeling RTTs is essential to correctly modeling queue dynamics.

Selecting link bandwidths. In some cases, we artificially increase the bandwidth of downstream links to ensure that they do not artificially add congestion. We say such links are *inflated*. For example, in cases A and B of Fig. 4, the bandwidths of the last-hop links are inflated. We want any queueing to be due to the target link and not the downstream link. By inflating downstream links, we remove store and forward delay (a small packet following a large packet would otherwise need to queue for the downstream link); it also addresses the case where core links are fatter than downstream links. Queueing at the downstream link itself is accounted for in case C. By contrast, we do *not* inflate first-hop links in cases B and C, as this would enable a long flow to arrive at the target link at a higher rate than it would in practice.

A cluster of sources sending simultaneously through an oversubscribed top-of-rack (ToR) switch in the original network will be throttled beyond what is implied by the edge link capacity. To improve simulation speed, we ignore this effect and are therefore slightly conservative in our estimates for oversubscribed networks.

Correcting for ACK traffic. Since Parsimon only simulates one direction at a time, we must account for the load induced by acknowledgments due to traffic in the reverse direction. This is usually small, but can be significant at high load and where average packet size is small. Instead of modeling ACK traffic in detail, we apply a simple rule, mechanically reducing the forward bandwidth on each simulated link by the average volume consumed by ACKs for flows in the opposite direction over the course of the simulation. This correction is applied to all links but is most necessary for the target link. Note that Parsimon does not account for extra delay caused by ACK jitter on the reverse path; this could be an issue when applying our ideas to networks with bandwidth asymmetry between forward and reverse paths [5].

3.3 Post-Processing Link-Level Results

Each link-level simulation produces an FCT for each flow in the link-level workload, and these FCTs are used to compute delays. Recall from §3.2 that the delay is just the observed FCT minus the ideal FCT on an unloaded network. For each flow, we could, theoretically, estimate the end-to-end delay as some function of the delay contributed by each link for that flow. We discuss how that function works in Parsimon, along with its sources of bias, later in this section.

First, we address a different issue. Recall that we cluster similar links together (§4.2) so that we only simulate the flows through a single representative link for each cluster of links. Thus, to compute the end-to-end delay for a particular flow, we take a sample from the delay distributions at each hop in the path, or from the hop's standin representative.

In post-processing the link-level results and constructing these distributions, our primary objective is to support accurate estimates for *all flow sizes*. It is not enough to produce the correct FCT distribution across the entire workload; we must also accurately estimate the FCT distribution for short flows containing just a few packets as well as for long flows that last for hundreds of round trips. This extra requirement necessitates some post-processing before distributions can be constructed. Here we describe how this is done.

Packet-normalized delay. Maintaining accuracy across all flow sizes would not be possible if we used delays directly. For example, long flows, which may experience variations in their bandwidth share over time, will almost always experience more absolute delay than short flows.

As a start, we can address this by normalizing delays by flow size: after computing the delay for a particular flow, we can then divide the delay by the flow's size in packets. We call the resulting metric the *packet-normalized delay*, and it has the intuitive interpretation of summarizing the flow's average delay per packet. Link-level distributions are constructed from packet-normalized delays rather than absolute delays. We normalize by the number of packets instead of the number of bytes because flows are discretized into—and therefore delays are incurred by—packets. Further, normalizing by the number of bytes loses accuracy for small flows, especially those smaller than the maximum packet size. For example, a 10 byte packet would be delayed by the same amount as would a 100 byte packet if it arrived in the switch queue just behind a jumbo (9 KB) frame [31].

Bucketing distributions. Even with packet-normalized delays, we should still expect long flows to have different delay distributions than short flows. The FCT of a long flow is mainly determined by the throughput it achieves, while the FCT of a short flow depends on how much queueing it encounters. Further, congestion control algorithms trade the throughput of long flows for the latency of shorter ones to varying degree. An aggressive congestion control algorithm

could try to keep queues near-empty [16], resulting in smaller short-flow delay and larger long-flow delay.

To ensure that estimates for different flow sizes are accurate, it is necessary to sample each packet-normalized delay from the appropriate distribution. We bucket the distribution of packet-normalized delays by flow size. Buckets need to contain enough samples to form statistically meaningful distributions, but they should also be small enough so that the values come from flows with similar delay characteristics (i.e., similarly-sized flows).

Parsimon uses a simple bucketing algorithm. In brief, we start with a packet-normalized delay per flow, and we sort them according to flow size. Then, starting with the shortest flow, we begin populating buckets. For each bucket b , let $\max_f b$ and $\min_f b$ be the maximum and minimum flow sizes associated with b , respectively, and let n_b be the number of elements in b . Each bucket b apart from the last one is locally subject to two constraints

$$n_b \geq B \quad \text{and} \quad \max_f b \geq x * \min_f b,$$

for some choice of B and x . Globally, Parsimon also ensures buckets are contiguous and non-overlapping. For any bucket, once the two local constraints are satisfied, Parsimon begins populating the next bucket, and the final bucket is assigned whatever elements remain.

In practice, we find $B = 100$ and $x = 2$ works well. Data center workloads have heavy-tailed flow size distributions in which short flows arrive much more frequently than long ones. With these parameters, the first buckets will have size boundaries that are approximately powers of two, and as flows get larger, buckets will cover larger and larger ranges. This is the desired behavior. Intuitively, a queueing-sensitive 1 KB flow should not be grouped with a throughput-sensitive 1 GB flow, but a 1 GB flow can be grouped with a 10 GB flow provided the distribution of throughput is stable on long timescales. Accuracy across different flow sizes at finer or coarser resolution can be achieved by modulating x . We examined sensitivity to the number of buckets by decreasing x for selected experiments and found no meaningful change in the predicted distributions.

In summary, each link-level simulation produces FCTs, and these FCTs are used to construct bucketed distributions of packet-normalized delay. Since different links have different workloads, bucketing is performed on a per-link basis. This means that the links in any given path are likely to have different bucket sizes with different flow size ranges. In the next subsection (§3.4) we describe how the data are aggregated.

3.4 Aggregating Link-Level Estimates

For any given range of flow sizes, the final distribution of (packet-normalized) delay for any path through the network can be estimated by selecting an appropriate distribution from each component link and then performing an n -ary convolution. However, the efficiency of this step must be considered. Since there are multiple distributions per link and potentially

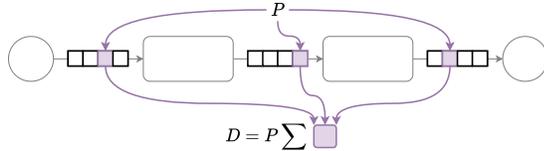

Figure 5. An illustration of how Parsimon aggregates link-level results into a path-level point estimate. Parsimon samples a packet-normalized delay (§3.3) from each link along the path, and combines these to estimate the end-to-end absolute delay D .

many paths through the network, performing all convolutions up front and storing one path-level distribution per path, per flow-size range would be costly in space and in time.

To avoid these costs, Parsimon uses an on-demand sampling strategy to perform the convolution. Recall that the simulation step resulted in bucketed distributions of packet-normalized delay per link, organized in a graph isomorphic to the original topology. Parsimon makes this graph a queryable object that is capable of supporting point estimates. Given a size, a source, and a destination, Parsimon computes a path from the source to the destination and uses the size to select a distribution per-link. Then, one packet-normalized delay is sampled from each distribution and the results are subsequently combined into a point estimate. Suppose there are n hops and let $D_1^*, D_2^*, \dots, D_n^*$ be the sampled packet-normalized delays. Then, the end-to-end absolute delay D is computed as

$$P \sum_{i=1}^n D_i^* = \sum_{i=1}^n D_i^* P = \sum_{i=1}^n D_i = D,$$

where P is the input flow size in packets and D_i is the absolute delay for hop i . Fig. 5 illustrates this process. Finally, to obtain a distribution of end-to-end delay estimates, we need only sample enough point estimates for the desired flow size range and source destination pairs.

3.5 Primary Source of Speedup

Parsimon speeds up large network simulations by considering the effect of each link in isolation, allowing it to scale in the size of the simulated network and the number of processing cores. Although the link is the unit of decomposition, Parsimon’s scaling ability is determined not by the total the number of links, but rather by the *fraction of total packets traversing any link*. In other words, Parsimon’s speed-up depends on the number of busy links and how well the load is balanced among them. This explains why Parsimon is most suited for large data center networks, where the total workload comprises many source destination pairs with many paths between them. If a network traffic is heavily skewed such that most of the workload traverses only a few paths, the amount of speedup will be limited.

3.6 Primary Sources of Error

To balance accuracy and performance, Parsimon makes a number of approximations, with some having more of an effect on accuracy than others. Here we catalog some of the main sources of error, describing 1) how we expect the errors

to manifest and 2) what modifications, if any, could be made to address them.

Bottleneck fan-in. To simulate a given target link in the network, Parsimon constructs a topology that connects all of the source nodes feeding traffic directly into that target. In practice, of course, there would be multiple stages of fan-in, and that fan-in would tend to spread out any burst of arriving flows due to upstream bandwidth capacity constraints. Any target link would experience slightly less queuing and less congestion in reality than in Parsimon. Of course, Parsimon also simulates the upstream link; because it is closer to the sources, its traffic and queuing behavior would be a closer model to what would happen in a full network-wide simulation.

Because Parsimon sums the delay contributed by each hop along a flow’s path, the lack of fan-in will tend to slightly overestimate the delays caused by downstream links. Put another way, any delay induced by fan-in constraints is counted twice—once when we simulate the upstream link and again when we simulate the downstream link. In our evaluation, accuracy is slightly lower for networks with higher degrees of oversubscription, as we would expect. We could potentially remove this inaccuracy by including the upstream fan-in as part of the topology for each link simulation. Since simulation time is proportional to the number of hops, this would decrease individual link simulation efficiency by a small but significant factor.

Lack of traffic smoothing. Similarly, any cross-traffic that shares a portion of a path with traffic destined for the target link will tend to smooth out traffic before it reaches the target. Parsimon does not include any cross-traffic in its per-link simulation, making it slightly overestimate the queuing delay at the target link. Assuming the simulation is stable—that the arrival rate does not exceed the service rate for any link—the target link will experience the correct long-term average rate, but without as much smoothing as would happen in practice. We see evidence of this effect in our evaluation, where error is slightly larger for workloads with a predominance of short flows which would benefit more from smoothing. Of course, correctly modeling the effect of cross-traffic on the traffic arriving at a downstream link would be difficult to accomplish without reverting to a full network simulation.

Link-level independence. A more fundamental approximation is that link-level simulations are treated independently. This technique enables wholesale parallelization, but its accuracy depends on the amount of correlation between the traffic intensities on the various hops along the path. The more correlated the traffic, the more error Parsimon’s method produces.

Since Parsimon produces estimates by convolving delay distributions (adding independent random variables), full accuracy requires the mutual independence of delays among the links in every path. Consider a single-packet flow that traverses two hops, both with load l . If the delays along the two hops are independent, the probability that the flow will encounter *no queueing* is simply $(1 - l)^2$. However, if both

hops tend to have queueing at the same time (i.e., if the traffic intensities and therefore the delays are correlated), then that probability is closer to $1 - l$. Since Parsimon does not distinguish between these two scenarios, the difference is not reflected in its estimates.

In very large networks with thousands of hosts and paths, and with realistic workloads, we expect the effects of correlation to be small. A basic result of queueing theory is that under some circumstances it is possible to analyze queues independently, even when the output of one queue connects to the input of another, so that queue behaviors are obviously correlated. One view of our work is that we are empirically observing that data center networks approximately admit product-form solutions for their equilibrium state queue distributions under realistic workloads.

However, some networks use PFC [36] to reduce packet loss due to go-back N error handling in some RDMA network interface cards. Because PFC suffers from head-of-line blocking, PFC can cause correlated congestion across multiple links, and so Parsimon would not be a good choice for modeling such networks. If correlation is a problem, we could potentially measure the degree of correlation and apply a correcting factor during the convolution step, but we leave that for future work.

One bottleneck at a time. Estimating the performance of long flows comes with an additional difficulty which is also exacerbated by correlated delays. While a single packet flow can only reside in one queue at a time, a long flow can be backlogged on multiple links *at the same time*. Depending on the specific congestion control mechanism, the throttling back of a long flow (the delay it experiences) is typically *not* the sum of the delays it would experience on individual links (as Parsimon approximates), but rather only the delay caused by the true (instantaneous) bottleneck. Since Parsimon sums all delays, it will overestimate the end-to-end delay for the long flow that encounters simultaneous cross-traffic congestion at multiple points along its path. In summary, Parsimon is more accurate when the congestion is episodic and temporary, appearing at different links at different times, and less accurate when congestion is persistent across multiple edge and core links of a given path.

Congestion on any link (and therefore simultaneous congestion on multiple links) becomes more common with higher network load, and we see this effect in our evaluation. We can potentially correct for this bias by using a more complex function for combining link delays when overall network utilization is high. Because network operators are often willing to over-provision their network hardware to reduce application tail latency, this is rare in practice. For example, some recent end-to-end congestion protocols, such as Homa [21], simply assume that network congestion predominantly occurs at the last hop of each path. We do not make such an assumption; we handle congestion equally wherever it might occur. However, we do assume that congestion events are not persistent and network wide.

Our approximations are biased toward producing overestimates rather than underestimates, because we expect network operators to be more sensitive to over-promising tail behavior, even if that comes at the cost of being too conservative with respect to capacity planning. Additional analyses on the errors induced by these approximations can be found in the appendix (§C).

4 Complementary Methods

The previous section described how we decompose a single large network simulation into many small, independent ones that can be executed in parallel and later combined. This section describes additional optimizations that reduce, cluster, and prune these link-level simulations for better computational efficiency. These reduce the number of cores needed to simulate a given network within some time bound, or equivalently, the execution time on a single server machine.

4.1 Fast Link-Level Simulation

By far the largest computational cost in Parsimon are the link-level simulations. Initially we used ns-3 as our link-level backend. However, as a general-purpose simulator, ns-3 is designed to support arbitrary protocols with arbitrary extensions, all the way down to hardware models. This is more flexible but means that every packet in ns-3 generates events at every host, queue, and link—as well as throughout the hosts' modeled network stacks.

Instead, we implemented a custom and minimal simulator optimized for high fidelity single link simulation. This backend only models the workload, topology, queueing, and congestion control. For congestion control, our prototype implements DCTCP's core algorithm [2] in a few tens of lines of code. For example, we do not need to model the mechanism for carrying ECN bits from switches back to endpoints. Switching to a custom simulator speeds up the individual link simulations by roughly an order of magnitude, with negligible loss of accuracy. Reducing the simulation time of the worst case (most congested) link also reduces the critical path dramatically. If more simulation features are needed, Parsimon can use ns-3 at the cost of using more cores.

4.2 Clustering and Pruning Simulations

Lastly, we recall that Parsimon's decomposition results in two simulations per link: one in each direction (§3.1). On a large-scale 6,144-host topology we use for evaluation, there are over 9,000 links, and therefore over 18,000 simulations generated. Fortunately, data center topologies commonly induce symmetries that render some of these simulations redundant. For example, up-links in the same ECMP grouping can be assumed to have the same characteristics and traffic patterns. Furthermore, the workloads themselves may also induce symmetries due to communication patterns and load balancing [28].

We can take advantage of these symmetries by clustering links that carry similar traffic and only simulating one representative from each cluster. Then, in each cluster, all links

Algorithm 1 Greedy link clustering

```
1: unclustered ← ALLLINKS      ▶ links here are unidirectional
2: clusters ← []                ▶ list of list of links
3: while not EMPTY(unclustered) do
4:   members ← []              ▶ new cluster
5:   representative ← POPFIRST(unclustered)
6:   PUSH(members, representative) ▶ with initial member
7:   for candidate in unclustered do ▶ find other members
8:     rfeature ← FEATURE(representative)
9:     cfeature ← FEATURE(candidate)
10:    if ISCLOSEENOUGH(rfeature, cfeature) then
11:      PUSH(members, candidate) ▶ new member
12:      REMOVE(unclustered, candidate)
13:   PUSH(clusters, members)
14: return clusters
```

inherit the delay distribution produced by the representative link. Parsimon’s clustering requirement is quite specific, which limits the range of popular clustering algorithms that can be used. Let $l_1, l_2 \in L$ be any two link-level simulations, and let $d: L \times L \rightarrow \mathbb{R}$ be a distance function. Ideally,

$$l_1 \text{ and } l_2 \text{ are clustered together} \iff d(l_1, l_2) < \epsilon,$$

where ϵ is some bound. The left-to-right direction preserves accuracy; the right-to-left supports efficiency. Most centroid-based and density-based clustering algorithms aren’t designed to provide the left-to-right property. Instead, Parsimon uses Alg. 1. This algorithm greedily clusters simulations together, using a distance function that predicts which links will have similar delay profiles. In our prototype, we check that the link flow size and inter-arrival time distributions—as well as their load levels—are close. We find this provides a reasonable tradeoff between efficiency and accuracy, but users can turn off the optimization at the cost of using more cores. Further details about the clustering can be found in the appendix (§D).

5 Evaluation

Parsimon’s goal is to quickly estimate tail latencies for a variety of large data center networks and workloads. In evaluating Parsimon, we would like to assess 1) Parsimon’s accuracy and performance at the scale of thousands of hosts, and 2) how accuracy is affected by a wide range of variables over the workload and the topology.

Our strategy is as follows. Using workloads extracted from industry datasets, we start with a 384-rack, 6144-host topology to evaluate Parsimon’s speed and accuracy in one scenario at scale. Then, to evaluate nearly 200 other topology and workload scenarios, we downsample the workload so that it can run on a smaller 256-host topology. This allows us to run enough ns-3 simulations quickly enough to perform a detailed sensitivity analysis.

To more clearly illustrate sources of error in Parsimon, we also construct and evaluate Parsimon on synthetic workloads on a small-scale parking lot topology in Appendix §C.

Variant	Clustering?	Link-level backend
Parsimon	No	custom
Parsimon/C	Yes	custom
Parsimon/ns-3	No	ns-3
Parsimon/inf	—	custom

Table 1. The Parsimon variants under consideration. Parsimon/inf is a variant that assumes infinite cores and memory.

5.1 General Setup

Each scenario we consider has six components: 1) a topology size, 2) an oversubscription factor, 3) a traffic matrix, 4) a flow size distribution, 5) a burstiness level, and 6) a maximum load level. Here, we briefly describe how these are specified and configured. We also discuss which Parsimon variants we will assess and how we establish a baseline.

Topology and oversubscription. To mimic an industry topology, our topologies are modeled after Meta’s data center fabric [4]. In brief, there are three layers of switches: hosts connected to a top-of-rack switch (ToR) with 10 Gbps links constitute a *rack*, racks connected to each other via fabric switches with 40 Gbps links constitute a *pod*, and pods connected to each other via spine switches with 40 Gbps links constitute a *cluster*. Spine switches are organized in *planes*. We can modulate the size of a topology (corresponding to a cluster) by adjusting the number of pods, the number of racks per pod, and the number of hosts per rack, and we can modulate the oversubscription factor by adjusting the number of spines per plane.

Traffic matrices. The traffic matrices are extracted from the datasets accompanying Roy *et al.*’s study of Meta’s data center network [28]. The data only allow us to construct reliable rack-to-rack matrices. When sampling workloads, we use the matrices to generate rack-to-rack traffic, but once a rack is chosen, we select its hosts uniformly at random. This may bear semblance to reality: according to Roy *et al.*, Meta’s racks typically only contain servers in the same role, and load balancing is used pervasively. We use traffic matrices from three different clusters: a database cluster (matrix A), a web server cluster (matrix B), and a Hadoop cluster (matrix C). Fig. 6a shows 32-rack samples of the matrices.

Flow sizes and burstiness. We use three flow size distributions, estimated from published data in Roy *et al.*’s study [28]. These are reproduced in Fig. 6b. For inter-arrival times, we use the log-normal distribution to model bursty traffic, and we modulate the burstiness by adjusting the log-normal shape parameter σ . For low burstiness, we select $\sigma = 1$, and for high burstiness, we choose $\sigma = 2$.

Maximum load level. When setting a load level, we ensure that the offered rate is less than the link capacity for each link by specifying the maximum load level that any link can have. Note that a given maximum load level may result in different link load distributions, depending on the traffic matrix and the topology. Fig. 6c shows the distribution of normalized link

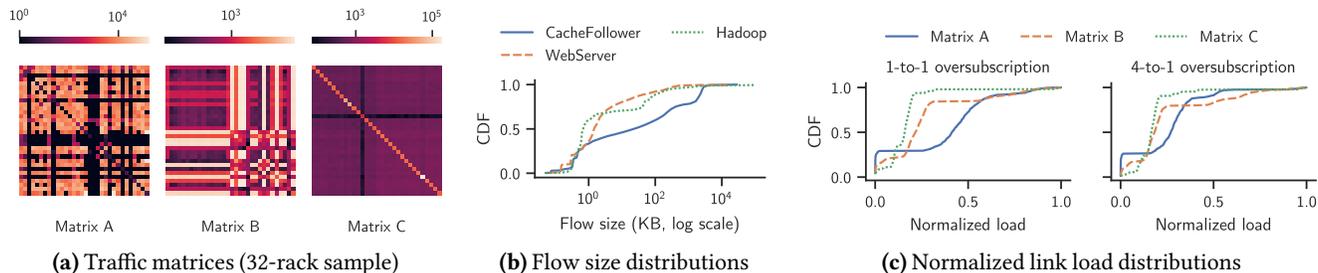

Figure 6. In the evaluation, we model workloads using data from Roy *et al.*'s study of Meta's data center network [28]. The traffic matrices in Fig. 6a are extracted from the accompanying dataset, and the flow size distributions in Fig. 6b are estimated from the published data. Lastly, for a given topology, the distribution of link loads depends on 1) the traffic matrix and 2) the degree of oversubscription. Fig. 6c shows the link loads induced by the matrices in Fig. 6a on two 32-rack topologies with different overprovisioning. The x-axis is normalized to the maximum link load.

Estimator	Time	Speed-up
ns-3	10h 48m 26s	—
Parsimon	4m 13s	154×
Parsimon/C	1m 19s	492×
Parsimon/inf	21s	1864×

Table 2. Running times and speed-up of Parsimon variants for five seconds of simulated time on a large oversubscribed network with thousands of hosts. We find that Parsimon estimates latencies orders of magnitude faster than does ns-3. If there is ample opportunity for clustering or if there are infinite compute resources, speed-up is substantially further increased. Measurements were taken on a 32-core machine.

loads on a 32-rack topology with the traffic matrices in Fig. 6a and two different oversubscription factors. When describing how loaded a topology is, we will usually specify the average load of the top 10% most loaded links.

Parsimon variants and baseline. To establish a baseline for Parsimon's accuracy and performance, we use ns-3 with the optimized build profile. We also consider several Parsimon variants, summarized in Table 1. By default, Parsimon uses the custom link-level backend (§4.1) with clustering turned off. This expresses a lower bound on Parsimon's expected speed-up given a particular machine. Parsimon/C adds clustering to the default variant using the methods described at the end of §4.2, and Parsimon/ns-3 replaces the default's custom backend with ns-3. Lastly, Parsimon/inf provides an estimate of Parsimon's performance given infinite cores and infinite memory, computed by adding the run time of the longest link-level simulation to the fixed costs of network setup and convolution sampling. This represents an upper bound on the Parsimon's achievable performance. All performance measurements are taken on a 32-core AMD Ryzen Threadripper 3970X.

5.2 Analysis on a Large-Scale Network

Here we evaluate Parsimon's accuracy and performance on a 384-rack, 6144-host topology. The topology has eight pods, 48 racks per pod, and 16 hosts per rack, with 2-to-1 oversubscription. For the workload, we use matrix B, the WebServer flow size distribution, and high burstiness ($\sigma = 2$). We set a

maximum link load of about 50%, which gives the 100 most loaded links an average load of 32%, and the top 10% most loaded links an average load of about 15%. We configure all simulations to run for five seconds of simulated time. To establish a baseline, we first run the scenario in ns-3, then we run the scenario in Parsimon and Parsimon/C (see Table 1). Due to memory constraints we omit Parsimon/ns-3 here, but we include its analysis at smaller scale in §5.3.

Fig. 7 shows the accuracy of Parsimon relative to ns-3 across four flow size bins. We find that across all bins, both variants accurately estimate tail latencies. If we consider all flow sizes together, we find that Parsimon and Parsimon/C overestimate the p99 FCT slowdown by 8.8% and 7.5%, respectively.

Table 2 shows the running time and speed-up for each estimator, which includes topology generation and convolution sampling overheads where applicable. While ns-3 took nearly 11 hours, Parsimon without clustering took four minutes and 13 seconds, for a speed-up of 154×. If we turn clustering on by using Parsimon/C, the running time is further reduced to one minute and 19 seconds, for a speed-up of 492×.¹ In this case, only 25% of links were simulated; the rest were pruned. Lastly, Parsimon/inf estimates Parsimon's best possible performance given infinite compute resources. The longest-running single-link simulation took 11 seconds, and with the additional 10 seconds required for network setup and convolution sampling, the fastest projected running time is 21 seconds.

We chose an oversubscribed topology to slightly disadvantage Parsimon's method, as oversubscription can lower Parsimon's accuracy. §5.3 analyzes the effect of oversubscription in more detail. We also ran the above experiment on a topology without oversubscription, which for the same maximum load setting increased the top 10% average link load from 15% to 25%. We found Parsimon's p99 accuracy improved from 9% to about 7%, while Parsimon/C's accuracy remained

¹We advise caution both in interpreting this number and in generalizing it to scenarios at large. While our workloads are modeled after industry data, they are still synthetic. There may be more or less opportunity to cluster and prune link-level simulations, depending on the structure of real workloads and the quality of the clustering algorithm.

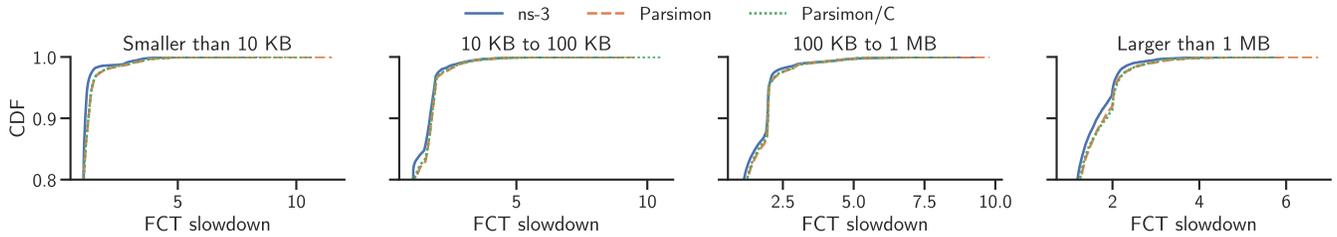

Figure 7. CDFs of FCT slowdown estimated by ns-3 and two Parsimon variants (note the y-axis). On a large network with 6,144 hosts, an industry traffic matrix (matrix B), and 2-to-1 oversubscription in the core, Parsimon’s latency estimates are similar to those produced by full-fidelity simulation. Table 2 shows the performance of each estimator.

Parameter	Sample space
Oversubscription	1-to-1, 2-to-1, 4-to-1
Traffic matrix	Matrix A, Matrix B, Matrix C
Flow size distribution	CacheFollower, WebServer, Hadoop
Burstiness	Low ($\sigma=1$), High ($\sigma=2$)
Max load	26% to 83% (continuous range)

Table 3. The sample space for the sensitivity analysis in §5.3.

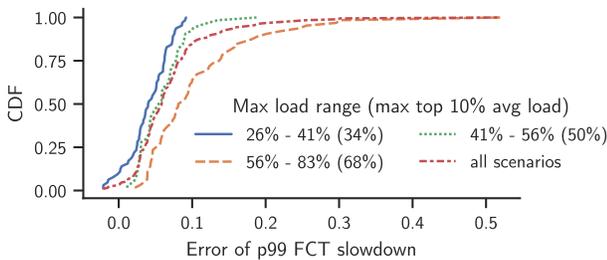

Figure 8. CDFs of p99 error between Parsimon and ns-3 across all scenarios drawn from the sample space in Table 3. The distributions are binned by maximum load. In parentheses, we give the maximum value for the top 10% average load in each bin. Under common conditions of low to moderate load, Parsimon’s estimates for the p99 FCT slowdown are reliably within 10% of the ground truth.

approximately the same. However, because aggregate load increased, ns-3 took 27 hours for five seconds of simulated time, and speed-ups for Parsimon, Parsimon/C and Parsimon/inf were 152 \times , 872 \times , and 3487 \times , respectively. Parsimon/C benefited from the increased number of links in each ECMP grouping, allowing it to prune 85% of the link-level simulations.

5.3 Sensitivity Analysis at Small Scale

Next we turn our attention to how different aspects of workloads and topologies affect Parsimon’s accuracy. To be able to simulate enough scenarios in ns-3 for a sensitivity analysis, we downsample the topologies and traffic matrices to 32 racks. The resulting topologies have two pods, 16 racks per pod, and eight hosts per rack, and the number of spines per plane varies to accommodate different oversubscription factors.

Our approach is as follows. First, we construct a sample space over the parameters defining the workload and the

topology (aside from the number of servers, which is fixed). The sample space is shown in Table 3. Then, we sample 192 scenarios uniformly at random, and we run ns-3 and the default Parsimon variant on each of them for several seconds of simulated time. Next, for each scenario, we take the p99 FCT slowdown estimated by both ns-3 and Parsimon, and we compute the error between them. If these values are n and p respectively, then the error is $(p - n)/n$. Negative values indicate that Parsimon produced an underestimate.

Since we have one error value per scenario, the errors give rise to distributions of error associated with the original sample space. Now what remains is to determine how the workload and topology parameters affect error distributions. To start, recall from the discussion in §3.6 that the magnitude of error is expected to be load-dependent, with higher errors typically manifesting at higher loads, so we begin by examining the effect of the maximum load setting on Parsimon’s accuracy.

Maximum load. Fig. 8 shows the error distributions binned by maximum load. Among all scenarios, Parsimon’s p99 estimates are within 10% of ns-3’s estimates 85% of the time. At high load, we observe larger overestimates of up to 52% in the worst case. In the most highly-loaded group of scenarios—with maximum link loads between 56% and 83%—Parsimon is within 10% of ns-3 62% of the time, with an average error of about 11%. However, this includes scenarios where 10% of the links have an average load of up to 68%, which is much higher than what is reported in the literature. For example, Roy *et al.* report that in Meta’s data center network, 99% of host links are less than 10% loaded, and the top 5% of core links have loads between 23% and 46% [28]. Among scenarios where the maximum link load is between 26% and 41%, Parsimon is within 10% of ns-3 100% of the time. If we further include scenarios with maximum link loads between 41% and 56%, that number falls to 96%. Finally, while Parsimon’s techniques tend to overestimate latencies, in 3% of the scenarios, Parsimon underestimates p99 slowdown by up to 2%.

Other parameters. We next turn to the effects of all other workload and topology parameters. We start by only considering scenarios where the maximum link load is less than or equal to 50%; this will tell us whether any of the parameters

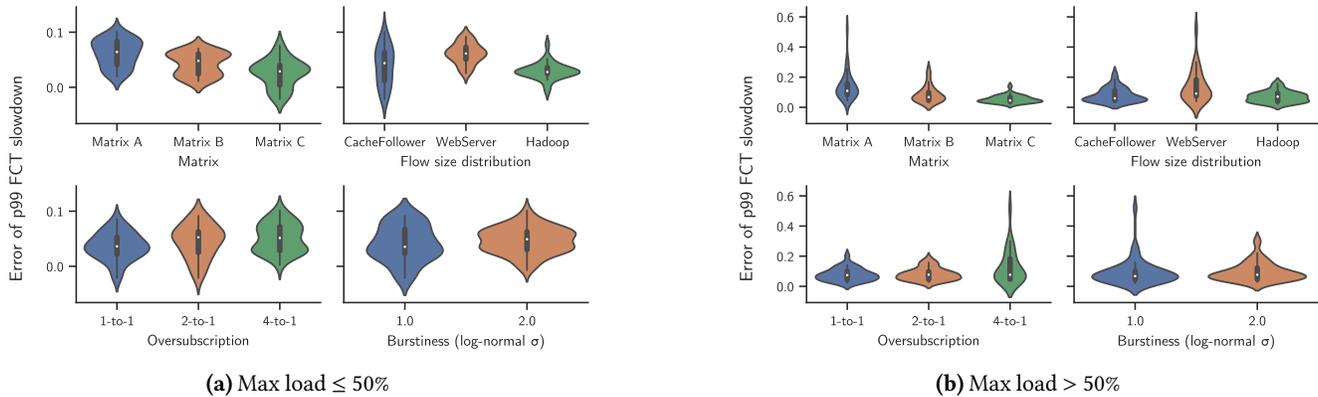

Figure 9. Distributions of p99 error between Parsimon and ns-3, faceted by different workload and topology parameters. For each distribution we show the median, the quartiles, and a rotated kernel density estimation. We consider the low-load regime (Fig. 9a) and the high-load regime (Fig. 9b) separately. At low load, the workload and topology parameters only have a modest effect on Parsimon’s accuracy, but at high load, the conditions leading to the largest errors come into view: high load, high oversubscription, with very short flows. Note the different y-axes between the two load regimes.

Error	Max load	Matrix	Sizes	Oversub	σ
51.9%	77.6%	A	WebServer	4-to-1	1
30.1%	67.3%	A	WebServer	4-to-1	2
29.6%	67.0%	A	WebServer	4-to-1	2
25.6%	65.9%	A	WebServer	4-to-1	1
24.6%	73.2%	B	WebServer	4-to-1	1

Table 4. The five scenarios with the highest error values from the sensitivity analysis in §5.3.

have a large effect on accuracy in the low-load regime. Fig. 9a shows the median error and error distributions as a violin plot for low-load scenarios grouped by traffic matrix, flow size distribution, oversubscription, and burstiness. Overall, changes to these parameters appear only to have a modest effect. The choice of traffic matrix has the clearest trend, but load is a confounder here: recall from Fig. 6c that different traffic matrices yield different link load distributions for the same maximum load setting.

When we look at the high load regime in Fig. 9b, a clear picture comes into view. We see much longer tails in error distributions for matrix A, the WebServer flow size distribution, and 4-to-1 oversubscription. Together with Fig. 9a, this suggests that none of these settings has a strong effect on its own, but *coupled together in the high load regime*, they have a pronounced effect on Parsimon’s accuracy. Matrix A induces higher average load and has more cross-rack traffic, making it more likely for its flows to encounter multiple simultaneous bottlenecks. The WebServer flow size distribution is dominated by short flows (Fig. 6b), a third of which are smaller than 1 KB and 80% of which are smaller than 10 KB. Because more of the traffic completes within a single round trip, there is more ephemeral congestion and bandwidth smoothing can have a larger impact.

Finally, oversubscription has an effect at high load: if we removed all scenarios with 4-to-1 oversubscription, the maximum error would only be 20% rather than 52%, even at high load. In addition to the double counting of delays described in §3.6, oversubscription can also increase correlations in link delays. To achieve 4-to-1 oversubscription in topologies as small as these, there are only four spine switches per plane forwarding traffic between groups of 16 racks, leaving relatively few paths through the core. Fewer paths can result in higher degrees of correlation—especially with matrix A, whose traffic is primarily inter-rack (Fig. 6a). Finally, this setting combined with the short flows from the WebServer distributions gives rise to errors of up to 52%.

Table 4 lists the scenarios with the top five highest error values. Four have matrix A, all have the WebServer distribution, and all five have 4-to-1 oversubscription. In this group, the average maximum load is 70.2%. Since we expect the combination of all-to-all workload, heavily oversubscribed topology, and persistently high core utilization to occur relatively infrequently, the data suggest that Parsimon maintains good accuracy under common conditions.

Mixed Workloads. We also use the small topology to study the Parsimon prediction error for subsets of traffic in heterogeneous workloads in Appendix §A.

5.4 Analysis of One Configuration

We pick one representative scenario to examine in more detail, to test if our approach is robust to alternate definitions of tail latency, congestion control protocol, workload, and topology. To pick a scenario whose accuracy is somewhat worse than the average case, we rank-order all scenarios by error and select the one at the 85th percentile. This has matrix A, the Hadoop flow size distribution, low burstiness, 2-to-1 oversubscription, and a maximum load of 68% (with a top 10% average load of 56%).

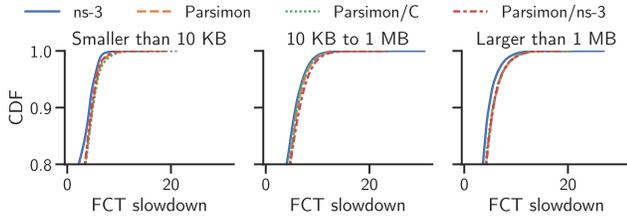

Figure 10. CDFs of FCT slowdown estimated by ns-3 and Parsimon for the scenario whose error is at the 85th percentile of the p99 error distribution. Note the y-axis. Even though the accuracy here is worse than in the common case, Parsimon’s estimates remain close across most of the tail. Also shown is Parsimon/ns-3.

Protocol	Max load	Error in p99 FCT slowdown		
		< 10 KB	10 KB - 1 MB	> 1 MB
DCTCP	45%	1.4%	9.2%	15.9%
TIMELY	45%	4.0%	17.9%	13.7%
DCQCN	45%	5.9%	11.6%	12.8%
DCTCP	56%	2.8%	9.2%	14.6%
TIMELY	56%	8.1%	20.0%	11.3%
DCQCN	56%	7.6%	14.6%	12.2%
DCTCP	67%	13.8%	11.3%	13.6%
TIMELY	67%	13.3%	18.2%	5.0%
DCQCN	67%	18.0%	15.2%	13.6%

Table 5. Prediction error of Parsimon/ns-3 for estimated p99 FCT slowdown with three different congestion control protocols for the sample configuration at different load levels and for different request sizes.

Tail distribution. Operators may differ in their definitions of tail latency, e.g., focusing on the 90th or 99.9th percentile, rather than just the 99th FCT slowdown. Fig. 10 shows the tail of the cumulative distribution of FCT slowdown for different flow sizes for the selected configuration, for ns-3 and each of the Parsimon variants. The prediction error is similar across the tail of the distribution for this scenario, with little accuracy difference between any of the variants.

Transport protocols. We use the sample scenario to test the generality of Parsimon to two additional congestion control protocols, DCQCN [36] and TIMELY [19]. DCQCN is designed for RDMA traffic, while TIMELY uses network delay, rather than ECN signals, to detect congestion. To focus on prediction error for our approximation methods, we use the pre-existing ns-3 implementation of the protocols as the Parsimon link level simulator for this part of the evaluation. Note that Parsimon and Parsimon/ns-3 exhibit a few percent difference in p99 error for DCTCP for this configuration. Because the prediction error for different congestion control protocols may depend on the amount of congestion, we also run the experiment at varying load levels.

Table 5 shows the prediction error for Parsimon/ns-3 relative to ns-3 in the estimated p99 FCT slowdown at three load

levels for the three transport protocols, aggregated by request size. For this configuration, Parsimon is most accurate for small flows and low to moderate maximum link utilization, and that is true for all three congestion control protocols. DCTCP has somewhat lower error for small and medium size flows at low to moderate utilization. Relative error is higher for larger transfers and higher maximum link utilization, with no clear pattern in the error for different protocols.

Simulated link failures. We also use the sample configuration to examine the prediction accuracy for topologies with simulated link failures in Appendix §B.

6 Conclusion

In this paper, we propose and evaluate a new method for computing a conservative estimate of flow-level tail latency for large scale data center networks, given an arbitrary traffic matrix, topology, flow size distribution, and inter-arrival process. Our approach decomposes the problem into a large number of individual link simulations, specially constructed to produce accurate estimates of the probability distribution of delay contributed by congestion at each link. We then mechanically combine these link-level delay distributions to produce flow-level estimates. On a large-scale network using a commercial workload, our approach outperforms ns-3 by a factor of 492 on a single multicore server with a loss of accuracy of less than 9% in the tail of the latency distribution.

A Mixed Workloads

Parsimon’s methods are designed to estimate performance distributions rather than per-flow metrics. However, it is often useful to aggregate FCT performance estimates in different ways. For example, an operator may wish to estimate the performance of individual virtual networks or individual services. In this section, we conduct a simple experiment to assess Parsimon’s ability to estimate performance for separate aggregates.

We start by mixing three different workloads—each with its own traffic matrix and flow size distribution—into one workload. Table 6 summarizes their differences. Each workload has a maximum load setting of 20% and a high burstiness setting ($\sigma=2$), and their combination results in a maximum link load of about 50%. We run the combined workload on the small-scale topology with 2-to-1 oversubscription from §5.3, and we observe the accuracy for each workload faceted by flow size. Fig. 11 shows the cumulative distribution function (CDF) of FCT slowdown for ns-3 and Parsimon. We observe that across all workloads and flow size bins, Parsimon maintains good accuracy.

B Link Failures

One operational use case for Parsimon is to estimate counterfactual network performance in the presence of potential link failures or planned outages. In this section, we use the sample scenario from §5.4 (matrix A, the Hadoop flow size distribution, low burstiness, 2-to-1 oversubscription, and a maximum link load of 68%) to evaluate Parsimon for this use case. For this configuration, the error in estimated p99 FCT slowdown between ns-3 and Parsimon was around 10%. Since link failures increase the load on the remaining links, we should expect some decreased accuracy for Parsimon in this case. On the other hand, simulating all possible network failures in ns-3 would be prohibitively expensive.

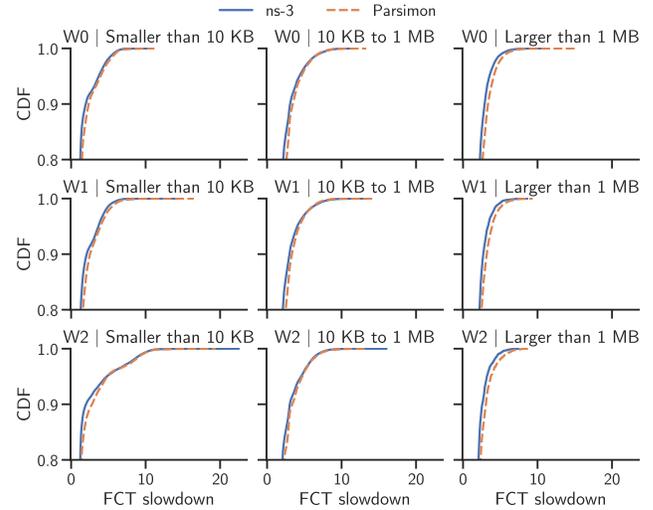

Figure 11. CDFs of FCT slowdown for ns-3 and Parsimon, bucketed by workload and flow size. Note the y-axes. When mixing workloads in a single simulation, Parsimon can accurately estimate performance distributions for individual workloads in addition to full-network aggregates.

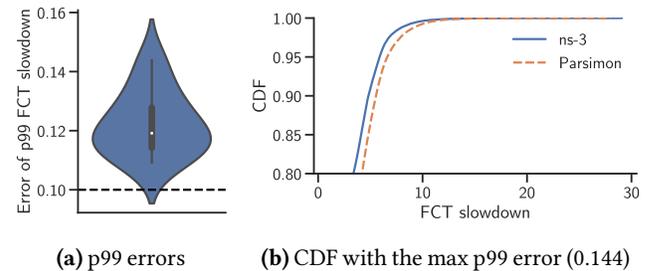

Figure 12. Errors between ns-3 and Parsimon in estimated FCT slowdowns when there is a link failure. Fig. 12a shows the error distribution for p99 estimates from ten trials—each with one random link failure—with the dashed line showing the error with no link failure. Fig. 12b shows the CDF of FCT slowdowns for the trial with the highest p99 error. For the small oversubscribed topology used in this experiment, a link failure modestly increases estimation error.

In selecting links to fail, we only consider links in ECMP groupings, such that the failure of one link causes traffic to be routed to the other links in the group. In Meta’s data center fabric [4], this corresponds to links between fabric switches and spine switches and links between ToR switches and fabric switches. In the small 32-rack topology used here (§5.3 for details), there are 96 such links. We run ten trials, each time picking a random one of the links to fail, keeping the workload constant. We note that this setting represents a particularly bad case for Parsimon: in addition to the high link loads, the scenario uses an all-to-all communication pattern on a small and oversubscribed topology, which means each link failure in the core can have an outsized effect on other core links.

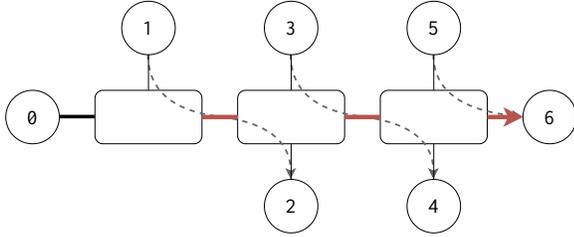

Figure 13. The parking lot topology used in §C. In this topology, zero sends to six, one sends to two, three sends to four, and five sends to six. We refer to the traffic from zero to six as *main traffic* and to all other traffic as *cross traffic*. The bolded red links contain both main traffic and cross traffic, and we call them *congested links*.

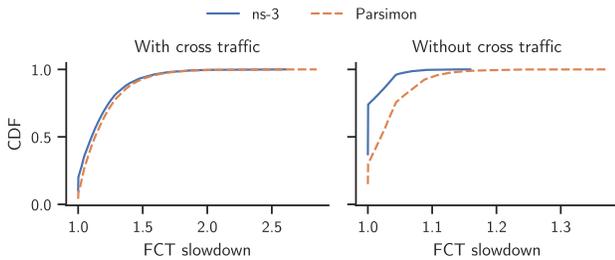

Figure 14. CDFs of FCT slowdown estimated by ns-3 and Parsimon for the main traffic, both with and without cross traffic. When there is cross traffic, errors arising from first-hop delays are second-order, as most delays are caused by queueing on the congested links. However, when there is no cross traffic, those errors become dominant. The graph on the right uses the same workload as the one on the left, except the cross traffic is removed. Note the different x-axes.

Fig. 12a shows the distribution of errors in p99 estimates. With a single link failure, the errors range from 11% to 14%, with a median error of 12%. Fig. 12b shows the estimated CDFs of FCT slowdown for the trial with the highest error.

C Studying Error Sources

Recall from §3.6 that Parsimon’s approximations induce errors in its end-to-end estimates. In this appendix, we use microbenchmarks to study the effects of some pathological cases on Parsimon’s accuracy. For an initial discussion on these topics, please refer to §3.6.

Throughout, we use the parking lot topology shown in Fig. 13 with 40 Gbps links. The flow of traffic through the topology is shown with arrows and described in the caption. We refer to the traffic from node zero to node six as *main traffic* and to all other traffic as *cross traffic*. The bolded red links contain both main traffic and cross traffic, and we call them *congested links*. In all experiments, we set the load of the main traffic to 25%. When there is cross traffic, its load is also 25%, yielding a total load of 50% on all three congested links. Lastly, to isolate the effects on the main path from zero to six, we measure FCT slowdown distributions only for the main traffic.

C.1 First-Hop Delays

First, consider the case where all traffic in Fig. 13 originates from node zero and is destined to node six, and recall that

all links have the same capacity. In a real network, all queueing in this scenario would occur at the first hop. Subsequent hops would see traffic completely smoothed, and they would therefore contribute zero queueing delay.

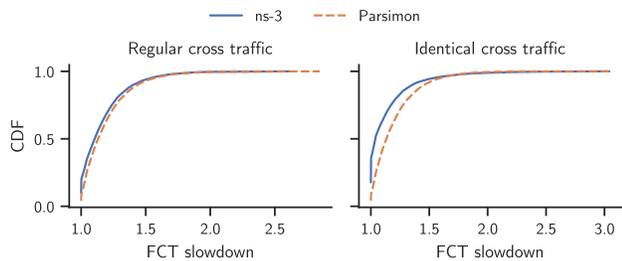

If we re-examine how link-level topologies are constructed in Fig. 4, we see that this smoothing effect is captured, since all traffic passes through edge links with the original edge-link capacities. However, for the link-level topologies in cases B and C of Fig. 4, it is possible for first-hop edge links to contribute delays that will be (erroneously) attributed to the target link. In most cases, we expect the magnitude of this error to be small. A target link will almost always have multiple sources, and only the traffic passing through the target link is simulated. Consequently, the first-hop delays in link-level simulation are expected to be small compared to delays accrued at target links.

The scenario which we first described—in which all traffic on a path originates from a single source—represents the worst case. Here, all target links (aside from the first hop) contribute no queueing delay, thus magnifying the error induced by repeatedly counting the first-hop delays for each target link. Fig. 14 shows this effect. In this experiment, the main traffic consists of one kilobyte flows, and the cross traffic consists of 10 kilobyte flows. All traffic follows a Poisson arrival process. With cross traffic, we see from the graph on the left that Parsimon accurately estimates the FCT slowdown distribution of the main traffic. However, when we remove the cross traffic, as done to produce the graph on the right, we see substantial error in Parsimon’s estimates due to the first-hop delays previously described. We note that this error exists *even when there is cross traffic*, but the error contributes so little to total delays—which are dominated by queueing at congested links—that Parsimon still maintains good accuracy.

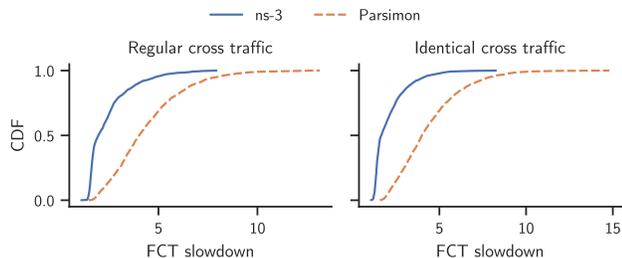

C.2 Correlated and Simultaneous Delays

Next we examine the effect of correlated and simultaneous delays on Parsimon’s accuracy. We begin by artificially correlating delays and examining the effect on estimated slowdown distributions. Note that if the delays along a path are positively correlated—for example, if the probability of encountering delay at hop $i+1$ is higher given there is delay at hop i —then we also expect to see more simultaneous delays along the path. We create these correlated delays by modulating the cross traffic. For regular unmodified cross traffic, we use the same setup as in the previous subsection (§C.1). To artificially correlate delays, we replicate the exact sequence of flows from source one on sources three and five in Fig. 13, so that all three sources of cross traffic send the same flows at the same time. This produces an extreme case of correlation.

Because short-flow and long-flow estimates have different sources of error, we separate the two cases when generating the main traffic. For short flows we use the same one kilobyte flows as before, and for long flows we generate flows that are 10 times the maximum bandwidth-delay product, or 400

(a) Short flows (1 KB), Poisson cross traffic

(b) Long flows (400 KB), Poisson cross traffic

Figure 15. CDFs of FCT slowdown estimated by ns-3 and Parsimon for the main traffic with regular or identical cross traffic. The main traffic consists either of short flows (Fig. 15a) or long flows (Fig. 15b). When delays are artificially correlated by replicating the same cross traffic across hosts, accuracy decreases for both short and long flows, with long flows seeing larger errors. In fact, long-flow estimates have significant error even when delays are not explicitly correlated; this is due to the simultaneous delays induced by the smooth Poisson cross traffic.

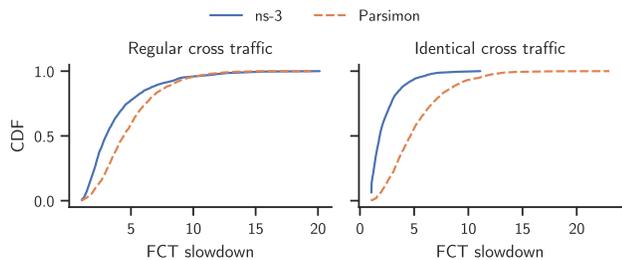

Figure 16. CDFs of FCT slowdown for the same scenario as in Fig. 15b, but with bursty cross traffic (log-normal inter-arrival times, $\sigma=2$). When the cross traffic is bursty, long flows experience fewer simultaneous delays with regular cross traffic. This results in less error in Parsimon's estimates.

kilobytes. Fig. 15 shows the effect of correlating delays on Parsimon's accuracy for short and long flows.

Short-flow main traffic. In the case of short flows (Fig. 15a), a chief effect of increased correlation is to alter the probability that a flow will encounter queueing. For example, suppose a short flow traverses only two links at 50% utilization. If the delays of the two links are independent, we can estimate the probability that the flow encounters no delay (i.e., no queueing) as $50\% \times 50\% = 25\%$. However, if the delays are

perfectly positively correlated, then the probability that the flow encounters no delay increases to 50%. Parsimon does not capture this effect because it treats all links independently; in this experiment, this manifests as slight overestimates in FCT slowdown distributions.

Long-flow main traffic. While the total delay for a short flow can be thought of as the sum of individual link delays, the same reasoning does not straightforwardly extend to long flows. Unlike a short flow, a long flow occupies multiple hops at the same time, and only the bottleneck at each instant contributes to end-to-end delay. Summing link delays is therefore only appropriate if different hops contribute significant delays at largely different times. However, Parsimon always aggregates individual link contributions by adding them, regardless of whether a link was the bottleneck when the delay was incurred. When we turn our attention to Fig. 15b, we see that not only is the effect of identical cross traffic more severe, but also there is significant error even with regular cross traffic. This is because the cross traffic is smooth (recall that it uses uniform flow sizes and a Poisson arrival process). Smooth traffic results in small but frequent delays at congested links, increasing the chance that long flows will experience simultaneous delays.

In Fig. 16, we duplicate the scenario in Fig. 15b, except we make the cross traffic bursty by using a log-normal inter-arrival time distribution with shape parameter $\sigma=2$. Because the cross traffic is bursty, there is less simultaneous delay in the regular case, and the induced error is less dominant. Consequently, Parsimon's estimates are closer to the ground truth in the graph on the left. Identical cross traffic still induces large and frequent simultaneous delays, so the errors remain in the graph on the right.

D Clustering Details

Here we briefly describe the distance function and the thresholding criteria we use in the evaluation (§5) for clustering link-level simulations. First, recall from §4.2 that the link features we extract are 1) the average load, 2) the flow size distribution, 3) the inter-arrival time distribution. For any two links, we compute distances between their features, and we cluster the links together if the distances are under some threshold.

Distance functions. To compute a distance between link loads, we compute the error. If a and b are two link loads, error e is computed as

$$e = \frac{|a-b|}{a}.$$

To compare distributions, there are many options. We opt for a function that is 1) easily interpretable, 2) scale-independent, and 3) adequately captures differences in the tail. To compute a distance between two distributions, we extract 1,000 percentiles from each of them, and we compute a weighted mean absolute percentage error (WMAPE) between them. Suppose A and B are the sequences of extracted percentiles.

Then, WMAPE is computed as

$$\text{WMAPE} = \frac{\sum_{i=1}^n |A_i - B_i|}{\sum_{i=1}^n |A_i|}.$$

For our purpose, A_i and B_i are non-negative for all i . We note it is a bit counterintuitive for our distance functions not to commute. However, we have found that it is easy to set thresholds for these metrics, and they produce adequate clustering for the workloads under study.

Distance thresholds. Recall that we only want to cluster two links together if we expect their simulation outputs to be similar. Consequently, when setting a threshold for link loads we must consider the network and the workload being assessed. At high load, small differences in link loads can yield

large differences in the tails of FCT distributions; in these cases, we typically set tighter thresholds to preserve accuracy (as usual, this is subject to a speed-accuracy trade-off). For highly-loaded networks, we commonly require $e < 0.001$ or $e < 0.002$ for links to be clustered together. Ideally, this decision would be made on a link-by-link basis, so that tighter thresholds would be set only for high-load links—doing so may allow for more liberal clustering of the low-load links contributing little delay, resulting in more pruned simulations. However, the current prototype sets a single threshold per simulation. To set a threshold between distributions, we typically require $\text{WMAPE} < 0.1$.

Shockwave: Fair and Efficient Cluster Scheduling for Dynamic Adaptation in Machine Learning

Pengfei Zheng¹, Rui Pan¹, Tarannum Khan², Shivaram Venkataraman¹ and Aditya Akella²

¹University of Wisconsin-Madison, ²The University of Texas at Austin

Abstract

Dynamic adaptation has become an essential technique in accelerating distributed machine learning (ML) training. Recent studies have shown that dynamically adjusting model structure (e.g., lottery ticket hypothesis [16]) or hyperparameters (e.g., batch size [1]) can significantly accelerate training without sacrificing accuracy. However, existing ML cluster schedulers are not designed to handle dynamic adaptation. We show that existing schemes fail to provide fairness and degrade system efficiency when the training throughput changes over time under dynamic adaptation. We design *Shockwave*, a scheduler with future planning that builds on two key ideas. First, *Shockwave* extends classic market theory from static settings to dynamic settings to co-optimize efficiency and fairness. Second, *Shockwave* utilizes stochastic dynamic programming to handle dynamic changes. We build a system for *Shockwave* and validate its performance with both trace-driven simulation and cluster experiments. Results show that for traces of ML jobs with dynamic adaptation, *Shockwave* improves makespan by 1.3× and fairness by 2× when compared with existing fair scheduling schemes.

1 Introduction

GPU-powered deep neural network (DNN) training is rapidly becoming a core workload in data centers [25, 28, 29]. Due to the sheer volume of training data and massive, ever-increasing model sizes, many DNN models cannot be trained on a single GPU device, and distributed, multi-GPU training has become the norm. The increasing demand for GPU devices motivates enterprises to consolidate their hardware resources and run their workloads in a shared GPU cluster [25]. Thus, building scheduling mechanisms that can fairly arbitrate among jobs competing for GPU resources and efficiently schedule them for high cluster utilization is important.

While there has been a plethora of work in designing schedulers for DNN workloads, they do not use a rigorous approach to co-optimize system efficiency and fairness. Systems like Gandiva [41] and Tiresias [21] optimize makespan and average JCT (Job Completion Time) with techniques such

as dynamic scaling, time-slicing, and over-subscription, but do not consider fairness. Processor sharing [40] based approaches such as DRF [17] and Gavel (Weighted Max-Min Fairness) [33] provide instantaneous fair share of (dominant) resources in each scheduling round, but this can significantly undermine efficiency [20, 35]. Stride [39] scheduling-based approaches such as Gandiva-Fair [10] require cluster operators to explicitly specify an individual job’s share (e.g., A 20% and B 80% of GPUs), and manually specified fixed shares can violate long-term fairness for ML jobs [29]. Finally, AlloX [28] and Themis [29] aim to provide long-term fairness by adopting a filter-based approach where within each round, a subset of jobs that are furthest from the fair share are filtered, and among the filtered jobs the ones which maximize efficiency are chosen by the scheduler. However, the filter value requires onerous hand-tuning; furthermore, even with careful tuning, using a fixed filter can lead to sub-optimal efficiency and fairness (§2).

We design *Shockwave*, a scheduler that leverages market theory to jointly optimize efficiency and fairness for ML training jobs in a systematic and principled fashion. We formulate a Fisher market [5] where every job receives an equal budget to purchase resources from a central arbiter. The arbiter then computes prices such that the market reaches an equilibrium; i.e., each job’s budget is spent to maximize its performance (e.g., training throughput) and all resources are completely sold. Formulating resource allocation using market theory is powerful because achieving market equilibrium guarantees both fairness and efficiency. Each job has equal purchasing power in acquiring resources, ensuring fairness. Further, market-clearing equilibrium ensures work conservation and that each job’s performance is maximized given its budget.

While economic theory has been the basis of many prior systems (e.g., DRF [17], Themis [29], and REF [43]), they all assume jobs have known static resource requests. This assumption is no longer true for elastic ML training jobs [24, 30, 36] whose resource requirements dynamically change over time; further, the changes in resource requirements depend on model update patterns, and thus they are unknown a priori.

For example, training jobs can dynamically scale their batch size by computing the gradient noise scale (GNS) [30, 31]. OpenAI has used batch size scaling (from 32 to 32M) to accelerate GPT-3 training by 500x [7] and similarly, BERT-Large training uses dynamic batch sizes (256 to 4096) to achieve a 2.5x speedup [37]. In this paper, we extend market theory to develop an efficient and fair scheduler for ML jobs with elastic resource requirements.

Existing schedulers are either agnostic or reactive to dynamic changes and our experiments show (§3) that they fail to guarantee fairness or significantly degrade efficiency. The key reason for this is that an optimal schedule or weight assignment [10] at the current instant can be suboptimal in the future, and reactively re-prioritizing jobs can be too late to compensate for the under-prioritization in the early phases. State-of-the-art schedulers that accommodate dynamism, e.g., Pollux [36] do so automatically on behalf of jobs, e.g., by automatically scaling batch sizes. We find that this can hurt training accuracy [1, 11] (§2.3); thus, our aim is to let users perform elastic changes as their algorithms demand. Achieving fair allocation under dynamism without assuming any control over said dynamism is challenging, and is not studied in existing research. We present a detailed comparison between *Shockwave* and other schedulers such as Themis [29], AFS [24] and Pollux [36] in Section 2.

To support dynamic changes in resource requirements over time, we extend the classic, static Fisher market and propose a new discrete-time, dynamic market that can ensure long-term efficiency and fairness. Using discrete time helps us capture the effects of running a market repeatedly over many rounds and a dynamic market helps us capture time-varying utility¹ for jobs. For example, consider a scenario where we are running 20 rounds of scheduling for a job. If a job’s per-GPU batch size increases by 2× after 10 rounds due to GNS scaling, its utility from being allocated one GPU (u_0) will also double after 10 rounds ($u_1 = 2u_0$). A static market will assume time-invariant utility, and will compute the accrued utility over 20 rounds for the job as $20u_0$; in contrast, a dynamic market can capture the change in utility for the job over time, and can accurately compute the accrued utility over 20 epochs as $30u_0$. Accurately computing the utility can enable the dynamic market to optimize fairness and efficiency over time. We prove that our dynamic market formulation (§4.2) guarantees long-term efficiency and fairness properties such as maximized Nash social welfare over time, Pareto optimality over time, and sharing incentive.

Implementing the dynamic market formulation in real systems is challenging for two main reasons. First, the market formulation needs to know utility values in the future to compute market equilibrium. Dynamic adaptations in jobs are non-deterministically triggered, as they are dependent on gradient values that vary across models and datasets, which makes

¹A utility function maps a job’s allocated resource (e.g., GPU) to the resulting performance (e.g., throughput).

it challenging to predict utility in the future. Second, solving the dynamic market equilibrium for an (infinitely) long time horizon is difficult and impractical. It is computationally prohibitive and requires forecasting every job’s future performance characteristics. Further, as jobs arrive and complete online, we need to periodically solve for the market equilibrium while maintaining low scheduling overheads.

To bridge the gap between theory and systems, *Shockwave* addresses these challenges and implements a dynamic adaptation predictor and an approximate dynamic market. First, we observe that dynamic adaptation for real-world ML workloads follows a handful of patterns, and these patterns can be predicted using Bayesian statistics. We then develop methods to integrate these predictions into our dynamic market formulation. Second, while performing round-based scheduling, we find that planning a schedule for an (infinitely) long time horizon can introduce significant overheads. To maintain low scheduling overheads, *Shockwave* only plans the schedule for a finite length window (e.g, 30-60 minutes), and we design estimators that can capture the effects on long-term fairness and long-term efficiency that arise from short-term planning. This design helps us balance the system overheads without sacrificing long-term objectives.

We evaluate *Shockwave* on a 32-GPU cluster testbed and use a simulator to study large-scale GPU clusters. Using multiple workloads derived from prior, real-world systems [33, 36], we find that *Shockwave* improves makespan by 1.3× and fairness by 2× compared to existing fair DNN cluster schedulers including Themis [29], Gavel [33], AlloX [28], etc. We further evaluate *Shockwave* on differently sized clusters. Using a simulator built with the same scheduler as in a physical cluster we find that *Shockwave* scales to schedule 900 active DNN training jobs on 256 GPUs and maintains the benefits in makespan (1.26-1.37×) and fairness (2.5-3.1×) when compared to existing schedulers. We show that our solver overhead remains low and is less than 12.5% of a two-minute-long round duration.² *Shockwave* is open sourced at <https://github.com/uw-mad-dash/shockwave>.

2 Motivation

We begin by motivating the need to design a new cluster scheduler for machine learning workloads.

Filter f	Worst FTF- ρ	SI	Avg. JCT	Makespan
Adaptive - $1/\frac{1}{3}/\frac{2}{3}$	0.83	✓	5	7
Fixed - 1/3	1.0	✓	5.7	7
Fixed - 2/3	1.1	×	5.7	7
Fixed - 1	1.1	×	6.0	7

Table 1: Themis example: using a fixed filter yields suboptimal JCT and/or fairness compared with an adaptive filter. Figure 1 visualizes the schedule for $f = 2/3$, showing the cluster and job setting, and demonstrates how a filter works.

²The solver runs asynchronously in a separate thread and does not block the main scheduling loop.

Cluster setting: 4 GPUs. Jobs: A, B, C are three DNN training jobs with one iteration. Serial (1-GPU) iteration times for A, B, and C are 12, 8, and 6. The number of requested GPUs per iteration for A, B, and C are 3, 2, and 2.

GPU ID \ round ID	0	1	2	3	4	5	6
0	A	B	A	A	B	A	A
1	A	B	A	A	B	A	A
2	B	C	C	B	C	A	A
3	B	C	C	B	C		
f	2/3	2/3	2/3	2/3	2/3	2/3	2/3

Figure 1: Example - Themis [29] with a static filter ($f = 2/3$). In each round of allocation, the filter (grey color) selects 2/3 of the jobs unfairly treated so far. The resulting FTF- ρ values for jobs (A, B, C) are (0.78, 0.83, 1.1), showing a static filter hurts fairness. As in Themis, we assume a linear slowdown when the number of allocated GPUs is less than requested.

2.1 Jointly Optimizing Fairness and Efficiency

Existing scheduling mechanisms lack a systematic approach to jointly optimize fairness and efficiency. We first formally define a fairness metric: we adopt the definition of fairness used in recent work such as Themis [29], Gavel [33], and Pollux [36]: Finish Time Fairness (FTF) $\rho(G) = \frac{t_{schedule}}{t_{egalitarian}}$; where $t_{schedule}$ represents the job finish time resulting from a policy G , and $t_{egalitarian}$ is $t_{exclusive} \cdot N$; N indicates the number of contending jobs, $t_{exclusive}$ indicates run time when running exclusively with requested resources. FTF $\rho > 1$ ($\rho \leq 1$) indicates that a job is unfairly (fairly) scheduled. Note that while we focus on FTF, *Shockwave*'s underlying market formulation can be extended to support other fairness metrics. For example, by assigning different budgets to jobs we can support weighted proportional fairness [27] with the budgets encoding priorities.

Second, we define a policy as efficient if it minimizes makespan, or correspondingly, maximizes cluster utilization given a sequence of jobs.

Instantaneous fair-share sacrifices efficiency. Existing fair sharing policies, such as Processor-Sharing (PS) [40] and its multi-dimensional extension, Dominant Resource Fairness (DRF) [17], guarantee that at each instant, any job in the schedule obtains exactly a $1/N$ share of the (dominant) resources. However, restricting schedulers to instantaneous fair share can adversely degrade long-term efficiency. Previous work in Altruistic Scheduling (AS) [20] has shown that sacrificing instantaneous fair share and letting some jobs altruistically contribute resources can improve efficiency by 26% [20].

Using filters to balance fairness and efficiency is sub-optimal. Given the limitations of instantaneous fair sharing schemes, recent work [28,29] has proposed using round-based schemes that optimize instantaneous efficiency and long-term fairness. Within each round of scheduling, AlloX [28] and Themis [29] select for allocation a fixed fraction (f) of jobs that have attained the least resource share in the past. Within these filtered jobs, the scheduler tries to maximize efficiency. Across rounds, the filter compensates for jobs unfairly scheduled in the past and thus pursues fairness in the long run.

Existing studies pre-specify a fixed value for filter f across

rounds, but we find that adopting a fixed filter can incur a loss in average JCT or makespan [29], and filter tuning is challenging. Table 1 uses a simple example with three jobs to show how different filters yield very different performance outcomes: fixed filter values $f = 1$ and $f = \frac{2}{3}$ violate finish time fairness ($\rho > 1$) while $f = 1/3$ leads to worse JCT. We included the full toy examples in Appendix B. Tuning the hand-crafted fairness filter is challenging without any insight into the resulting performance outcomes, and it is more difficult when the workload varies.

Overall, this argues for a rigorous, systematic approach that jointly and intrinsically (i.e., without knob-tuning) optimizes efficiency and fairness in resource sharing.

2.2 Handling Dynamic Batch Size Scaling

The above goal of optimizing for fairness and efficiency is made further challenging in the presence of dynamism. Dynamism can result in a number of different scenarios. For example, dynamism can result from job arrivals leading to time-variant cluster contention, and systems like AFS [24] are designed to improve JCT by adjusting shares based on job arrivals. On the other hand, dynamism can arise from training jobs that can change their training configurations dynamically. For example, if a job uses gradient noise scale (GNS) [30,31], the batch size used can change dynamically. This can affect fair scheduling because when a job switches to using a large batch size, the per epoch time will decrease, and thereby its remaining running time will also decrease (Figure 2(a)). Unlike prior systems which only handle dynamism that arise from job arrivals, *Shockwave* (and prior work in Pollux [36]) focus on handling dynamic changes in batch sizes of training jobs.

Being agnostic or reactive to dynamic adaptation breaks finish time fairness. We show that being agnostic or reactive to dynamic changes (or dynamic adaption) can yield severe unfairness. Finish time fairness (FTF) implies a soft deadline $t_{egalitarian} = t_{exclusive} \cdot N$ for job completion; the later the job finishes after the deadline, the more unfair the schedule is. Computing FTF requires computing the exclusive run time (i.e., $t_{exclusive}$), which is straightforward for static jobs since run time roughly equals training throughput (samples per second) times the remaining amount of work (remaining number of epochs). However, for jobs that use dynamic adaptation, future training epochs could be significantly faster because of using a larger batch size. Agnostic scheduling and reactive scheduling are both unaware of future speedups and hence overestimate run time, and thus mistakenly extend the deadline $t_{egalitarian}$ leading to significant unfairness.

Figure 2b uses a job from our trace to show the difference between Themis, which uses a reactive approach, and *Shockwave*, which uses a proactive approach. The job dynamically doubles batch size three times from 32 to 256, and gradually boosts training speed by up to 1.7 \times (Figure 2a). Themis is notified and updates the job's throughput immediately after each batch size scaling, and recomputes the estimated finish

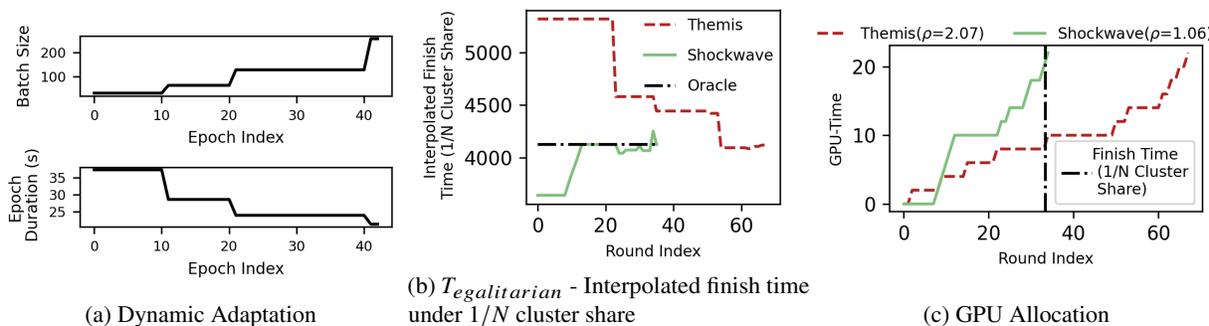

Figure 2: Example - Reactive scheduling (Themis [29]) for dynamic adaptation breaks finish time fairness. Proactive scheduling (*Shockwave*) for dynamic adaptation preserves finish time fairness.

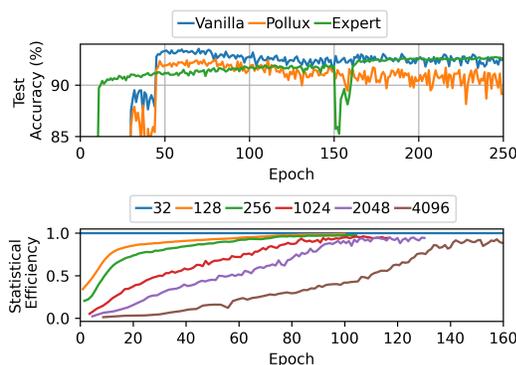

Figure 3: Comparing model accuracy (ResNet18-CIFAR-10) for vanilla training, expert-set batch size scaling, and Pollux autoscaling. The legends in the bottom figure indicate batch size.

time based on that (red dashed line in Figure 2b). Changes in the estimated finish time lead Themis to detect that the job has received less than its fair share and Themis attempts to prioritize this job in future scheduling rounds. However, the job has already suffered from under-prioritization in its early phases and misses the fairness deadline by $2.07\times$ (Figure 2c). Agnostic scheduling is even worse and increases the job's FTF ρ to 3.07; we omit this from the figure.

Being agnostic or reactive to dynamic adaptation degrades system efficiency. Many makespan-minimizing algorithms, such as Mixed Integer Linear Programming (MILP), Longest Processing Time (LPT) [14], and JCT (Job Completion Time) minimization algorithms such as Shortest Remaining Time (SRPT) and AlloX [28], rely on the exact job run time, or the ordering of jobs' run time to derive a schedule.

However, dynamic adaptation adaptively changes a job's throughput, and thus a job's run time can be reduced (when batch size is increased) or prolonged (when batch size is decreased) on the fly. This means that when making scheduling decisions, the job run time estimated using initial or current throughput is only valid for the current instant, and if it is used beyond that system efficiency can be significantly undermined. In Figure 4, the example shows that for MILP makespan minimization, being reactive to dynamic adaptation yields a 22.3%

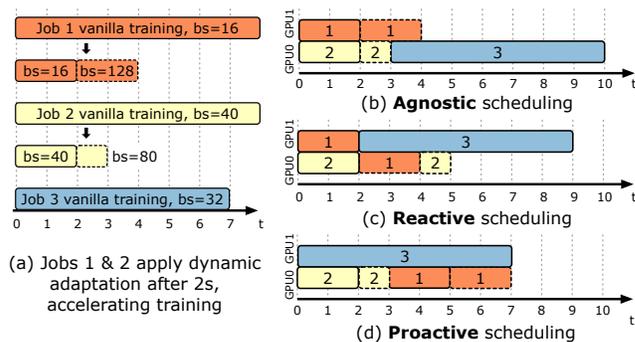

Figure 4: Being agnostic and/or reactive to dynamic adaptation undermines efficiency while proactive scheduling minimizes makespan and maximizes efficiency.

worse makespan and 28% worse cluster utilization compared to proactive scheduling. Reactive scheduling considers $J1$ and $J2$ as long-running jobs from their initial throughput and prioritizes them to minimize makespan. But due to dynamic adaptation, $J1$ and $J2$ become shorter than $J3$ in their second epoch, and it is too late to compensate and re-prioritize $J3$. Being completely agnostic to dynamic adaptation is even worse, yielding a 30% worse makespan.

Overall, the above points motivate the need for a scheduler that can model future dynamic adaptation and account for this uncertainty while optimizing for both fairness and efficiency.

2.3 Supporting User-defined Dynamic Dadaptation

While dynamic adaptation with batch size scaling is a key enabler for efficient training of large-scale DNNs, improper changes to the batch size can adversely impact convergence properties and degrade model accuracy. Thus, unlike systems such as Pollux [36] which automatically modify the batch size of training jobs, we argue that schedulers should support user-defined dynamic adaptation schedules to avoid affecting training accuracy. This is mainly because no adaptive batch size scaling technique works consistently well across all datasets and optimizers. As a result, ML researchers have developed many different batch sizing scaling policies including linear scaling rule [7], Accordion [1], Gradient Noise scale (GNS) [36], SimiGrad [37], Hessian eigenspectrum [42], etc.

We next study an example of how choosing an incorrect batch size schedule can affect accuracy. In Figure 3, we consider a CIFAR-10 training job on 2 GPUs with ResNet18 with an initial batch size of 32. When using Pollux [36], the end-to-end training time reduces by 5× as Pollux scales up the batch size from 32 to 64 at epoch 1, and then up to 314 at epoch 2, then to 690 at epoch 30, and finally up to 1682 at epoch 70 till completion. However, this aggressive scaling leads to a 2-3% accuracy loss. Plotting the statistical efficiency (as defined in Pollux [36]), we find that using large batch sizes in the first 30 epochs leads to accuracy degradation. Our conversation with the authors of Pollux suggests that the accuracy degradation depends on the initial batch size used (32 in this case) and can thus vary across jobs.³

We also tested an expert heuristic for batch size scaling of ResNet18 training on CIFAR-10. The heuristic scales up the batch size when the gradient norm [1] has insignificant (<50%) changes, and does not scale in the initial epochs 20 epochs and the 10 epochs before and after each learning rate decay. This expert-defined scaling schedule has minimal accuracy loss and is 3× faster than vanilla training. Such expert heuristic and the associated thresholds vary across models and datasets; the above heuristic is specific to ResNet-18-CIFAR-10 training and is not easily transferable. For example, for ResNet-50-ImageNet training, the experts propose a different heuristic that scales up the batch size by a factor of ten at the 30th, 60th, and 80th epoch, respectively [38]. Thus, while prior work has developed scheduling mechanisms for specific dynamic adaptation techniques, in *Shockwave*, on the other hand, we assume no preference for any technique and respect any choice made by users regarding how to dynamically scale a training job’s batch size.

In summary, we find that automatically performing dynamic adaptation runs the risk of accuracy degradation. Hence in this work, we aim to develop a scheduler that can observe and forecast future scaling events but treats dynamic adaptation as a part of the user’s program that cannot be modified.

3 Overview

We next present an overview of *Shockwave*, a new scheduling framework that jointly optimizes efficiency and fairness for machine learning workloads in shared clusters.

Using Market Theory for Efficiency and Fairness In *Shockwave* we propose using market theory to provably guarantee efficiency and fairness for resource sharing. While prior schedulers [29, 44] have also leveraged market theory for fair sharing, they are built on static market models which assume that resource requests for a job don’t change over time. We find that the fairness and efficiency guarantees of a static market do not hold when jobs dynamically change over time [15]. Thus, *Shockwave* extends the classic, static market

³We also found that the statistical efficiency metric in Pollux can be incorrect for Neural-MF models [22]. We include details of this experiment in Appendix A.

to a discrete-time, dynamic market, to support efficient and fair resource sharing under dynamic adaptation.

Predicting Dynamic Adaptation Building a dynamic market alone is not enough as it presumes perfect future knowledge of jobs’ dynamic adaptation behavior; that is, the market needs to know when and how much jobs’ performance (e.g., training throughput) is changed by dynamic adaptation as training progresses. As ML training itself is a stochastic process, the trajectory of dynamic scaling is intrinsically uncertain. We address this problem in *Shockwave* by forecasting the trajectory of dynamic adaptation and developing methods to use these forecasts in the dynamic market.

Scalable System Implementation Solving a dynamic market and predicting dynamic adaptation introduces scheduling overhead. We build a centralized, round-based scheduler [33] and incorporate tractable approximations that can ensure the overhead remains low even as we scale the number of GPUs and cluster size. We find that *Shockwave* can maintain low overhead while scheduling every 120 seconds and scale to handle 900 active jobs running on a cluster of 256 GPUs.

4 Dynamic Market Theory Formulation

We begin by describing our theoretical formulation of a discrete-time, dynamic market and the properties it provides.

4.1 Volatile Fisher Market

Market theory provides a fundamental approach to provably guarantee efficiency and fairness in resource sharing. The equilibrium of a Fisher Market [5], which is solved by maximizing Nash Social Welfare (NSW) [8], is a strong condition that implies all fairness guarantees used in prior systems. It is known that Fisher market equilibrium (under equal endowment) implies Pareto Optimality (PO), Envy-freeness (EF), and Proportionality (PR), which are fairness properties adopted by existing systems like DRF [17].

We define efficiency in terms of the utility of a job, where utility is a function that maps allocated resources to the resulting job progress (e.g., throughput improvement if we allocate more resources). The market equilibrium for a Fisher market has also been shown to maximize efficiency [6]. Thus, we explore the applicability of Fisher markets for DL jobs.

From static market to dynamic markets: Volatile Fisher Market. Classic Fisher Market assumes static, time-invariant utility for jobs, and a recent study [15] shows that efficiency and fairness guarantees can be violated for dynamic, time-variant utilities. Prior work [2,3] on dynamic markets has also studied settings where goods (resources) arrive online, while our market considers a different setting where buyers in the market have time-variant utilities over goods.

To perform efficient fair sharing under dynamic adaptation, we extend the static Fisher market to a discrete-time, dynamic market. We name this new market **Volatile Fisher Market (VFM)**. We prove that maximizing Nash Social Welfare Over Time (i.e., NSW_{OT} in Equation 1) solves the market

equilibrium of VFM and establishes long-term efficiency and fairness properties, such as Proportionality Over Time, i.e., PR_{OT} , which has strong implications for finish time fairness and sharing incentive. We leave the formulation and related proofs of VFM in Appendix C-D, and provide a succinct description below.

VFM operates at discrete time intervals $t = 1, \dots, T$. At each time instant, a central seller (the scheduler) sells resources (e.g., GPUs and/or CPUs) to buyers (jobs). All resources are volatile. That is, resources bought by a job at time t' cannot be carried over to the future time steps $t > t'$. To model dynamic adaptation, the utility for any job i is a sequence of time-variant functions u_{it} ($t = 1, \dots, T$). For example, a job might have a utility u_0 when the batch size is 16 and its utility could double $u_1 = 2u_0$ when the batch size doubles at $t = 1$. Since jobs' utilities can change over time, this creates dynamic changes in demands over time, and thus, resource price, which is achieved at equilibrium, is also time-variant. We assume that each job is endowed with an initial budget to spend across rounds. The budget for a job reflects its purchasing power and different budgets can reflect scheduling priority.

Given the resource demands, budget, and utility for each job, at every time instant, the VFM solves for an allocation and assignment of prices that can lead to market equilibrium. We define the market to have reached an equilibrium when two conditions are satisfied. **(a) Optimal Spending:** Each job's utility accrued over time, i.e., $\sum_{t=1}^T u_{it}$, is maximized under its budget. **(b) Work-conserving:** There are no leftover resources if the price for the resources is non-zero.

4.2 Equilibrium Properties

The market equilibrium achieved by VFM has a number of powerful properties that we define below. Proofs for them are in Appendix C-E.

Cluster-level performance. The equilibrium of VFM maximizes Nash Social Welfare Over Time (NSW_{OT}) which is an indicator of cluster-level performance.

$$NSW_{OT}(U_1(\mathbf{X}_1), \dots, U_N(\mathbf{X}_N)) = \prod_i U_i(\mathbf{X}_i)^{\frac{B_i}{\sum_i B_i}}, \quad (1)$$

$$U_i(\mathbf{X}_i) = \sum_t u_{it}(x_{it})$$

Let $U_i(X_i) = \sum_t u_{it}(x_{it})$ represent the utility (e.g., epoch progress) for a job i accrued over rounds $t = 1, \dots, T$, \mathbf{X}_i represent the sequence of allocations $\mathbf{x}_{i1}, \dots, \mathbf{x}_{it}, \dots, \mathbf{x}_{iT}$ received for individual rounds, and B_i represent the budget provided for the job. Maximized NSW_{OT} guarantees that the (weighted) geometric mean of job progress is maximized for a T -round-long time horizon. In effect, this property guarantees that the overall cluster-wide utility is maximized across all jobs, thus leading to improved utilization.

Pareto Optimality over time. We prove that maximized NSW_{OT} also implies Pareto Optimality Over Time (PO_{OT}), which guarantees resource allocation efficiency. Specifically, PO_{OT} ensures that each job has no surplus resources at each

instant; i.e., we cannot increase one job's training progress without depriving that of another job.

Finish Time Fairness (FTF) over time. We also show that maximized NSW_{OT} minimizes the product of FTF across all jobs and that this directly leads to sharing incentive (assuming budgets are equal). A formal statement is in Corollary 4.0.1 and the proof is in Appendix E.

Corollary 4.0.1. *The equilibrium of the Volatile Fisher Market with linear or Leontief utility at each instant (a) minimizes the product of FTF (ρ) across all jobs (i.e., $\prod_i \rho_i$); (b) when the budgets assigned to jobs are equal, the equilibrium provably guarantees Sharing Incentive (SI), i.e., all jobs' FTF ρ are no greater than 1, i.e., $\rho_i \leq 1, \forall i$.*

Thus, our formulation of volatile Fisher markets can capture time-varying utility for jobs while providing a number of powerful guarantees in terms of fairness and efficiency.

4.3 Handling Uncertainty

The Volatile Fisher Market model described above assumes perfect knowledge of the future. That is, the model requires knowing at which time point t will the throughput change due to dynamic adaptation. However, dynamic adaptation in jobs is non-deterministically triggered, as they are dependent on stochastic gradient values and can thus vary across models and datasets. To handle this, in §5, we develop methods to predict dynamic adaptation in jobs. But given that the predictions are random variables, we further extend our above formulation to derive a VFM that can handle uncertainty in future request demands. We show that this extension guarantees Maximized Nash Social Welfare Over Time in Expectation ($MNSW_{OTE}$). Details are provided in Appendix F.

5 Predicting Dynamic Adaptation

In this section, we develop techniques to predict the dynamic adaptation of the batch size that occurs in elastic ML training workloads. Our key insight in developing a predictor is to leverage our knowledge about techniques that are used for batch size scaling [1, 31] and thereby restrict the search space of possible batch size changes. We next define how changes in batch size over time can be viewed as trajectories and then describe how we can use Bayesian statistics to predict which trajectories are most likely.

Dynamic adaption, regimes, and randomness. We define a regime of training R as a tuple $R = (c, f)$; where c indicates the job configuration (e.g., batch size) used in the regime and f represents the duration (as a fraction of the total epochs) that this regime lasts. For example, if a 100-epoch-long DNN training job starts with batch size 32 (denoted BS_{32}) for epoch 1-20, then the first regime is denoted as $c1 = BS_{32}, f1 = 0.2$. We define a trajectory as a sequence of regimes. For example, if the same job scales up to BS_{64} for epoch 21-80, and finally scales down to BS_{32} for epoch 81-100, then its trajectory is represented as $(c1 = BS_{32}, f1 = 0.2) \rightarrow (c2 = BS_{64}, f2 = 0.6) \rightarrow (c3 = BS_{32}, f3 = 0.2)$. Thus, given a new job, each

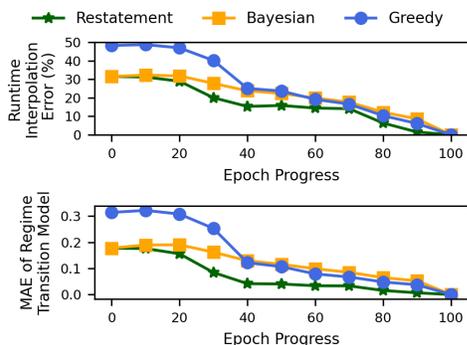

Figure 5: *Shockwave* Dynamic Adaptation Modeling Error.

regime c_i, f_i is a tuple of random variables.

Leveraging domain knowledge. We leverage domain knowledge about techniques used for batch size scaling to constrain the random variables. Techniques for scaling batch size have deterministic patterns. (a) **Accordion [1]** only alternates between two configurations c_1 for small batch size and c_2 for large batch size. When gradient values change slowly (below a threshold) during training, Accordion scales up the batch size from c_1 to c_2 , and when gradient values change rapidly, Accordion scales from c_2 back to c_1 . (b) **GNS [31]** only scales up the batch size up to the pre-specified limit and never scales down. Existing studies show that the gradient noises tend to grow throughout training, implying that GNS will gradually scale up the batch size and never scale down [30, 31]. We use a simple model of GNS scaling where, as the gradient noise grows above a relative threshold, the batch size doubles.

We choose Accordion and GNS as representative batch size scaling patterns as they have been used in prior systems like KungFu [30] and Pollux [36]. Further, their scaling decisions are completely determined by gradient states (i.e., gradient norms and noises), which encode the stochasticity induced in back-propagation algorithms. Most other dynamic batch sizing policies also adapt to gradient states and we plan to add support for more policies in the future.

Prior for regime transition. Given that batch size scaling rules have deterministic configuration transitions, the only random variable is a regime’s duration. For a job with K regimes, we define a probabilistic model $P(f_1, \dots, f_K)$ to represent the probability that regime k ($k=1, \dots, K$) lasts for f_k fraction of epochs. We also note that the sum of all regimes’ epoch fractions needs to sum up to 1⁴. Given this formulation, we use an approach based on Bayesian statistics to predict regime duration. At a high level, our approach is to define a prior distribution of regime duration and then update the posterior distribution in real time as training progresses. The key challenge here is in determining how we can update the posterior as training progresses.

The restatement posterior update rule. Given our problem formulation, we adopt the commonly used Dirichlet prior $Dir(n_1, \dots, n_K)$. A standard Bayesian posterior update rule

assumes the epoch samples of individual regimes are independently and randomly drawn as training progresses. But this does not hold in practice. Epochs of the k -th regime can only emerge if the $k-1$ -th regime finishes. To deal with the temporal-dependence issue, we design a simple update rule, named the restatement rule, for posterior updates. The restatement rule only updates the prior’s parameters that correspond to completed epochs, while continuing to believe that the ongoing and future regimes will evenly split the remaining epochs. Specifically, suppose a user specifies that at a maximum, K regimes can exist, the prior is set as $Dir(N/K, \dots, N/K)$ for the K potential regimes. When the k -th ($k=1, \dots, K-1$) regime finishes, suppose the observed epochs for past regimes $1, \dots, k$ are m_1, \dots, m_{k-1} , we update the posterior distribution to $Dir(m_1, \dots, m_k, S_k, \dots, S_k)$, where $S_k = (N - \sum_{k=1}^K m_k)/(K - k)$. We compare the Bayesian update rule with the restatement rule in Figure 5 and find the restatement rule has a lower interpolation error; the interpolation error is averaged over 200 jobs randomly drawn from the Gavel workload trace (Section 8.1), each with a batch size scaling schedule imposed by Accordion or GNS. **Predicting job remaining time.** Given the predictions from the Bayesian model, we next predict the remaining runtime for a job. This is necessary for estimating finish time fairness. We sum up individual regimes’ expected duration to calculate total job runtime. Total job time minus cumulative run time in the past (i.e., T_j) gives the remaining time.

Computational tractability. Finally, as each job can comprise of many possible regime trajectories, at the cluster level, the trajectory space for all jobs is combinatorially large. To avoid space explosion, the scheduler only considers a single regime transition trajectory for each job, which is the mean (expectation) of its posterior distribution model [4].

Evaluating prediction accuracy. Figure 5 shows the online prediction (i.e., mean of posterior distribution) accuracy for regime transition and job run time. We compare *Shockwave*’s restatement rule with two baselines. The first is a standard Bayesian posterior update rule; the second is a greedy approach that forecasts future job run time only using the most up-to-date job throughput, which is used by all reactive schedulers. The evaluation includes 200 Accordion and GNS jobs with real dynamic adaptation trajectories. *Shockwave*’s restatement rule converges to the oracle job run time and the oracle dynamic adaptation trajectory faster than the baselines. Throughout the training, the error in modeling the duration of each regime is on average 6%, which results on average an 84% accuracy in run time prediction. In summary, we see that our proposed predictor for elastic training jobs is able to accurately capture the total run time without prior training and by only observing job progress across epochs. We next discuss how our predictor can be integrated with the market formulation.

⁴We don’t make any stationary assumptions about the distribution.

6 Shockwave Design

Overview. Figure 6 presents the overall system design of *Shockwave*. When a new job arrives (1), the Bayesian predictor will construct a prior model for the job’s batch size scaling schedule and the job is added to the active pool.

As a job makes progress, upon epoch completion or when the job triggers a dynamic batch size scaling (2), the job’s Dirichlet posterior model is updated using the restatement rule (3). The posterior model then forecasts the future batch size schedule for this job and delivers it to the scheduler solver. Further, the posterior model predicts the job’s (remaining) run time under dynamic batch size scaling and delivers this to the long-term efficiency and fairness estimator.

We design two estimators: a long-term efficiency estimator (4) that can estimate the makespan (time to finish all active jobs) and a long-term fairness estimator (5) that can estimate FTFs for all active jobs. The schedule solver converts the predicted batch size schedules into the utility for each job and synthesizes a generalized Nash social welfare function (6) that uses jobs’ FTF estimate as weights and the makespan estimate as a regularizer. Finally, the output of the solver is a schedule for the next T rounds, and this schedule is used by the cluster manager to launch jobs (more details in §7).

We next discuss some design details of how the generalized Nash social welfare function is derived from its inputs. We also present an overview of how the efficiency and fairness estimators work. We include a more detailed explanation in Appendix G.

6.1 Schedule Solver

Output. The solver plans the schedule for a configurable number of future rounds T (the default is 20 two-minute-long rounds). Thus, the output is a $N \times T$ binary matrix X , where N is the total number of active jobs available for scheduling. $X[j, t] = 1$ ($X[j, t] = 0$) represents scheduling (descheduling) job J_j in round t .

Objective. The inputs to the schedule solver include the batch size schedule for all jobs, which can be used to derive their utility (epoch progress) $UTIL_j$, the estimated FTFs $\hat{\rho}_j$, and the estimated makespan H .

The objective of the solver is to maximize the generalized Nash social welfare as shown in Equation 2. $\sum_t UTIL_j(X[j, t])$ represents the summed utility of all active jobs. The utility increases when a job is scheduled for more rounds within the planning window, and the sum of the logarithm of utilities, across all jobs, represents the Nash social welfare. We use the k -th (default: 5) power of FTF values $\hat{\rho}_j$ as weights to prioritize jobs that are at risk of violating FTF (e.g., jobs that have been waiting in the queue for a long time). Finally, we add a regularization term that penalizes schedules (in the planning window) that could potentially increase the makespan estimate $H(X)$. Coefficient λ (default: $1e-3$) controls the magnitude of the regularizer, Z_0 is a normalization factor that renders the regularizer insensitive to the scale of

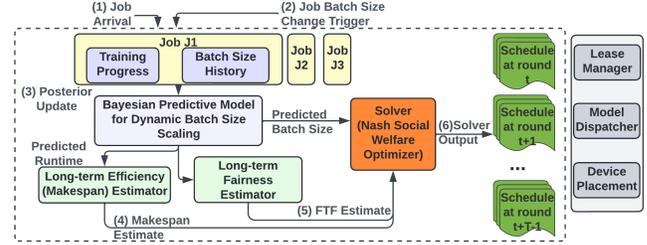

Figure 6: Design of *Shockwave* showing how the different components interact with each other to derive a schedule.

$H(X)$, and M is the total number of GPUs in the cluster:

$$\text{Maximize}_X \frac{\sum_{j=1}^N \hat{\rho}(j)^k \log \sum_t UTIL_j(X[j, t])}{NM} - \frac{\lambda H(X)}{Z_0} \quad (2)$$

We tune the hyperparameters over a large range and find that *Shockwave* performs consistently well around the default hyperparameter values (k in $[1, 10]$ and λ in $[1e-4, 1e-2]$). Exceedingly large or small hyperparameters make the regularization term dominate the Nash social welfare term (or vice versa) and push *Shockwave* away from the Pareto frontier of fairness and efficiency, while the default values strike a balance between them.

Similar to prior work [29, 33, 36], the solver recomputes the program in Equation 2 either when the planned rounds elapse, or when jobs arrive or complete. If dynamic adaptation is predicted to occur within the planning window, the scheduler needs to incorporate dynamic changes in jobs’ throughputs when computing the utility. To account for dynamic changes, we decompose a job’s schedule into regimes, where each regime has a fixed batch size and throughput. The generalized Nash social welfare (Equation 2) can then be implemented at a regime level, where the utility of a job equals the summed utility over all regimes.

6.2 Long-term Fairness and Efficiency Estimators

Finish time fairness estimator. We estimate job J_j ’s finish time fairness (FTF) $\hat{\rho}(j)$ as its predicted job completion time (the sum of attained service time, waiting time, and the predicted remaining run time), divided by its predicted total job run time. Note that a job’s predicted runtime is related to its predicted batch size scaling schedule. *Shockwave* plugs in FTF ρ s of jobs into social welfare function (see Equation 2) as weights. The weights in the social welfare function act as the budgets assigned to jobs in the volatile Fisher market. If a job is predicted to be unfairly scheduled (large FTF ρ) in long term, VFM correspondingly assigns a higher budget for it and proactively prioritizes the job in the planning window. **Makespan estimator.** The efficiency estimator estimates the makespan to complete all active jobs and penalizes schedules in the planning window that increase the makespan. However, it is challenging to estimate the makespan for all active jobs at a given instant. Thus, in practice, *Shockwave* uses a lower bound [12] of the makespan as a proxy and penalizes

Model	Task	Dataset	Batch Size(s)
ResNet-50	Image Classification	ImageNet	16 - 128
ResNet-18	Image Classification	CIFAR-10	16 - 256
LSTM	Language Modeling	Wikitext-2	5 - 80
Transformer	Language Translation	Multi30k (DE-EN)	16 - 256
Recoder Autoencoder	Recommendation	ML-20M	512 - 8192

Table 2: Workloads used in the evaluation.

increasing the lower bound. More details are in Appendix G.

7 Implementation

Scheduler and worker. *Shockwave* scheduler and worker implement time-sharing of cluster resources with round-based scheduling. Each round is a fixed interval (default: 2 minutes). In each round, the scheduler selects a set of jobs from the active job pool to run. The lease manager translates the schedule to job leases and notifies the workers to launch, suspend, or resume jobs. Each worker binds to a single GPU device.

We adopt a simple job placement engine along with Gavel. The placement engine tries to tightly pack jobs’ workers over the machines to minimize fragmentation, and it also tries to place scheduled jobs on their previously executed machines to maximize job locality.

Scheduler solver, lease manager, and model dispatcher. If a job does not run in round T , but is scheduled for round $T + 1$, the scheduler will notify the lease manager to create a new lease for it, and dispatch the job to GPU workers before the next round starts. The assigned workers will launch the job when the next round begins. If a job is actively running in round T and the scheduler continues to schedule it for round $T + 1$, the lease manager will send a lease extension signal to the job’s workers. This job will stay running on the same workers in round $T + 1$. If a job is actively running in round T , but the scheduler decides to suspend it in round $T + 1$, the job’s workers will stop it since its lease will not be renewed.

Shockwave also penalizes frequent restarts as it adds overheads in dispatching models and datasets to workers. The schedule solver prefers to schedule jobs to continuous rounds in the window and penalizes scattering the job’s execution across rounds. Furthermore, the underlying device placement engine prefers mapping a job to its previously allocated workers to reduce restarts.

Dynamic adaptation support. When a training job triggers dynamic adaptation (i.e., batch size scaling), it notifies the scheduler solver of the occurrence of the event. The cluster manager can configure *Shockwave*’s responsiveness to dynamic scaling. The reactive mode requires *Shockwave* to invalidate its current schedule and immediately trigger resolving in response to dynamic adaptation. The lazy mode continues the original

schedule and postpones resolving until the next rescheduling interval. *Shockwave* is by default configured in reactive mode.

Prototype. *Shockwave* is implemented in Python atop ML cluster manager Gavel [33]. We integrate *Shockwave* into Gavel by implementing a schedule solver, meta-data collector, and schedule translator, which translates *Shockwave*’s produced schedule to job leases. Furthermore, *Shockwave* provides an interface for users to monitor gradients and trigger batch size scaling. Scaling requests are sent to the scheduler with gRPC. The schedule solver is implemented with Gurobi [34]. *Shockwave* uses Linux NFS to store model checkpoints. Our checkpointing overhead is less than 3%.

8 Evaluation

We next evaluate *Shockwave* using ML job traces derived from real-world clusters and compare *Shockwave* to state-of-the-art deep learning schedulers.

8.1 Experiment Setup

Testbed. We conduct experiments using a 32-GPU, 8-node cluster on TACC [9]. Each node has 4 NVIDIA Quadro RTX 5000 GPUs (16GB GRAM), 2 Intel Xeon E5-2620 v4 “Broadwell” CPUs, and 128GB DDR4 RAM. The network bandwidth is 200 GB/s inter-switch and 100 GB/s inter-node.

Workload. *Shockwave*’s evaluation uses two separate workloads to reinforce its practical applicability. These traces include diversity in job sizes, model types, and arrival patterns. Unless otherwise specified, we use Gavel’s workload generator [33] to construct synthetic distributed training workloads. Job information is detailed in Table 2. The jobs used in this paper range from 0.2 to 5 hours long, with 1, 2, 4, or 8 workers for distributed training, and the arrival of jobs follows a Poisson arrival process with an inter-arrival rate λ ranging from 0.1 to 0.2 [33]. We use a mix of job durations also derived from prior work [36]. We categorized jobs based on total GPU-time, and similar to prior work, we set the probability of generating Small (0.2-8 GPU-hours), Medium (8-16 GPU-hours), Large (16-72 GPU-hours), and Extra Large (>72 GPU-hours) jobs to be 0.72, 0.2, 0.05, 0.03, respectively. Each job is configured with one of the three modes: Static, Accordion [1], or GNS [31]. We increase the total batch size by increasing the per-GPU batch size while preserving the number of workers. In addition to traces generated by Gavel, we also evaluate a production trace of real job duration and arrival timestamps used by Pollux [36] in Appendix J. We also tune the hyperparameters k and λ with the range discussed in Section 6.1.

8.2 Baseline Schedulers

We compare *Shockwave* to six schedulers: **OSSP (Open Shop Scheduling)** [18], **AlloX** [28], **Themis** [29], **Gavel** [33], **MSS (Max-Sum-Throughput)** [33], **Gandiva-Fair** [10], and **Pollux** [36]. All baselines, except Pollux, do not change the number of workers, whereas Pollux dynamically tunes the number of workers (and batch size) to adapt to varied resource avail-

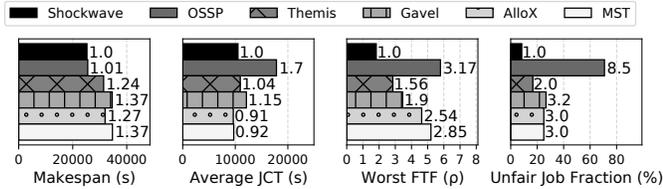

Figure 7: [Physical] Evaluating *Shockwave*’s scheduling efficiency and fairness in a 32-GPU physical cluster. The annotated number beside each bar is the relative value compared to *Shockwave*.

ability. To perform a fair comparison against the scheduling policies of most baselines, in our *Shockwave* prototype, we only perform time-sharing and maintain a fixed number of workers through a job’s lifetime, even though the *Shockwave* market formulation can be easily re-parameterized to support worker scaling. Nevertheless, we compare our “constrained” version of *Shockwave* to Pollux in §8.7 and show significant fairness gains and matching efficiency.

Efficiency baseline: makespan. OSSP minimizes makespan using MILP. As minimizing makespan usually translates to maximizing cluster utilization, OSSP provides a baseline for efficiency, but with no guarantee of fairness.

Efficiency baseline: throughput. Max-Sum-Throughput (MST) maximizes the cluster-level throughput at each instant, which is the sum of throughput across all training jobs. MST is an instantaneous efficiency baseline.

Fairness baseline. Gavel [33] implements Max-Min-Fairness [32], an algorithm that performs fair sharing of cluster resources within each allocation round.

Fairness and responsiveness baseline. AlloX [28] minimizes average job completion time with maximal bipartite matching and provides a baseline for responsiveness. Pollux [36] maximizes cluster-wide goodput and uses the p -norm of individual jobs’ training goodput for improved responsiveness, while tuning p to penalize unfair allocations.

Fairness and efficiency baseline. Themis [29] uses Partial Allocation [13] for efficient and fair allocation. We use the default filter value for Themis. We also compare against Gandiva-Fair [10], a framework that uses lottery scheduling to guarantee a proportionally fair share of resources and efficiency by being work-conserving.

Performance metrics. We quantify efficiency using makespan and utilization. We measure fairness using two metrics: The first is the fraction of unfairly scheduled jobs, i.e., the fraction of jobs with FTF $\rho > 1.0$; The second is the worst-case FTF ρ , which is the worst-case slowdown due to unfair scheduling. The smaller the unfair fraction and worst FTF ρ are, the better a scheduler is at preserving sharing incentive. We quantify responsiveness using average JCT.

8.3 Evaluating Efficiency and Fairness

We first study the benefits of *Shockwave* using experiments on the physical TACC cluster.

[Cluster - 32 GPUs, 120 Jobs] Efficiency. (cf., Figure 7) *Shockwave* is more efficient than existing fair schedulers with a makespan on average 1.3× less than Themis, Gavel, and AlloX. Compared to our efficiency baselines that have no fairness constraints, *Shockwave* achieves a 37% improvement in makespan over MST and produces a similar makespan as OSSP. Analyzing cluster utilization data we also find that *Shockwave* outperforms Themis, Gavel, and AlloX in cluster utilization by 28% on average.

[Cluster - 32 GPUs, 120 Jobs] Finish time fairness (cf., Figure 7). *Shockwave* is fairer than existing fair schedulers. *Shockwave*’s worst-case FTF (Finish Time Fairness) ρ is 1.82, outperforming Themis, Gavel, and AlloX by 2× on average. OSSP and MST are not fair schedulers, and severely break finish time fairness, the worst-case FTF ρ of which reach 5.79 and 5.2. In addition, *Shockwave* keeps the fraction of unfairly scheduled jobs (i.e., the fraction of jobs with FTF $\rho > 1$) low, outperforming Themis, Gavel, and AlloX by 2.7× on average. OSSP and MST unfairly schedule jobs, and their fraction of jobs that have FTF ρ larger than 1 are 70.8% and 25%.

[Cluster - 32 GPUs, 120 Jobs] Average job completion time (cf., Figure 7). *Shockwave* does not sacrifice system responsiveness in exchange for improved makespan and finish time fairness. *Shockwave* produces a similar average job completion time when compared with Themis, Gavel, and MST. AlloX achieves a better average JCT by aggressively prioritizing short jobs (but at the cost of delaying long jobs), while in contrast, OSSP achieves the worst average JCT due to aggressively prioritizing long jobs for tight resource packing over time (but at the cost of delaying short jobs).

Overall, we find that by solving for the optimal efficiency-fairness trade-off, *Shockwave* can improve efficiency and fairness when compared with existing schedulers. By analyzing the scheduling decisions, we find that with *Shockwave*, jobs are opportunistically prioritized to improve long-term efficiency if such prioritization does not affect finish time fairness. Second, we find that *Shockwave*’s solver improves fairness by smart arbitrating. “Rich” jobs (i.e., jobs which have lower chances of violating FTF) yield resources to “poor” jobs which have a higher chance of violating FTF. We next take a closer look at the schedule decisions on a smaller trace to further distill the benefits of *Shockwave*.

8.4 A Closer Look at *Shockwave*’s Schedule

We compare the schedules for a batch of 50 jobs, and the FTF ρ between *Shockwave* and baselines to further understand the wins in efficiency and fairness. We categorize jobs into four groups based on their sizes (GPU-time): (X)Large, Medium, Small, and (X)Small (different colors in Figure 8a).

Understanding efficiency improvement. AlloX optimizes system responsiveness (average JCT) by prioritizing small jobs. In Figure 8a, in the first 100 rounds, most of the jobs scheduled are XSmall jobs. The filter in AlloX ensures medium and large jobs do not get starved but these jobs are

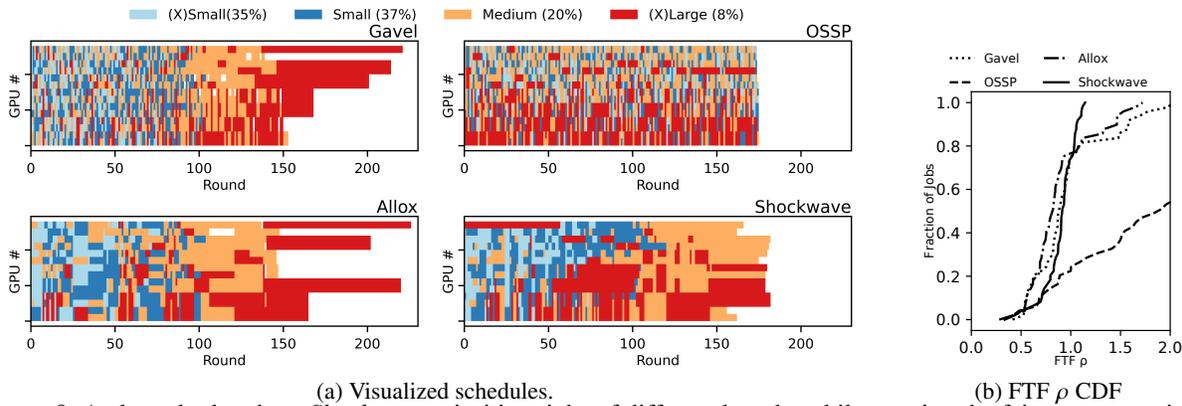

Figure 8: A closer look at how *Shockwave* prioritizes jobs of different lengths while meeting the fairness constraints. (a) Visualized schedules. (b) FTF ρ CDF

not prioritized. Large jobs trail until round 230 and leading to worse makespan and cluster utilization.

Gavel's max-min fair scheduling prioritizes the least performant jobs. In Figure 8a, throughout the schedule, *Gavel* prioritizes neither small nor large jobs; jobs of all sizes evenly partition GPUs when compared with other policies. However, restricting scheduling to instantaneous fairness significantly hurts long-term efficiency, and large jobs run on a mostly idle cluster from round 170 to round 220.

Shockwave improves efficiency by opportunistically scheduling (X)Large jobs across rounds but without hurting small and medium jobs' sharing incentive (Figure 8b shows the CDF of FTF). In Figure 8a, between round 0 and 50, and 50 to 120, large jobs are opportunistically scheduled by *Shockwave*, and the cluster is tightly packed over the time horizon, resulting in a low makespan. Note that *Shockwave* also preserves responsiveness since most XSmall and small jobs are completed fast (before round 50 and 110, respectively), which is comparable to *AlloX*.

OSSP over-prioritizes (X)Large and medium jobs throughout the timeline, but significantly delays XSmall jobs' completion (see delayed blocks at the end of the schedule). Delaying small jobs significantly breaks the sharing incentive and undermines cluster responsiveness.

Understanding fairness improvement. Figure 8b shows the FTF ρ CDFs of different policies for the batch of jobs visualized in Figure 8a. *Shockwave* improves efficiency without sacrificing the sharing incentive: the worst-case FTF ρ for the batch of jobs is 1.23, and the fraction of unfair jobs is low. In Figure 8a, *AlloX* and *Gavel*'s CDF grows faster than *Shockwave*'s for $\rho \leq 1$, although more than 20% of jobs have $\rho > 1$. *AlloX* and *Gavel* over-prioritize some jobs and this results in an allocation that exceeds sharing incentive. *Shockwave* avoids over-prioritization and is thus able to have more jobs meet the sharing incentive. *Shockwave* also improves fairness by predicting dynamic adaptation for a more accurate estimate of the FTF deadline. Figure 2 shows an example where *Shockwave* produces an accurate prediction of the FTF deadline and enables the job to finish on time.

Makespan (s)	Average JCT (s)	Unfair Fraction (%)
4.97%	4.62%	3.83%

Table 3: Fidelity of *Shockwave*'s simulator – difference between simulator and physical cluster.

8.5 Scaling to Large Clusters

We next use simulation to compare *Shockwave*'s and baseline algorithms' efficiency and fairness in larger-scale cluster settings. We scale both the cluster size and the number of jobs and study 64 GPUs with over 220 jobs, 128 GPUs with over 460 jobs, and 256 GPUs with over 900 jobs. We preserve the contention factor as roughly three to maintain a constant level of resource contention regardless of scale. Note that our physical cluster implementation and the simulator use the same scheduling code base and solver engine. We begin by validating our simulator's fidelity.

Simulation Fidelity

We evaluate the simulation fidelity by comparing our simulator's results with the 32 GPU physical cluster results (Table 3). We run all policies supported by our system under different workloads, and the average difference is reported in Table 3. Overall, the performance difference between a simulated and physical cluster run is around 5%.

[Simulation - 64-256 GPUs, 220-900 Jobs] Efficiency. As shown in Figure 9, *Shockwave* scales to large cluster settings and preserves the improvement in makespan over baseline algorithms. *Shockwave* achieves 1.26-1.35 \times , 1.3-1.34 \times , 1.35-1.37 \times , and 1.21-1.3 \times speedup in makespan when compared with Themis, *Gavel*, *AlloX*, and *Gandiva-Fair* respectively. *Shockwave* achieves a marginally worse (5%-9%) makespan compared with *OSSP*.

[Simulation - 64-256 GPUs, 220-900 Jobs] Finish time fairness. The worst-case FTF ρ for *Shockwave* when scaling to large clusters is on average 1.32, outperforming fair scheduling policies Themis, *Gavel*, *AlloX*, and *Gandiva-Fair* by 2.5 \times , 2.4 \times , 3.1 \times , and 3.9 \times respectively. In addition, *Shockwave* maintains the fraction of unfairly scheduled jobs (FTF $\rho > 1$) on average at 4%, outperforming other fair scheduling baselines by 6 \times .

[Simulation - 64-256 GPUs, 220-900 Jobs] Average job

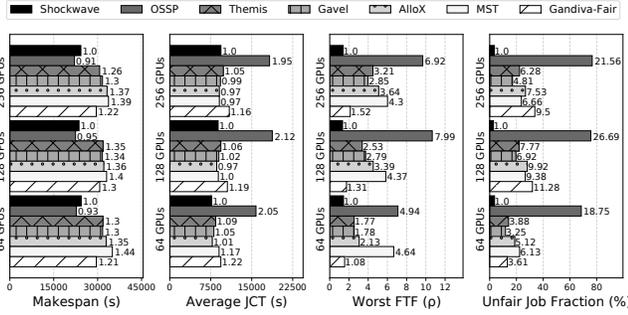

Figure 9: [Simulation] Evaluating *Shockwave*'s scheduling efficiency and fairness in differently sized large clusters.

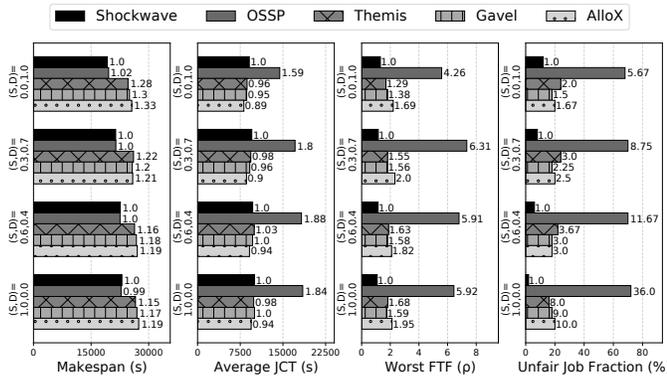

Figure 10: [Simulation] Effects of varying the mix of static and dynamic Jobs. (S, D)=(x, y) indicates x fraction of static jobs and y fraction of dynamic jobs.

completion time. At a large scale, *Shockwave* maintains similar responsiveness when compared with fair schedulers. One exception here is Gandiva-Fair which prolongs average JCT by 16-22%. Gandiva-Fair uses stride scheduling [39] where, by default, a job's number of tickets is equal to the job size (i.e., the number of workers). Thus, large jobs have a higher proportional share when compared with small jobs, and can delay small jobs, thereby degrading system responsiveness.

We study the solver overhead with large clusters in §8.9.

8.6 Benefits of Proactive Scheduling

We next compare *Shockwave* and baseline policies while varying the mix of static and dynamic jobs in simulation.

All static jobs. We first analyze the case where all jobs disable dynamic adaptation. This isolates *Shockwave*'s win due to social welfare maximization. The results (Figure 10) show that all fair scheduling policies, i.e., *Shockwave*, Themis, Gavel, and AlloX exhibit a relatively low fraction (<18%) of unfairly scheduled jobs (FTF $\rho > 1.0$), but *Shockwave* outperforms the baseline algorithms by limiting the unfair fraction to less than 5%. *Shockwave* has on average an 18% improvement in makespan over Themis, Gavel, and AlloX, with no loss in average JCT. Overall, these results show how maximizing social welfare over time can achieve a better fairness-efficiency trade-off when compared to existing approaches.

Fairness and efficiency while being proactive. *Shockwave*

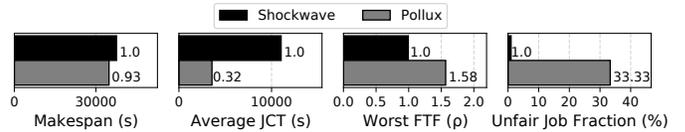

Figure 11: [Simulation] Evaluating *Shockwave*'s and Pollux's efficiency and fairness.

sees a larger win in makespan as the fraction of dynamic jobs increases. The speedup over Gavel, Themis, and AlloX increases to 1.3 \times when the fraction of dynamic jobs grows from 0.4 to 1.0. Our results also show that existing schedulers that are reactive to dynamic scaling have suboptimal fairness outcomes. Both Themis and AlloX exhibit an increased unfair job fraction as the number of dynamic jobs increases. When all jobs are dynamic, Themis schedules 28% of jobs unfairly and AlloX schedules 22% of jobs unfairly, while *Shockwave* has a relatively (9%) low fraction of unfairly-scheduled jobs.

8.7 Shockwave versus Pollux

To compare the scheduling policies used by Pollux and *Shockwave*, we run both systems using the same workload trace provided by Pollux. We also first run the Pollux simulator to collect the batch size schedule observed at runtime and use that as an input to the *Shockwave* simulator. Thus, both systems see the same set of input jobs and the same batch size schedule, and hence, job processing times should match even with dynamic scaling.

JCT. From Figure 11, we see that Pollux has a 3 \times improvement in average JCT over *Shockwave*. Pollux can scale the number of workers of a job, which leads to reduced resource contention and improved responsiveness. In fact, we found that Pollux reduces the requested GPU hours per job by 2.4 \times when compared to the original trace. As our *Shockwave* prototype does not change the number of workers used by a job, it preserves the contention level in the trace (2.4 \times larger than Pollux) and thus exhibits inferior responsiveness. We note that as seen in Figure 7, *Shockwave* has comparable JCTs with other baselines and the Pollux paper [36] also reports a 3 \times speedup over the baselines.

Finish time fairness. *Shockwave* significantly outperforms Pollux w.r.t finish time fairness. This is because Pollux focuses on instantaneous fairness at each allocation but does not systematically address long-term fairness. At every round, Pollux's p -norm formulation penalizes unfair allocations that lead to low instantaneous throughput for jobs but does not preserve long-term fairness over multiple allocation rounds. On the other hand, *Shockwave*'s dynamic market formulation provably guarantees long-term fairness.

Makespan. *Shockwave* benefits from optimizing for long-term efficiency and has a similar makespan as Pollux despite not changing the number of workers dynamically.

Finally, we note that as discussed in 2.3 and Appendix A.2, Pollux's approach of automatically tuning the batch size and the number of workers can lead to accuracy loss (e.g., 2% for

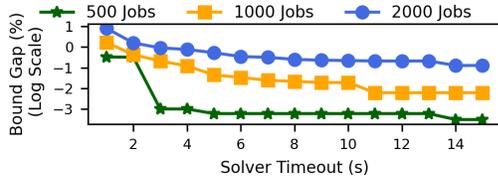

Figure 12: Solver Overhead.

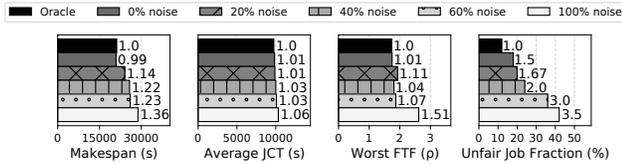

Figure 13: *Shockwave*'s scheduling efficiency and fairness under different levels of prediction errors.

ResNet18 and up to 4% for DeepSpeech [36]). We argue that Pollux's accuracy loss and poor fairness properties make it less attractive for practical deployments.

8.8 Varying Cluster Contention and Workload

We also vary the workload contention factor and compare all policies on a smaller 14-GPU physical cluster. We find that *Shockwave*'s fairness and efficiency win over the baseline schedulers increases (decreases) as cluster contention grows (drops). We include more details in Appendix I. We also compared *Shockwave* using arrival patterns from the Pollux [36] trace. Appendix J includes these results.

8.9 Solver Overhead

Shockwave uses a timeout knob (default 15s) to limit the overhead of solving our market formulation. Figure 12 uses simulation to show that on a 256 GPU cluster, the solver quality improves with diminishing returns as we increase the solver timeout from 1 second to 15 seconds. We measure solver quality using the bound gap (how far the solution found at the timeout is from the optimal). The relative bound gap at 15 seconds is small (0.03%, and 0.11%) for 500 and 1000 active jobs. The bound gap at 15 seconds for 2000 jobs increases to 0.44%. While this exceeds the criterion (0.1%) recommended by Gurobi [34], our results show a limited impact on efficiency and fairness. We note that our solver runs in a separate thread and is proactively invoked in the middle of the current round. Thus, the solver overhead is hidden when it is less than half-round duration.

8.10 Resilience to Prediction Error

Figure 13 shows *Shockwave*'s resilience to prediction errors when varying levels of random noises (i.e., $\pm p\%$) are injected into its interpolated job run time (under dynamic adaptation). The experiment settings in Figure 13 are similar to those in Figure 10 with all jobs enabled for dynamic batch size scaling (i.e., $(S, D)=(0, 1.0)$). First, we observe that as the injected errors grow, *Shockwave*'s worst-case FTF ρ and the fraction of unfairly scheduled jobs inflate slowly. A similar steady trend holds for *Shockwave*'s average JCT. We argue

such robustness originates from the design principle of Nash social welfare, which emphasizes common ownership and fair sharing of cluster resources; the penalty is huge if skewed training progress is present in the cluster and it leads the scheduler to be conservative to jobs' interpolated schedule slacks that are predicated by the biased FTF estimates. Second, we find that *Shockwave*'s scheduling efficiency drops as the errors grow. *Shockwave* opportunistically prioritizes long-running jobs over the short ones to improve makespan. Having 100% injected noise affects *Shockwave*'s estimation of job length and lowers its scheduling efficiency by over 30%. Note that this deteriorated efficiency is still on par with the baseline schedulers (e.g., Themis, Gavel, and AlloX in Figure 10).

9 Related Work

We detail the comparison between *Shockwave* and existing schedulers (e.g., Gandiva [41], Optimus [35], DRF [17], REF [43], Themis [29], AlloX [28], Tiresia [21], GandivarFair [10]) in Section 2, and spotlight *Shockwave*'s contribution from two angles. First, *Shockwave* is built on Nash social welfare, a theoretically-grounded approach to co-optimize long-term, rather than instantaneous, fairness and efficiency. Second, *Shockwave* proactively plans schedules for dynamic adaptation, while most existing schedulers only react to dynamic adaptation. Section 2 presented more details on the limitations of existing DL cluster schedulers.

AFS (Apathetic Future Share) [24] is another elastic sharing mechanism proactive to system dynamics. However, dynamic changes in AFS refer to job arrival and time-variant cluster contention, while jobs themselves do not change. *Shockwave* has a different focus: jobs' resource demands (and efficiency) dynamically change due to batch size scaling. Further, AFS primarily focuses on improving average JCT while *Shockwave* maximizes social welfare over time.

10 Conclusion

We presented *Shockwave*, a market-theory-based efficient and fair scheduling framework for DNN training workloads. We showed how existing schedulers fail to preserve fairness and degrade efficiency by being reactive to dynamic adaptation. To address these challenges, we proposed a proactive approach that uses dynamic markets and Bayesian statistics for scheduling. Our experiments show that *Shockwave* can improve efficiency and fairness compared to state-of-the-art schedulers.

A Dynamic Batch Scaling Degrades Accuracy

A.1 When does batch size scaling degrade accuracy

Improper batch size scaling can adversely affect convergence and degrade the accuracy of the trained model. This is known as **generalization gap** [23, 26] and its underlying reasons are still not well understood. We next list different analyses on when batch size scaling can affect final model quality: (a) scaling up the batch size by $k\times$ reduces the number of iterations per epoch by $k\times$, and given a pre-specified number of epochs, it reduces the overall iterations of back-propagation by $k\times$. Accuracy loss stems from a reduced number of model updates [23]. (b) Scaling up the batch size reduces the noise in the gradient estimate, but noise serves to regularize training and can navigate the optimizer away from local minima. Batch size scaling thus hurts generalization by reducing healthy gradient noises. (c) Scaling up the batch size causes training to converge to sharp minima, and the model outputs are sensitive to small perturbations in the input. This results in a poorer generalization [26].

Researchers have developed heuristics [1, 38] and adaptive batch size scaling techniques (e.g., Gradient Norm [1], GNS (Gradient Noise Scale) [31] and Heissan Eigenspectrum [42]) to mitigate generalization gap, but no single technique handles all models, datasets and optimizers. Thus, today, there are many different batch size scaling techniques in the ML community. Pollux adopts GNS while recent work points out some of the limitations in applying GNS [37] for batch size scaling.

A.2 Example: Pollux’s automatic batch size scaling leads to accuracy loss in NeuMF-m1-lm training

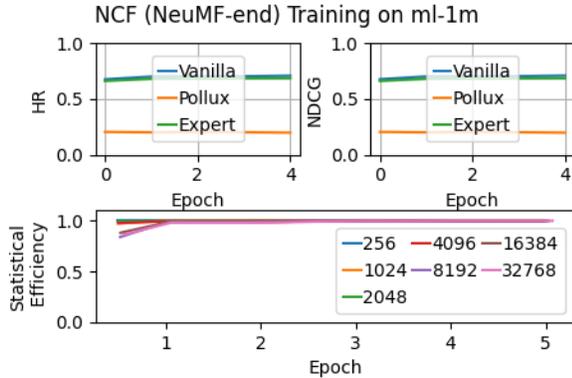

Figure 14: Comparing model accuracy (NCF-m1-lm) for vanilla training (no batch size scaling), expert-set batch size scaling, and Pollux’s autoscaling. The legends in the bottom figure indicate batch size.

Figure 14 shows that statistical efficiency minimally degrades when scaling up from a batch size of 256 to 32768, and that this is true even for early training epochs. Therefore, Pollux immediately scales up the batch size from 256 to 32768 at epoch 1. However, we found that such early, aggressive

scaling leads to inferior validation accuracy, i.e. lower HR (Hit Rate) and NDCG (Normalized Discounted Cumulative Gain), when compared with vanilla training where dynamic batch size scaling is disabled. An expert-set dynamic scaling schedule that scales up the batch size to 32768 at epoch 3 and this helps match the validation accuracy of vanilla training.

C Volatile Fisher Market (VFM)

C.1 Market formulation

VFM is a dynamic market and continues through rounds indexed by $t = 1, \dots, T$. Each round is a fixed time interval, e.g., 120s. Within each round, a central seller (i.e., the scheduler) sells multiple types of resources (e.g., GPUs and/or CPUs) to buyers (i.e., the contending jobs).⁵ All resources are volatile. Resources bought by a job in round t cannot be carried over to future rounds. There is a dynamic price for each resource type in each round, and each job is endowed with an initial budget to spend across rounds. The amount of endowment reflects the priority of jobs. VFM assumes divisible resources [8].

(a) Buyers, Seller, and Resources. There exist N buyer jobs competing for J different types of resources. **(b) Allocation (Purchase).** Let x_{ijt} denote the allocation (purchase) of job i for resource j in round t . The resource provision is normalized to one unit. For brevity, let \mathbf{x}_{it} denote the allocation vector $[\dots, x_{ijt}, \dots]$ for job i in round t , and let \mathbf{X}_i denote the $J \times T$ allocation matrix for job i over rounds, with rows and columns corresponding to the resource types and round indices. **(c)**

⁵VFM supports multiple-resource allocation, but evaluation in this paper is carried out only for GPU allocation.

Budget, Price, and Payment. Job i is endowed with a budget B_i to spend over rounds. The price for resource j in round t is p_{jt} ; The accrued payment over rounds for job i is $\sum_{j,t} p_{jt} x_{ijt}$. Let \mathbf{P} denote a $J \times T$ price matrix, with $\mathbf{P}[j, t] = p_{jt}$. **(d) Performance (Utility) Function for Dynamic Adaptation.** We use the performance (utility) function $U_{it}(\mathbf{x}_{it})$ to map received resources, that is, \mathbf{x}_{it} , to the performance gain of job i (e.g., epoch progress). Note that U_{it} can be different over rounds to model time-variant performance under dynamic adaptation. We limit performance functions in the CES family [5], which are extensively used in system research.⁶

C.2 Solving Equilibrium of VFM

The market equilibrium captures the optimal allocation for the N jobs in each round, i.e. $\mathbf{X}_1^*, \dots, \mathbf{X}_N^*$, and the optimal prices \mathbf{P}^* for different types of resources in each round. An equilibrium is established if the following two properties are satisfied. **(a) Maximized Performance Under Budget Constraint (Optimal Spending):** Each job's performance is maximized under budget constraints. $\mathbf{X}_i^* = \arg \max_{\mathbf{X}_i} U_i(\mathbf{X}_i), s.t., \sum_t \sum_j p_{jt} x_{ijt} \leq B_i, \forall i$. **(b) Work-conserving (Market Clearing):** There is no leftover resource if the price for the resource type is non-zero. That is, if $p_{jt} > 0$, then $\sum_i x_{ijt} = 1, \forall j, t$.

Theorem C.1. *For Volatile Fisher Market with linear or Leontief (e.g., DRF [17]) utility, the solution of (3) captures the optimal allocation in the market equilibrium and the Lagrangian dual to capacity constraints (i.e., $\sum_i x_{ijt} \leq 1, \forall j, t$) captures the equilibrium price.*

$$\begin{aligned} & \text{Maximize } \sum_{\mathbf{X}_1, \dots, \mathbf{X}_N} B_i \log U_i(X_i) \quad s.t., \quad U_i(X_i) = \sum_t u_{it}(\mathbf{x}_{it}), \forall i, \\ & \begin{cases} u_{it}(\mathbf{x}_{it}) = \sum_j u_{ijt} x_{ijt}, \forall i, t \text{ (Linear)} \\ u_{it}(\mathbf{x}_{it}) = \min_j \frac{x_{ijt}}{a_{ijt}}, \forall i, t \text{ (Leontief)} \end{cases}, \\ & \sum_i x_{ijt} \leq 1, \forall j, t, \quad x_{ijt} \geq 0, \forall i, j, t \end{aligned} \quad (3)$$

For VFM with linear and Leontief performance function at each instant, Theorem C.1 states that the solution of an Eisenberg-Gale [5] styled program defined in (3) captures the market equilibrium (cf., proof in Appendix D). **Note that even if the instantaneous utility is Leontief, the summed utility over time is not Leontief in general.**

D Proof of Theorem C.1

D.1 Linear Utility

Volatile Fisher Market (VFM) with linear utilities reduces to a special case of static Fisher market, if we consider volatile resource j at each different time t a unique type of resource. Upon substituting the tuple of resource and time index (j, t)

⁶Themis [29] and Gavel [33] uses linear utility, Dominant Resource Fairness (DRF) [17] uses Leontief utility, and REF (Resource Elasticity Fairness) [43] uses Cobb-Douglas utility, which are all CES utility functions.

with a new resource index k (i.e., $(j, t) \rightarrow k$), the Eisenberg-Gale program defined in (3) is equivalent to the program (4).

$$\begin{aligned} & \text{Maximize } \sum_{\mathbf{x}} B_i \log u_i(\mathbf{x}_i) \quad s.t. \\ & u_i(\mathbf{x}_i) = \sum_k u_{ik} x_{ik} \\ & \sum_i x_{ik} \leq 1, \quad \forall k \\ & x_{ik} \geq 0, \quad \forall i, k \end{aligned} \quad (4)$$

Existing work [5] has proven that program (4) captures the market equilibrium of a static Fisher market, and thus, it also captures the market equilibrium of the equivalent VFM.

D.2 Leontief Utility

However, VFM with Leontief utilities has no direct link to the classic static Fisher market. We prove the Eisenberg-Gale (EG) program defined in (3) captures market equilibrium by characterizing the Karush–Kuhn–Tucker (KKT) [19] conditions. We rewrite (3) in a standard convex optimization form and number the constraints as follows:

$$\text{Minimize } - \sum_{\mathbf{X}_1, \dots, \mathbf{X}_N} B_i \log U_i(X_i) \quad s.t. \quad (5a)$$

$$U_i(X_i) \leq \sum_t u_{it}(\mathbf{x}_{it}), \quad \forall i \quad (5b)$$

$$u_{it}(\mathbf{x}_{it}) \leq x_{ijt} / a_{ijt}, \quad \forall i, j, t \quad (5c)$$

$$\sum_i x_{ijt} \leq 1, \quad \forall j, t \quad (5d)$$

$$x_{ijt} \geq 0, \quad \forall i, j, t \quad (5e)$$

Let $\beta_i, \lambda_{it}, p_{jt}, \eta_{ijt}$ denote the Lagrangian multipliers corresponding to constraints (5b), (5c), (5d), (5e), respectively. The Lagrangian dual function is

$$\begin{aligned} L(x, \boldsymbol{\beta}, \boldsymbol{\lambda}, \mathbf{p}, \boldsymbol{\eta}) = & - \sum_i B_i \log U_i(X_i) + \\ & \sum_{i,j,t} (u_{it}(\mathbf{x}_{it}) - \frac{x_{ijt}}{a_{ijt}}) \lambda_{ijt} \\ & + \sum_i (U_i(\mathbf{X}_i) - \sum_t u_{it}(\mathbf{x}_{it})) \beta_i + \\ & \sum_{j,t} (\sum_i x_{ijt} - 1) p_{jt} - \sum_{i,j,t} x_{ijt} \eta_{ijt} \end{aligned}$$

First, KKT requires a first-order condition of the Lagrangian function; the gradients to all primal variables and Lagrangian multipliers should be zero. This implies that

$$\frac{\partial L}{\partial U_i(\mathbf{X}_i)} = 0 \implies -\frac{B_i}{U_i(\mathbf{X}_i)} + \beta_i = 0 \implies \beta_i = \frac{B_i}{U_i(\mathbf{X}_i)}$$

$$\frac{\partial L}{\partial u_{it}(\mathbf{x}_{it})} = 0 \implies \sum_j \lambda_{ijt} - \beta_i = 0 \implies \beta_i = \sum_j \lambda_{ijt}$$

$$\frac{\partial L}{\partial x_{ijt}} = 0 \implies -\frac{\lambda_{ijt}}{a_{ijt}} + p_{jt} - \eta_{ijt} = 0$$

The combination of the first two equations implies that

$$\sum_j \lambda_{ijt} = \frac{B_i}{U_i(\mathbf{X}_i)}, \forall i, t$$

Lagrangian multipliers are nonnegative, and thus, $\eta_i \geq 0$ implies

$$p_{jt} a_{ijt} \geq \lambda_{ijt}$$

Combining the last equation and the last inequality implies that

$$\begin{aligned} \sum_j p_{jt} a_{ijt} &\geq \sum_j \lambda_{ijt} = \frac{B_i}{U_i(\mathbf{X}_i)}, \forall i, t \\ \implies U_i(\mathbf{X}_i) &\geq \frac{B_i}{\sum_j p_{jt} a_{ijt}}, \forall i, t \\ \implies U_i(\mathbf{X}_i) &= \frac{B_i}{\min_{j'} \{\sum_j p_{jt'} a_{ijt'}\}}, \forall i \end{aligned}$$

This states that for any job i , its overall utility is achieved by purchasing resources only in certain time periods that guarantee **MBB (Maximal Bang-Per-Buck)** [5] for the job, where $\sum_j p_{jt} a_{ijt}$ represents the unit cost to obtain one unit of utility. MBB guarantees that any job's utility accrued over time is maximized given a fixed budget B_i .

We have proved optimal spending (i.e., maximized utility under budget limit) for each job at the solution of program (D). The last step is to prove market clearing. KKT conditions also require complementary slackness:

$$\begin{aligned} p_{jt} (\sum_i x_{ijt} - 1) &= 0, \forall j, t \implies \\ \text{if } p_{jt} > 0 \text{ then } \sum_i x_{ijt} &= 1, \forall j, t \end{aligned}$$

This implies that if a resource j is traded in time period t , then it must be exhaustively allocated to the jobs and the amount of leftover resources is zero. Therefore, we prove **MC (Market Clearing)**. An extra fact implied by the solution of the EG program (D) is that since the objective is to maximize social welfare (budget-weighted geometric mean of jobs' utilities), and thus, there should be no money left by a job in the solution of (D). This proves **BC (Budget Clearing)**. That is, the budget for all jobs will be completely burnt over periods.

In summary, proving Maximal Bang-Per-Buck, Market Clearing and Budget Clearing establishes the VFM market equilibrium produced by solving program (5).

E Proof of Theorem 4.0.1

Proof of (a): $\prod_i \rho_i = \prod_i U_i(\frac{C}{N}) \cdot \prod_i U_i(\frac{\mathbf{X}_i}{N})^{-\frac{B_i}{B}} = \prod_i U_i(\frac{C}{N})$ $\text{NSW}_{\text{OT}}^{-1}$. Since $\prod_i U_i(C/N)$ is a constant independent of X_i , VFM equilibrium that maximizes NSW_{OT} equivalently minimizes the product of FTF (Finish Time Fairness) metrics over all jobs, i.e., $\prod_i \rho_i$.

Proof of (b). At VFM equilibrium, any job i has maximized utility under budget. When all job have an equal budget, job i will not prefer any other jobs j 's allocation, since job i can afford to buy any other job's allocation under same budget. Formally, we get that $U_i(\mathbf{X}_i) \geq U_i(\mathbf{X}_j), \forall i, j$. Since the mar-

ket clears in VFM equilibrium, it is not possible that all jobs have a strictly smaller resource share than C/N , and there must exist a job k such that its resource share is greater than or equal to C/N , then we know $U_i(\mathbf{X}_j) \geq U_i(\mathbf{X}_k) \geq U_i(\frac{C}{N})$, and thus, Finish Time Fairness if proved.

F Stochastic Dynamic Program for Efficiency and Fairness in Expectation

(a) State. Each job has a private, finite set of states. For dynamic scaling of the batch size, a state is a tuple (BatchSize, Epoch), which denotes the current batch size and the current epoch (index). Let s_{it} (\mathbf{s}_t) denote the state of job i in round t . **(b) Policy.** Let \mathbf{x}_t (\mathbf{x}_t) denote the resource allocated to job i in round t . An allocation policy $\pi(\mathbf{s}_t, \mathbf{x}_t)$ indicates the probability of making allocation \mathbf{x}_t to the jobs, conditional on job states \mathbf{s}_t , in round t . We further limit π to be a deterministic policy in this study. **(c) Transition Probability.** We model the state transition with a probability matrix $P_i(s_{it+1}|s_{it}, \mathbf{x}_t)$, which indicates the probability of job i transitioning to state s_{it+1} from state s_{it} , under resource allocation \mathbf{x}_t . Let $P(s_{t+1}|\mathbf{s}_t, \mathbf{x}_t)$ denote the transition probabilities for all the jobs. **(d) Performance (Utility) Function for Dynamic Adaptation.** Let $U_i(s_{it}, \cdot, s_{it+1})$ denote the performance gain (e.g., epoch progress) of job i when transitioning from state s_t to the next state s_{t+1} . Let $U_i(\mathbf{s}_t, \cdot, \mathbf{s}_{t+1})$ denote the performance function for all jobs.

Maximized Nash social welfare in expectation. We construct a linear program in (6) to search for an optimal policy that maximizes Nash social welfare in expectation, i.e., NSW_{OTE} . Maximized NSW_{OTE} co-optimizes efficiency and fairness in expectation sense. The first constraint in (6) defines expected cumulative utility under the policy; The second constrains the summed allocation at each period t not exceeding resource provision, and allocation should be non-negative. The third constrains valid probability transition between states. Other constraints are omitted.

$$\pi^* = \underset{\pi}{\text{argmax}} \sum_i B_i \log \mathbb{E}_{\pi}[U_i], s, t. \quad (6)$$

$$\mathbb{E}_{\pi}[U_i] = \sum_{t=1}^{T-1} \sum_{\mathbf{s}_t \in S} \sum_{\mathbf{x}_t \in X} \sum_{\mathbf{s}_{t+1} \in S} [\pi(\mathbf{s}_t, \mathbf{x}_t) \cdot P(\mathbf{s}_{t+1}|\mathbf{s}_t, \mathbf{x}_t)$$

$$\cdot U_i(\mathbf{s}_t, \mathbf{x}_t, \mathbf{s}_{t+1})], \pi(\mathbf{s}_t, \mathbf{x}_t) \geq 0 \text{ and } \pi(\mathbf{s}_t, \mathbf{x}_t) = 0$$

$$\text{if } \|x_t\|_{\ell_1} > 1 \text{ or } x_t < 0, \forall \mathbf{s}_t \in S, \forall \mathbf{x}_t \in X, t = 1, \dots, T$$

$$\sum_{\mathbf{x}_1} \pi(\mathbf{s}_1, \mathbf{x}_1) = b(\mathbf{s}_1),$$

$$\sum_{\mathbf{x}_t} \pi(\mathbf{s}_t, \mathbf{x}_t) = \sum_{\mathbf{s}_{t-1}} \sum_{\mathbf{x}_{t-1}} P(\mathbf{s}_t|\mathbf{s}_{t-1}, \mathbf{x}_{t-1}) \pi(\mathbf{s}_{t-1}, \mathbf{x}_{t-1}),$$

$$t = 2, \dots, T$$

G Shockwave Design Details

Shockwave plans the schedule for a configurable number (T) of future rounds (default T : 30 two-minute rounds) and re-

computes the schedule when the planned rounds elapse or when jobs arrive or complete. *Shockwave*'s solved schedule is a $N \times T$ binary matrix $X[j, t]$. N is the total number of active jobs available for scheduling. $X[j, t] = 1$ ($X[j, t] = 0$) represents scheduling (descheduling) job J_j in round t ($t = 1, \dots, T$). We next describe the logic in one shot of schedule solving.

Decomposing job schedules to regime schedules. If dynamic adaptation is predicted to occur within the future planning window, the scheduler must incorporate dynamic changes of jobs' throughputs when solving the schedule.

Example - A job's dynamic adaptation process has two regimes. The job is currently in the first regime at epoch 5 and the scheduler predicts that the second regime will start from epoch 15. Suppose the planning window is 30-minute long and the epoch duration for the first and second regime are 2 minutes and 1 minute, respectively. Then dynamic adaptation can start as early as the 20th minute in the window, and a $2 \times$ change in throughput should be concerned.

To support dynamic changes in job throughputs, we decompose a job's schedule into its regimes' schedules, such that each regime is a micro-job with static throughput. In our above example, epochs 5 to 14 will be one micro-job while epoch 15 onward will be the second micro-job. We build a $K \times T$ -dimensional binary matrix $Y_j[k, t]$ to represent the schedule of job J_j 's K regimes that can fit in the planning window. $Y_j[k, t] = 1$ ($Y_j[k, t] = 0$) indicates scheduling (descheduling) the k -th regime of job J_j to the t -th round in the window. Note that partial order constraints are needed to preserve the sequential order between regimes.

G.1 Implementing Nash Social Welfare over Time

We compute the utility of job J_j under schedule $Y_j[\cdot, \cdot]$ as:

$$\text{UTIL}_j(Y_j[\cdot, \cdot]) = \frac{F_j}{E_j} + \sum_{t=1}^T \sum_{k=1}^K \frac{Y_j[k, t] \cdot D \cdot \text{TH}(j, k)}{Q_j \cdot E_j} \quad (7)$$

Job J_j 's utility equals its current epoch progress percentage (num. finished epochs F_j divided by total num. epochs E_j), plus the resulting epoch progress percentage under allocation; the latter sums up the progress percentages for the job across regimes and rounds in the window.⁷ At the cluster level, the (logarithm of) Nash social welfare over time (NSW_{OT}) integrates the utilities of individual jobs. $Y[\cdot, \cdot, \cdot]$ is a three-dimensional array that includes the schedule variable for all active jobs' regimes, at all rounds, in the planning window. As stated in §4.2, maximizing NSW_{OT} yields an equilibrium and establishes efficiency and fairness guarantees.

$$\text{WELFARE}(Y[\cdot, \cdot, \cdot]) = \sum_{j=1}^N \log \text{UTIL}_j(Y_j[\cdot, \cdot]) \quad (8)$$

⁷The epoch progress at a single round t for the k -th regime equals the duration of each round (D_j) times if the regime is scheduled to the round ($Y[k, t]$), then divided by epoch duration $Q(j)/\text{THPT}(j, k)$

G.2 Implementing Estimators for Long-Term Effects

As previously stated, maximizing social welfare for an (infinitely) long time horizon is difficult due to prohibitive computational overhead and limited predictability. Another reason is that jobs arrive and complete online, and frequent re-planning is unavoidable. In practice, *Shockwave* only plans the schedule for a finite length window (e.g, 30-60 minutes), and we design estimators that can capture the long-term fairness and long-term efficiency that arise from short-term planning.

An estimator for long-term fairness.

$$\hat{\rho}(j) = \frac{L_j + W_j + \hat{R}(j) \cdot N_{\text{avg}}(j)}{\hat{P}(j) \cdot N_{\text{avg}}(j)} \quad (9)$$

We estimate the finish time fairness (FTF) $\hat{\rho}(j)$ of job J_j as its predicted job completion time (the sum of attained service time L_j , waiting time W_j , and the interpolated remaining run time $\hat{R}(j)N_{\text{avg}}(j)$), divided by its predicted job run time ($\hat{P}(j)N_{\text{avg}}(j)$).

$\hat{P}(j)$ ($\hat{R}(j) = \hat{P}(j) - L_j$) is the total (remaining) run time under isolated resources predicted using the Bayesian posterior. Similarly to prior work [29], we linearly scale the isolated run time with a contention factor $N_{\text{avg}}(j)$ to compute the run time under contention. In this paper, we define the contention factor as, within a fixed time range, the ratio between the number of jobs requesting GPUs and the overall number of GPUs provisioned in the cluster, and a job's contention factor $N_{\text{avg}}(j)$ only accounts for the time range it is either queued or running.

Shockwave plugs in the k -th power of FTF ρ s of jobs into social welfare function (see Equation 11) as weights. The weights in the social welfare function act as the budgets assigned to jobs in the volatile Fisher market. If a job is predicted to be unfairly scheduled (large FTF ρ) in the long term, VFM correspondingly assigns a higher budget for it and proactively prioritizes the job in the planning window.

An estimator for long-term efficiency. The efficiency estimator estimates the final makespan to complete all current jobs' training epochs and penalizes schedules (in the planning window) that potentially increase the makespan estimate. However, the final makespan is unknown at the current instant and, in practice, *Shockwave* penalizes increasing the lower bound of it. *Shockwave* uses the lower bound given in [12]. Let $R(Y_j[\cdot, \cdot])$ denote the remaining run time of job J_j from the planning window. The lower bound of makespan (for the remaining epochs) is estimated as the maximum between the sum of the remaining run time divided by the number of GPUs in the cluster (i.e., M), and the longest remaining run time among jobs. Intuitively this takes the maximum between the longest job remaining and the makespan if all remaining jobs were evenly spread out across the cluster.

$$H(Y[\cdot, \cdot, \cdot]) = \max\left\{\frac{\sum_j R(Y_j[\cdot, \cdot])}{M}, \max_j R(Y_j[\cdot, \cdot])\right\} \quad (10)$$

Finally, we plug in the long-term efficiency estimator to so-

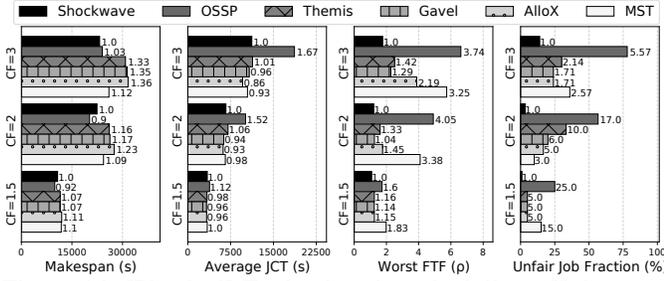

Figure 16: [Physical] Evaluating the scheduling efficiency and fairness of *Shockwave* under different contention factors (CF) in a 14-GPU physical cluster.

cial welfare maximization as a regularizer (See Equation 11). λ is a tunable coefficient that controls the degree of regularization. *Shockwave* yields similar makespan and fairness for different workloads when λ is between $1e-1$ and $1e1$.

G.3 An End-to-End Schedule Optimizer

Finally, Equation 11 shows the optimization problem solved by *Shockwave* in a given round. The output of the solver is schedule for each regime and the job schedule for the round can be simply translated from the regime schedule.

$$\text{Maximize}_{Y_1, \dots, Y_N} \frac{1}{NM} \sum_{j=1}^N \rho(j)^k \log [\text{UTIL}_j(Y_j[\cdot, \cdot])] - \frac{\lambda}{Z_0} H(Y_1[\cdot, \cdot], \dots, Y_N[\cdot, \cdot]) \quad (11)$$

Z_0 is a normalization coefficient, which is the sum of the interpolated run time across all jobs. More details about the constraints can be found in Appendix H.

Handling dynamic job arrival. Similar to existing schedulers, such as Themis [29], Tiresias [21], Pollux [36] and Gavel [33], *Shockwave* periodically adds newly arriving jobs to the schedule solver (Equation 11). The fairness objective in *Shockwave* (Equation 9) automatically handles selecting between newly-arrived short jobs or jobs that have been waiting in the queue for a long time, according to their pressure on breaking finish time fairness.

H Constraints Of Program 11

Program 11 requires the following constraints (details omitted). (1) *Preserving the order of regimes.* Any regime is prohibited to run before precedent regimes are complete. (2) *Work-conserving (Market Clearing).* Idle resources are not allowed when there are ready jobs. (3) *Capacity Limits.* GPUs assigned to jobs should not exceed the overall provision.

I Varying Contention Factor

We define the contention factor as, within a fixed time range, the ratio between the number of jobs requesting GPUs and the overall number of GPUs provisioned in the cluster. A larger contention factor indicates more jobs competing GPU resources at an instant. So far, we have assumed a default

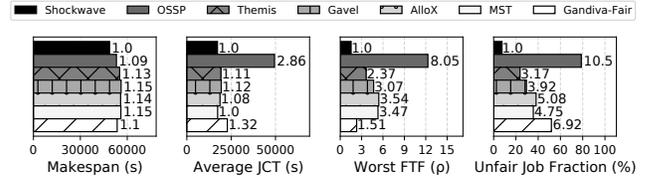

Figure 17: [Simulation] Evaluating *Shockwave*'s scheduling efficiency and fairness for Pollux trace on a 32-GPU cluster.

contention factor (three). We next vary the contention factor and compare policies on a smaller 14-GPU physical cluster.

Shockwave's win in efficiency decreases as there is more resource slack and less contention in the cluster. *Shockwave*'s improvement in makespan over Gavel, AlloX, and Themis decreases (from 35% for contention factor 3) to 19% (8%) when the contention factor is lowered to 2 (1.5) (cf. Figure 16). A similar trend for cluster utilization is found. *Shockwave*'s improvement in cluster utilization drops to 19% (5%). Although the finish time fairness of all policies improves as the contention factor decreases, *Shockwave* still performs better than the baselines. *Shockwave* keeps the fraction of unfairly scheduled jobs (i.e., the fraction of jobs with FTF $\rho > 1$) low when varying the contention factor. The average fraction of unfairly scheduled jobs for *Shockwave* is 8.67% when varying the contention factors, outperforming the baselines by 2.85 \times (see Figure 16). When the contention factor is lowered to 2, *Shockwave* maintains a worst-case FTF ρ of 1.2, outperforming Themis, Gavel, and AlloX by 1.27 \times . When the contention factor is further lowered to 1.5, *Shockwave* and all the baselines worst-case FTF approach 1 and the difference is insignificant.

J Varying the Cluster Trace

In previous subsections, we presented the results of *Shockwave* using synthetic traces generated by the Gavel [33] workload generator. In this subsection, we extend the evaluation using real DNN training traces provided by the Pollux [36] system. The Pollux trace provides the duration and arrival timestamps for training jobs and is extracted from a previous workload analysis [25]. Figure 17 shows the comparison between *Shockwave* and the baseline algorithms and we can see a similar trend as in previous sections. However, the win in makespan over Themis, Gavel, and AlloX drops from 30-35% to 20% on the Pollux trace. In previous synthetic traces, the duration of jobs has a greater diversity (2 \times) than in the Pollux trace, and thus long-running jobs have a larger impact on final makespan and cluster utilization. Therefore, opportunistically prioritizing these long-running jobs leads to greater improvement when there is more diversity among jobs.

Protego: Overload Control for Applications with Unpredictable Lock Contention

Abstract

Modern datacenter applications are concurrent, so they require synchronization to control access to shared data. Requests can contend for different combinations of locks, depending on application and request state. In this paper, we show that locks, especially blocking synchronization, can squander throughput and harm tail latency, even when the CPU is underutilized. Moreover, the presence of a large number of contention points, and the unpredictability in knowing which locks a request will require, make it difficult to prevent contention through overload control using traditional signals such as queueing delay and CPU utilization.

We present Protego, a system that resolves these problems with two key ideas. First, it contributes a new admission control strategy that prevents compute congestion in the presence of lock contention. The key idea is to use marginal improvements in observed throughput, rather than CPU load or latency measurements, within a credit-based admission control algorithm that regulates the rate of incoming requests to a server. Second, it introduces a new latency-aware synchronization abstraction called Active Synchronization Queue Management (ASQM) that allows applications to abort requests if delays exceed latency objectives. We apply Protego to two real-world applications, Lucene and Memcached, and show that it achieves up to $3.3\times$ more goodput and $12.2\times$ lower 99th percentile latency than the state-of-the-art overload control systems while avoiding congestion collapse.

1 Introduction

One of the key objectives of datacenter operators is to maximize the utilization of limited resources. While operating a server close to its capacity maximizes its throughput, it also makes it susceptible to overload due to surges in demand. Such surges can occur due to variability in request arrival patterns and sizes, and service failures. The resulting server overload can cause *receive livelock*, where the server builds up a long queue of requests that get starved because the server is busy processing new packet arrivals instead of completing pending requests [22].

The conventional solution is to use *overload control* to regulate incoming requests and shed excess load, ensuring that the server can achieve both high utilization and low latency. Existing overload control schemes focus on CPU overload [9, 34] or end-to-end response time [32]. However, we found these approaches perform poorly under lock contention, especially with blocking synchronization (e.g., mutexes) that causes a thread to yield rather than spinning on the CPU (§2). For these cases, contention leads to long queues of requests waiting to acquire a critical section, increasing tail latency and wasting CPU resources.

To better understand the challenge of managing lock contention, consider a key-value store, where the key-value pairs are grouped together based on the hashes of their keys. Access to a bucket (i.e., a group of items with the same hash) is protected by an item lock. This means that in a key-value store, the number of locks corresponds to the number of buckets. However, a GET request acquires only a single lock which synchronizes access to the bucket holding the data it's accessing. As a specific piece of data becomes popular, the lock protecting its bucket becomes highly contended, negatively impacting the latency of all requests attempting to access that bucket. However, it is important to note that such contention and high delay impact *some but not all* of the requests the application handles. The remainder of the requests can be accessing different buckets incurring no contention, finishing with minimal latency.

To maintain good performance under lock contention, one must reduce the load on the contended lock, and thus the latency of requests attempting to acquire it. On the other hand, this should not be done in a way that affects the throughput of requests not facing contention. The classic tension between throughput and latency is exacerbated in this case due to the unpredictability of request behavior: the locks accessed by a request can only be known after the execution of the request starts. Thus, the delay faced by different requests, that look identical when admitted to the server, can be very different depending on whether they attempt to access a contended resource or not. This renders overload signals that consider the

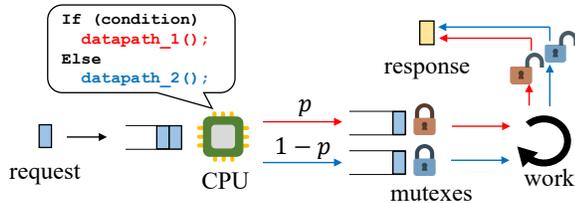

Figure 1: A simple example application with two global mutexes. With a probability p , the request takes the first data path (red arrow).

overall delay of requests ineffective. Furthermore, blocking locks can prevent the load from saturating the CPU, rendering CPU-based overload signals ineffective as well.

In this paper, we attempt to answer the following question: *how should an overload controller decide to admit a request when it can't estimate the delay the request will face?* Tackling this challenge is exacerbated by the fact that some applications have thousands of locks. Moreover, shedding load after processing a request requires cleaning up the state and resources touched by that request.

We present **Protego**, a system that provides overload control for applications that can experience lock contention (§3). Instead of using traditional overload control signals, it admits load as long as it observes throughput improvements. This approach ensures high throughput for requests not experiencing contention. However, it can exacerbate lock contention. Thus, Protego introduces new latency-aware synchronization primitives that allow applications to maintain low latency at contended critical sections, aborting requests when lock contention is too severe. As a result, Protego can offer the right load to maximize a server's throughput, even if some requests must be aborted during processing. We implemented Protego and compared it to SEDA and Breakwater, two state-of-the-art overload schemes, for three applications: Memcached, Lucene, and a synthetic application (§4). Our evaluation demonstrates that Protego outperforms SEDA and Breakwater for a wide range of workloads and applications (§5). For example, when Memcached is handling a SET-heavy workload, Protego achieves up to $1.6\times$ more goodput with $5.7\times$ lower 99th percentile latency compared to SEDA.

Protego has some limitations. It requires application-level code changes to adopt our synchronization API. Furthermore, existing overload control schemes can achieve slightly higher throughput than Protego when locks are not the bottleneck and requests are shorter than a microsecond.

Protego is an open-source software available at <https://inchocho89.github.io/protego/>.

2 Motivation

2.1 Locking Complicates Overload Control

In modern datacenter applications, RPC requests often require blocking synchronization (e.g., mutexes, semaphores, and conditional variables) to serialize access to shared data. However, blocking synchronization primitives can experience

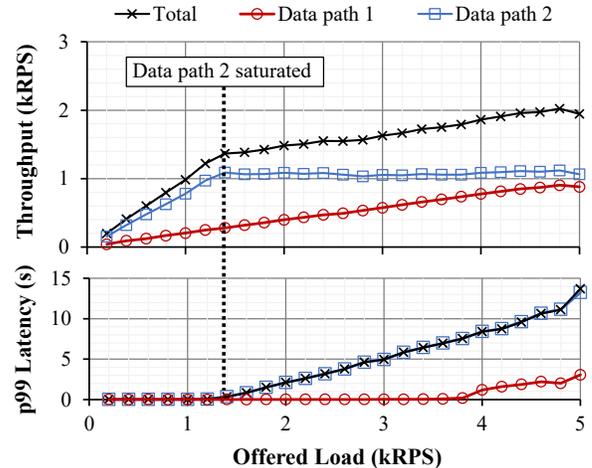

Figure 2: gRPC performance for the example application of Figure 1 ($p = 20\%$). After acquiring a mutex, requests busy-loop for a time sampled from an exponential distribution with 1 ms average. Four cores are allocated for this experiment, one for each data path and two to absorb any system overhead, ensuring that the CPU is not bottlenecked.

contention when multiple requests attempt to access the same critical section, leading to a performance bottleneck. This is further complicated by the fact that the locks required by each request may be different depending on the request payload and the program's state. This makes it hard to know the data path a request will take before its actual execution.

The crux of this problem is that seemingly identical requests can have different execution paths at the server with different latency and throughput characteristics. This unpredictable behavior makes admission control hard, leading to the question: *which data path should admission control consider when admitting new requests?* To better understand this dilemma, consider the scenario in Figure 1. Incoming requests can take one of two paths, each protected with a different mutex. Requests can take the first data path with probability p , where $0 \leq p \leq 1$, and the second path with probability $1 - p$. We implemented this simple scenario in gRPC running on Linux. Figure 2 shows the performance of this scenario with $p = 20\%$ under various loads generated by client machines with an open-loop Poisson arrival process.

The existence of multiple data paths with different lock bottlenecks creates a dilemma. As shown in Figure 2, different datapaths are saturated at different offered load levels. Typically, clients and servers can't predict whether a request will take the datapath currently bottlenecked (data path 2 in the example). Here, the admission control dilemma emerges from the existence of multiple desirable operating points. If the operator desires low latency for all paths, then they have to sacrifice throughput, admitting only enough load to saturate the most congestion execution path (i.e., 1.2 kRPS in this example). On the other hand, if they desire high throughput, then they have to admit a high load and deal with the congested path through other means (e.g., dropping a request

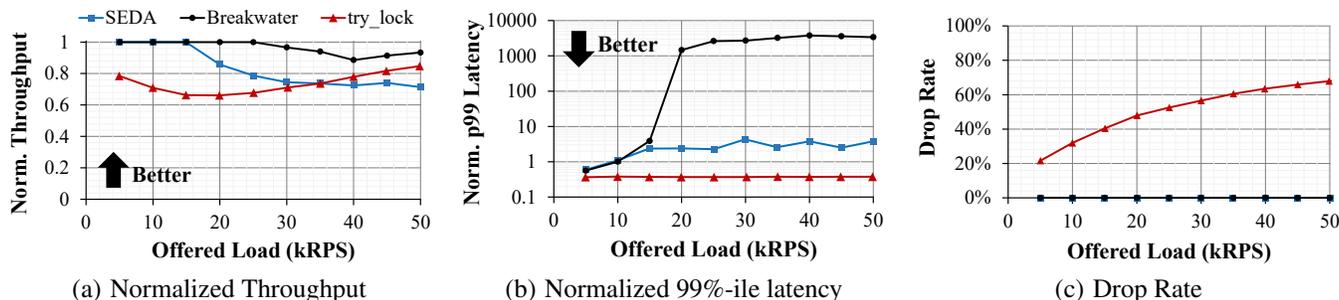

Figure 3: Performance of Breakwater, SEDA, and trylock for the example application of Figure 1 ($p = 20\%$) with $100 \mu\text{s}$ average service time on Shenango. Throughput and 99th percentile latency are normalized by the performance of Protego.

after admitting it). Next, we show that no existing overload control scheme can navigate this dilemma and produce good results in such scenarios.

2.2 Problems with Existing Overload Control Schemes

Overload control attempts to operate a server near its capacity with minimal SLO violations and request drops. The basic idea behind overload control is to keep track of the load on the server using a signal, adjusting the admitted load based on that signal. Multiple signals have been proposed to improve the accuracy of admission control, including CPU utilization [30], end-to-end delay [32], and queuing delay [9, 19, 34]. However, none of these signals are useful in lock contention scenarios where the operator attempts to maximize throughput while maintaining low latency.

For example, Breakwater [9] and Swift [19] use past observations to predict the amount of queueing delay each request will face. However, in the presence of thousands of locks, it’s unclear which queueing delay value (or statistic), if any, can be used to perform admission control. This is because admission control doesn’t know in advance which locks requests will access, making it impossible to decide which value to react to without overestimating or underestimating overload. Note that any CPU-based metrics also fail as the CPU might not be the bottleneck in lock contention scenarios.

One possible approach to handle problematic or unpredictable lock behavior is to leverage existing primitives like `try_lock()` or `timed_mutex()`. Specifically, such primitives will allow requests to fail, avoiding latency, if the lock cannot be acquired due to congestion. However, overload control schemes that rely exclusively on request drops do not scale well due to the large overhead of packet drops. Furthermore, relying on existing primitives is not straightforward; `try_lock()` is a very aggressive overload control mechanism because it causes a request to fail on the first failed attempt to acquire a lock. On the other hand, `timed_mutex()` is too relaxed, forcing a request to wait for the full waiting time even under severe congestion conditions.

We demonstrate the limitation of existing overload control schemes, including the usage of `try_lock()`, by implementing those schemes for the scenario described in Figure 1, setting the average service time to $100 \mu\text{s}$. However, rather

than using gRPC, we leverage the existing implementation of SEDA and Breakwater [3]. Breakwater spawns a new thread per incoming request. We limit the number of spawned threads to bound the memory usage of the system. When a request is aborted, a failure message is reported to the client. The results are shown in Figure 3, comparing the throughput, tail latency, and drop rate of existing schemes, normalized by the performance of Protego.

SEDA successfully bounds the tail latency as it rate-limits clients based on the measured tail end-to-end latency. However, by considering only the tail latency, it reacts to the most congested path, leading to poor throughput as it underutilizes the uncongested path. Breakwater reacts only to queueing delay in the thread queue or the packet queue, reacting only to CPU and network overload. Thus, it doesn’t perform any rate-limiting because neither the CPU nor the network is the bottleneck. Breakwater’s behavior leads to high utilization and very high latency. Using `try_lock()` allows the system to achieve near-ideal latency while suffering from an extremely high drop rate and poor throughput. This is caused by `try_lock()`’s aggressiveness in dropping requests, wasting CPU and throughput even at low loads. Our proposal overcomes the shortcomings of existing systems, achieving the highest throughput while keeping the latency and drop rate low.

2.3 Challenges

Existing overload control schemes, developed for CPU overload scenarios, suffer significant performance degradation when handling lock contention. The key issue when dealing with lock contention is the unpredictability of the latency that a request will face. Particularly, the overload controller doesn’t know which lock a request will require. This issue leads to the following challenges:

1. *No existing overload control signal is viable.* As discussed earlier, delay reflects the state of the most congested path. On the other hand, CPU utilization is not helpful when the bottleneck is not the CPU. Thus, we need a new approach to assessing the capacity of the server in order to make accurate admission control decisions.
2. *Drops are inevitable to achieve high throughput.* An overload controller that doesn’t react to the most congested data

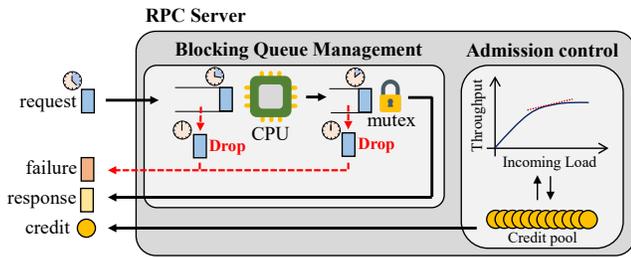

Figure 4: Protego Overview

path will incur a high delay for requests taking that path. However, it must offer enough load to keep other, less-congested paths busy. Therefore, maintaining both an acceptable SLO and high CPU utilization requires dropping requests on the most congested paths and reporting failures to the client. Early failure reporting allows the client to issue the requests to another replica while maintaining the SLO of the request.

3. *Any viable solution must scale to a large number of locks.* Modern programs can have thousands of data paths and synchronization primitives. An incoming request can take any of them depending on the data it carries. Thus, the admission control scheme needs to scale to a large number of locks with minimal per-lock overhead.

3 System Design

There is a fundamental tradeoff between throughput and drop rate in the presence of unpredictable synchronization. To achieve high throughput, clients should offer enough load for the server to fully utilize its uncontended data paths. Unfortunately, this permits some congestion to occur in its contended data paths. Thus, our high-level strategy is to use an admission control scheme that admits enough load to keep all data paths operating at full capacity, combined with an Active Queue Management (AQM) mechanism that drops excess load on the contended data paths. Our admission control scheme draws insight from network congestion control algorithms like PCC [12]. Specifically, Protego does not react to a specific overload signal. Rather, it observes the impact of its current admission rate on the behavior of the system, admitting more load only when it improves overall system performance.

Figure 4 illustrates an overview of Protego combined with a simple RPC server that uses a global mutex. Protego is composed of two main components: an admission controller and an AQM mechanism. The admission controller leverages a credit-based scheme, similar to the scheme used in Breakwater [9]. Protego only changes the way the number of available credits is decided, adjusting the number of credits by observing the impact of increasing the number of available credits on achieved throughput. The AQM mechanism uses *Active Synchronization Queue Management (ASQM)*, a novel form of AQM that drops requests at lock acquisition time to prevent blocking on a critical section for an excessive amount of time. When a request is dropped, Protego reports this failure as

quickly as possible to clients, allowing them to resend their requests to another replica.

3.1 Performance-driven Admission Control

Our goal is to develop an admission control algorithm that allows a server operator to navigate the tradeoff between throughput and drop rate. Note that the admission control algorithm should support scaling to a large number of data paths. Thus, we avoid developing an algorithm that has to take into account the state of every data path in the server.

Intuition. To better understand the intuition behind our algorithm, we go back to the setup in Figure 1. Specifically, we rerun the experiment discussed in Section 2.2. However, we use a smaller service time per request (10 μ s rather than 100 μ s) because these results help to make our point clearer. Moreover, we don't use any admission control scheme but rely on the AQM scheme, discussed in the next section, to keep latency bounded. The results are shown in Figure 5. The design of our admission control scheme stems from observing that as the load increases, the system operates in four different phases:

Phase I (uncongested) is the phase where none of the locks or CPUs is congested. Throughput grows linearly with load increases because the system has capacity to handle all incoming demand. Further, tail latency increases only marginally because of bursts in the queue caused by the variable request arrivals, modeled as a Poisson arrival process. With no congestion, AQM does not drop the requests.

Phase II (partially congested) is the phase where a subset of locks are contended. As load increases, throughput increases sub-linearly because the system has capacity to handle only a fraction of incoming demand (i.e., the uncongested path still has capacity). Incoming requests that take the congested path will face high queueing delay, leading AQM to start dropping requests while keeping the tail latency near the target value. To generalize, different applications will produce a different concave line like that shown in Figure 5(a), where the slope of the curve decreases as more paths become congested. The exact shape of the curve depends on the number of congested paths, and their capacities along with the load.

Phase III (congested) is the phase where all the data paths become congested. Thus, as the load increases, the throughput doesn't change. However, the increase in load increases CPU utilization because of the increase in network processing load and the increasing overhead of dropping requests. Eventually, the CPU also becomes congested, increasing tail latency.

Phase IV (congestion collapse) is the phase where the system enters a livelock state, spending more time dropping requests than processing them. During that phase, throughput degrades and latency keeps increasing.

Overview. Admission control should bound the incoming load to make the server operate in Phase II. Note that the values of latency, drop rate, and CPU utilization do not help

```

identify the phase in which the server operates. However, by observing the slope of the throughput curve, one can identify the boundaries of Phase II. Specifically, Phase II starts when the slope of the throughput curve drops from 1 (i.e., the system can no longer handle *all* incoming requests) and ends when the slope reaches 0 (i.e., the system can no longer handle *any* additional incoming requests). A server operator that’s interested in achieving a near-zero drop rate would operate the server at the leftmost edge of Phase II, where the slope of the throughput curve is slightly lower than one. On the other hand, a server operator that’s interested in achieving the highest possible throughput would operate the server at the rightmost edge of Phase II, where the slope of the throughput curve is slightly higher than zero. The server operator can

operate between those two points by choosing desired slope value. Additionally, the operator could specify the region of operation further by capping the maximum allowed drop rate.

We propose a performance-driven admission control algorithm with two parameters: efficiency threshold (t_e) and maximum drop rate (t_d). The efficiency threshold represents the target operating point on the throughput curve in terms of the slope of the curve at that point. Specifically, t_e takes values between zero and one, with zero representing the highest possible throughput, and one representing zero drop rate. The maximum drop rate, t_d , allows a service operator to cap the drop rate at the expense of throughput to reduce the expected number of request drops. Protego uses the maximum drop rate in addition to the efficiency threshold to determine whether to accept more incoming load. Protego judges an RPC server to be overloaded, accepting no further load, if throughput improvement with additional load is less than the efficiency threshold or if the drop rate exceeds the maximum drop rate.

Operation. A Protego server controls the number of incoming requests through the credit-based scheme we developed for Breakwater [9]. We chose a receiver-driven credit-based admission control scheme because it was shown to be robust to incast scenarios, efficiently scaling to a large number of clients while maintaining its performance [8, 9, 17, 23]. Like IRMA [29] and Breakwater [9], Protego requires a new client to declare its intent to send requests to the server by sending an initial Request To Send (RTS) message. For Protego, this message is needed only when a new client connects to the server and is not needed for every request. The server issues credits to clients. A credit represents availability at the server to process a single request by the client that receives the credit. A client only sends a request after it receives a credit. A client disconnecting from the server has to send a Disconnect message to inform the server to stop allocating credits to it. Note that credits in Protego provide minimal commitment as the server cannot know in advance whether an incoming request will take a congested or an uncongested path. Protego determines the total number of available credits, C , before distributing them to individual clients.

The server measures its efficiency (the change in throughput divided by the change in admitted load). If measured

efficiency is less than the efficiency threshold (t_e), the server reduces the credit pool size, reducing the admitted load; otherwise, it increases the credit pool size. In particular, the server operates in iterations, each lasting a few end-to-end RTTs.¹ We measure the end-to-end RTT with the elapsed time between credit issue and the successful response return which is tracked with an 8B unique credit ID. The server keeps track of the number of admitted requests from the current iteration and the previous iteration, in_{cur} and in_{last} , respectively. It also keeps track of the current throughput and the throughput in the previous iteration, out_{cur} and out_{last} , respectively. The efficiency metric $e = (out_{cur} - out_{last}) / (in_{cur} - in_{last})$ is compared to the efficiency threshold t_e . The server continuously monitors the drop count $drop_{cur}$ and decreases the admitted load if $drop_{cur}$ exceeds $t_d \cdot in_{cur}$. Protego uses additive increase / multiplicative decrease (AIMD) for credit management due to its simplicity. The details of the algorithm are shown in Algorithm 1.

3.2 Active Synchronization Queue Management (ASQM)

Protego assumes a standard queue abstraction per blocking synchronization object. However, to ensure scalability, Protego requires no coordination between queues, no per-queue parameter setting, and only minimal changes to the existing implementation of the synchronization API. Specifically, ASQM caps the total time a request is allowed to spend in a queue, assigning each request a queueing delay budget. The value of the budget represents the maximum queueing delay a request can tolerate for the server to respond within a target latency. The queueing delay budget is computed by subtracting the 99th percentile network latency and 99th percentile service time from the *target delay* of the request, leaving the slack time that the request can afford to spend in the server.

When a request arrives at the server, Protego assigns it a queueing delay budget. Before placing the request in each queue for a contended resource, it first checks the instantaneous queueing delay of the queue and drops the request if the queueing delay is larger than the request's remaining queueing delay budget. After the request is dequeued, it deducts the queueing delay it incurred from its budget. The queueing delay is measured by computing the difference between the current timestamp and the enqueue timestamp of the oldest item in the queue. In this paper, we only consider the runnable thread queue in the CPU scheduler and the wait queues for blocking synchronization primitives. However, we believe the same idea can be applied to other queues for contended blocking interfaces such as blocking I/O.

Target delay vs. SLO. It's critical to note that the target delay used to compute the queueing delay budget is different from the RPC's Service Level Objective (SLO). The target delay is a per-server metric: a single server should finish a request

¹We found that four RTTs allows for accurate measurement of all parameters while allowing for fast reaction to changes in the workload.

or report failure within the target delay. On the other hand, an SLO is a per-request metric: a request of a specific type should finish within its SLO, taking into account that multiple attempts at multiple servers might be needed for the request to succeed. In Protego, the target delay is set by default to SLO divided by the maximum number of retries.

Handling dropped requests. Upon a request drop, the server returns a failure message immediately to the client. At the server, a request drop incurs some CPU overhead to partially process the request and generate the failure message. Further, the failure message and retransmission of the request can incur networking overhead. If the overhead of dropping requests is large, a service operator can reduce the drop rate by choosing a higher value for the efficiency threshold (t_e), sacrificing throughput. At the clients, the dropped request may be handled in various ways: retransmission to another replica, triggering failure handling operations (e.g., online banking transaction), or degrading the quality of the response (e.g., search). For systems with replication and auto-scaling, retransmission is the most common failover mechanism. For the rest of the paper, we focus on scenarios where an overloaded server has a non-overloaded replica which can serve dropped requests.

Retransmission of dropped requests introduces additional latency, inflating the overall delay faced by such requests, potentially harming their SLOs. Protego drops requests before they consume their delay budget. Thus, clients receive failure messages within the target delay. In the worst case, for each retransmission, a request will be delayed by at most the target delay (§5.3). Alternatively, if the SLO is tight, the client can send tied or hedged requests to multiple replicas to avoid the retransmission delay but incur the cost of coordination overhead and/or CPU wasted by duplicate executions [11].

3.3 System Parameters

In total, Protego has five parameters: four universal parameters whose value can be fixed across workloads, and one workload-specific parameter.

Universal parameters. The efficiency threshold and maximum drop rate parameters, t_e and t_d , do not need to change per workload. We show that the performance of Protego is not very sensitive to the choice of t_e (§5.4). We use an efficiency threshold of 10% by default. The maximum drop rate puts a cap on the allowed drop rate. Operators that want to maximize throughput should set it to 100%, which is the default value we choose in the paper.

AIMD algorithms have two parameters: an increment step size (a) and a decrement factor (d). Large values of a and d make the algorithm more aggressive in reaching the desired operating point but less stable with large fluctuations. We choose small values for a and d , preferring stability. We set a as 0.1% of the number of the client sessions and d as 2%, which leads to good performance in incast scenarios [9].

Workload-specific parameters. The target delay specifies

the maximum delay allowed in a single server. Its value is calculated as the SLO divided by the expected number of attempts that a request can make before it succeeds.

4 Implementation

We implemented Protego as a library that uses Shenango [25] and builds upon the RPC-layer implementation of Breakwater [9]. Furthermore, Protego extends Shenango’s synchronization library to implement ASQM, facilitating the adoption of Protego to Shenango applications.

Performance measurement. Protego adjusts the credit pool size, once every iteration, based on five measures of efficiency and drop rate: in_{cur} , out_{cur} , $drop_{cur}$, in_{last} and out_{last} . The measures are updated (i.e., current measures are reset after their values are assigned to the last measures) after one end-to-end RTT from the time the credit pool size is updated to accurately reflect performance during an iteration. This period is selected because the incoming load changes in correspondence to the new pool size after at least one end-to-end RTT.

Dispatcher threading model. Protego assigns a queueing delay budget per request, deducting from it after a request is serviced from a queue. This operation requires accurately tracking the time a request spends in various queues, avoiding any variability that might be introduced due to the operating system or the network stack. Thus, we implement Protego with a dispatcher threading model where a dispatcher thread parses the network payloads into requests, spawning a new thread for each incoming request. This approach minimizes the delay requests face in the network stack because packets are parsed quickly by the dispatcher thread, out of the critical path of request processing. When a new thread is created by a dispatcher, it’s assigned a queueing delay budget by subtracting the 99th percentile network latency and the 99th percentile service time from the target delay.

Latency-aware Active Synchronization Queue Management (ASQM) API. Protego provides the following latency-aware APIs to enable ASQM:

```
bool mutex_lock_if_uncongested(mutex_t *);
bool condvar_wait_if_uncongested(condvar_t *,
                                 mutex_t *);
```

These interfaces are similar to those of `try_lock()`, but their behavior is different. If the queueing delay of a blocking critical section exceeds a request’s queueing delay budget, it returns false without waiting. Otherwise, it returns true after successfully acquiring the lock. An application developer can leverage the existing synchronization API provided by Shenango, including `mutex_lock()` and `condvar_wait()` for parts of the program that cannot handle dropping. For example, a maintenance thread running in the background may need to acquire a lock no matter how long it has to wait.

Queueing delay measurement. Protego needs to measure instantaneous queueing delay to compare it against a request’s

remaining budget. We instrument the waiter queue for mutexes and conditional variables to measure the queueing delay. When a thread is enqueued to the waiter queue, Protego timestamps the request. When the blocking synchronization is queried for the queueing delay, it returns the difference between the current timestamp and the enqueue timestamp of the oldest thread in the waiter queue. Using an efficient hardware timestamp read function, Protego can measure the queueing delay of blocking synchronization with little overhead.

Identifying contended locks. In order to get the full performance benefits of Protego, developers must identify all the contended locks to replace with Protego’s ASQM APIs. A developer needs to hypothesize which locks are likely to be contended based on the application-specific knowledge and run experiments to verify which locks introduce a large queueing delay with per-lock queueing delay measurements. This process requires iterating multiple times until all the contended locks are identified and their code is modified to use the Protego API. Alternatively, a developer can use high-resolution latency profilers [16] to identify contended locks.

Application modification. Enabling Protego requires replacing blocking synchronization primitives with the ones provided in the Protego API. Further, Protego allows requests to be dropped after they have been partially processed by the server, potentially modifying some states or reserving some resources. Thus, enabling Protego requires the application to perform all necessary clean-up after a request is dropped (e.g., freeing memory it allocated to the request and releasing other locks the request currently holds). However, the complexity of handling request drops can be significantly reduced by utilizing features of modern programming languages, such as RAII in C++ with smart pointers and scoped locks.

5 Evaluation

Our evaluation answers the following key questions:

1. Can Protego balance high throughput and low latency for real-world applications?
2. How much code change is required to enable Protego?
3. Does Protego maintain its benefits for different workloads?
4. Can requests maintain their SLO in the presence of drops?
5. How much does each component of Protego contribute to its overall performance?
6. How sensitive is the performance of Protego to its parameter values?
7. What are the limitations of Protego?

5.1 Evaluation Setup

Testbed: We use eleven x1170 nodes in Cloudlab [13]. Each node has a ten-core (20 hyper-threads) Intel E5-2640v4 2.4GHz CPU, 64GB ECC RAM, and a Mellanox ConnectX-4 25GbE NIC. Nodes are connected through a single Mellanox 2410 switch. The average and 99th percentile network RTT between any pair of two nodes are 10 μ s and 20 μ s, respectively. We use one node as an RPC server and the other ten nodes

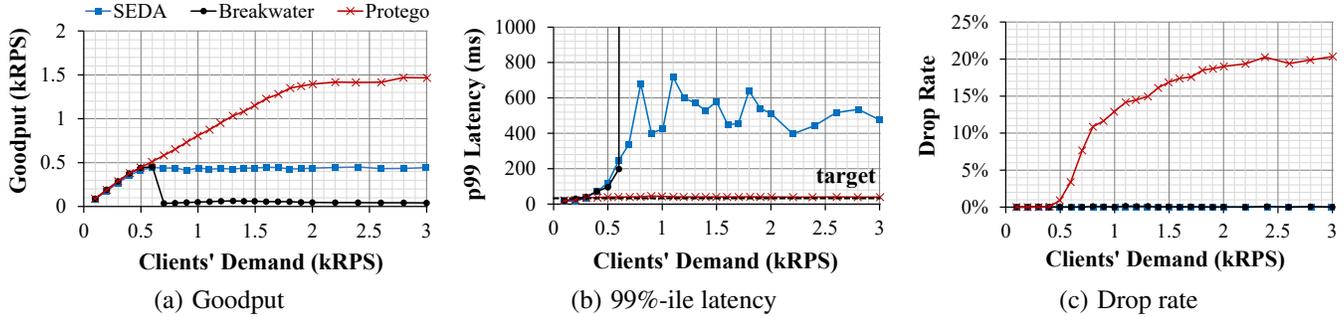

Figure 6: Performance of SEDA, Breakwater, and Protego for Lucene

as RPC clients. The server application uses up to ten hyper-threads for real-world applications and four hyper-threads for synthetic application. Each client machine simulates one hundred RPC client connections with sixteen dedicated, spinning hyper-threads. Requests are generated following an open-loop Poisson arrival process.

Workloads: We evaluate Protego using three workloads: 1) Lucene, a search application with significant lock contention overhead, 2) Memcached, a latency-sensitive in-memory key-value store that exhibits both locking bottlenecks and CPU bottlenecks, and 3) a synthetic workload with its execution time drawn from an exponential distribution.

Baseline: We compare Protego to SEDA, a latency-based overload control system, and Breakwater, a queueing delay-based one. SEDA controls the load at the server by rate-limiting the clients. Each SEDA client adjusts its request sending rate based on the 99th percentile end-to-end latency faced by requests. Breakwater controls the load at the server through a credit-based mechanism, adjusting the credit pool size based on the sum of packet queueing delay and CPU thread queueing delay. To ensure low latency, Breakwater drops a request if the queueing delay exceeds a workload-based threshold.

Evaluation metrics: To incorporate throughput, latency, and the target latency into one single metric, we compute goodput as the throughput of the requests whose latency is below the target delay. For Breakwater and Protego, we report the drop rate as the ratio of the number of dropped requests to the number of requests received by the server during an experiment. SEDA does not drop the request at the server. We run the experiments for 8 seconds and collect the data for the last 4 seconds to capture the steady-state behavior.

Parameter settings: We tune the parameters of all systems to allow each system to achieve its best goodput for each workload. For SEDA, we adjust *timeout* (request sending rate update interval), *adj_i* (rate increase factor), and *adj_d* (rate decrease factor). We use the default configuration from [32] for all other parameters. For Breakwater, we tune the target queueing delay and the drop threshold which we set to 40% and 80% of Protego’s target delay, respectively, for all workloads. We use the default configuration from [9] for all other

parameters. For Protego, we use an efficiency threshold (t_e) of 10%, a maximum drop rate (t_d) of 100%, an increment step size (a) of 1, and a decrement factor (d) of 2% for all workloads. We determine the queueing delay budget for ASQM by deducting 99th percentile service time and 99th percentile network delay ($20 \mu\text{s}$) from the target delay for each workload. We determine the target delay as the maximum value between $10 \times$ the sum of average network RTT ($10 \mu\text{s}$) plus the average service time, and $2 \times$ the sum of 99th percentile network RTT ($20 \mu\text{s}$) plus the 99th percentile service time. For example, for the exponential service time distribution with $10 \mu\text{s}$ average whose 99th percentile is $46 \mu\text{s}$, we set the target delay to $200 \mu\text{s}$ because $10 \cdot (10 + 10) = 200 \mu\text{s}$ is higher than $2 \cdot (20 + 46) = 132 \mu\text{s}$. The way we set the target delay is comparable to how the SLO is calculated in recent proposals [9, 10, 26]. We set the SLO as twice the target delay, assuming that a request fails at most once.

5.2 Mutex-intensive Application: Lucene

Lock contention inside Lucene: Lucene is a search engine library that maintains two main types of structures: 1) inverted indices, called *Segments*, and 2) per-term scores of all indexed documents, called *TermDocs*. Every *Segment* and *TermDocs* is protected by its own mutex. Every request performs a binary search over all *Segments* to find the documents corresponding to its search query. Then, documents are ranked based on the information found in the *TermDocs* corresponding to the identified documents.

As load increases on the server, the per-*Segment* lock becomes contended because every request needs to search over all the *Segments*. *Segments* containing more entries are more likely to be contended because it takes more time to perform a binary search over their entries. Further, if a specific document becomes popular, the per-*TermDocs* lock protecting its data becomes contended.

Application modification: We ported the C++ version of Lucene, Lucene++ [31], to Shenango and built a simple in-memory search application, where all the data is stored in memory with *RAMDirectory*. We replaced the per-*Segment* lock and per-*TermDocs* lock with Protego’s latency-aware synchronization API to allow request drops. In total, we modified 40 LOC of Lucene++ after porting it to Shenango. Note that, while Lucene allows for reporting partial search results,

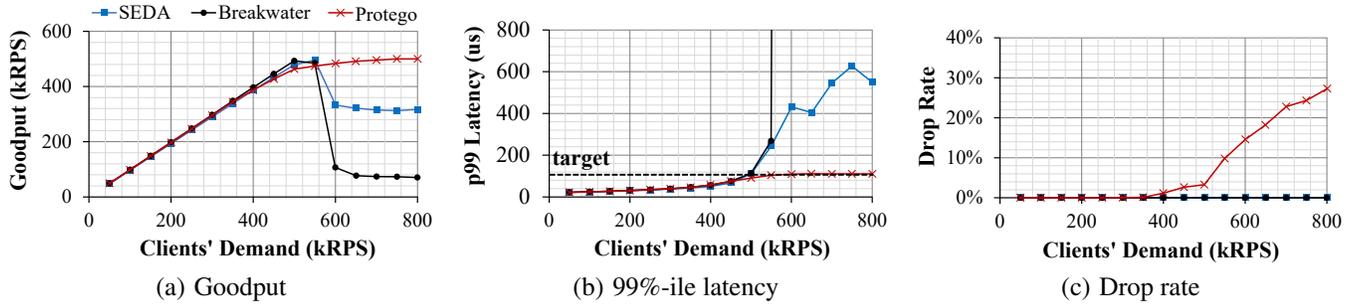

Figure 7: Performance of SEDA, Breakwater, and Protego for Memcached with VAR workload

we don't allow that to provide a fair comparison between overload control schemes that don't drop requests. The response contains either the complete search result or a failure notification.

Workload and configuration: We populate the server with a dataset of 403,619 COVID-19-related tweets [6] in English posted between 27th and 29th November 2021. The clients generate single-term search queries. The search term (or word) is sampled from the word distribution in the data set excluding stop words like "a", "the", "and", etc. All the tweets are loaded to the server before serving clients, and tweets are not modified or deleted during an experiment. This workload yields an average processing time of 1.7 ms and a 99th percentile latency of 20 ms on a lightly-loaded server. Thus, we set the target delay to 40 ms. For SEDA, we set $timeout = 1$ s, $adj_i = 0.1$, and $adj_d = 1.3$. For Protego, we use an initial queuing delay budget of 20 ms.

Overall performance: Figure 6 shows the goodput, 99th percentile latency, and drop rate for all three overload control schemes. Note that Lucene does not suffer from any CPU congestion. Thus, Breakwater's admission control and AQM are never triggered, leading to congestion collapse as mutexes become congested with demand exceeding 600 RPS. SEDA reduces clients' request sending rate as soon as it measures high latency due to a mutex congestion, reacting to the most congested data path, which limits the system's goodput to 500 RPS. SEDA's tail latency is bounded but more than 10 times higher than the target latency because of incast. By better utilizing uncongested data paths and dropping the excess load, Protego achieves up to 3.3 times higher goodput and 17 times lower 99th percentile latency than SEDA.

5.3 Latency-critical Application: Memcached

Lock contention inside Memcached: The key-value pairs are stored in a giant hash table, composed of multiple hash buckets. Memcached has two main types of locks that may be contended. First, each hash bucket is protected by a mutex called `item_lock`, and this mutex may get contended not only by concurrent accesses (i.e., reads or rights) to the same key but also by accesses on different keys sharing the same key hash. Thus, it's difficult to predict which `item_lock` a request will need before executing it. Second, Memcached manages its memory by assigning items memory from a global pool,

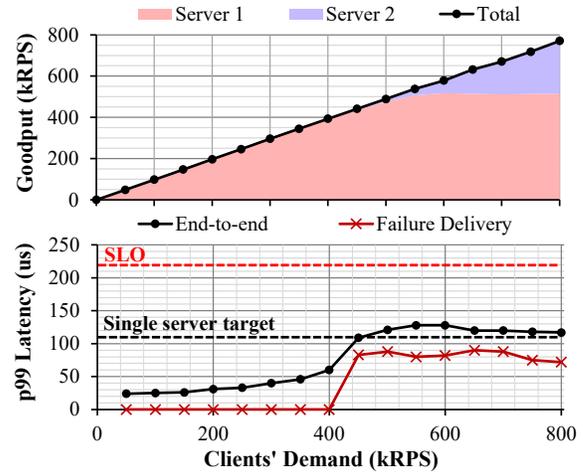

Figure 8: Service-level performance of Protego for the Memcached VAR workload with retransmission

which is protected by a global lock called `slabs_lock`. Every `SET` and `UPDATE` request must grab the `slabs_lock` to allocate memory for the new value.

Application modification: We replaced the `item_locks` and `slabs_lock` with Protego's latency-aware mutexes. When a request is dropped, Protego delivers a failure message to the client immediately. Furthermore, it cleans up the intermediate state processed by the request, freeing up the chunk allocated to the request before the thread handling that request exits. We don't allow drop when a request tries to reacquire `slabs_lock` to free up the memory to avoid memory leaks. In total, we modified 50 LOC in Memcached [4], excluding the modifications to port it to Shenango.

Workload and configuration: For Memcached experiments, we use the VAR workload from Facebook Memcached cluster [33]. VAR is a `SET`-heavy workload for server-side browser information where 82% of the requests are `SET` requests. The key distribution of the workload is skewed with 10% of the keys used by 90% of the requests. With a `SET`-heavy workload, `slabs_lock` becomes the bottleneck as all `SET` requests require `slabs_lock` to allocate memory region. We approximately follow the key and value size distribution for each workload as described in [33]. We generate 100,000 key-value pairs and use the hash power of 17, providing 131,072 buckets in the hash table, which is sufficient to avoid severe hash col-

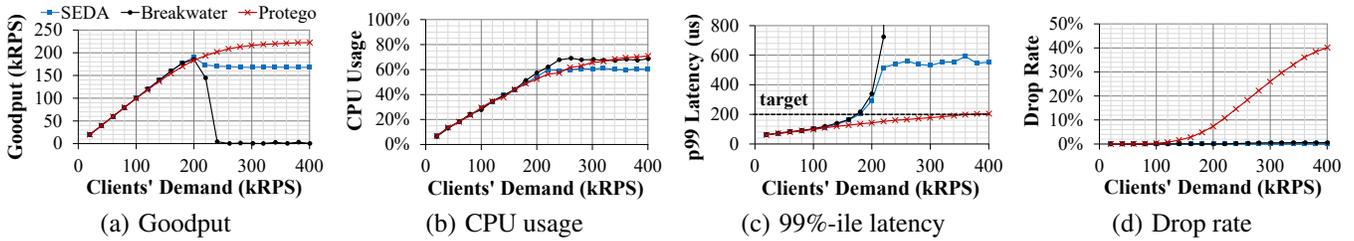

Figure 9: Performance of SEDA, Breakwater, and Protego for synthetic workload with $p = 50\%$ and $10 \mu s$ average service time

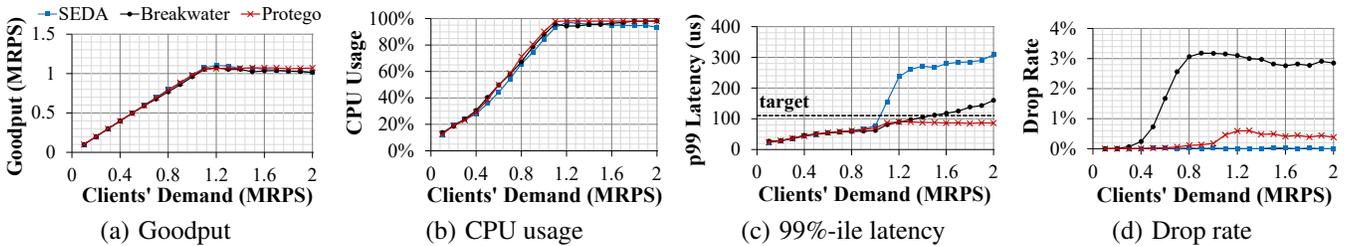

Figure 10: Performance of SEDA, Breakwater, and Protego for synthetic workload with $p = 50\%$ and $1 \mu s$ average service time

lisions. Since SET requests complete within less than $1 \mu s$ on average, we set the target delay to $110 \mu s$. For SEDA, we set *timeout* to 1 ms, *adj_i* to 100, and *adj_d* to 1.02. For Protego, we set the initial queuing delay budget to $70 \mu s$.

Performance with a global mutex bottleneck: Figure 7 demonstrates the performance of the three overload control schemes. When the *slabs_lock* becomes contended with clients' demand of more than 550 kRPS, both Breakwater and SEDA experience a goodput drop because of the increase in latency. As with Lucene, the admission control and AQM of Breakwater are not triggered because the CPU is not congested. On the other hand, SEDA suffers from incast. The goodput of Protego increases further by utilizing uncongested data paths with GET requests achieving 1.6 times higher goodput than SEDA and 7 times higher goodput than Breakwater. The increment in Protego's goodput is limited by the overhead of request drops. Most of the dropped requests are SET requests, and some of them require the *slabs_lock* to free the allocated memory. As more requests are dropped, the *slabs_lock* becomes more contended by new SET requests that need to allocate the memory as well as old and dropped requests that need to release their memory, resulting in lower throughput of SET requests at very high loads.

Maintaining the SLO under retransmissions: To better understand the impact of request drops on the overall SLO, we construct a simple scenario where Memcached has two replicas, but we otherwise use the same configuration as before. When a client makes a request, it sends the request to Server 1. If it is dropped, the client then retransmits it to Server 2 (after receiving a failure message from Server 1). This structure is similar to how Memcached is operated at Facebook [24] where they don't provide a strong consistency guarantee. Note that if both servers are overloaded, the problem ceases to be an overload control problem as the service operator needs to

allocate more servers. Thus, our experiment captures the case where there is sufficient capacity to handle all requests, but retransmission may still be necessary. We anticipate up to one retransmission could happen, considering the capacity of the two servers and the demand the clients generate during the experiment, so we set the service-level objective (SLO) to two times the single server target delay, or $220 \mu s$.

Figure 8 demonstrates the total goodput of both servers, the 99th percentile end-to-end latency, and failure message delay for the VAR workload. When the clients' demand exceeds 400 kRPS, Server 1 starts to drop requests. Protego drops the requests before they wait for the contended mutex if the delay at the mutex exceeds a request's budget. Thus, most of the failure messages are delivered within the target delay. Note that if a client doesn't receive a credit for a request within $10 \mu s$ from Server 1, it sends the request to Server 2 with the locally generated failure message. As clients' demand increases, the 99th percentile delay of failure messages decreases because more requests are retransmitted to Server 2 with local failure message. The overall 99th percentile end-to-end latency achieved by Protego is higher than the per-server target delay because some requests need to be retransmitted. However, it is still $1.7 \times$ lower than the SLO.

5.4 Microbenchmark

Workload and configuration: To further analyze Protego's performance, we run the synthetic application depicted in Figure 1. We choose the configuration $p = 50\%$, making both data paths equally likely to be congested, to provide a best-case scenario for SEDA. We use a workload with exponential service time distribution of $10 \mu s$ and $1 \mu s$ average. The target delay values are $200 \mu s$ and $110 \mu s$, respectively for the two settings. For SEDA, we set *timeout* = 1 ms, *adj_i* = 10, and *adj_d* = 1.04 for the first setting, and *timeout* = 1 ms, *adj_i* = 40, and *adj_d* = 1.04 for the second setting. For Protego, we set the initial queuing delay budget to $134 \mu s$ and

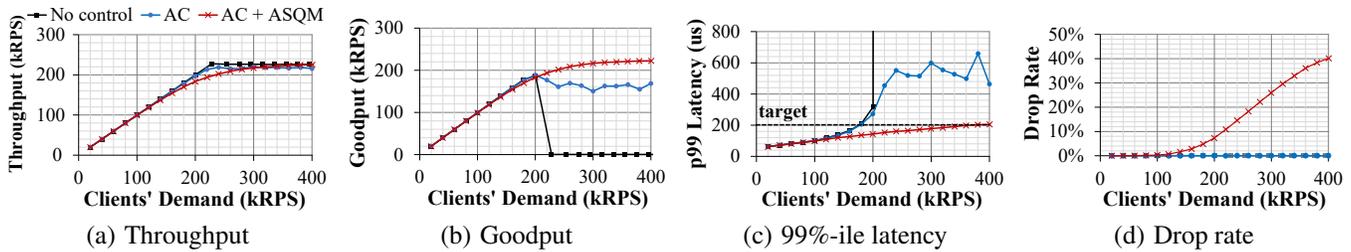

Figure 11: Performance of Protego by incrementally applying performance-driven admission control (AC) and ASQM with the synthetic application with 10 μ s average service time

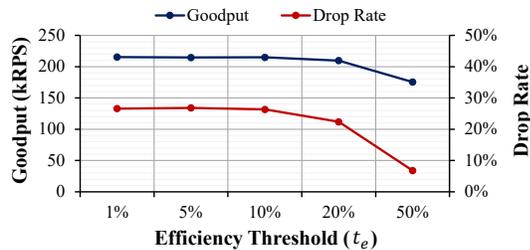

Figure 12: Protego parameter sensitivity (efficiency threshold, t_e)

85 μ s, respectively, for the two settings.

Overall performance: Figure 9 shows the goodput, CPU usage, 99th percentile latency, and drop rate for a workload with 10 μ s average service time. The performance is bottlenecked by the mutexes, leaving the CPU underutilized even with a high clients' demand. Thus, at high load, the admission control or AQM logic of Breakwater is not triggered, leading to congestion collapse. SEDA limits the sending rates of clients as soon as it measures high tail latency with a single temporarily congested data path. Thus, SEDA's goodput is limited to 168 kRPS leaving the other data path uncongested. With a larger clients' demand, SEDA suffers from incast because 1,000 clients are each running a control loop separately. As a result, it shows up to three times higher tail latency than the target delay. Protego improves goodput by up to 32% compared to SEDA, maintaining latency within the target delay by dropping up to 40% of incoming requests. Note that the performance benefits of Protego compared to SEDA increase as p deviates from 50%, making SEDA more conservative as it reacts to the most congested path.

Impact of average service time: We reduce the average service time to 1 μ s, reducing the time requests can spend with the lock, allowing the CPU to become the bottleneck. The results are shown in Figure 10. As demand exceeds 1.1 million RPS, the CPU is saturated, triggering Breakwater mechanisms. However, it still suffers at high loads when the mutexes become contended. SEDA still suffers from high tail latency up to three times of the target delay because of the incast, but its impact on goodput is limited. Protego maintains the tail latency lower than the target delay while dropping less than 1% of the requests in a CPU-bounded scenario.

Performance breakdown: We measure the performance of Protego after incrementally activating its two components: the

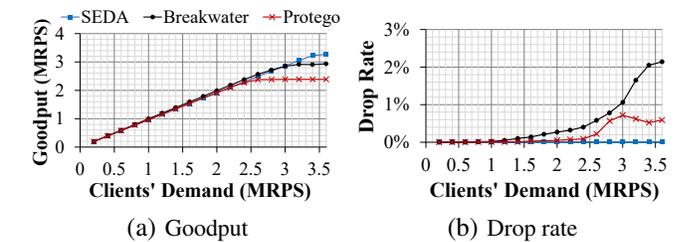

Figure 13: Performance of SEDA, Breakwater, and Protego for Memcached with USR workload

performance-driven admission control scheme (AC) and Active Synchronization Queue Management (ASQM). We run the experiments with the synthetic application with $p = 50\%$ and an average service time of 10 μ s. Figure 11 shows the throughput, the goodput, the 99th percentile latency, and drop rate. With no overload control, goodput collapses as soon as one of the data paths becomes congested. Enabling admission control bounds the tail latency by limiting incoming load if there is no throughput improvement. However, when mutexes start to be congested, its goodput degrades with up to three times higher tail latency than the target because one of the mutexes can have a high queueing delay with the requests' probabilistic data path selection. By employing ASQM, Protego ensures the tail latency does not miss the target delay by dropping requests.

Parameter sensitivity: Protego balances goodput and drop rate using the efficiency threshold (t_e). To quantify the trade-off between them, we repeat the experiment with the synthetic application with $p = 50\%$ and the average service time of 10 μ s varying the t_e from 1% to 50%. Figure 12 shows the goodput and drop rate of Protego with different t_e values when the clients' demand is 300 kRPS, around $1.4 \times$ of the capacity (consider Figure 11 as a reference). For all values of t_e smaller than 10%, the goodput and drop rate don't change because throughput improvements with a small t_e are always marginal. With larger t_e values, both the goodput and drop rate decrease as admission control targets to operate the server on the left side of the Phase II region in Figure 5. With $t_e = 50\%$, it achieves 23% less goodput and $4 \times$ lower drop rate than $t_e = 1\%$, allowing server operators to navigate the tradeoff between goodput and drop rate.

5.5 Limitations of Protego

To demonstrate the limitations of Protego, we repeat the Memcached experiment in §5.3 with the USR workload, a GET-dominated workload for user account status information where 99.8% of the requests are GET requests and about 20% of the keys are used by 80% of the requests. With the USR workload, Memcached saturates the CPU when it's configured with a high enough hash power (i.e., a large number of buckets compared to the number of key-value pairs). However, some `item_locks` can still become congested intermittently because of the skewed key distribution. Figure 13 shows the goodput and drop rate, comparing Protego to Breakwater and SEDA. With clients' demand of 3.6 million RPS, Protego achieves 37% less goodput than SEDA and 23% less goodput than Breakwater.

The USR workload is CPU bottlenecked, allowing Breakwater mechanisms to be triggered. Protego achieves lower goodput than Breakwater due to the slow reaction of Protego's admission control. In particular, Protego changes its credit pool size every four end-to-end RTTs. On the other hand, Breakwater adjusts its credit pool size every network RTT. As a result, Protego reacts to both congestion and added capacity slowly, leading to a lower goodput. Breakwater and Protego achieve lower goodput than SEDA because of the overhead of credit management at the server. Specifically, SEDA doesn't add any extra logic at the server while Breakwater and Protego perform all their admission control and AQM calculations at the server. This overhead is significant when the request execution time is very small. Note that increasing the number of clients from 1,000 to 10k can lead to performance degradation in SEDA with a larger size of incast [9]. This experiment shows that Protego can lead to goodput degradation in some scenarios where the CPU is bottlenecked. However, if the setting has any significant likelihood of mutex congestion, Protego can introduce significant benefits even when the CPU is bottlenecked (Figure 10).

6 Discussion

Fairness. Protego does not provide any mechanisms to ensure fairness between clients. For example, a client issuing more requests that require contended locks will get more failure messages because it faces a higher drop rate. However, it does provide flexibility for clients in their selection of replicas. A client can choose to send requests to a replica with a lower drop rate or distribute requests to multiple replicas to lower its drop rate. In this paper, we assume that the system as a whole has enough capacity to handle requests, relying on elastic resource allocation schemes like auto-scaling.

Generalizing Protego for other in-application congestion. An evaluation of DeathStarBench [14] revealed a challenging overload scenario where the tail latency of an upstream service (NGINX) spiked more than 10× while its CPU usage remains low due to the blocking network socket call used in HTTP. The delay introduced by such calls cannot be detected

with the overload signal used in DeathStarBench (i.e., CPU Usage). Thus, the auto-scaler is never triggered to launch a new instance, causing high tail latency. Protego can be used to handle such overload scenarios where blocking calls (e.g., network or storage system calls) are the bottleneck. More specifically, the performance-driven admission control can back-pressure upstream services when it observes that there is no throughput improvement as load increases due to blocking calls. If the invocation of blocking calls by requests is unpredictable, it would require editing those calls to support ASQM. Furthermore, in a multi-tier microservice architecture, upstream microservices might be able to abstract calls made to downstream microservices as blocking calls, allowing Protego to be used to perform overload control over the entire microservice chain.

7 Related Work

Overload control. To avoid congestion collapse with receive live lock, an overload control system tries to bound the incoming requests or drop the request to prevent overload. Overload can be detected using several metrics. Breakwater [9] and DAGOR [34] use thread and network queueing delay. SEDA [32] and ORCA [20] use response time as a congestion signal. The way a system controls the overload also differs across these systems. Breakwater utilizes credit-based admission control with AQM. DAGOR utilizes priority-based admission control with AQM. SEDA adjusts the request sending rate at the client side. ORCA uses TCP-like window-based approach at the client side.

Flow Control. In TCP and eRPC [18], flow control advertises the size of the available receive buffer to clients to prevent receiving more packets than the network stack can accommodate. Akka [1] Stream has a similar but more flexible flow control mechanism where a server signals the maximum number of requests it can handle to the clients based on the remaining buffer size, the amount of idle resources, etc. The clients do not send more requests than the demand signaled by the server. Flow control is useful to avoid high latency when the CPU is the bottleneck. However, when a blocking synchronization becomes the bottleneck, it achieves either low throughput by underutilizing uncongested data paths or high latency with long queueing delay.

Measurement-based network congestion control. BBR [7] and PCC [12] employ mechanisms similar to Protego's performance-driven admission control. BBR explores the maximum network bandwidth by measuring the throughput with increasing window size. It concludes that the network bandwidth has reached its maximum value if it observes less than 25% of bandwidth increase with doubled window size. Unlike Protego, BBR does not utilize a performance-based approach to detect network congestion but to determine a parameter used for congestion control. In PCC, the system operator defines a utility function (e.g., TCP friendliness, latency, or throughput). PCC conducts multiple micro-experiments

with a randomized set of parameters to find the configuration that achieves the highest utility. PCC-like algorithms require multiple rounds to find the best configuration, which slows down the reaction of the algorithm to the congestion. Unlike PCC, Protego deterministically modifies the credit pool size based on the measurement, which makes its reaction to congestion faster.

Auto-scaling. Auto-scaling [2, 5, 15, 21, 27, 28] dynamically changes the amount of resources allocated to a service based on various signals including CPU usage, estimated demand, or custom-defined signals. It ensures that a service has enough resources to serve requests by allocating more resources when the chosen signal indicates that a load has exceeded a configurable threshold. Some auto-scalers [15, 21] let service operators specify the signal (e.g., response time, SLO violation, cost, etc.). More recently, machine learning models are used for auto-scaling. Facebook [5] and Google Autopilot [28] auto-scale resources based on the estimated demand learned from historical data. FIRM [27] uses system-wide performance metrics (CPU, Memory, Disk I/O, Network usage, or arrival rate) to train and predict which microservices require how much additional resources not to violate SLO. Auto-scaling mechanisms are useful with consistent overload over a long time scale, but it does not handle transient bursts in a load that happen over small timescales. Such bursts can be handled by Protego. In addition, auto-scaling alone is not enough to achieve both high throughput and low latency in the presence of lock contention as it does not provide any way to drop requests in a congested data path.

8 Conclusion

In this paper, we presented Protego, an overload control system that handles overloaded blocking synchronizations with performance-driven admission control and Active Synchronization Queue Management (ASQM). Protego's admission control decisions are based on measured throughput, admitting more load only if it improves throughput, admitting less load otherwise. To ensure low latency even for congested data paths, Protego sheds load by dropping requests at contended blocking synchronization points using ASQM. Our extensive evaluation of Protego demonstrates that it can effectively handle overload when combined with lock contention, achieving high goodput and low latency for a wide range of conditions. In particular, Protego achieves up to $3.3\times$ higher goodput with $12.2\times$ lower 99th percentile latency than state-of-the-art overload control schemes when applied to Lucene, a realistic search workload.

Abstract

We propose TOPOOPT, a novel direct-connect fabric for deep neural network (DNN) training workloads. TOPOOPT co-optimizes the distributed training process across three dimensions: computation, communication, and network topology. We demonstrate the mutability of AllReduce traffic, and leverage this property to construct efficient network topologies for DNN training jobs. TOPOOPT then uses an alternating optimization technique and a group theory-inspired algorithm called TotientPerms to find the best network topology and routing plan, together with a parallelization strategy. We build a fully functional 12-node direct-connect prototype with remote direct memory access (RDMA) forwarding at 100 Gbps. Large-scale simulations on real distributed training models show that, compared to similar-cost Fat-tree interconnects, TOPOOPT reduces DNN training time by up to $3.4\times$.

1 Introduction

Our society is rapidly becoming reliant on deep neural networks (DNNs). New datasets and models are invented frequently, increasing the memory and computational requirements for training. This explosive growth has created an urgent demand for efficient distributed DNN training systems.

Today’s DNN training systems are built on top of traditional datacenter clusters, with electrical packet switches arranged in a multi-tier Fat-tree topology [47]. Fat-tree topologies are traffic oblivious fabrics, allowing uniform bandwidth and latency between server pairs. They are ideal when the workload is unpredictable and consists mostly of short transfers—two inherent properties of legacy datacenter workloads [49, 50, 54, 67, 68]. But Fat-tree networks are becoming a bottleneck for distributed DNN training workloads [58, 69, 77, 85, 102, 105, 136].

Previous work has addressed this challenge by reducing the size of parameters to transmit through the network [48, 58, 59, 69, 73, 79, 82, 83, 94, 105, 123, 139] and developing techniques to discover faster parallelization strategies while considering

the available network bandwidth [46, 48, 85, 105, 129]. These proposals co-optimize computation and communication as two important dimensions of distributed DNN training, but they do not consider the *physical layer topology* as an optimization dimension.

In this paper, we analyze DNN training jobs from production clusters of Meta. We demonstrate that training workloads do not satisfy common assumptions about datacenter traffic that underlie the design of Fat-tree interconnects. Specifically, we show that (i) the communication overhead of large DNN training jobs increases dramatically as we increase the number of workers; and (ii) the traffic pattern of a DNN training job depends on its parallelization strategies.

Motivated by these observations, we propose TOPOOPT, a direct-connect DNN training system that co-optimizes network topology and parallelization strategy. TOPOOPT creates dedicated partitions for each training job using reconfigurable optical switches and patch panels, and jointly optimizes the topology and parallelization strategy within each partition. To achieve our goal, we grapple with the *algorithmic* challenges of finding the best topology, such as how to navigate the large search space across computation, communication, and topology dimensions, and also with various *operational* challenges, such as which optical switching technologies match well with the traffic patterns of DNN models.

We cast the topology and parallelization strategy co-optimization problem as an off-line alternating optimization framework. Our optimization technique *alternates* between optimizing the parallelization strategy and optimizing the network topology. It searches over the parallelization strategy space assuming a fixed topology, and feeds the traffic demand to a TOPOLOGYFINDER algorithm. The updated topology is then fed back into the parallelization strategy search algorithm. This alternating process repeats until the system converges to an optimized parallelization strategy and topology.

We demonstrate that finding an optimized network topology for DNNs is challenging because the ideal network topology needs to meet two goals simultaneously: (i) to complete large AllReduce transfers efficiently, and (ii) to ensure a small

hop-count for Model Parallel transfers. To meet these goals, we propose a novel *group theory-based technique*, called TotientPerms, that exploits the *mutability* of AllReduce transfers. Our TotientPerms approach builds a series of *AllReduce permutations* that not only carry AllReduce transfers efficiently, but are also well-positioned to carry Model Parallel transfers and, hence, improve the overall training performance.

Optical circuit-switched networks traditionally support point-to-point traffic across hosts with direct circuits between them. As a result, for a given set of circuits, only directly connected hosts can communicate leaving the rest of the hosts wait for new circuits to be established. To support arbitrary communication across all hosts participating in a job, we enable TOPOOPT’s hosts to act as relays and forward the traffic that does not belong to them. Host-based forwarding introduces a new challenge for RDMA flows since RDMA NICs drop packets that do not belong to them. To enable host-based RDMA forwarding, we exploit the network partition (NPAR) function of modern NICs, creating an efficient logical overlay network for RDMA packet forwarding (§6).

To evaluate TOPOOPT, we build a 12-server prototype with NVIDIA A100 GPUs [37], 100 Gbps NICs and a Telescent reconfigurable optical patch panel [43]. Moreover, we integrate our TotientPerms AllReduce permutations into NCCL and enable it to load-balance parameter synchronization across multiple ring-AllReduce sub-topologies. Our evaluations with six representative DNN models (DLRM [20], CANDLE [4], BERT [134], NCF [75], ResNet50 [74], and VGG [126]) show that TOPOOPT reduces the training iteration time by up to $3.4\times$ compared to a similar-cost Fat-tree. Moreover, we demonstrate that TOPOOPT is, on average, $3.2\times$ cheaper than an ideal full bisection bandwidth Fat-tree. TOPOOPT is the first system that co-optimizes topology and parallelization strategy for ML workloads and is currently being evaluated for deployment at Meta. The source code and scripts of TOPOOPT are available at <https://topoopt.csail.mit.edu>.

2 Motivation

Prior research has illustrated that *demand-aware* network fabrics are flexible and cost-efficient solutions for building efficient datacenter-scale networks [64, 68, 113]. However, predicting the upcoming traffic distribution is challenging in a traditional datacenter setting. This section demonstrates that DNN training workloads present a unique opportunity for demand-aware networks, as the jobs are long-lasting, and the traffic distribution can be *pre-computed* before the jobs start to run. First, we provide the necessary background to understand distributed DNN training and introduce three types of data dependencies between accelerator nodes in training jobs (§2.1). Then, we present measurements from production clusters in Meta (§2.2), and discuss the important properties of DNN training traffic.

2.1 Background on Distributed DNN training

Training iteration. A common approach to training DNNs is stochastic gradient descent (SGD) [90]. Each SGD *iteration* involves selecting a random batch of labeled training data, computing the error of the model with respect to the labeled data, and calculating gradients for the model’s weights through backpropagation. The SGD algorithm seeks to update the model weights so that the next evaluation reduces the error [55]. Training iterations are repeated with new batch of data until the model converges to the target accuracy.

Data parallelism. Data parallelism is a popular parallelization strategy, whereby a batch of training samples is distributed across training accelerators. Each accelerator holds a replica of the DNN model and executes the forward and backpropagation steps locally. In data parallelism, all accelerators synchronize their model weights during each training iteration. This step is commonly referred to as *AllReduce* and can be performed using various techniques, such as broadcasting [141], parameter servers [93], ring-AllReduce [3, 83, 130], tree-AllReduce [116], or hierarchical ring-AllReduce [131, 133].

Hybrid data and model parallelism. Large DNN models cannot fit in the memory of a single accelerator or even a single server with multiple accelerators. As a result, the model needs to be divided across multiple accelerators using *model parallelism* [84, 92]. Moreover, pure data parallelism is becoming suboptimal for large training jobs because of the increasing cost of synchronizing model parameters across accelerators [20, 78, 85, 104, 106, 125]. As a result, large DNNs are distributed using a hybrid of data and model parallelism, where different parts of a DNN and its dataset are processed on different accelerators in parallel.

Types of data dependencies in DNN training. Each training iteration includes two major types of *data dependencies*. Type (1) refers to *activations* and *gradients* computed during the Forward and Backpropagation steps. This data dependency is required for each input sample. Type (2) refers to synchronizing the *model weights* across accelerators through the AllReduce step once a batch of samples is processed. Depending on the parallelization strategy, these data dependencies may result in local memory accesses or cross-accelerator traffic. For instance, in a hybrid data and model parallelization strategy, type (1) and (2) both result in cross-accelerator traffic, depending on how the model is distributed across accelerators. Given that type (1) is related to model parallelism, we refer to the network traffic created by type (1) as *MP transfers*. Similarly, we refer to the network traffic created by type (2) as *AllReduce transfers*. Note that AllReduce transfers do not strictly mean data parallelism traffic, as model parallelism can also create AllReduce transfers across a subset of nodes.

Example: DLRM traffic pattern. Deep Learning Recommendation Models (DLRMs) are a family of personalization and recommendation models based on embedding table lookups that capitalize on categorical user data [107]. DLRMs

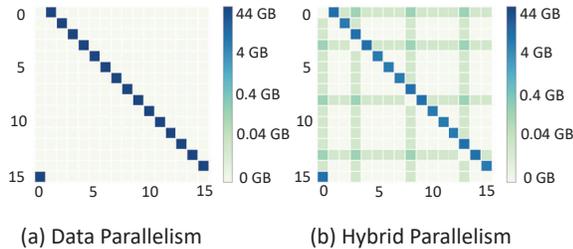

Figure 1: DLRM traffic heatmaps for different parallelization strategies.

are large, typically with 100s of billions of parameters, primarily because of their large embedding tables. Using pure data parallelism to distribute a DLRM results in massive AllReduce transfers. For instance, consider a DLRM architecture with four embedding tables E_0, \dots, E_3 , each with embedding dimensions of 512 columns and 10^7 rows (total size 22 GB for the model) distributed across 16 servers S_0, \dots, S_{15} with data parallelism. We compute the resulting traffic distribution, and Figure 1a illustrates the traffic pattern for a single training iteration. The rows and columns indicate source and destination servers, while the color encodes the amount of traffic between server pairs. The heatmap shows that using ring-AllReduce for synchronization, a pure data parallelism strategy results in 44 GB of AllReduce transfers.

Hence, a common parallelization strategy for DLRMs is to use a hybrid of data and model parallelism where the embedding tables are divided across nodes, while the rest of the model is replicated on all nodes [102]. Following the parallelization strategy used at Meta, we place E_0 on S_0 , E_1 on S_3 , E_2 on S_8 , and E_3 on S_{13} , and replicate the rest of the model on all servers. This parallelization strategy creates a mix of MP and AllReduce traffic, shown in Figure 1b. It reduces the maximum transfer size from 44 GB to 4 GB.

Note that MP transfers in DLRM form one-to-many broadcast and many-to-one incast patterns to transfer the activation and gradients to all nodes because the servers handling embedding tables must communicate with *all other servers*. In this example, the size of each AllReduce transfer is 4 GB, whereas the size of MP transfers is 32 MB, as shown by darker green elements in the heatmap.

2.2 Production Measurements

We study traffic traces from hundreds of production DNN training jobs running on multiple clusters at Meta. We instrument each job to log its training duration, number of workers, and the total amount of data transferred across its workers during training.

Number of workers and job duration. Figure 2a shows the cumulative distribution function (CDF) of the number of workers for different models in Meta’s clusters. Most jobs are distributed across 32 to 700 workers, agreeing with recent an-

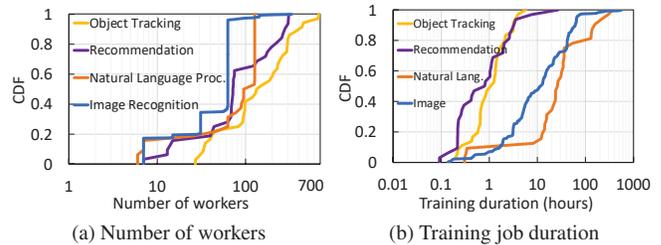

Figure 2: Profiling distributed DNN training jobs in Meta.

nouncements by other major players in the industry [45, 104], where each worker is a single GPU. Figure 2b demonstrates the CDF of total training job duration; as the figure shows, most jobs last over 10 hours. In fact, the top 10% of jobs take more than 96 hours (four days) to finish. This measurement shows production DNN jobs at Meta are long-lasting, and take up to weeks to finish.

Network overhead. Figure 3 illustrates the percentage of network overhead as the number of GPUs is increased from 8 to 128 for six DNN jobs in production. We use RDMA to transmit packets between servers and measure the percentage of time consumed by communication during training as network overhead. The figure shows that as the number of GPUs increases, the network quickly takes up a significant portion of training iteration time. In fact, the network overhead accounts for up to 60% of a DNN training iteration time in Meta’s production environment. Similar observations have been made in prior work [59, 77, 89, 105, 110, 123]. Such bottleneck suggests the existing datacenter networks are insufficient for the emerging DNN training workloads.

Traffic heatmaps. Figure 4 shows the heatmap of server-to-server traffic for four training jobs running in Meta’s production GPU clusters. The values on the colormap and the exact names of DNN models are not shown for confidentiality reasons. All heatmaps in the figure contain diagonal squares (in dark blue), indicating a ring communication pattern between servers. This is expected, as ring-AllReduce is the common AllReduce communication collective at Meta. But the MP transfers (light blue and green squares) are *model-dependent* because MP transfers depend on the parallelization strategy and device placement of a training job. Moreover, we find that the traffic patterns of training jobs do not change between iterations *for the entire training duration*, resulting in the same per-iteration heatmap throughout the training. Once a training job starts, the same parallelization strategy and synchronization method are used across training iterations, resulting in a periodic and predictable traffic pattern. Similar observations have been made in previous work [140]. In particular, the traffic heatmap is identical *across* training iterations. Note that the traffic pattern changes *within* a training iteration during forward, backward, and AllReduce phases.

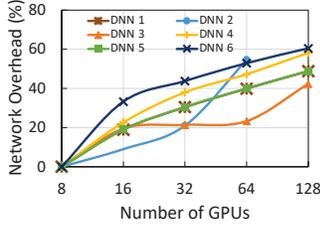

Figure 3: Network overhead measurements in Meta.

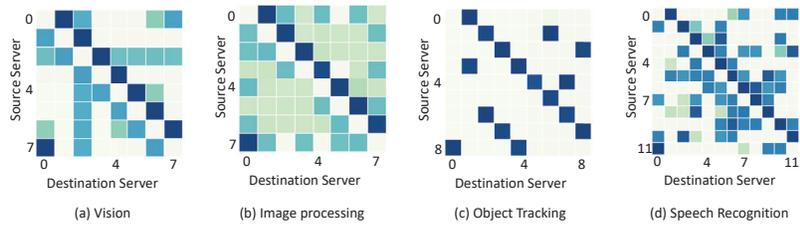

Figure 4: Traffic heatmaps of production jobs in Meta.

3 TOPOOPT System Design

The observations in the previous section suggest that demand-aware fabrics are excellent candidates for a DNN training cluster. In this section, we seek to answer the following question: “Can we build a demand-aware network to best support distributed training?” To answer this question, we propose TOPOOPT, a novel system based on optical devices that jointly optimizes DNN parallelization strategy and topology to accelerate today’s training jobs.

TOPOOPT interconnect. A TOPOOPT cluster is a *shardable* direct-connect fabric where each server has d interfaces connected to a core layer of d optical switches, as shown in Figure 5. The optical switches enable TOPOOPT to shard the cluster into dedicated partitions for each training job. The size of each shard depends on the number of servers the job requests. Given a DNN training job and a set of servers, TOPOOPT first finds the best parallelization strategy and topology between the servers off-line (§4.1). Then, it reconfigures the optical switches to realize the target topology for the job. Appendix C provides details on how TOPOOPT achieves sharding and dynamic job arrivals in shared clusters.

Degree of each server. We denote the number of interfaces on each server (i.e., the degree of the server) by d . Typically, d is the same as the number of NICs installed on the server. In cases where the number of NICs is limited, the degree can be increased using NICs that support break-out cables or the next generation of co-packaged optical NVLinks [11]. In our testbed, we use one 100 Gbps HPE NIC [29] with 4×25 Gbps interfaces to build a system with degree four ($d = 4$).

Direct-connect topology. In TOPOOPT, optical switches connect the servers directly, forming a *direct-connect topology*. To further scale a TOPOOPT cluster, we create a hierarchical interconnect by placing the servers under Top-of-Rack (ToR) switches and connecting ToR switches to the optical layer, creating a direct-connect topology at the ToR or spine layers, similar to previous work [53, 71, 72, 100, 114].

Host-based forwarding. In DNN training workloads, the degree of each server is typically smaller than the total number of neighbors with whom the server communicates during training. To ensure traffic is not blocked when there is no

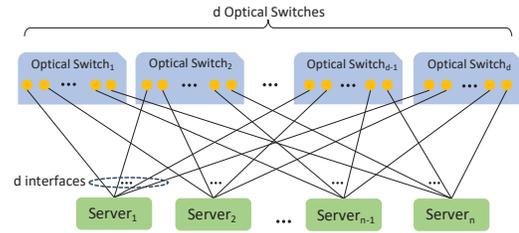

Figure 5: Illustration of TOPOOPT’s interconnect.

direct link between two servers, we use a technique called *host-based forwarding*, where hosts act as switches and forward incoming traffic toward the destination. Previous work used similar technique at the ToR switch level [53, 99, 100].

Optical switching technologies. A wide range of optical switches is suitable for TOPOOPT, including commodity available optical patch panels [43] and 3D-MEMS [6, 41], as well as futuristic designs such as Mordia [113], MegaSwitch [57], and Sirius [53, 60]. Table 1 lists the characteristics of these devices. TOPOOPT is compatible with any of these technologies. Appendix B provides details about these devices.

One-shot reconfiguration. Patch panel and OCS are both applicable for an immediate deployment of TOPOOPT, as shown in Table 1. The choice of which technology to use depends on several factors, including scale of the cluster, iteration time of jobs, and frequency of job arrivals. For instance, OCSs can potentially be used to reconfigure the topology of a job *within* training iterations, whereas patch panels are only suitable when the topology remains intact throughout the entire training of a particular job. Our evaluations demonstrate that the reconfiguration latency of today’s OCSs is too high for today’s DNNs, leading to sub-optimal performance when the topology is reconfigured within iterations (§5). As a result, given that faster technologies are not yet available, TOPOOPT uses a one-shot reconfiguration technique based on an offline co-optimization framework (§4) that jointly optimizes the parallelization strategy and topology. TOPOOPT then reconfigures the interconnection between training servers of each job before the job starts and keeps the topology intact until the training is complete (or to recover from failures).

Technology	Port-count	Reconfig. latency	Insertion Loss (dB)	Cost/port
Optical Patch Panels [43]	1008	minutes	0.5	\$100
3D MEMS [6, 41]	384	10 ms	1.5–2.7	\$520

4 Co-optimizing Parallelization Strategy and Network Topology

This section describes TOPOOPT’s co-optimization framework for finding a network topology and parallelization strategy for a given DNN training job.

4.1 Alternating Optimization

The search space is too large. Finding the optimal parallelization strategy alone is an NP-complete problem [85], and adding network topology and routing makes the problem even harder. An extreme solution is to jointly optimize compute, communication, and topology dimensions using a *cross-layer optimization formulation*. Theoretically, this approach finds the optimal solution, but the search space quickly explodes, even at modest scales (e.g., six nodes [129]).

Naive approach. The other extreme is to optimize the network topology *sequentially after* the parallelization strategy has been found. While this approach is able to reconfigure the network to better match its traffic demand, the eventual combination of topology and parallelization strategy is likely to be sub-optimal in the global configuration space.

TOPOOPT’s approach: alternating optimization. In TOPOOPT, we seek to combine the best of both worlds. To make the problem tractable, we divide the search space into two planes: *Comp. \times Comm.* and *Comm. \times Topo.* We use an alternating optimization technique to iteratively search in one plane while keeping the result of the other plane constant. Figure 6 illustrates our alternating optimization framework. We use FlexFlow’s MCMC (Markov Chain Monte Carlo) search algorithm [85] to find the best parallelization strategy for a given network topology while considering the communication cost. If the parallelization strategy improves the training iteration time, we feed it to the *Comm. \times Topo.* plane to find the efficient network topology and routing using our TOPOLOGYFINDER algorithm. The discovered topology is then fed back into the *Comp. \times Comm.* plane, which further optimizes the parallelization strategy and device placement based on the new topology. This optimization loop repeats until convergence or after k iterations, where k is a configurable hyper-parameter.

Figure 6: TOPOOPT searches for the best parallelization strategy, jointly with routing, and topology.

4.2 TOPOLOGYFINDER Algorithm

TOPOLOGYFINDER steps. Algorithm 1 presents the pseudocode of our TOPOLOGYFINDER procedure. The algorithm takes the following inputs: n dedicated servers for the training job, each with degree d , as well a list of AllReduce and MP transfers ($T_{AllReduce}$ and T_{MP}) based on the parallelization strategy and device placement obtained from the *Comp. \times Comm.* plane. The algorithm then finds the best topology (G) and routing rules (R) and returns them to the *Comp. \times Comm.* plane for the next round of alternating optimization. Our algorithm consists of the following four steps.

Step 1: Distribute the degree. This step distributes the degree d between AllReduce and MP sub-topologies proportionally, based on their share of total traffic. We specifically start with AllReduce transfers and allocate at least one degree to the AllReduce sub-topology to ensure the network remains connected (line 2). The remaining degrees, if any, are allocated to the MP sub-topology (line 3).

Step 2: Construct the AllReduce sub-topology. To find the AllReduce sub-topology, the algorithm iterates over every AllReduce group k and allocates degree d_k to each group proportionally based on the amount of traffic (line 6). Note that in hybrid data and model parallelism strategies, the AllReduce step can be performed across a subset of servers when a DNN layer is replicated across a few servers instead of all servers. To efficiently serve both AllReduce and MP transfers, TOPOOPT constructs the AllReduce sub-topology such that the diameter of the cluster is minimized. Section 4.3 explains two algorithms, called *TotientPerms* (line 8) and *SelectPermutations* (line 9) to construct the AllReduce sub-topology.

Step 3: Construct the MP sub-topology. We use the Blossom maximum weight matching algorithm [63] to find the best connectivity between servers with MP transfers (line 14). We repeat the matching algorithm until we run out of degrees. To increase the likelihood of more diverse connectivity across server pairs, we divide the magnitude of T_{MP} for pairs that already have an edge between them by two (line 17). In general, division by two can be replaced by a more sophisticated function with a diminishing return.

Step 4: Final topology and routing. Finally, we combine the MP and AllReduce sub-topologies to obtain the final topology (line 18). We then use a modified version of the coin-change algorithm [52] (details in Appendix E.1) to route

Algorithm 1 TOPOLOGYFINDER pseudocode

```

1: procedure TOPOLOGYFINDER( $n, d, T_{AllReduce}, T_{MP}$ )
  ▷ Input  $n$ : Number of dedicated training servers for the job.
  ▷ Input  $d$ : Degree of each server.
  ▷ Input  $T_{AllReduce}$ : AllReduce transfers.
  ▷ Input  $T_{MP}$ : MP transfers.
  ▷ Output  $G$ : Topology to give back to the  $Comp. \times Comm.$  plane.
  ▷ Output  $R$ : Routing rules to give back to the  $Comp. \times Comm.$  plane.
  ▷ Distribute degree  $d$  between AllReduce and MP sub-topologies
2:  $d_A = \max(1, \lceil d \times \frac{\text{sum}(T_{Reduce})}{\text{sum}(T_{Reduce}) + \text{sum}(T_{MP})} \rceil)$ 
3:  $d_{MP} = d - d_{AllReduce}$ 
  ▷ Construct the AllReduce sub-topology  $G_{AllReduce}$ 
4:  $G_{AllReduce} = \{\}$ 
5: for each AllReduce group  $k$  with set of transfers  $T_k$  do
  ▷ Assign degree  $d_k$  to group  $k$  according to its total traffic
6:  $d_k = \lceil d_A \times \frac{\text{sum}(T_k)}{\text{sum}(T_{Reduce})} \rceil$ 
7:  $d_A = d_A - d_k$ 
  ▷ Find all the permutations between servers in group  $k$ 
8:  $P_k = \text{TotientPerms}(n, k)$  ▷ (Details in §4.3)
  ▷ Select  $d_k$  permutations from  $P_k$ 
9:  $G_{AllReduce} = G_{AllReduce} \cup \text{SelectPermutations}(n, d_k, P_k)$  ▷ (§4.3)
10: if  $d_{AllReduce} == 0$  then
11:   break
  ▷ Construct the MP sub-topology  $G_{MP}$ 
12:  $G_{MP} = \{\}$ 
13: for  $i : i < d_{MP}$  do
  ▷ Find a maximum weight matching according to  $T_{MP}$ 
14:  $g = \text{BlossomMaximumWeightMatching}(T_{MP})$ 
15:  $G_{MP} = G_{MP} \cup g$ 
  ▷ Reduce the amount of demand for each link  $l$  in graph  $g$ 
16:   for  $l \in g$  do
17:      $T_{MP}[l] = T_{MP}[l] / 2$ 
  ▷ Combine the AllReduce and MP topologies
18:  $G = G_{AllReduce} \cup G_{MP}$ 
  ▷ Compute routes on  $G_{AllReduce}$  using the coin change algorithm [52]
19:  $R = \text{CoinChangeMod}(n, G_{AllReduce})$  ▷ (Appendix §E.1)
  ▷ Compute routes on  $G_{MP}$  with shortest path
20:  $R += \text{ShortestPath}(G, T_{MP})$ 
21: return  $G, R$ 

```

AllReduce on the AllReduce sub-topology (line 19). Further, we use k-shortest path routing for the MP transfers to take advantage of the final combined topology (line 20).

4.3 Traffic Mutability and AllReduce Topology

Finding an efficient AllReduce sub-topology. At first blush, finding an AllReduce sub-topology for a given DNN seems straightforward: we just need to translate the parallelization strategy and device placement from the $Comp. \times Comm.$ plane into a traffic matrix and map the traffic matrix into circuit schedules. Several papers have used this technique for datacenter networks [57, 64, 68, 72, 89, 95–97, 113, 137]. However, the conventional wisdom in prior work is to allocate as many direct parallel links as possible to *elephant flows* and leave *mice flows* to take multiple hops across the network. In principle, this approach works well for datacenters but it leads to sub-optimal topologies for distributed DNN training. While the size of AllReduce transfers is larger than MP transfers, MP transfers have a higher communication degree than AllReduce (Appendix D). Hence, the conventional approach creates parallel direct links for carrying AllReduce traffic and forces MP flows to have a large hop-count, thereby degrading the training performance.

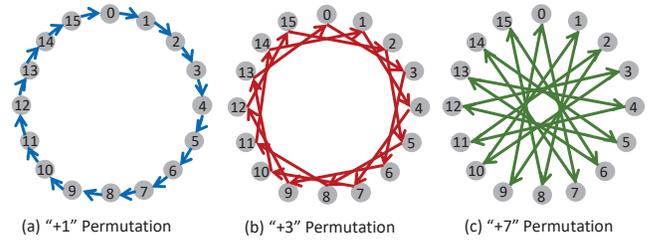

Figure 7: Ring-AllReduce permutations.

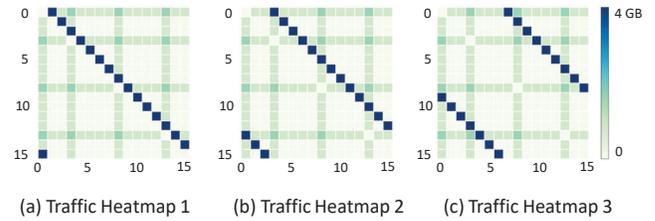

Figure 8: DLRM traffic heatmaps.

TOPOOPT’s novel technique. In TOPOOPT, we seek to meet two goals simultaneously: (i) allocate ample bandwidth for AllReduce transfers, as the bulk of the traffic belongs to them, but (ii) ensure a small hop-count for MP transfers. We meet both goals by demonstrating a unique property of DNN training traffic – the AllReduce traffic is *mutable*.

Mutability of AllReduce transfers. We define traffic mutability as the ability to change the traffic pattern without altering parallelization strategy or device placement while maintaining correctness, and demonstrate that AllReduce transfers are *mutable* whereas MP transfers are not. Intuitively, this is because MP traffic is composed of network flows among nodes that contain *different* parts of a DNN model thus creating immutable data dependencies, while AllReduce transfers contain network flows among nodes that handle the *same* part of the model, providing flexibility in the order of nodes participating in AllReduce. For instance, consider a DLRM distributed across 16 servers each with three NICs. The common AllReduce pattern is shown as a ring with consecutive node IDs, as shown in Figure 7a. However, *this is not the only possible permutation*. Each heatmap in 8a, 8b, and 8c corresponds to a different ring-AllReduce permutation, shown in Figures 7a, 7b, and 7c. We denote each of these permutations as $+p$, where server S_i connects to server $S_{(i+p)\%n}$, and n is the number of servers, as shown in Figure 7. Although all three heatmaps correspond to the *exact same parallelization strategy and device placement*, the blue diagonal lines appear at different parts of the heatmaps, depending on the order of servers in the ring-AllReduce permutation. But MP transfers (green vertical and horizontal lines in each heatmap) are dictated by the parallelization strategy and device placement; thus, they remain at the same spot in all three heatmaps.

Algorithm 2 TotientPerms pseudocode

```
1: procedure TOTIENTPERMS( $n, k$ )
  ▷ Input  $n$ : Total number of nodes
  ▷ Input  $k$ : AllReduce group size
  ▷ Output  $P_k$ : Set of permutations for AllReduce group of size  $k$ 
    ▷ Initially,  $P_k$  is empty
2:  $P_k = \{\}$ 
  ▷ This loop runs  $\phi(p)$  times, where
  ▷  $\phi$  is the Euler Totient function,  $\phi(p) = |\{k < p : \gcd(k, p) = 1\}|$ 
  ▷ one can also restrict  $p$  to be prime only
3: for  $p \leq k, \gcd(p, k) == 1$  do
4:    $one\_perm = []$ 
5:   for  $i$  in  $0$  to  $N/k$  do
6:      $one\_perm += [i + j \times p \text{ for } j \text{ in } 0 \text{ to } k]$ 
7:    $P_k += one\_perm$ 
8: return  $P_k$ 
```

Algorithm 3 SelectPermutations pseudocode

```
1: procedure SELECTPERMUTATIONS( $n, d_k, P_k$ )
  ▷ Input  $n$ : Total number of nodes
  ▷ Input  $d_k$ : Degree allocated for group this AllReduce group of size  $k$ 
  ▷ Input  $P_k$ : Candidate permutations for this AllReduce group of size  $k$ 
  ▷ Output  $G_k$ : Parameter synchronization topology, given as a set of
    permutations
    ▷ Initially,  $G_k$  is empty
2:  $G_k = \{\}$ 
  ▷  $q$  now is the minimum candidate in  $P_k$ 
3:  $q = P_k[0]$ 
  ▷ GetConn( $q$ ) gives the connection described
  ▷ by the permutation corresponding to  $q$ 
4:  $G_k = G_k \cup \text{GetConn}(q)$ 
  ▷ Ratio of the geometric sequence to fit
5:  $x = \sqrt[k]{N}$ 
6: for  $i \in \{1, \dots, d_k - 1\}$  do
  ▷ Select the next candidate based on the ratio
7:    $q' = x \times q$ 
  ▷ Project  $q'$  onto  $P_k \setminus G_k$  with minimal distance (L1-norm)
8:    $q' = \text{argmin}_{r \in P_k \setminus G_k} |r - q'|$ 
  ▷ Add this candidate to final topology
9:    $G_k = G_k \cup \text{GetConn}(q')$ 
10:   $q = q'$ 
11: return  $G_k$ 
```

Leveraging AllReduce traffic mutability. Traffic mutability implies that if a group of servers is connected in a certain order, simply permuting the label of the servers gives another ordering that will finish the AllReduce operation with the same latency while potentially providing a smaller hop-count for MP transfers. Instead of selecting just one AllReduce order, TOPOOPT finds multiple permutations for each AllReduce group and overlaps their corresponding sub-topologies. In doing so, TOPOOPT efficiently serves the AllReduce traffic while decreasing the hop-count for MP transfers.

TotientPerms algorithm. While overlapping multiple permutations sounds straightforward, navigating through the set of all possible AllReduce orderings is non-trivial, since the number of possible permutations is $O(n!)$. To reduce the search space of all possible permutations, we design the TotientPerms algorithm to find the ring generation rule for all regular rings, based on group theory. Regular rings are those

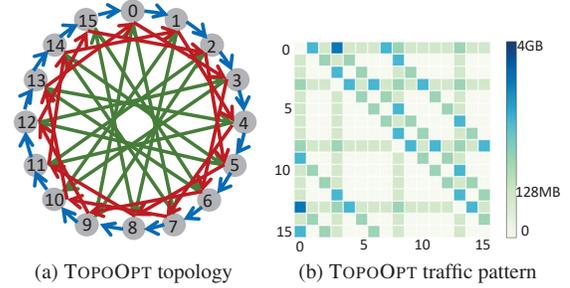

Figure 9: TOPOOPT’s topology and traffic matrix.

where the distance between indices of consecutive servers is equal; i.e., server S_i is connected to server $S_{(i+p)\%n}$ for some p . Algorithm 2 presents the pseudocode of TotientPerms. Inspired by Euler’s totient function [25], we find all integer numbers $p < n$, where p is co-prime with n (i.e. $\gcd(p, n) = 1$, line 3, Algorithm 2), represent a valid ring-AllReduce permutation (§E.1). For instance, for $n = 12$ servers, the ring generation rule for $p = 1, 5, 7, 11$ will lead into four distinct ring-AllReduce permutations between the servers. Note that each p describes a unique regular permutation. To handle large scale clusters, we restrict p to be a prime number, thereby reducing the search space size to only $O(\frac{n}{\ln n})$, as per the Prime Number Theorem [66].

SelectPermutations algorithm. For a group of n servers participating in AllReduce, TotientPerms finds a set of regular permutations $P_k = \cup_{p:\gcd(p,n)=1} \{p\}$ across them. TOPOLOGYFINDER then selects d_k permutations using a module called SelectPermutations, where d_k is the number of degree allocated to the group of nodes running AllReduce (line 6, Algorithm 1). Algorithm 3 presents the pseudocode of SelectPermutations. Several metrics can be used in the SelectPermutations module. In our implementation, SelectPermutations aims to reduce the cluster diameter to benefit the MP transfers. To this end, SelectPermutations chooses $\{p_1, \dots, p_{d_k}\} \subset P_k$, such that $\{p_1, \dots, p_{d_k}\}$ is close (in L1-norm) to a geometric sequence (line 7, Algorithm 3).

Theorem 1. TOPOOPT’s *SelectPermutations algorithm* bounds the diameter of the AllReduce sub-topology to $O(d_A \cdot n^{1/d_A})$, under certain assumptions.

We list the assumptions and proof of Theorem 1 in Appendix E.2. Intuitively, each server in the topology is able to reach a set of servers with a geometrically distributed hop-count distance (line 5, Algorithm 3), creating a topology similar to Chord [128].

Example. Consider the DLRM model in Figure 8. Instead of choosing one of the AllReduce permutations in Figure 7, TOPOOPT combines the three ring-AllReduce permutations to load-balance the AllReduce transfers while providing a short hop-count for MP transfers. Figure 9 illustrates TOPOOPT’s topology and traffic matrix and shows a more balanced traffic matrix than Figure 8.

5 Large Scale Simulations

This section evaluates the performance of a large-scale TOPOOPT interconnect. First, we explain our simulation software and methodology (§5.1). Then, we provide a cost analysis of TOPOOPT to inform our simulations when comparing different interconnects (§5.2). Next, we demonstrate the performance of TOPOOPT when a cluster is dedicated to a single distributed DNN training job (§5.3). We perform a sensitivity analysis to quantify the impact of all-to-all traffic (§5.4) and host-based forwarding (§5.5). We extend this setting to a case where a training cluster is shared among multiple jobs (§5.6). Finally, we evaluate the impact of reconfiguration latency (§5.7) on TOPOOPT’s performance.

5.1 Methodology & Setup

We implement two simulators to evaluate TOPOOPT.

FlexNet simulator. We augment FlexFlow’s simulator [27] to be network-aware and call it *FlexNet*. Given a DNN model and a batch size, FlexFlow’s simulator explores different parallelization strategies and device placements to minimize iteration training time. The output of this simulator is a *task graph* describing the set of computation and communication tasks on each GPU and their dependencies. The current implementation of FlexFlow ignores the network topology by assuming servers are connected in a *full-mesh* interconnect. Our *FlexNet* simulator extends the FlexFlow simulator and enables it to consider multiple networks, including Fat-trees, TOPOOPT, and expander networks. Moreover, *FlexNet* implements our alternating optimization framework (§4) to find an optimized network topology and routing rules for TOPOOPT.

FlexNetPacket simulator. FlexFlow’s simulator only provides course-grind estimation of training iteration time, because it does not simulate individual packets traversing through a network. Extending *FlexNet* to become a packet-level simulator is computationally infeasible, because FlexFlow generally requires thousands of MCMC iterations to converge. To faithfully simulate per-packet behavior of network switches, buffers, and multiple jobs sharing the same fabric, we build a second event-based packet simulator, called *FlexNetPacket*, on top of htsim [7]. *FlexNetPacket* takes the output of *FlexNet* (i.e., the optimized parallelization strategy, device placement of each operator, network topology, and routing rules) and simulates several training iterations. The link propagation delay is set to $1 \mu\text{s}$ throughout this section.

Simulated network architectures. We simulate distributed training clusters with n servers equipped with four NVIDIA A100 GPUs [37]. We vary n in different experiments and simulate the following network architectures:

- **TOPOOPT.** A TOPOOPT interconnect where each server is equipped with d NICs, each with bandwidth B connected via a flat layer of optical devices. At the beginning of each job, a shard of the network is selected, and the topology of the

shard is reconfigured based on the output of our alternating optimization framework (§4) and remains unchanged throughout the entire training job. Both OCS and patch panels are suitable for this architecture.

- **OCS-reconfig.** To study the impact of changing the network topology within training iterations, we simulate a reconfigurable TOPOOPT interconnect. We rely on commercially available Optical Circuit Switches (OCSs) for this design and assume the reconfiguration latency is 10 ms. Given that FlexFlow’s parallelization strategy search is not aware of dynamically reconfigurable networks, following prior work [89], we measure the traffic demand every 50 ms and adjust the circuits based on a heuristic algorithm to satisfy the current traffic demand as much as possible. We also enable host-based forwarding such that the communication is not blocked even when a direct link is not available (Appendix E.4).

- **Ideal Switch.** An ideal electrical switch that scales to any number of servers, where each server is connected to the switch via a link with $d \times B$ bandwidth. For any pair of d and B , no network can communicate faster than this ideal case. In practice, the Ideal Switch can be approximated with a full-bisection bandwidth Fat-tree where the bandwidth of each link is $d \times B$.

- **Fat-tree.** To compare the performance of TOPOOPT to that of a similar-cost Fat-tree architecture, we simulate a full bisection bandwidth Fat-tree where each server has one NIC and the bandwidth of each link is $d \times B'$, where B' is lower than B and is selected such that Fat-tree’s cost is similar to TOPOOPT (§5.2).

- **Oversub. Fat-tree.** This is a 2:1 oversubscribed Fat-tree interconnect, where the bandwidth of each link is $d \times B$ but half of the links in the ToR uplink layer are omitted.

- **SiP-ML [89].** SiP-ML is a futuristic DNN training cluster with Tbps of bandwidth per GPU. While having a Tbps network is beneficial, our goal is to compare the algorithmic contributions of TOPOOPT and SiP-ML. Hence, to make a fair comparison, we allocate d wavelengths, each with bandwidth B , to each SiP-ML GPU and follow its SiP-Ring algorithm to find a topology with a reconfiguration latency of $25 \mu\text{s}$. Appendix F elaborates on our modifications to SiP-ML.

- **Expander [127, 135].** Finally, we simulate a fabric where each server has d NICs with bandwidth B interconnected via an Expander topology.

DNN Workloads. We simulate six real-world DNN models: DLRM [20], CANDLE [4], BERT [62], NCF [75], ResNet50 [74], and VGG [126]. List 1 (Appendix D) provides details about model configurations and batch sizes used in this paper.

Parallelization strategy. We use *FlexNet*’s topology-aware parallelization strategy search for Ideal Switch, Fat-tree, Oversub. Fat-tree, SiP-ML, and Expander networks. For TOPOOPT, we use *FlexNet*’s alternating optimization framework to find the best parallelization strategy jointly with topology, where the final parallelization strategy is either hybrid or pure data-

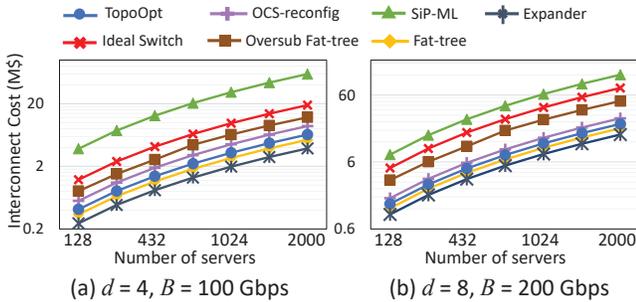

Figure 10: Interconnect cost comparison.

parallel. We use ring-AllReduce and distributed parameter server [93] as default AllReduce communication collectives between servers and within servers, respectively. Each data point averages 5–10 simulation runs.

5.2 Cost Analysis

We begin our evaluations by comparing the cost of various network architectures. Details about the cost of each component used in each architecture are given in Appendix G.

Figure 10 compares the interconnect cost across various network architectures as the number of servers is increased. We estimate the cost of Ideal Switch with a full-bisection Fat-tree of the same bandwidth. We make the following observations. First, using OCSs for TOPOOPT is more expensive ($1.33\times$, on average) than patch panels. Note that OCSs can be used in both TOPOOPT and OCS-reconfig interconnects. Second, the cost of TOPOOPT overlaps with that of the Fat-tree. This is intentional, because having a cost-equivalent architecture enables us to compare the performance of TOPOOPT to a cluster at the same price point. Third, the ratio of Ideal Switch’s cost to TOPOOPT’s cost is $3.2\times$ on average. Finally, the most and least expensive fabrics are SiP-ML and Expander, respectively, and as this section shows, they both perform worse than TOPOOPT for certain workloads.

We acknowledge that estimating the cost of networking hardware is challenging because prices are subject to significant discounts with bulk orders. Assuming all components in this analysis are subject to similar bulk order discounts, the relative comparison across architectures remains valid. As a point of comparison, we compute the cost of a cluster with 4,394 servers ($k = 26$ Fat-tree) by following the discounted cost trends in Sirius [53] and with 50% discounts for patch panels. For a cluster at this scale, the cost of full-bisection bandwidth Fat-tree (which approximates our Ideal Switch baseline) relative to the cost of TOPOOPT changes from $3.0\times$ to $3.6\times$, indicating our estimates are reasonable. Moreover, a TOPOOPT cluster incurs lower energy cost than Fat-trees, as optical switches are passive.

5.3 Performance Comparison on Dedicated Clusters

This section compares the training iteration time of TOPOOPT with that of other network architectures when the cluster is dedicated to serving one DNN training job.

Figure 11a compares the training iteration times of various architectures for CANDLE distributed on a dedicated cluster of 128 servers with a server degree of four ($d = 4$). We vary the link bandwidth (B) on the x-axis. The figure shows that Ideal Switch, TOPOOPT, and SiP-ML architectures achieve similar performance because the best parallelization strategy for CANDLE at this scale is mostly data parallel, with few MP transfers. The OCS-reconfig architecture performs poorly because it uses the instantaneous demand as the baseline to estimate the future traffic to schedule circuits. This estimation becomes inaccurate during training, in particular when the current AllReduce traffic is about to finish but the next round of AllReduce has not started. The Expander architecture has the worst performance, as its topology is not optimized for DNN workloads. Averaging across all link bandwidths, compared to Fat-tree interconnect, TOPOOPT improves the training iteration time of CANDLE by $2.8\times$; i.e., the ratio of CANDLE’s iteration time on Fat-tree to TOPOOPT is 2.8. TOPOOPT’s servers have more raw bandwidth, resulting in faster completion time.¹

Figures 11b and 11c show the training iteration times for VGG and BERT. The trends are similar to CANDLE, as these models have similar degree requirements. Compared to Fat-tree, on average, TOPOOPT improves the iteration time of VGG and BERT by $2.8\times$ and $3\times$, respectively.

The cases of DLRM and NCF are more interesting, as they have more MP transfers than the other DNNs. As shown in Figures 11d and 11e, TOPOOPT’s performance starts to deviate from Ideal Switch, especially for NCF, because it uses host-based forwarding for the many-to-many MP transfers (§5.4 and §5.5). For DLRM (and NCF), TOPOOPT is $2.8\times$ (and $2.1\times$) faster than Fat-tree, while Ideal Switch further improves the training iteration time by $1.3\times$ (and $1.7\times$) compared to TOPOOPT. SiP-ML performs poorly, and even when we increase the link bandwidth, its training iteration time stays flat. This happens because MP transfers in DLRM and NCF require several circuit reconfigurations to meet the traffic demand.

Finally, Figure 11f shows most architectures achieve similar training iteration times for ResNet50 since it is not a communication-heavy model. The Expander architecture performs poorly when the link bandwidth is lower than 100 Gbps, as the topology does not match the AllReduce traffic pattern.

We repeat this simulation with $d = 8$ and observe a similar performance trend (Appendix H).

¹It is possible to improve the performance of the Expander fabric by augmenting Blink’s approach [136] to a cluster-level solution.

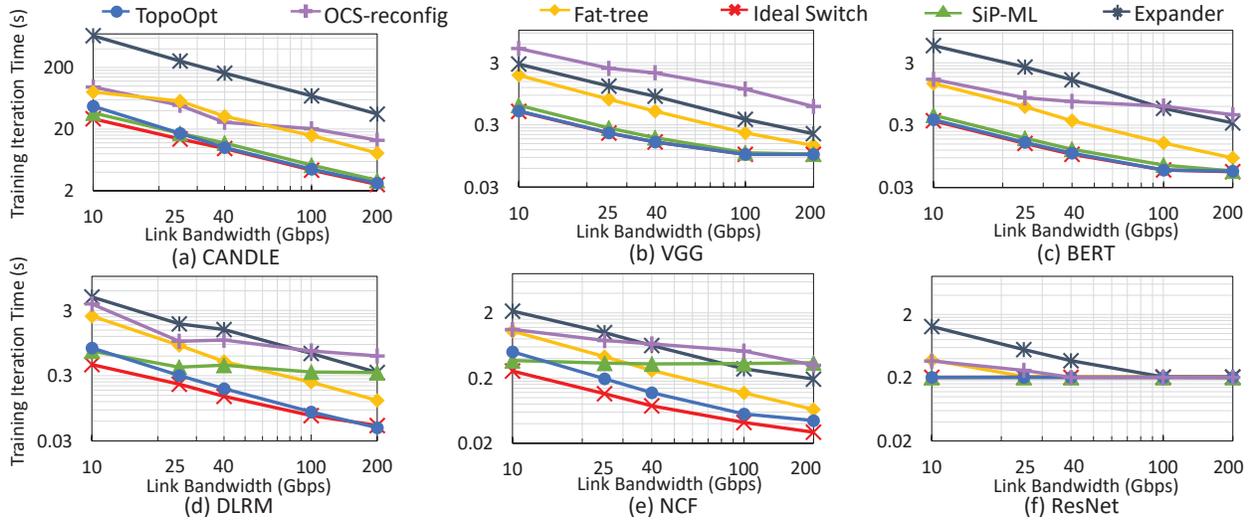

Figure 11: Dedicated cluster of 128 servers ($d = 4$).

5.4 Impact of All-to-all Traffic

This section evaluates the impact of all-to-all traffic patterns on TOPOOPT’s performance. In particular, TOPOOPT’s host-based forwarding approach incurs bandwidth tax [99] exacerbated by *all-to-all* and *many-to-many* communication patterns. This tax is defined as the ratio of the traffic volume in the network (including forwarded traffic) to the volume of logical communication demand. Hence, the bandwidth tax for a full bisection bandwidth Fat-tree topology is always one, because hosts do not act as relays for each other.

Consider a DNN model with R bytes of AllReduce traffic and A bytes of all-to-all traffic, distributed on a full bisection bandwidth topology with total network bandwidth $N \cdot B_F$ (i.e., number of servers multiplied by the bisection bandwidth). The training iteration time of this DNN is: $T_F = \frac{R}{N \cdot B_F} + \frac{A}{N \cdot B_F} + C_{bs}$, where C_{bs} is the computation time of the model with batch size bs .²

Now suppose the same DNN is distributed on a TOPOOPT topology with total network bandwidth NB_T . In this case, assuming the entire AllReduce traffic is carried on Totient-Perms with direct links, the training iteration time becomes $T_T = \frac{R}{N \cdot B_T} + \frac{\alpha \cdot A}{N \cdot B_T} + C_{bs}$ (Eq. 1), where α represents the slow-down factor that all-to-all transfers create in the network, due to host-based forwarding. The value of α depends on the amount of bandwidth tax and routing strategy (§5.5).

Increasing the amount of all-to-all traffic (A) increases the iteration time for both T_F and T_T . But when $N \cdot B_F$ and $N \cdot B_T$ are equal, TOPOOPT’s performance degrades faster because of the α factor in the numerator. To quantify this behavior concretely, we distribute a DLRM training task with 128 em-

bedding tables on a cluster with 128 servers. We choose large embedding tables and distribute each table on each server, creating worst-case all-to-all traffic.

Figure 12 compares the training iteration times of TOPOOPT, Ideal Switch, and Fat-tree as the batch size is increased. The top x-axis lists the ratio of all-to-all to AllReduce traffic for each batch size value given on the bottom x-axis. As shown in Figure 12a, when the batch size is 128 and $d = 4$, TOPOOPT’s performance matches that of Ideal Switch, while Fat-tree is a factor of 2.7 slower. This result agrees with the performance gains in Figure 11d, as the batch sizes are the same.

Increasing the batch size increases A , and this, in turn, increases the training iteration times in all three architectures. As predicted by Eq. (1), TOPOOPT’s iteration time increases faster. Specifically, when the batch size is 2048 and all-to-all traffic is 80% of AllReduce traffic, TOPOOPT performs poorly, and the iteration time is a factor of 1.1 higher than that of the Fat-tree architecture. Increasing the server degree d mitigates the problem, as shown in Figure 12b. Note that increasing the batch size does not always result in faster training time [89, 109, 124]. Moreover, publicly available data suggest 2048 is the largest batch size for training DLRM [102]. The number of columns in the embedding tables and the number of servers are smaller in their workload: (92, 16) vs. (128, 128), respectively. Hence, the DLRM workload we evaluate contains more all-to-all traffic than the state-of-the-art model used in industry.

5.5 Impact of Host-based Forwarding

Two factors impact the performance of host-based forwarding in TOPOOPT: bandwidth tax and routing strategy.

²For clarity of presentation, this formulation assumes no overlap between communication and computation stages and no competing traffic.

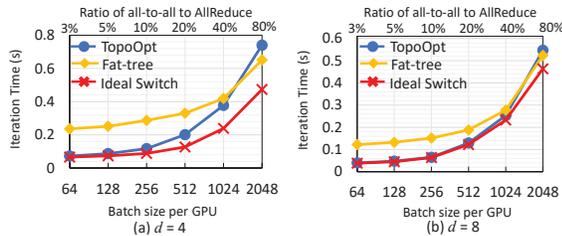

Figure 12: Impact of all-to-all traffic on a dedicated cluster of 128 servers ($B = 100$ Gbps).

Bandwidth tax. Figure 13 shows the amount of bandwidth tax experienced by the DLRM job in the previous section. Each bar represents a different batch size. At batch size 64 with $d = 4$, TOPOOPT experiences a bandwidth tax of 1.11, indicating that host-based forwarding creates 11% extra traffic in the network. Increasing the degree to $d = 8$ further improves this number to 1.05. In the worst-case scenario with batch size 2048, TOPOOPT pays a bandwidth tax of 3.03 when $d = 4$, causing it to perform worse than Fat-tree, as shown in Figure 12a. Determining the value of tolerable bandwidth tax is challenging for a TOPOOPT cluster, as it depends on the compute time and the amount of compute-communication overlap, and this varies for different DNN models.

Impact of path length. Intuitively, the amount of bandwidth tax grows with the path length [99]. Figure 14 shows the CDF of path length across all server pairs. When $d = 4$, the average path length is 5.7, resulting in at least $5.7\times$ overhead of host-based forwarding relative to Ideal Switch for all-to-all traffic. Based on Eq. (1), and since the total network bandwidth in TOPOOPT is higher than Fat-tree ($NB_T > NB_F$), the overhead of host-based forwarding becomes at least $1.4\times$ for the Fat-tree architecture. Increasing the server degree to 8 reduces the average path length to 3, thereby reducing the overhead bound. Appendix H evaluates the impact of increasing node degree on performance for other models.

Routing strategy. Building a topology with a small path length is necessary but not sufficient to reduce the impact of host-based forwarding. To handle forwarded traffic with minimum performance impact, the routing strategy also needs to be efficient. The best routing strategy *minimizes the maximum link utilization* for a given network topology, similar to WAN traffic engineering solutions [91]. However, finding the optimal routing strategy requires solving a set of linear equations with a centralized controller [76, 81]. To quantify the load imbalance in TOPOOPT, Figure 15 illustrates the CDF of the amount of traffic carried by each physical link for an all-to-all traffic matrix. When the batch size is 128 (Figure 15a), the link with the least traffic carries 39% and 59% less traffic than the link with the most traffic, for $d = 4$ and $d = 8$, respectively. This imbalance in load suggests further opportunities to improve the performance of TOPOOPT. Achieving optimal routing makes α (Eq. (1)) equal to the aver-

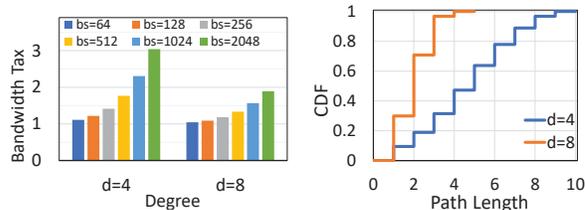

Figure 13: Bandwidth tax. Figure 14: Path length CDF.

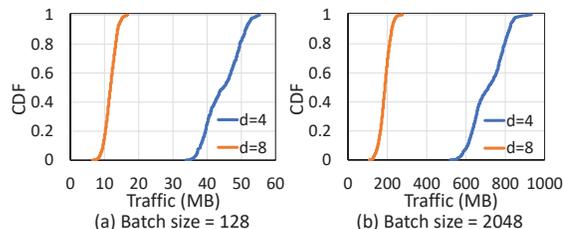

Figure 15: Traffic distribution.

age path length. Without a centralized controller, however, the link utilization becomes non-uniform, and the average path length only serves as a lower bound. We leave optimizing the routing strategy in TOPOOPT to future work.

5.6 Performance on Shared Clusters

We now compare the performance of different network architectures when the cluster is shared across multiple DNN jobs. Following prior work [98, 115], we run a series of simulations where 40% of the jobs are DLRM, 30% are BERT, 20% are CANDLE, and 10% are VGG16. We change the number of active jobs to represent the load on the cluster. Assuming each job requests 16 servers (64 GPUs), we execute 5, 10, 15, 20, and 27 jobs on the cluster to represent 20%, 40%, 60%, 80% and 100% load, respectively.

Figure 16 compares the average and 99%-tile iteration time at different loads for a cluster with 432 servers where $d = 8$ and $B = 100$ Gbps. SiP-ML does not support multiple jobs; hence, we omit it in this experiment. We omit OCS-reconfig and Expander networks, as they both show poor performance in this setting. Instead, we add the Oversub. Fat-tree interconnect to demonstrate the impact of congestion on Fat-tree topologies. Figure 16a shows that TOPOOPT improves the average iteration time by $1.7\times$ and $1.15\times$, compared to the Fat-tree and Oversub. Fat-tree architectures, respectively. We observe a similar trend for the tail iteration completion times, depicted in Figure 16b. At the extreme case when all servers are loaded, TOPOOPT's tail training iteration time is $3.4\times$ faster compared to Fat-tree architecture. Averaging across all load values on the x-axis, TOPOOPT improves the tail training iteration time by $3\times$ and $1.4\times$ compared to Fat-tree and

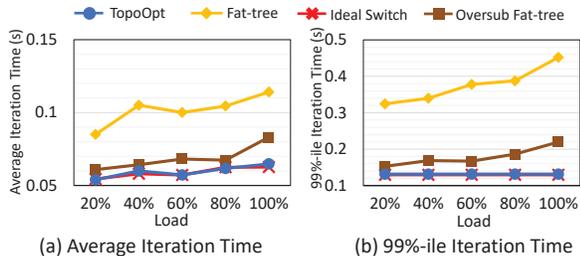

Figure 16: Shared cluster of 432 servers ($d = 8, B = 100$ Gbps).

Oversub. Fat-tree architectures.

5.7 Impact of Reconfiguration Latency

Figure 17 shows the training iteration time of DLRM and BERT in the same setting as Figure 11, while sweeping the reconfiguration latency of OCSs in OCS-reconfig from $1 \mu\text{s}$ to 10ms . The horizontal blue line corresponds to TOPOOPT’s iteration time; it remains constant as it does not reconfigure the network topology. We find host-based forwarding is challenging when the network is reconfigurable, as the circuit schedules need to account for forwarding the traffic while the topology reconfigures. Therefore, we evaluate the performance of OCS-reconfig with and without host-based forwarding. The purple line corresponds to OCS-reconfig with host-based forwarding (same as OCS-reconfig evaluated in Figure 11), denoted by OCS-reconfig-FW. For the orange line, we disable host-based forwarding (similar to SiP-ML) and call it OCS-reconfig-noFW.

We find enabling host-based forwarding when the topologies reconfigures within a training iteration is not always beneficial. For DLRM (Figure 17a), OCS-reconfig-FW achieves better performance than OCS-reconfig-noFW, as DLRM has all-to-all MP transfers which benefit from host-based forwarding. However, for BERT (Figure 17b), enabling forwarding increases the chance of inaccurate demand estimation and imposes extra bandwidth tax, therefore increasing the iteration time of OCS-reconfig-FW by a factor of 1.4 compared to OCS-reconfig-noFW.

Reducing the reconfiguration latency all the way to $1 \mu\text{s}$ enables OCS-reconfig-noFW to match the performance of TOPOOPT. However, OCS-reconfig-FW still suffers from inaccurate demand estimations. Although fast reconfigurable switches are not yet commercially available, they are going to be essential in elastic scenarios where the cluster is shared across multiple jobs and servers join and leave different jobs unexpectedly, or when large, high-degree communication dominates the workload. We believe futuristic fast reconfigurable switches, such as Sirius [53], are well-suited for this setting. Finding a parallelization algorithm that is aware of reconfigurability within training iterations is a challenging and exciting future research problem.

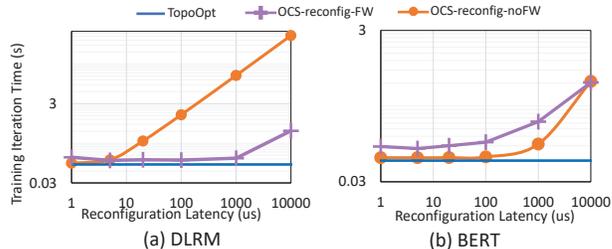

Figure 17: Impact of reconfiguration latency ($d=8, B=100$ Gbps).

6 Prototype

Testbed setup. We build a prototype to demonstrate the feasibility of TOPOOPT. Our prototype includes 12 ASUS ESC4000A-E10 servers and a G4 NMT patch panel [43]. Each server is equipped with one A100 Nvidia GPU [37] (40 GB of HBM2 memory), one 100 Gbps HP NIC [29], and one 100 Gbps Mellanox ConnectX5 NIC. Our HP NICs are capable of supporting 4×25 Gbps interfaces using a PSM4 transceiver with four breakout fibers [8], enabling us to build a TOPOOPT system with degree $d = 4$ and $B = 25$ Gbps. We use RoCEv2 for communication, and enable DCB [19] and PFC on these interfaces to support a lossless fabric for RDMA. We build a completely functional TOPOOPT prototype with our patch panel (Figure 18). We compare TOPOOPT’s performance with two baselines: (i) Switch 100Gbps, where the servers are connected via 100 Gbps links to a switch, and (ii) Switch 25Gbps, where the servers are connected via 25 Gbps links to a switch. The Switch 100Gbps baseline corresponds to the Ideal Switch case in our simulations.

Distributed training framework. We use FlexFlow’s training engine [26], based on Legion’s parallel programming system [30], to train four DNN models: ResNet50 [74], BERT [62], VGG16 [126], and CANDLE [4]. For DLRM, we use Facebook’s implementation from [20]. Since our prototype is an order of magnitude smaller in scale than our simulation setup, we use smaller model and batch sizes.

Modifications to NCCL. By default, the NCCL communication library [36] assumes all network interfaces are routable from other interfaces. This assumption is not ideal for TOPOOPT because we have a specific routing strategy to optimize training time. We modify NCCL to understand TOPOOPT’s topology and respect its routing preferences. Moreover, we integrate our TotientPerms AllReduce permutations into NCCL and enable it to load-balance parameter synchronization across multiple ring-AllReduce permutations.

RDMA forwarding. Implementing TOPOOPT with today’s RDMA NICs requires solving an engineering challenge, because the RDMA protocol assumes a switch-based network. Packet processing and memory access in RDMA protocol are offloaded to the NIC, and a RoCEv2 packet whose destination

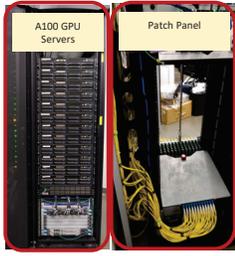

Figure 18: Testbed photo.

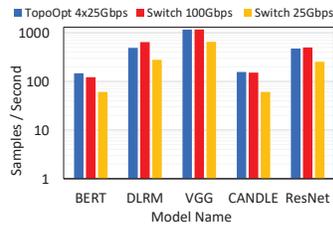

Figure 19: Training throughput (samples/second).

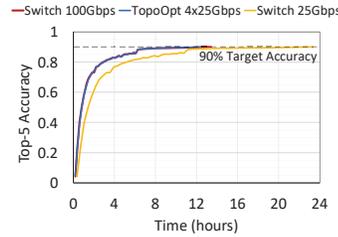

Figure 20: Time-to-accuracy of VGG19 with ImageNet.

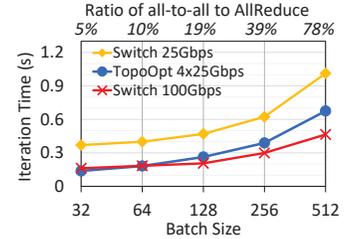

Figure 21: Impact of all-to-all traffic in our testbed.

IP address is different from that of the host is assumed to be corrupted. Therefore, the NIC silently drops forwarded packets. To address this issue, we collaborated with engineers at Marvell who developed the firmware and driver of our HP NICs. Our solution uses a feature called network partitioning (NPAR) which enables the NIC to separate host-based forwarding traffic from direct traffic, and uses the Linux kernel to route them (details in Appendix I). Our conversations with Marvell indicate that updating the firmware and the driver enables the NIC to route forwarded RoCEv2 packets, thereby bypassing the kernel entirely.

Training performance. Figure 19 demonstrates that TOPOOPT’s training throughput (samples/second) is similar to our Switch 100 Gbps baseline for all models. The performance of Switch 25Gbps baseline is lower because its available bandwidth is lower than TOPOOPT. Figure 20 shows the time-to-accuracy plot of training VGG19 on the ImageNet [61] dataset. As the figure indicates, TOPOOPT reaches the target accuracy of 90% 2.0× faster than the Switch 25Gbps baseline. TOPOOPT achieves similar performance to the Switch 100Gbps baseline, as the blue and red lines overlap in Figure 20.

Impact of all-to-all traffic. Similar to Section 5.4, we evaluate the impact of all-to-all MP traffic on our RDMA-forwarding enabled testbed by measuring the average iteration time across 320 iterations of a DLRM job distributed in our testbed. We vary the amount of all-to-all traffic by changing the batch size. To create worst-case traffic, we increase the embedding dimensions by 128× relative to the state-of-the-art [20] (model details are in List 1, Appendix D). Figure 21 shows the training iteration time for various batch sizes. The results are consistent with Figure 12, but since the bandwidth tax in our 12-server testbed is much smaller than a 128-server cluster in simulations, TOPOOPT performs better relative to the switch-based architectures for a given all-to-all to AllReduce traffic ratio. For instance, for batch size 512, the ratio of all-to-all traffic to AllReduce is 78%, and the training iteration time with TOPOOPT is 1.6× better than the Switch 25Gbps baseline.

7 Discussion

Target workload. The most suitable workload for a TOPOOPT cluster is a set of large DNN training jobs with hybrid data and model parallelism (or simply data parallelism). We assume the set of servers assigned to each job remains the same throughout the lifetime of the job, and the GPUs are not shared across multiple jobs.

Storage and control plane traffic. Meta’s training clusters consist of custom-designed servers, each with eight GPUs, eight dedicated NICs for training traffic (GPU NICs), and four additional NICs for storage and other traffic (CPU NICs) [102]. Other companies, such as NVIDIA, have similar architectures [10]. TOPOOPT only considers GPU NICs as server degree and partitions the network dedicated for training traffic. The CPU NICs are connected through a separate fabric to carry storage and other control plane traffic.

Supporting dynamic scheduling and elasticity. Others have demonstrated the benefits of dynamically choosing the training servers for elastic training jobs [98, 115]. Our target use case in Meta is to leverage TOPOOPT for the vast number of long-lasting training jobs that do not change dynamically. In cases where elasticity is required, instead of using patch panels, we use OCSs (or other fast reconfigurable optical switches) to change the servers participating in a job quickly. Note that dynamically changing the set of servers participating in a job while keeping both the topology and the parallelization strategy optimal requires augmenting the optimization space with an additional dimension, making the problem even more challenging. We leave this to future work.

Handling failures. Unlike SiP-ML’s single ring topology [89], a single link failure does not disconnect the graph in TOPOOPT. When a fiber fails, TOPOOPT can temporarily use a link dedicated to MP traffic to recover an AllReduce ring. In case of permanent failures, TOPOOPT reconfigures to swap ports and recover the failed connection.

Supporting multi-tenancy. To support multi-tenancy [142, 143], TOPOOPT can leverage NVIDIA’s MIG [39] to treat one physical server as multiple logical servers in its topology.

TotientPerms in Fat-trees. Although our TotientPerms technique is well-suited for reconfigurable optical interconnects, it may be of independent interest for Fat-tree intercon-

nects as well since load-balancing the AllReduce traffic across multiple permutations can help with network congestion.

TOPOOPT’s limitations. TOPOOPT’s approach assumes the traffic pattern does not change between iterations. However, this assumption may not hold for Graphic Neural Network (GNN) models [121] or Mixture-of-Expert (MoE) models [80]. In addition, we plan to extend TOPOOPT by bringing its demand-awareness design within training iterations. This is an open research question, and as shown in Section 5.7, we will need fast-reconfigurable optical switches, as well as a more sophisticated scheduling algorithm. Another limitation of TOPOOPT is that a single link failure within a AllReduce ring causes the full ring to become inefficient for AllReduce traffic. A fast optical switch addresses this problem by quickly reconfiguring the topology.

8 Related Work

Optimizing DNN training. To address the increasing computation and network bandwidth requirements of large training jobs, a plethora of frameworks have been proposed [5, 46, 58, 69, 77, 79, 85, 86, 105, 108, 111, 117, 118, 123, 129, 136, 146]. These frameworks distribute the dataset and/or DNN model across accelerators while considering the available network bandwidth, but unlike TOPOOPT, they do not consider optimizing the *physical layer topology*. Specifically, Blink [136] builds collectives for distributed ML, but it needs a physical topology to generate spanning trees. Zhao et al. [147] study the optimal topology for collective communication operations, but this does not apply for general MP traffic. In addition, several methods have been proposed to quantize and compress the gradients to reduce the amount of communication data across servers [48, 56, 144]. While these approaches are effective, they are designed for data parallel strategies and do not consider the large amount of data transfers caused by model parallel training. Wang et al. [138] compare the performance of Fat-trees and BCube topologies for distributed training workloads and highlight several inefficiencies in Fat-trees. SiP-ML [89] demonstrates the benefits of 8 Tbps silicon photonics-based networks for distributed training. However, unlike TOPOOPT, these proposed approaches do not *co-optimize* topology and parallelization strategy.

DNN parallelization strategies. Data and model parallelism are widely used by today’s DNN frameworks (e.g., TensorFlow [44], PyTorch [42], MXNet [17]) to parallelize training across multiple devices. Recent work has also proposed *automated frameworks* (e.g., FlexFlow [85], ColocRL [101], MERLIN [38]) that find efficient parallelization strategies by searching over a comprehensive space of potential strategies. These frameworks rely on and are optimized for the conventional Fat-tree interconnects. TOPOOPT proposes a new approach to building DNN training systems by jointly optimizing network topology and parallelization strategy.

DNN training infrastructures and schedulers. Several

training infrastructures have been proposed recently, including NVIDIA DGX SuperPOD [10], TPU cluster [9], and supercomputers [1]. All these systems assume non-reconfigurable network topologies, such as Fat-tree, Torus, and other traffic-oblivious interconnects. TOPOOPT is the first DNN system to use commodity reconfigurable interconnects to accelerate DNN jobs. Gandiva [140], Themis [98], Tiresias [70], BytePS [86, 111], and Pollux [115] seek to improve the utilization of GPU clusters through scheduling algorithms. These approaches are complementary to ours, and many of their techniques can be applied to a TOPOOPT cluster.

Optical Interconnects. Several papers have demonstrated the benefits of optically reconfigurable interconnects for datacenters [51, 53, 57, 60, 64, 68, 95–97, 99, 100, 113]. These designs lead to sub-optimal topologies for distributed DNN traffic. Similarly, *traffic oblivious* interconnects, such as RotorNet [99, 100], are a great fit for datacenter workloads, but they are not suitable for DNN training jobs characterized by repetitive traffic demands. Hybrid electrical/optical datacenter proposals [64, 137] can be used to route AllReduce traffic through the optical fabric and MP flows through a standard electrical Fat-tree network. But hybrid clusters are not cost effective and suffer from many problems, including TCP ramp-up inefficiencies [103], segregated routing issues [65], and uncertainty in terms of how to divide the cluster between electrical and optical fabrics [68, 72].

9 Conclusion

We present TOPOOPT, a novel system based on optical devices that jointly optimizes DNN parallelization strategy and topology to accelerate training jobs. We design an alternating optimization algorithm to explore the large space of *Computation* \times *Communication* \times *Topology* strategies for a DNN workload, and demonstrate TOPOOPT obtains up to 3.4 \times faster training iteration time than Fat-tree.

A Tree-AllReduce and Other AllReduce Permutations

Section 2 established that we can manipulate the traffic of a ring-AllReduce collective by permuting the labeling of servers in the AllReduce group. Here, we illustrate how to use the same technique on another AllReduce algorithm, called tree-AllReduce.

In the tree-AllReduce algorithm, the servers are connected logically to form a tree topology. The AllReduce operation starts by running a reduce operation to the root node with recursive halving, followed by a broadcast to the rest of the cluster with recursive doubling [132].

A common instantiation of tree-AllReduce is the double binary tree (DBT) algorithm [120]. In this algorithm, the first step is to create a balanced binary tree for the nodes. The properties of balanced binary trees guarantee that one half of the nodes will be leaf-nodes, and the other half will be in-tree; thus, a second binary tree is constructed by flipping the labeling of the leaf and in-tree nodes. This way, each node (except the root in both trees) has the same communication requirements for the AllReduce operation, as described in the last paragraph, and bandwidth-optimally is achieved. Figure 23a shows an example where in the first binary tree, the in-tree nodes are even, and the leaf nodes are odd, while the second tree flips the labeling.

The DBT itself is essentially an example of permuting the node labeling to achieve an AllReduce operation with balanced communication load. We also note that we can permute the labeling *for the entire set of nodes* for a pair of DBTs to create a new pair of trees that can perform the AllReduce operation at the same speed. Figures 23b and 23c illustrate two other possible double binary trees, and their corresponding traffic demand matrix for the DLRM and CANDLE example shown in Figures 22 and 24 (§2). Arbitrary permutations can be used, and to limit the cases, we could simply consider the cyclic permutations in the modular space as described in TotientPerms.

In general, all AllReduce operations can be described as a directed graph $G = (V, E)$ where V is the set of nodes in the cluster, and E denotes data dependencies. The *permutable* property says every graph $G' = (V, E')$ that is isomorphic to G can perform the AllReduce operation equally well, where the homomorphism between G and G' is described by the symmetric group on V (generally denoted by $Sym(V)$ in group theory).

B Commercially Available Patch Panels and Optical Circuit Switches

Optical patch panels. A patch panel is a device to facilitate connecting different parts of a system. For instance, electrical patch panels are used in recording studios and concert sound

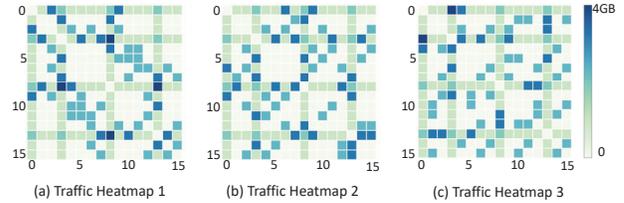

Figure 22: DLRM traffic heatmaps with double binary tree AllReduce.

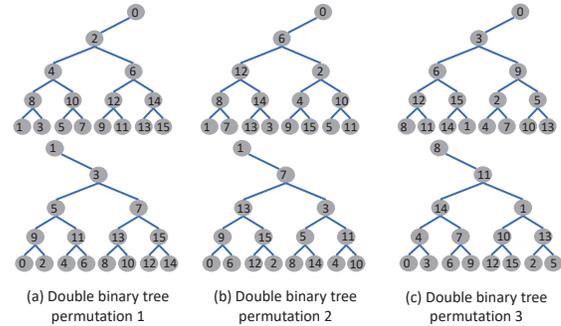

Figure 23: Double binary tree (DBT) permutations.

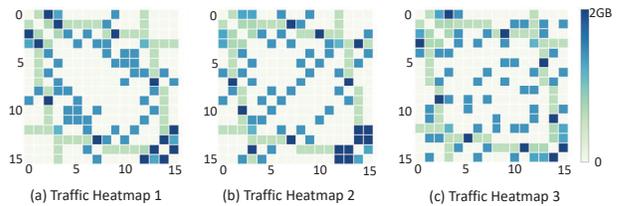

Figure 24: CANDLE traffic heatmaps with double binary tree AllReduce.

systems to connect microphones and electronic instruments on demand [40]. Fiber optic patch panels are commonly used for cable management, and have been proposed in recent datacenter topology designs [145]. Reconfigurable optical patch panels are a new class of software-controlled patch panels and are already commercialized at scale [119]. For instance, Telescent offers 1008 duplex ports with insertion loss less than 0.5 dB and cost $\approx \$100K$ ($\$100/\text{port}$) [88, 119]. Reconfiguration is performed using a robotic arm that grabs a fiber on the transmit side and connects it to a fiber on the receive side [88]. However, the reconfiguration latency of optical patch panels is several minutes [43]. Note that reliability is of utmost concern for operation in unmanned locations; for example, Telescent NTM patch panels have been certified to NEBS Level 3 and have over 1 billion port hours in operation [31].

3D MEMS-based Optical Circuit Switches (OCSs). An OCS uses tiny mirrors to change the direction of light, thereby

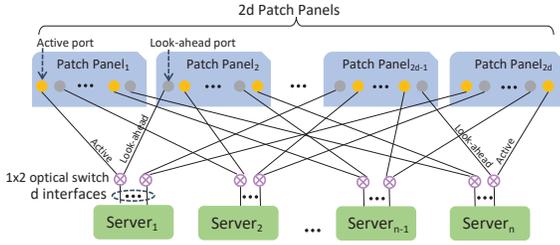

Figure 25: Active & Look-ahead ports for high reconfiguration latency.

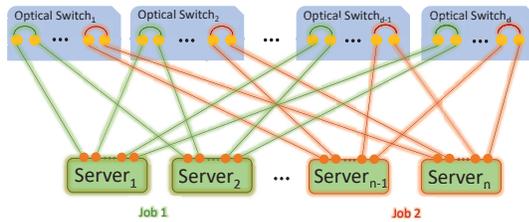

Figure 26: Sharding TOPOOPT cluster for two jobs.

reconfiguring optical links. The largest optical circuit switch on the market has 384 duplex ports with ≈ 10 ms reconfiguration latency and is available for \$200K (\$520/port) [41]. However, the optical loss of these switches is 1.5–2.7 dB [2]. Compared to patch panels, OCSs have the following disadvantages: (i) each port is five times more expensive; (ii) their insertion loss is higher; and (iii) their port-count is three times lower. The main advantage of OCSs is that their reconfiguration latency is *four orders of magnitude* faster than patch panels.

C Handling Sharding and Dynamic Job Arrivals in Shared Clusters

Section 3 explained how TOPOOPT can support multiple job sharing the cluster through sharding; here we provide a detailed explanation of how sharding works. Figure 26 shows how a TOPOOPT cluster is sharded to train two jobs together. In this scenario, the optical switches are configured in a way such that the green part (Server 1, 2 and their corresponding links) is completely disjoint from the red part (Server $n - 1$, server n). The complete isolation ensures each job gets its dedicated resources, and benefits the performance (especially the tail latency) as shown in Section 5.6.

To start a job with k servers, we need to reconfigure the interconnection between these k servers before the job starts. This can be done quickly when OCSs are used, but when patch panels are used, there could be several minutes of delay before the job can start. To address this challenge, we use a look-ahead approach to pre-provision the next topology while

current jobs are running. More specifically, we use a simple 1×2 mechanical optical switch [112] at each server’s interface to choose between *Active* and *Look-ahead* ports. These 1×2 switches are inexpensive (\$25) and have 0.73 dB optical loss measured in our prototype. Unlike optical splitters [14], that incur 3 dB loss, these switches choose where to send light between their two output ports. We then connect the two ends of each 1×2 switch to different patch panels, as shown in Figure 25. As a result, a TOPOOPT cluster with n servers, each with d interfaces, has $2d$ patch panels where each interface is split into two parts: *Active* and *Look-ahead*. At any point in time, only one end of each 1×2 switch is participating in the active topology; the other end is pre-provisioning the topology for the next job. Since the topology and parallelization strategy are calculated off-line, we already know the sequence of job arrivals and the number of servers required by each job. This design allows each server to participate in two independent topologies. Hence, when a set of servers uses one topology for a training job, TOPOOPT pre-provisions the next topology, optimized for the next task by reconfiguring Look-ahead ports. Once all the servers for the new job are ready, TOPOOPT immediately *flips* to the new topology by reconfiguring the corresponding 1×2 switches.

D Model Configurations and Transfer Sizes

List 1 summarizes the parameters we used in our simulation and testbed. Model parameters and batch sizes are selected based on common values used in Meta for simulations. For the prototype, we reduce parameter values and batch sizes to fit the models in our 12-node cluster.

In most workloads observed in Meta, the size of AllReduce transfers is larger than the size of MP transfers for each iteration, because in most cases, it would not be worthwhile if MP transfers were as large as AllReduce transfers. Consider the DLRM example in Section 4.3 with 20 GB embedding tables with double-precision floating parameters. If we were to distribute this embedding table using data parallelism, each server would need to send and receive 37.5 GB of data for the AllReduce operation. On a 100 Gbps fabric, this would take 3 seconds by itself, but if we put it on one server, it would only need to transfer 32 MB/server (assume we have a per-server batch size of 8192; then, MP traffic is calculated as $16 \text{ servers} \times 8192 \text{ samples/server} \times 512 \text{ activation per sample} \times 8 \text{ bytes per activation} / 16 \text{ servers} = 32 \text{ MB}$). We note that adding *pipeline parallelism* can increase the amount of MP traffic as it overlaps forward and backward passes. Efficient ways to pipeline batches remains an active research area [77, 105] especially when hybrid parallelism is employed. Pure model parallelism creates another type of sparse traffic pattern where only accelerators with inter-layer dependencies need to communicate. Our TOPOLOGYFINDER algorithm can support such communication patterns.

Conceptually, however, when the network bandwidth goes

to infinity, other overheads in the system (e.g. CUDA kernel launch) will dominate the latency. In such cases, it might be beneficial to choose model parallelism instead of data parallelism, to reduce the amount of system overheads. In particular, prior work shows 10 Tbps Silicon Photonics links enable more aggressive model parallelism where the size of MP traffic is significant [89]. TOPOOPT's approach to distribute the degree between the MP and AllReduce sub-topologies enables us to accommodate this case as well.

E Algorithm Details

E.1 TOPOLOGYFINDER

Using group theory to find AllReduce permutations. For a ring-AllReduce group with n servers labeled S_0, \dots, S_{n-1} , a straightforward permutation is $(S_0 \rightarrow S_1 \rightarrow S_2 \dots \rightarrow S_{n-1} \rightarrow S_0)$. We denote this permutation by a ring generation rule as: $S_i \rightarrow S_{(i+1) \bmod n}$. Since the servers form a ring, the index of the starting server does not matter. For instance, these

two rings are equivalent: $(S_0 \rightarrow S_1 \rightarrow S_2 \rightarrow S_3 \rightarrow S_0)$ and $(S_1 \rightarrow S_2 \rightarrow S_3 \rightarrow S_0 \rightarrow S_1)$.³

We first provide the mathematical foundation of the ring permutation rule.

Theorem 2 (Ring Generation). *For a cluster of n nodes $V = \{S_0, S_1, \dots, S_{n-1}\}$, all integer numbers $p < n$, where p is coprime with n (i.e. $\gcd(p, n) = 1$) represent a unique ring-AllReduce permutation rule.*

Proof. Consider the integer modulo n group with addition $\mathbb{Z}_n^+ = \{0, 1, \dots, (n-1)\}$. \mathbb{Z}_n^+ is a cyclic group. By the fundamental theorem of cyclic groups, p is a generator of \mathbb{Z}_n^+ if and only if $\gcd(p, n) = 1$. Hence we can cover the entire \mathbb{Z}_n^+ by repeatedly adding p to itself.

Now consider the graph $G_{\mathbb{Z}_n^+, p} = (V_{\mathbb{Z}_n^+, p}, E_p)$ where the set of vertices $V_{\mathbb{Z}_n^+, p} = \mathbb{Z}_n^+$ and $E_p = \{(a \times p, (a+1) \times p) \in V_{\mathbb{Z}_n^+, p}^2, a \in \mathbb{Z}_n^+\}$. The set E_p forms a cycle on $G_{\mathbb{Z}_n^+, p}$. Now denote our cluster as $G = (V, E)$ where V is defined as above and E represents a set of directed links. Then $G_{\mathbb{Z}_n^+, p}$ is isomorphic to G , hence following the rule in E_p we can define a valid ring in G . Furthermore, since $\forall p_i \neq p_j$ we can guarantee that $(0, p_i) \in E_{p_i}$ and $(0, p_j) \notin E_{p_i}$, and each p_i is guaranteed to describe a unique ring. \square

One way to extend our approach to other AllReduce algorithms is to generalize TotientPerms (Algorithm 2) so that the E_p described in theorem 2 simply represents a *permutation* which we apply to the original node labeling, while keeping the edge relation, to create an isomorphic graph that describes the new AllReduce topology.

E.2 Bounding maximum hop count with TotientPerms

In this section, we argue that fitting a geometric sequence for choosing permutation provides an approximately $O(d \sqrt[d]{n})$ bound for the maximum diameter of a cluster with n nodes and degree d . Denote $x \equiv \sqrt[d]{n}$. We simplify the question to the following: given a contiguous set of numbers $\mathcal{N} = \{1, \dots, n\}$ and a set of numbers from the geometric sequence $S = \{x^0, x^1, \dots, x^{d-1}\}$, choose h numbers (allow repetition) s_1, \dots, s_h from S so that $m = \sum_{i=1}^h s_i$ for some $m \in \mathcal{N}$. Let $h = \kappa(m)$, find $\min_{m \in \mathcal{N}} \kappa(m)$.

Again for simplicity, assume $x \in \mathbb{Z}$. Then for a given $m \in \mathcal{N}$, we get the recursive relation $\kappa(m) = 1 + \kappa(m - x^i)$ where $i = \operatorname{argmax}_{i \leq d, x^i \leq m}$. $m = N - 1$ gives the maximum $\kappa(N - 1) = dx$.

The problem above is simpler than the one in TOPOOPT. In TOPOOPT, x is rarely an integer, and S is a projection of the geometric sequence $S = \{x^0, x^1, \dots, x^{d-1}\}$ onto the

³Given that ring-AllReduce is the dominant AllReduce collective, we describe our algorithms based on ring-AllReduce. Appendix E.1 explains how to extend our algorithm to other AllReduce communication collectives.

Algorithm 4 CoinChangeMod pseudocode

```
1: procedure COINCHANGEMOD( $n, G$ )
  ▷ Input  $n$ : Total number of nodes
  ▷ Input  $G$ : Network Topology
  ▷ Output  $R$ : Routings
  ▷  $R$  is the routing result
2:    $R = \{\}$ 
  ▷ Acquire the set of "coins" from the topology,
  ▷ which are the choices of Algorithm 3
3:    $C = \text{GetCoins}(G)$ 
4:   for  $i \in [1, N - 1]$  do
  ▷  $\text{curr\_dist}$  denotes the "distance" of a value
  ▷ (node distance) counted by number of "coins"
5:      $\text{curr\_dist}[i] = \infty$ 
  ▷  $\text{curr\_bt}$  record a back-trace of "coins" to
  ▷ get to a value (node distance)
6:      $\text{curr\_bt}[i] = \infty$ 
7:     for  $c \in C$  do
8:        $\text{curr\_dist}[c] = 0$ 
9:        $\text{curr\_bt}[c] = c$ 
10:    while  $\text{curr\_dist}$  has at least one  $\infty$  in it do
11:      for  $i \in [1, N - 1]$  do
12:         $\text{new\_dist}[i] = \text{curr\_dist}[i]$ 
13:         $\text{new\_bt}[i] = \text{curr\_bt}[i]$ 
14:        for  $c \in C$  do
15:          if  $\text{curr\_dist}[(i - c) \bmod N] < \text{new\_dist}[i]$  then
16:             $\text{new\_dist}[i] = \text{curr\_dist}[(i - c) \bmod N] + 1$ 
17:             $\text{new\_bt}[i] = c$ 
18:         $\text{curr\_dist} = \text{new\_dist}$ 
19:         $\text{curr\_bt} = \text{new\_bt}$ 
  ▷ Construct the routing for each node distance from the back-trace
20:    $R = \text{GetRouteSeq}(\text{curr\_bt})$ 
21:   return  $R$ 
```

candidates (co-prime numbers with the size of a subset of node participating in AllReduce). The intuition still holds.

Note that when $\sqrt[d]{n} < 2$, it is advantageous to choose $x = 2$ and spend less degree to create a geometric sequence with a ratio of at least 2. In this case, the d factor becomes the actually used degree $d = \log_2 n$, and the bound holds at $O(\log_2 n)$.

E.3 Coin Change Routing

Consider servers S_i and S_j that need to exchange AllReduce transfers but do not have a direct edge between them. We use a modified version of the classical coin change problem [52] to find an efficient routing path (line 19). In classical coin change, the goal is to find the minimum number of *coins* that would sum to a certain *total value*. Our ring generation rules enable us to treat the routing problem similarly. In particular, the p values of AllReduce permutations that have been selected in the AllReduce sub-topology are the coin values, and the difference between server i and j indices $((j - i) \bmod n)$ is the target total value that we want to achieve. The only difference is that our problem runs with *modulo* n arithmetic, as the server IDs wrap around in the ring structure. Algorithm 4 lists the pseudocode of CoinChangeMod.

E.4 OCS-reconfig Heuristic

Algorithm 5 describes the heuristic we use for OCS-reconfig. As mentioned in Section 4, our goals are (i) to have enough bandwidth for large transfer demands, (ii) while also minimizing the latency of indirect routing for nodes that do not have a direct link between them.

To achieve this goal in a reconfigurable interconnect, we propose a utility function that finds a balance between the two goals by maximizing the number of parallel links between high demand nodes but with a *diminishing return*. More formally, assume a network topology is represented by graph $G = (V, E)$ and each node has degree d . We define $L(i, j)$ to be the number of parallel links between node-pair (i, j) . Let $T(i, j)$ be the amount of unsatisfied traffic demand. We define a topology G 's utility function as follows:

$$\text{Utility}(G) = \sum_{\{i,j\} \in E} T(i, j) \times \text{Discount}(L(i, j)) \quad (1)$$

The *Discount* function can be defined in different ways; in Algorithm 5 and Algorithm 1's MP construction, we use

$$\text{Discount}(l) = \sum_{x=1}^l 2^{-x} \quad (2)$$

to reduce the utility of additional links exponentially. We can also explore other discount scaling, such as linear or factorial functions.

When the fabric is reconfigurable (as in OCS-reconfig), we collect the unsatisfied traffic demand every 50 ms and run Algorithm 5 to decide the new network topology. After the new topology is computed, we pause all the flows for 10 ms representing the reconfiguration delay of the OCS, apply the new topology, and then resume the flows with one or more corresponding physical links across the flow source and destination. The two-edge replacement algorithm from OWAN [87] in line 21 ensures the topology is connected, when we enable host-based forwarding.

F Modifications to SiP-ML

Since SiP-ML's SiP-Ring proposal is based on a physical ring topology, its reconfiguration algorithm has several constraints on wavelength allocation for adjacent nodes. Given that TOPOOPT's physical topology is not a ring, directly applying SiP-Ring's optimization using the original C++ code causes SiP-ML to perform extremely poorly in our setup. To give SiP-ML a leg up, we observe that its formulation tries to optimize a utility function very similar to Equation 1 without the *Discount* part (i.e. $\text{Discount} = 1$), but with an integer liner program (ILP). While an ILP gives the optimal solution, its runtime makes it prohibitive for the amount of simulation parameters we explore. Therefore, we substitute the ILP

Algorithm 5 OCS-reconfig pseudocode

```
1: procedure OCS-RECONFIG( $V, T, d, L$ )
  ▷ Input  $V$ : Nodes in the network
  ▷ Input  $T$ : Unsatisfied traffic demand matrix
  ▷ Input  $d$ : Node degree limit
  ▷ Input  $L$ : Number of links between ordered node-pair, initially zero
  ▷ Output  $E$ : Allocated links, initially empty
    ▷ Initially,  $E$  is empty
2:  $E = \{\}$ 
    ▷ Initially, each node has  $d$  available tx and rx interfaces
3: for  $v \in V$  do
4:    $available_{tx}[v] = d$ 
5:    $available_{rx}[v] = d$ 
    ▷ Create new links according to the demand list
6: while  $\exists i, j < |V| : i \neq j, available_{tx}[v_i] > 0, available_{rx}[v_j] > 0$  do
    ▷ allocate a direct connection for the highest demand pair
7:    $(v_1, v_2) = \text{node-pair with highest demand in } T$ 
8:    $e = \text{NewLink}(v_1, v_2)$ 
9:    $E = E \cup \{e\}$ 
    ▷ Increment the number of parallel links from  $v_1$  to  $v_2$ 
10:   $L(v_1, v_2) += 1$ 
    ▷ Scale the demand down by the number of links
11:   $T(v_1, v_2) \times = 1/2$ 
    ▷ Update available interfaces
12:  for  $v \in (v_1, v_2)$  do
13:     $available_{tx}[v] -= 1$ 
14:     $available_{rx}[v] -= 1$ 
    ▷ Stop considering nodes with zero available interfaces
15:  if  $available_{tx}[v_1] == 0$  then
16:    for  $u \in V$  do
17:      Remove  $(v_1, u)$ 's entry from  $T$ 
18:  if  $available_{rx}[v_2] == 0$  then
19:    for  $u \in V$  do
20:      Remove  $(u, v_2)$ 's entry from  $T$ 
    ▷ Ensure the network graph is connected
21:  2-EdgeReplacement( $E, T$ )
    ▷ Update route for host-based forwarding
22:  UpdateRoute( $E$ )
23: return  $E$ 
```

with Algorithm 5 with $Discount = 1$, a heuristic that tries to achieve a similar goal.

Note that the SiP-ML paper has another design called SiP-OCS, which is similar architecturally to TOPOOPT. In the paper, SiP-OCS is proposed as a one-shot reconfiguration approach due to the long reconfiguration latency of 3D-MEMS based OCSs.

G Cost of Network Components

Table 2 lists the cost of network components we use in Section 5.2, namely NICs, transceivers, fibers, electrical switches, patch panels, and optical switches. The cost of transceivers, NICs, and electrical switch ports is based on the lowest available prices in official retailer websites [18, 28]. Note that for 200 Gbps, we use more 100 Gbps ports and fibers, because they were less expensive than high-end 200 Gbps and 400 Gbps components, or their price was not available. To estimate the cost of electrical switch ports, we consider Edgecore

⁴200 G transceivers and switch ports are estimated as $2 \times 100\text{G}$ cost.

Link bandwidth	Transceiver (\$)	NIC (\$)	Electrical switch port (\$)	Patch panel port (\$)	OCS port (\$)	1×2 switch (\$)
10 Gbps	20 [13]	185 [32]	94 [21]	100 [43]	520 [41]	25 [112]
25 Gbps	39 [15]	185 [32]	144 [23]	100 [43]	520 [41]	25 [112]
40 Gbps	39 [16]	354 [33]	144 [22]	100 [43]	520 [41]	25 [112]
100 Gbps	99 [12]	678 [34]	187 [24]	100 [43]	520 [41]	25 [112]
200 Gbps ⁴	198 [12]	815 [35]	374 [24]	100 [43]	520 [41]	25 [112]

Table 2: Cost of network components.

bare metal switches with L3 switching and maximum number of ports to amortize the per port cost. The cost of NICs is taken from the Mellanox ConnectX series, and we consider two 2-port NICs as one 4-port NIC. We obtain the cost of the patch panel, OCS, and 1×2 optical switch directly from their suppliers, Telescent [43] and Polatis [41] (with 40% discount). The cost of transceivers matches that reported in Sirius [53].

To compute the network cost of Fat-tree and Ideal Switch, we consider number of nodes in a full bisection bandwidth Fat-tree. For example, a standard $k = 8$ Fat-tree has 80 switches with 64 ports, or 640 switch ports in total, in addition to 1 NIC per host and one transceiver per NIC and switch port. A TOPOOPT system of 128 nodes with degree d uses $128 \times d$ NICs and transceivers, but $128 \times 2 \times d$ patch panel ports because of the look-ahead design. Note that the cost of optical components stays constant as link bandwidth increases, an inherent advantage of optics. Following prior work, we estimate the cost of fiber optics cables as 30 cents per meter [68] and select each fiber's length from a uniform distribution between 0 and 1000 meters [148]. We calculate the cost of TOPOOPT based on $2d$ patch panels and 1×2 switches at each link to support its look-ahead design (§C). OCS-reconfig's cost is based on d OCSs connected to all servers in a flat topology.

H Impact of Server Degree on TOPOOPT's Performance

Figure 27 shows the same setting as Figure 11 except that each server has a degree of eight ($d = 8$). The results show a similar trend: even though per server bandwidth has increased, the behavior of different network architectures remains consistent.

Next we do a sensitivity analysis of impact of server degree d on TOPOOPT's performance. Specifically, we vary the degree of each server in TOPOOPT for two link bandwidths: 40 Gbps and 100 Gbps. Figure 28 shows the trend for different DNN models. Both DLRM and CANDLE are network-heavy; therefore, they benefit more from the additional bandwidth obtained by increasing d . CANDLE's improvement is almost linear as degree goes up, as the strategy is closer to data parallel and the amount of bandwidth available to AllReduce operation increases linearly as well. In the case of DLRM, we observe a super-linear scaling when $B = 100$ Gbp because DLRM has one-to-many and many-to-one

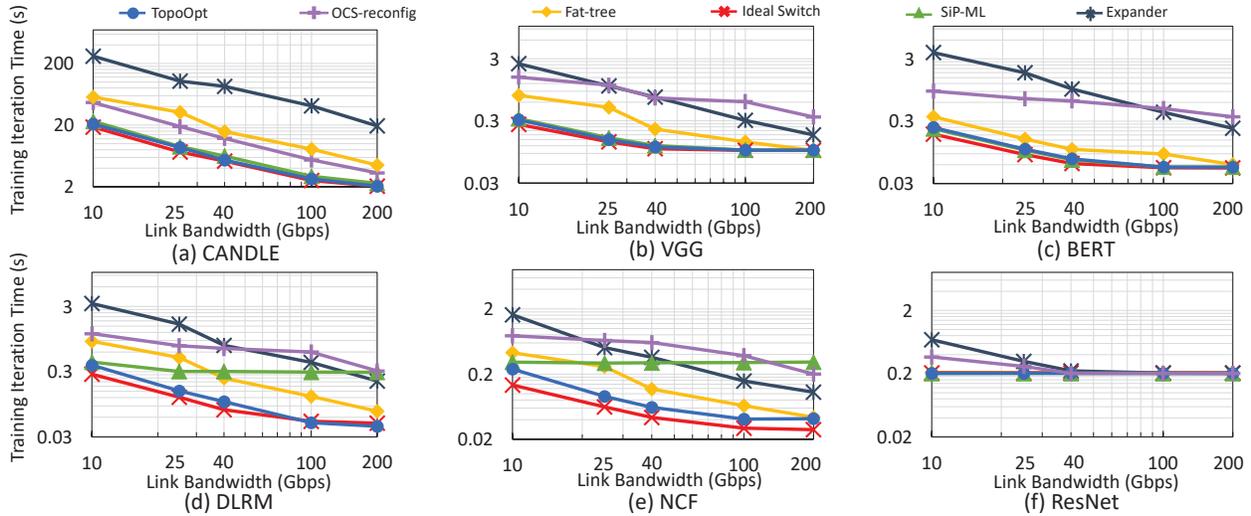

Figure 27: Dedicated cluster of 128 servers ($d = 8$).

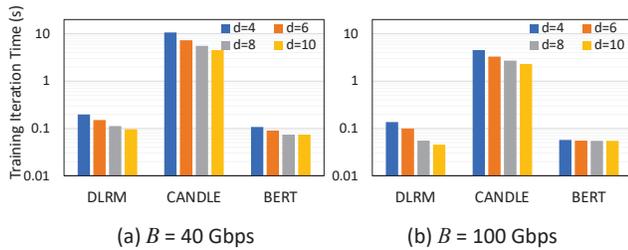

Figure 28: Impact of server degree (d) on performance.

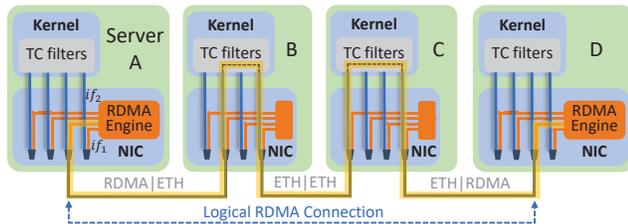

Figure 29: Host-based RDMA forwarding to create a logical RDMA connection between end hosts.

MP transfers which require a low hop count in the topology. As we increase d , TOPOLOGYFINDER is able to find network topologies with much lower diameter, consequently benefiting the performance by both increasing bandwidth and reducing hop-count for MP transfers. Finally, BERT is mostly compute bound at higher bandwidth; hence, increasing the server degree and bandwidth per node has marginal impact on its iteration time.

I Enabling Host-based Forwarding in RDMA

To support a multihop TOPOOPT interconnect using host-based forwarding, we enable RDMA RoCEv2 forwarding on

all our HP NICs. RoCEv2 is an implementation of RDMA on top of UDP/IP protocol, by utilizing a particular UDP port (4791) and encapsulating an InfiniBand (IB) data packet. Hence, each RoCEv2 packet can be routed with its source and destination IP addresses. However, host-based forwarding is challenging in RDMA protocol, as the packet processing and memory access are offloaded to the NIC, and the host does not have access to individual packets. More precisely, if a packet's IP destination IP address does not match the NIC's IP address, the RDMA engine silently drops the packet.

To address this issue, we collaborated with engineers from Marvell, the provider of the firmware and driver for our HP NICs. The solution that came out of our collaboration does not require proprietary software or firmware, and is applicable to commodity NICs with the same ASIC. We will release our scripts publicly. At a high-level, we use a feature called *NPAR*, or *network partitioning*. It allows us to split each 25 Gbps physical interface into two *logical interfaces* in the hardware level: if_1 and if_2 , as shown in the right-most port of server A in Figure 29. if_1 is a normal RDMA interface, where the RDMA engine of the NIC bypasses the kernel, and it has an IP address. This enables the upper layer software to consider if_1 as a normal RDMA interface. However, if_2 does not have an IP address and RDMA is disabled. if_2 has a different MAC address from if_1 , and we use this address to split the traffic across if_1 and if_2 . The traffic that needs to be forwarded uses the MAC address of if_2 and hence is delivered to the host networking stack instead of NIC's RDMA engine.

Furthermore, we establish a set of `iproute`, `arp`, and `tc flower` rules in Linux to enable the proper forwarding of packets. If two servers are directly connected, such as the third port of server A and the second port of Server B in Figure 29, we only need to indicate the outgoing interface

on each of these servers. RDMA engines will handle the communication. However, for the connection between server A and D, we set the `iproute` and `arp` tables on server A and server D to dictate which port the traffic should go out, as well as the proper MAC address of the next server in the forwarding chain. In this case, the packets are delivered to the kernel. Then, on servers B and C, we set the `tc flower` rules to forward the packets to the next server with the proper MAC address. In these `tc flower` rules, we look-up the final destination IP and assert the routing that was computed by our algorithm.

Walk-through of an example of a packet going from server A to server D. In Figure 29, the RDMA engine of server A assumes server D is connected on the third port. It uses the kernel's routing tables for the destination MAC address, which is set to the MAC address of if_2 of the second port on server B. Therefore, a packet which starts as an RDMA packet of server A is treated as an Ethernet packet when it arrives at server B, and goes to server B's kernel. In the kernel, based on the packet's final destination IP of server D, server B redirects the packet to the fourth port, with destination MAC

address set to if_2 of server C. In this connection, the packet is treated as a normal Ethernet packet. Finally, on server C, the kernel rewrites the destination MAC address to that of if_1 on the third port of server D, and redirects it to that port. In this connection, the outgoing Ethernet packet is considered an RDMA packet because of the destination MAC address. For the reverse connection from server D to A, the same process happens in reverse, to support a bidirectional connection.

With these forwarding rules, we construct logical RDMA connections between all pairs of servers. Upper layer communication libraries such as NCCL requires all-to-all connectivity, and they will utilize these connections. We also modify NCCL to be topology-aware, as certain pairs of servers are only connected through specific ports.

Compared to native point-to-point RDMA, this approach takes a performance penalty. Our experiments indicate the overhead is negligible when the amount of forwarded traffic is small. Our NICs currently support TCP forwarding offload. With firmware and driver modifications or future versions of the NICs, they will also support RDMA forwarding offload. This will further reduce the overhead of our approach.

ModelKeeper: Accelerating DNN Training via Automated Training Warmup

Fan Lai, Yinwei Dai, Harsha V. Madhyastha, Mosharaf Chowdhury

University of Michigan

Abstract

With growing deployment of machine learning (ML) models, ML developers are training or re-training increasingly more deep neural networks (DNNs). They do so to find the most suitable model that meets their accuracy requirement while satisfying the resource and timeliness constraints of the target environment. In large shared clusters, the growing number of neural architecture search (NAS) and training jobs often result in models sharing architectural similarities with others from the same or a different ML developer. However, existing solutions do not provide a systematic mechanism to identify and leverage such similarities.

We present ModelKeeper, the first automated training warmup system that accelerates DNN training by repurposing previously-trained models in a shared cluster. Our key insight is that initializing a training job’s model by transforming an already-trained model’s weights can jump-start it and reduce the total amount of training needed. However, models submitted over time can differ in their architectures and accuracy. Given a new model to train, ModelKeeper scalably identifies its architectural similarity with previously trained models, selects a parent model with high similarity and good model accuracy, and performs structure-aware transformation of weights to preserve maximal information from the parent model during the warmup of new model weights. Our evaluations across thousands of CV and NLP models show that ModelKeeper achieves $1.3\times$ – $4.3\times$ faster training completion with little overhead and no reduction in model accuracy.

1 Introduction

Modern machine learning (ML) clusters train thousands of deep neural networks (DNNs) every day [37, 67]. For a specific ML task, ML developers often start with exploring various model architectures using Neural Architecture Search (NAS) to find the one with desired accuracy [77]. In preparation for model serving, developers may train tens of models to customize the latency-accuracy trade-off across hardware [21, 35], to organize weak and powerful DNNs into different inference stages for fast feature extraction [20], and/or to dynamically select tens of models and combine their predictions to maximize ensemble accuracy [26, 30, 65]. Overall, from inception to deployment, ML development often requires training hundreds of models across developers [62, 75].

Naturally, many recent advances in ML training optimizations have focused on faster DNN execution, e.g., by increasing parallelism [50, 70], improving communication [40, 55], or increasing GPU utilization [28, 68, 69, 73]. However, little has been done to exploit the natural similarity between models that are trained as part of the same NAS process, models targeting the same ML task in different hardware, or models embedded in different applications. Indeed, our analysis of three large CV and NLP model zoos shows that more than 60% of widely-used models can find an architecturally similar counterpart within the same zoo (§2.2).

In this paper, our key insight is that *one can reduce the amount of training needed for model convergence by leveraging a well-trained model’s weights to warm up the training of a new model*. This is because any DNN model is fundamentally a computation graph of tensor weights and operators; transforming weights of trained models with similar architectures to a new model can accelerate model convergence (similar to transfer learning [60, 71] but across architectures).

Despite the potential for large benefits, there exists little systematic support for automated repurposing of weights. Today’s frameworks may provide pre-trained models, but are limited to a few models and specific datasets, and/or require domain knowledge to manually search, transfer and contribute a trained model’s weights [6]. As such, ML developers have to train models from scratch more often [56]. A few recent AutoML frameworks (e.g., Retiarii [77]) repurpose trained models. However, they are limited to individual jobs within a NAS task because they rely on the lineage of model mutation to enable the transfer. When models are submitted by various developers and/or frameworks with distinct architectures and performance requirements, these solutions do not apply.

We introduce ModelKeeper, a cluster-wide training warmup system, to reduce the training execution needed for model convergence via automated model weight transformation (§3). ModelKeeper adaptively manages a collection of trained models (i.e., *model zoo*) from prior training jobs corresponding to different ML tasks. For a new training job, ModelKeeper selects and transforms a trained model’s weights (i.e., *parent model*) to the training model (i.e., *query model*) before training takes place. It can benefit various ML applications, including exploratory training (e.g., improving Retiarii [77] further) and general training (e.g., using PyTorch [9]) of CV/NLP models, with few-lines-of-code change.

ModelKeeper addresses two primary challenges toward selecting a suitable parent model and repurposing its weights. First, ModelKeeper must determine similarity between two models (§4.1). Intuitively, we can treat each DNN model as a directed graph, where nodes represent tensors (layers) and edges represent data flows, and use heuristics for the classic NP-hard graph edit distance problem [31] to find the matching similarity. However, maximizing matching by skipping nodes can be harmful because the computation of each tensor affects that of the subsequent ones in a trained parent model. To this end, we present a structure-aware dynamic programming approach to capture the similarity (transformable tensor weights) between two models. To scale to real-world zoos with thousands of models, we then introduce a two-stage hierarchical search algorithm to identify similar models efficiently.

Second, perfect matching is unlikely as two models are seldom identical. Therefore, given many candidate parent models with different similarity scores and each with different accuracy, which one to pick and then how to transform its weights to the query model (§4.2)? A more similar parent model enables transforming more weights, while a more accurate one implies a better training jump start after the transformation. When the two are at odds, we adopt a bucketing heuristic: potential parent models are put into different buckets in terms of their similarity to the query model, grouping comparable parent models together. We then pick the most accurate parent from the bucket containing the most similar parent models. Nevertheless, tensor mappings from the parent to the query model can be incomplete (e.g., due to non-identical architectures). To preserve maximal parent model information, we introduce width and depth operators to transform parent model weights into the query model with negligible overhead.

We have integrated ModelKeeper with four popular ML frameworks (§5): Ray [49], AutoKeras [41], MLFlow [75], and Microsoft NNI with Retarii backend [77].¹ Our evaluations across thousands of DNN training jobs in CV and NLP applications (§6) show that ModelKeeper can save 23%–77% total amount of training needed (i.e., 1.3×–4.3× faster training) than the state-of-the-art without model accuracy drop, while efficiently serving cluster-scale warmup requests.

Overall, we make the following contributions in this paper:

1. We present ModelKeeper, a system to enable automated training warmup for faster DNN training in clusters;
2. In order to maximize training speedup, we demonstrate how to scalably compute similarities between models and how to transform an already-trained model’s weights to a yet-to-be trained model with little overhead;
3. We integrate ModelKeeper with multiple advanced ML frameworks, and evaluate it across thousands of CV and NLP models to show large improvements.

¹ModelKeeper is available at <https://github.com/SymbioticLab/ModelKeeper>.

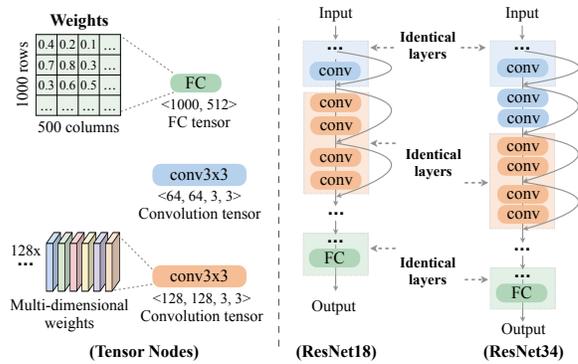

Figure 1: A DNN model is essentially a graph of tensors. Model outputs are determined by tensor weights and their control flow.

2 Background and Motivation

2.1 DNN Model Training

Modern DNN frameworks represent DNN computations as a directed computation graph with tens to thousands of nodes across branches (Figure 1) [9, 38]. Each node implies a mathematical tensor operation (e.g., matrix multiplication or convolution) along with its tensor weights and input, where weights are n-dimensional arrays typically consisting of floats. DNN training often covers thousands of iterations across mini-batches of data to minimize the training loss. In each iteration, the computation graph takes a data mini-batch as the input, and performs a (1) *forward pass*, where each node conducts the tensor operation on the output of parent nodes to get the training loss regarding the model output and ground truth; and a (2) *backward pass*, which updates the weight values, from the last to front tensors, using the gradients derived by the training loss with respect to the current weight. Therefore, the DNN model is essentially a graph of weights orchestrated by tensor operators, and training searches the best weight values.

2.2 Opportunities for Repurposing Models

In this paper, we focus on *reducing the amount of training needed* to train a new model by automatically repurposing the weights of previously trained models. Our approach of warming up the weights of a new model before its training starts is based on the following observations.

Pervasive model similarity. With the rapid increase in the number of ML training jobs in datacenters [28, 37], similarities between training jobs are increasing too [67]:

- First, for a specific ML task, ML developers often explore various model architectures using Neural Architecture Search (NAS) to find the preferred model architecture (e.g., better capacity-accuracy frontier [77]), or to investigate the performance consistency of new optimizations across models (e.g., ML ablation study) [48]. For example, Microsoft tuning clusters perform as many as 75 exploratory training jobs in median for user apps [46].
- Second, in preparation for ML deployment, developers can train dozens of models to either customize the latency-

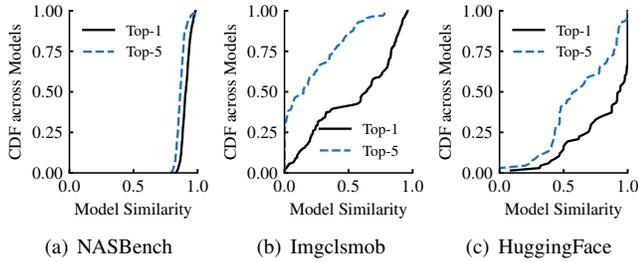

Figure 2: Pervasive model similarity in today's model zoos. We measure the top-1 and top-5 architectural similarities of each model to other models, and report the distribution across models. 1 indicates identical model architectures.

accuracy tradeoff across hardware (e.g., in video analysis systems [35, 39]), or to dynamically select tens of models and combine their predictions in order to maximize accuracy under changing loads in today's ensemble-serving systems [30, 65] (e.g., AWS Autogluon [26]).

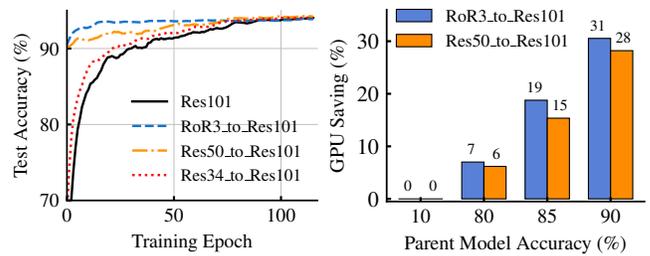

- Third, the potential for similar models increases with increasing users. For example, over 100K ML models are submitted to Kaggle competitions each month [3]. Each competition can have thousands of participants developing their models independently, and participants are reported to have trained many similar models [22].

Indeed, our analysis of three large public model zoos – Imgcsmob [10] for ImageNet classification (435 models), HuggingFace [2] for English text generation (2.5K models), and NASBench [24] for NAS task (16K models) – reinforces these observations. Figure 2 reports the pairwise architectural similarity across models in each model zoo. We measure the similarity of each model to other zoo models² in terms of the normalized graph edit distance of two directed model computation graphs [27] ($\in [0, 1]$), where 1 indicates identical graphs. We observe that more than 60% of the models have at least one other model (top-1) in the zoo with a similarity over 0.6. Pervasive similarity is prominent in all these model zoos because modern models often rely on similar architecture designs but with wider/deeper layers or branches. For example, convolution layers are widely-used in CV models [33, 36], while NLP models are often stacked by attention layers [63].

Similar models can warm-start training. Recent theoretical [60] and empirical [71] efforts from the transfer learning community show that inheriting well-trained parent model weights can speed up the training of a new model, because this warm start enables an informed weight initialization (e.g., training from the basin of loss curvature). Yet, different from their focus that manually transfers the same model across datasets for better model generalization accuracy [53, 78], we notice that transforming a trained model's weights to a new model (i.e., across architectures) can accelerate its training.

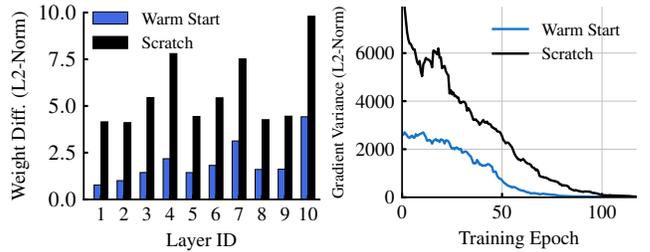

Consider the training of ResNet101 on CIFAR-10 dataset

²To avoid over-optimistic identification of model similarity, we removed identical models in each zoo and focus on different model architectures.

(a) Warm start accelerates training. (b) Parent model accuracy matters.

Figure 3: Transferring model weights from well-trained models with similar architectures can accelerate new model training.

(a) Smaller divergence to the optimal. (b) Smaller gradient variance.

Figure 4: Warm start provides better initial weights search space. We use RoR3 to warm start ResNet101.

as an example. We copy the tensor weights of a well-trained parent model (e.g., ResNet50 or RoR3 [76]) to the ResNet101 tensor if two tensors have identical properties (e.g., same operator and weight dimensions), while the rest of the training proceeds as normal. We notice that (1) warmup training can reduce the amount of training needed, while obtaining the same final accuracy to that of training from scratch with random weight initialization (Figure 3(a)); and (2) the savings are more encouraging when inheriting from more similar models – similarity of ResNet34, ResNet50, and RoR3 to ResNet101 is 0.19, 0.48, and 0.85, respectively – and better performing models (Figure 3(b)), which respectively determine whether it is possible and beneficial to transform the weights.

These improvements are because they speed up the search in the space of weight values. If we consider ResNet101 as an example, (1) warming it up using RoR3's weights before training starts results in a smaller distance to the final weights achieved when the model converges (Figure 4(a)), and (2) during the training, this informed weight initialization enables smaller gradient variance (i.e., more consistent gradient directions) towards the basin of loss curvature (Figure 4(b)), thus requiring fewer iterations to convergence in theory [12, 53].

3 ModelKeeper Overview

ModelKeeper is an automated training warmup system for various ML tasks that accelerates DNN training by warm-starting models with weights from already-trained models.

Design Space Large training clusters are shared between users with varying expertise, and they can train a large num-

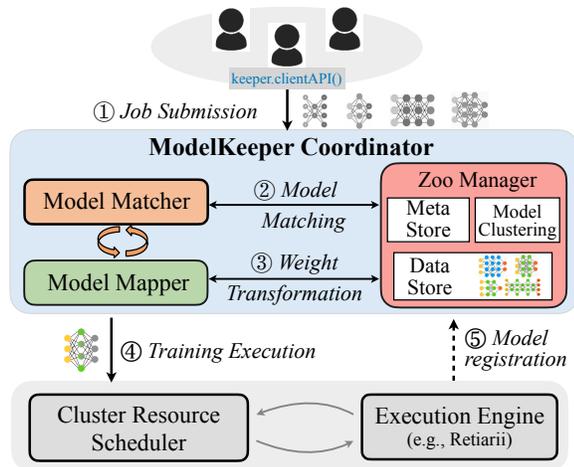

Figure 5: ModelKeeper architecture. It can run as a cluster-wide service to serve different users and/or frameworks.

ber of jobs with different model architectures. Consequently, ModelKeeper must minimize the information needed and overhead incurred for each training model (i.e., *query model*), while offering users the flexibility in their request (e.g., using ImageNet model zoo to warm start models on other image datasets). In fact, determining which dataset (model zoo) as the source to transfer is as yet an open problem in the transfer learning community [45, 71, 78]. ModelKeeper is complementary to and benefits existing ML efforts as it automates training warmup (e.g., searching, transforming, and contributing a trained parent model’s weights) for a given model zoo, instead of making the developer keep tracking all models and handcraft which model to repurpose [6]. We empirically show that ModelKeeper can benefit the model training across datasets too (§6.4).

For a given model zoo, the effectiveness of transforming parent model weights relies on two key aspects: (i) *Model similarity*: it dictates the similarity of two model architectures, including the weights shape and operation type of a tensor; and (ii) *Parent model accuracy*: it determines the value of transformation. Having architectural similarity is the prerequisite to transforming more weights information of a parent model, while better parent model accuracy implies potentially better warm start after transformation.

As such, ModelKeeper should repurpose a parent model with large similarity and better accuracy. We provide the theoretical analysis to support why ModelKeeper can benefit model convergence following this principle in Appendix A.

System Components ModelKeeper is a complementary system to existing ML training (Figure 5), and has integrations with various frameworks (e.g., Microsoft NNI [4] and Ray [49]). It consists of the remote coordinator, which serves user query models before their training executes, and the client agent that allows users to submit model warmup requests. ModelKeeper coordinator employs three key components to warm up models by transforming a trained model’s weights:

- *Model Matcher*: to identify architecturally similar models in the zoo of trained models;
- *Model Mapper*: to select a zoo model with good architectural similarity and accuracy as the parent model, and transforms the parent model weights to the query model;
- *Zoo Manager*: to adaptively manage zoo models that can be submitted from users to support transformation at scale.

Figure 6 reports the example interface on the client agent, where the user benefits from ModelKeeper with a few lines of code in training (Coordinator interfaces are in Section 5).

```

1 from modelkeeper import ModelKeeperClient
2
3 def training_with_keeper(model, dataset):
4     # Create client session to keeper coordinator
5     keeper_client = ModelKeeperClient(coordinator_ip)
6     warmed_model, meta = keeper_client.query_for_model(
7         model, meta={'data': 'Flowers102',
8                     'task': 'classification', 'tags': None})
9
10    acc = train(warmed_model, dataset) # Training starts
11
12    # Register model to ModelKeeper when training ends
13    keeper_client.register_model(warmed_model,
14                                meta={'data': 'Flowers102', 'accuracy': acc,
15                                    'task': 'classification', 'tags': None})
16    keeper_client.stop()

```

Figure 6: Code snippet of ModelKeeper client service APIs.

Training Lifecycle When the developer creates a new training job, ① she first initiates a client connection to the remote ModelKeeper coordinator, and then issues a query with the specified job meta information. ModelKeeper client agent will automatically extract the model information needed (e.g., model computation graph) and issue a request (mostly size < 1 MB) to the coordinator. ② Upon receiving the request, Matcher consults its metadata store, identifies zoo models that the user can access and meet the specified tag (e.g., name of the preferred parent models), and measures their architectural similarity to the query model. ③ Mapper selects a parent model with large architectural similarity and good accuracy out of these zoo models. Thereafter, it loads model weights of this parent model from the data store, and transforms parent model weights, based on pairwise tensor mapping from the Matcher, to the query model. Note that this transformation only updates tensor weight values, while others (e.g., model architecture) remain the same. ④ The coordinator responds to the developer with warmup model weights, and the rest of the training remains as usual. ⑤ When the training completes, ModelKeeper can automatically register the trained model to the Zoo Manager to benefit future jobs.

4 ModelKeeper Design

In large shared clusters, models are often submitted by various developers and/or frameworks with diverse architectures at different points in time. The large variety in model architectures and accuracy characteristics lead to novel system challenges in automating weight transformation from a parent model with high similarity and better accuracy:

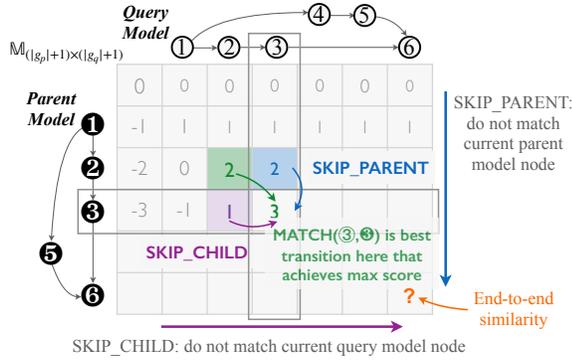

Figure 7: ModelKeeper relies on dynamic programming-like heuristics to measure graph-level model architectural similarity.

- Having similar model architectures is the prerequisite to transforming weights across architectures. How to identify more architecturally similar zoo models (§4.1)?
- As the similarity and accuracy of many potential parent models can come at odds, which one to pick and then how to transform its weights to the query model even in the presence of non-identical architectures (§4.2)?
- New training jobs and trained models can join the cluster on the fly. How to serve user warmup requests at scale for high throughput clusters in the wild (§4.3)?

4.1 Matcher: Identify Similar Models

The similarity between two model architectures determines the number of tensor weights that we can transform. Hence, we need to identify the graph-level architectural similarity of each parent and query model pair (Figure 7) and their pairwise tensor mappings. It is tempting to model it as a classic NP-hard graph edit distance (GED) problem [15] by treating tensors as nodes and data flows as edges with the goal to morph one graph to the other with minimum edits (e.g., add/delete a node). However, model matching encounters new challenges: (i) *Prefix Preference*: we prefer to match the prefix over the suffix of model graphs. Because prefix tensors are more transferable since they capture general input features (e.g., image color blobs) [53, 71]. Moreover, model weights are trained systematically over tensors, so any edit on prefixes can result in information loss to subsequent tensors [25]; (ii) *Partial Matching*: we can partially transform the weights of a smaller dimensional tensor to a wider one to match more tensors, or postpone its matching to preserve its exact weights information; and (iii) *Scalability*: as each model can consist of thousands of nodes across branches, capturing the similarity to thousands of zoo models is challenging.

ModelKeeper Matcher measures the graph-level similarity of models, in terms of the total number of transformable weights after mapping tensor pairs from the parent to the query model. It uses the widely-used ONNX tool [7] to extract the computation graph. ONNX supports various model formats (e.g., Tensorflow and PyTorch), which allows us to perform the cross-framework transformation.

Structure-Aware Pairwise Model Matching We introduce a dynamic programming-based heuristic to measure the end-to-end similarity (i.e., number of weights to transform) of two models. It relies on a similarity table $\mathbb{M}_{(|g_p|+1) \times (|g_q|+1)}(i, j)$ to record the best similarity after matching the prefixes of the parent and the query model. Here, $|g_p|$ and $|g_q|$ respectively denote the number of tensors of the parent model and the query model. Then, it enumerates plausible matching operations from previous states (e.g., $\mathbb{M}(i-1, j-1)$), and takes the operation that can acquire the maximum similarity to enter the next state (i.e., $\mathbb{M}(i, j)$).

Figure 7 shows the execution of our structure-aware matching algorithm. It traverses the similarity table in the topological order of graph tensors. This allows us to embed graph-level information while prioritizing the match of prefixes. To advance to the current tensor pair (i, j) , it enumerates three plausible operations:

1. *MATCH*: transform weights of i 's parent to j 's parents.
2. *SKIP_PARENT*: give up transforming tensor i 's parent;
3. *SKIP_CHILD*: give up transforming to tensor j 's parent;

Then, it updates the table to obtain the maximum similarity after each step based on previous states as follows:

$$\mathbb{M}(i, j) = \max_{k \in \text{parent}(i)} \begin{cases} \mathbb{M}(k, j_{\text{parent}}) + \text{MATCH}(k, j_{\text{parent}}) & (1) \\ \mathbb{M}(k, j) + \text{SKIP_PARENT} & (2) \\ \mathbb{M}(i, j_{\text{parent}}) + \text{SKIP_CHILD} & (3) \end{cases}$$

To get the overall transformable weights, we can reward each operation based on the number of tensor weights transformed. When tensor i and j belong to the same operator (e.g., convolution), the fraction of transformed weights along each weights dimension in *MATCH* operation (1) is:

$$\text{MATCH}(i, j) = \frac{\prod_{\text{dim}=1} \min(\text{dim}(i), \text{dim}(j))}{\prod_{\text{dim}=1} \max(\text{dim}(i), \text{dim}(j))} \quad (\in [0, 1]) \quad (4)$$

Otherwise, we assign *MATCH*(i, j) to -1, as this transformation is useless and even loses the weights of that parent model tensor. Similarly, *SKIP_PARENT* is set to -1 as it loses the parent model tensor, and *SKIP_CHILD* is 0, since it does not transform the parent model tensor.

Capturing the graph-level similarity is more challenging when tensor j of the query model is the intersection of multiple upstream branches. Because different upstream branches to j may follow the same branch of the parent model during their matching, leading to repetitive (conflicting) matching. As shown in Figure 7, when we reach $(6, 6)$, branch $(2 \rightarrow 3)$ and $(4 \rightarrow 5)$ may both be matched to $(2 \rightarrow 3)$ that maximizes their own similarity. To avoid conflicting matching, the similarity to j is the sum of upstream branches ($\mathbb{M}(i, j) = \sum_{k \in \text{parent}(j)} \mathbb{M}(i, k)$), and we greedily adopt the matching of a branch to tensor j , whose trajectory achieves the largest similarity (i.e., match $2 \rightarrow 3$ to $2 \rightarrow 3$), to maximize their sum. Meanwhile, we discard the trajectory of other

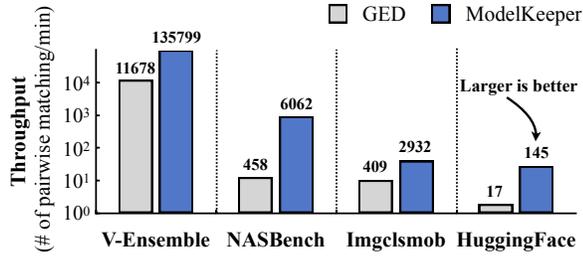

Figure 8: Keeper is order-of-magnitude more scalable than existing GED. V-Ensemble is a model zoo for ensemble training (§6.1).

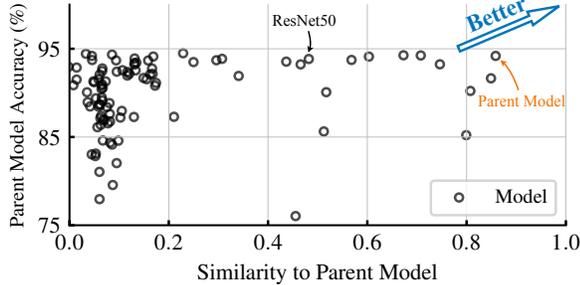

Figure 9: Models vary in accuracy and architecture (Imgelsmob zoo). We measure their similarity w.r.t. ResNet101, and prefer to transform a parent model with better similarity and accuracy.

branches where conflict exists. As such, branch (4)→(5) takes the inferior match (5), where (4) is skipped.

The last entry of the table, i.e., $\mathbb{M}(|g_p|, |g_q|)$, gives the end-to-end similarity. Note that we can learn the pairwise tensor mappings by backtracking operations taken to reach $\mathbb{M}(|g_p|, |g_q|)$ over the table in linear time. For a specific model, our heuristic will naturally treat the model itself as the most similar model, because matching will always take operation $MATCH(i, i)$ in each step to maximize the similarity.

Figure 8 reports that our pairwise matching can match thousands of model pairs in a second, and achieves higher throughput than the state-of-the-art GED solution [57] in this model matching scenario. More importantly, our empirical results report that our structure-aware matching achieves better training warmup than the GED solution (§6.3).

4.2 Mapper: Transform Maximal Parent Information

The effectiveness of weight transformation is determined by the similarity (transfer more weights) and accuracy (transfer better weights) of parent models. Unfortunately, it is impractical to pick the optimal parent model, since the performance of transformation can only be known after training each derived warmup model to converge. Worse, the variety of model similarity and performance leads to the tussle in selecting the parent model. As shown in Figure 9, while some models (e.g., ResNet34) possess high accuracy, their low similarity to ResNet101 can cap the number of weights that can transform. Next, we introduce Mapper to exploit the sweet spot of both aspects, and then to transform maximal parent model weights in the presence of partial matching.

As shown in Algorithm 1, Mapper relies on Matcher to

Input: Query model q , Model Zoo M

Output: Warmup Model Weights

```

1 NumOfBuckets  $B = 10$  ▷ Model similarity  $\in [0, 1]$ 
2 Function GetModelSim (Query  $q$ , Models  $M$ )
   /* Structure-aware matching for model similarity. */
3   topo_query_tensors = SortByTopo( $q$ )
4   model_similarity = {}

17  top_similar_bucket =
18    BucketBySimilarity(model_similarity,  $B$ ).first
19  for model  $\in \text{top\_similar\_bucket}$  do
20    if model.perf > best_parent.perf then
21      best_parent = model
22  /* Perform width and depth weight transformation */
23  warmup_weights = TransWeight(best_parent,  $q$ )
24  return warmup_weights

```

Algorithm 1: Select the parent model to transform.

identify similar models (Line 2). As having a good similarity is the prerequisite for transformation, we need to first ensure picking similar models. To this end, Mapper takes the popular bucketing strategy to allocate models into B buckets in terms of their similarity (Line 14). Taking Figure 9 as an example, with $B = 10$ by default, *bucket 10* will accommodate models with similarities between 0.9 and 1.0, so models in the same bucket have comparable similarities. Then, Mapper traverses from the last bucket (*bucket 10*) to the first until reaching the first one with nonempty models (*bucket 9*), from which it selects the model with the best performance as the parent model (Line 15). As such, the parent model approaches the boundary of better model similarity and accuracy. Later, Mapper performs structure-aware weight transformation to initialize the query model weights (Line 18).

Information-Preserving Weight Transformation To maximize the end-to-end number of weights to transform, Mapper allows partial matching: it may map a small tensor of the parent to a wider one of the query model, or skip the

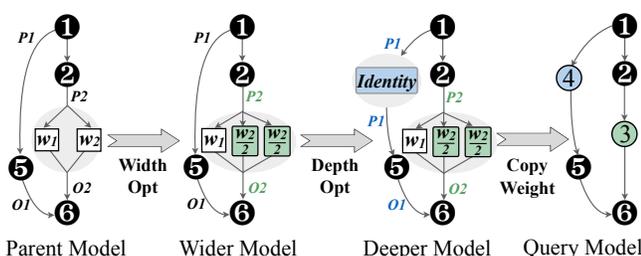

Figure 10: Width and depth operator to transform parent model.

mapping of some tensors in the parent or the query model. Here, the straw-man solution (e.g., in Retarii [77]), which transfers the weights of parent model tensors if and only if two tensors are identical, can be suboptimal (§6.3), since losing the parent model tensor can make the transfer of its subsequent tensors useless.

To preserve maximal parent model information under partial mappings, Mapper employs a width operator and a depth operator, which extend the well-known ML technique for function-preserving model transformation (e.g., Net2Net [17] and Network Morphism [66]). But unlike existing model transformation techniques [41], which are limited to *expand* the depth and width of a pre-determined model, or complicated transfer learning (e.g., knowledge distillation [34]) that requires additional computation (e.g., pre-training) and/or intrusive implementation, our operators transform the parent model weights into the query model with little overhead.

Our graph-level transformation proceeds in the topological order of tensors. Mapper handles the expanding case similar to today’s function-preserving transformation (Figure 10): (i) to transform a parent model tensor to a wider query model tensor, the width operator copies the parent model weights to its mapping tensor of the query model, and pads the rest of the columns via weighted replication from other columns; and (ii) when the mapping requires inserting a new tensor into the parent model (i.e., SKIP_CHILD), the depth operator will initialize the weights of this mapping tensor to be an identity tensor. i.e., this tensor will directly pass the output of its parent tensors to the child tensors, in order to keep the same parent model’s output. Readers can refer to Net2Net [17] for more details. We note that both expanding operations, in theory, can preserve the parent model information (i.e., with the same tensor output) for many tensor operators (e.g., the wide-used full connection and convolution layers).

The pruning case, however, cannot preserve full parent model information, because we lose some tensor weights of the parent model in transformation. Our solution is inspired by today’s ML model pruning criteria [32]. Specifically, when we need to fit wider tensor weights (i.e., with larger array dimensions) to a smaller dimensional tensor of the query model, the width operator will progressively pick and copy the largest weight values of the parent model tensor to the mapping tensor of the query model. This is because, intuitively and empirically, larger magnitude values often have more impact on the model output [14]. From the depth perspective, when we skip

transforming (i.e., SKIP_PARENT) a parent model tensor, the depth operator will add noise to the weight values of that tensor’s neighbors. It disturbs the affinity of trained parent model weights so that neighboring tensors can still keep most information while being able to learn new weights [51].

Our transformation can be applied to various models for informed weight initialization. Thereafter, training proceeds as normal, and the warmup model will gradually converge the weight values that fit its architecture the best. As a generic system, ModelKeeper can accommodate other transformation techniques too as they become available. We provide a theoretical analysis of our transformation in Appendix A.2, and empirically show performance improvements using our transformation over its counterparts (§6.3).

4.3 Zoo Manager: Transform Effectively At Scale

In reality, cluster users register their trained models to the model zoo on the fly, leading to scalability and performance challenges. First, while gathering more models increases the opportunity to transform better parents, the ever-growing number of models (e.g., > 70K models in the HuggingFace model hub of all tasks [2]) and model size (e.g., NLP models can be tens of GBs [16]) can lead to large matching overhead and storage cost. Moreover, models registering to the zoo may have low accuracy (e.g., due to insufficient training), which can harm the effectiveness of weight transformation. As such, ModelKeeper employs a Zoo Manager to support effective transformation at scale under dynamics.

Two-Stage Hierarchical Model Matching Despite being able to match thousands of lightweight CV models every minute (Figure 8), our pairwise matching heuristic can still be insufficient for model zoos with tens of thousands of models or complicated model architectures (e.g., NLP models). For example, to serve a query model using the HuggingFace model zoo for English text generation (2.5K models), performing pairwise matching on these zoo models can take ~17 minutes, namely, 2.5K models over the throughput (145 matching/minute). This long search time is further exacerbated in today’s large cluster with sub-minute job arrivals [37], eventually hurting the user experience.

To ensure an *interactive* service, Zoo Manager adaptively clusters zoo models into a well-defined number of groups, whereby Matcher can perform *two-stage* matching to reduce the number of matching pairs needed to identify more similar models. Intuitively, models with similar architectures would have comparable model similarity to the same query model, so we may be able to cluster zoo models into multiple groups, and then perform pairwise matching on the group members of top similar model groups. However, it is non-trivial to decide what features to use for clustering models, and how many groups are needed. Clustering too few groups does not scale down the problem enough, while too many can lead to a large overhead in identifying which group to prioritize.

We deploy K-medoids clustering [52] to combine pair-

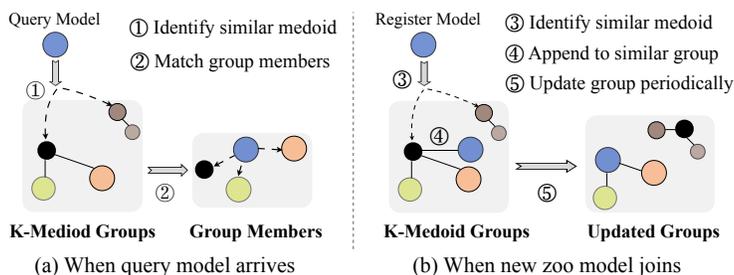

Figure 11: Matcher clusters models into groups to reduce the search space, and then performs model matching within groups.

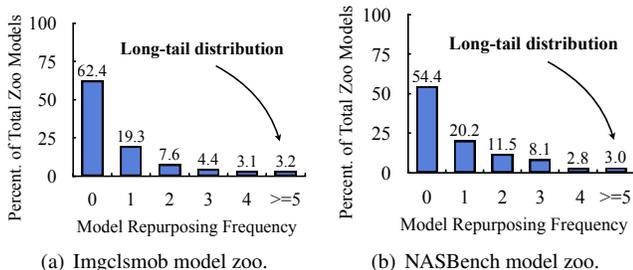

Figure 13: A few zoo models are more frequently repurposed as the parent by Keeper. Numbers are from our evaluations (§6.2).

wise model matching and clustering to find a sweet spot. K-medoids can directly take the distance of two points as input to minimize the distance between data points and their cluster center. Here, models can be taken as different points, and the distance is the reciprocal of their similarity. Compared to other clustering methods (e.g., K-means), K-medoids circumvents the need for embedding complicated model graphs, and it is more compatible with pairwise model matching.

As shown in Figure 11, when a query model arrives, Matcher identifies its similarity to each group medoid, and then conducts pairwise matching on the members of top similar groups. Similarly, when a new model registers, Matcher measures its similarity to group medoids, and assigns this new model to the group whose medoid is the most similar. This enables interactive queries to the latest models. Later, Matcher periodically triggers K-medoids to update the clustering.

To select the most similar models for each query model, Matcher identifies the best group medoid i by performing K pairwise matching, followed by K_i runs to match the members of group i . Assuming a zoo of M models ($M = \sum_i K_i$), to minimize the average matching runs on each group (i.e., $\min((K + K_i)/K)$), we can get the optimal number of groups $K^* = \sqrt{M}$. Figure 12 reports that, compared to the non-clustering design (i.e., $K = 1$), this two-stage design requires matching only 5%-16% of all zoo models to identify the most similar models, thus reducing the query hang time (§6.3).

Capping Zoo Size Hosting all zoo models can consume noticeable storage space. For example, the HuggingFace model zoo takes tens of TBs of storage [2]. In fact and understandably, we notice that a small portion of zoo models are more

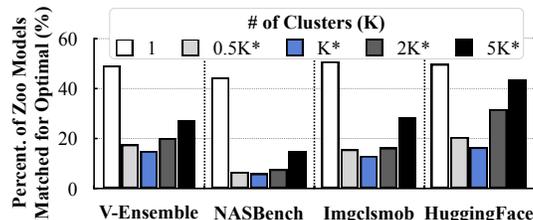

Figure 12: ModelKeeper can find the optimal number of clusters K^* in hierarchical matching, and can identify the most similar models with fewer zoo models (e.g., 5% in NASBench) needed to explore.

frequently repurposed than others (Figure 13). This is because certain models contain more similar blocks to other models (e.g., ResNet50 is more likely to be used to warm up other large ResNet models than ResNet18).

To harvest more warmup opportunities subject to the zoo capacity limit, we can formulate it as a knapsack packing problem, where each item (model) is associated with a weight (model size) and a value (repurposing frequency as the parent model), and our goal is to maximize the total value achieved. Namely, warm up as many jobs as possible (aka maximum total repurposing frequency). As such, solving this packing problem enables us to identify which item (model) to keep in the knapsack (model zoo). But on the other hand, models that are popular to train can change over time. For example, users incline to train more recent and/or advanced models. To account for the temporal variation in the repurposing frequency of each zoo model, we take the moving average of model values (e.g., decaying their repurposing frequency by 0.9 every day), and trigger the packing solver upon reaching the storage limit. We show that ModelKeeper can perform well even under severe storage limit (§6.4).

Avoiding Low-Accuracy Models Low accuracy models registering to the zoo (e.g., due to user error) not only wastes storage but can harm the transformation, so we need to ensure the zoo uses models with decent accuracy. To this end, other than selecting the model with better accuracy as the parent using the bucketing design at the query time, Zoo Manager evicts zoo models with outlier accuracy at runtime. By default, we take the popular Z-score criteria (i.e., model accuracy below the mean by more than two standard deviations) to identify outliers [58]. Moreover, for the same model architecture, it only keeps the model with the best accuracy. We show that ModelKeeper can accelerate training even in the presence of low accuracy models in unfavorable environments (§6.4).

Complexity Analysis The complexity of pairwise model matching is $O(|g_p| \times |g_q|)$,³ and that of model clustering is $O(M^{2.5})$ for the zoo with M models. Mapper takes linear time to select and transform the parent model. The magnitude of these factors is mostly within $O(1K)$ (§6.1). Our evaluations

³We omit the complexity in enumerating tensor parents (i.e., $k \in \text{parent}(i)$), since the node degree is orders of magnitude smaller than $|g_p|$.

show that ModelKeeper incurs negligible overhead (§6.3).

5 Implementation

We have implemented a system prototype of ModelKeeper, with around 2K lines of Python code as the frontend library and 1K lines of C++ code as the backend. Our implementation provides user-friendly APIs and supports many popular ML frameworks, such as Microsoft NNI [4], AutoKeras [41], Ray [49], and MLflow [5], with few-lines-of-code plugins.

ModelKeeper Components ModelKeeper coordinator supports distributed deployment across machines. Each coordinator controller processes a single scheduling thread to poll client requests from its queue, and reserves a thread pool for Matcher. Matcher performs pairwise model matching in parallel for each query model, and then Mapper creates a worker thread to transform parent model weights using *numpy* format. Zoo Manager updates the model clustering every 5 minutes, and uses *ortools* library to solve the knapsack problem. The client agent communicates with the coordinator via TCP connections.

Fault Tolerance ModelKeeper uses *Redis* in the coordinator to store the metadata and model weights in a fault-tolerant manner, and this metadata is cached in the memory with small footprints. Changes to the model zoo (e.g., registering new models) follow the write-ahead transaction to the storage. At runtime, the coordinator runs a daemon process to monitor the liveness of the service, which will create a new service process if the existing one crashes. The new process then fetches the latest checkpoint from *Redis* to catch up.

Interfaces We pack interfaces into a Python library. The cluster manager can initiate the coordinator in three lines:

```
from modelkeeper import ModelKeeperCoordinator
keeper_service = ModelKeeperCoordinator(config)
keeper_service.start()
```

Users can initiate the client agent in a few lines (Figure 6).

6 Evaluation

We evaluate the effectiveness of ModelKeeper on three mainstream frameworks for exploratory and general DNN training, using five large-scale CV and NLP model zoos across thousands of models. We summarize the results as follows:

- ModelKeeper saves 23%-77% total amount of training execution needed (i.e., $1.3\times$ - $4.3\times$ faster training) than the state-of-the-art without accuracy drop of models (§6.2).
- ModelKeeper outperforms its counterparts by exploiting the parent model with high similarity and better accuracy using different design components (§6.3).
- ModelKeeper improves performance over a wide range of parameters and practical cluster setups in the wild (§6.4).

6.1 Methodology

Cluster setup. We evaluate ModelKeeper on an 80-node cluster (40 GPU nodes and 40 CPU nodes). Each GPU node

has a Tesla P100 GPU with 16 GB GPU memory and 16-core CPUs. Since most HuggingFace NLP models exceed our GPU memory capacity, we resort to CPU nodes. Each node has 32-core CPUs and 384 GB of memory. ModelKeeper coordinator runs on a 32-CPU server with 10 Gbps bandwidth.

Workloads. We evaluate ModelKeeper using five widely-used CV/NLP model zoos and realistic workloads (Table 1):

- *NASBench* [24]: an image classification model zoo with thousands of lightweight models for NAS task.
- *AutoKeras Zoo* [41]: a CNN model zoo generated by AutoKeras during the bayesian NAS searching.
- *Imgclsmb* [10]: a popular zoo of state-of-the-art CV models (e.g., DenseNet [36]). Most models are heavyweight.
- *V-Ensemble* [65]: a benchmarking workload for ensemble training, which has hundreds of variants of VGG models.
- *HuggingFace* [2]: a collection of advanced HuggingFace NLP models (e.g., Bert [23]) for next word prediction.

We train *Imgclsmb*-Small models on CIFAR dataset and *ImageNet32* dataset for 32×32 small image inputs, *Imgclsmb* models on *Flowers102* dataset for 224×224 large images, and *HuggingFace* models on the large *WikiText* dataset. *ImageNet32* is a downsampled 120-category *ImageNet* dataset (e.g., smaller input size) for efficient computation.

To emulate practical cluster setups, NAS models are generated by the searching algorithm on the fly, and training jobs are submitted following the arrival of Microsoft Trace [37]. The same workload does not contain identical model architectures. ModelKeeper model zoo starts empty for each workload, and jobs contribute (upload) their trained models to the zoo as they complete over time.

Parameters. We follow the default setting specified in each model zoo: (1) *CV models*: the SGD optimizer with minibatch size 64 and initial learning rate 0.01; and (2) *NLP models*: the AdamW optimizer with minibatch size 32 and initial learning rate $8e-5$. We use the *ReduceLROnPlateau* scheduler to decay the learning rate by 0.5 once the training loss stagnates.

Baselines. We compare ModelKeeper to the following:

- *Retiarii* [77]: Microsoft’s training framework that relies on the lineage of graph mutation to warm up NAS models.
- *AutoKeras* [41]: An advanced AutoML system based on Keras that applies lineage-based warmup for NAS models.
- *MotherNet* [65]: An ad-hoc ensemble training algorithm that trains a model subnet, which introduces intrusive overhead and implementation, to warm start models.

Existing efforts limit to individual NAS/ensemble jobs, while ModelKeeper can support various tasks across jobs and users.

Metrics. We care about the *training execution time* needed to train to converge and the *model convergence accuracy*.

We run with five realistic Microsoft Traces [56], and report the average over 5 runs.

Category	Task	Workload	# of Models	Dataset	Avg. Time	Avg. Acc.	
					Improvement	Difference	
Exploratory Training	Grid Search NAS		1,000	CIFAR-100	2.9×	0.39%	
	Evolution NAS				2.4×	0.38%	
	AK-Bayesian NAS [41]	AutoKeras Zoo [41]	500		4.3×	0.31%	
General Training	Image Classification	Imgclsmob [10]	389	Flowers102 [54]	2.8×	0.23%	
		Imgclsmob-Small	179	CIFAR-10	2.1×	0.02%	
				CIFAR-100	1.6×	0.18%	
	Ensemble Training		V-Ensemble [65]	104	CIFAR-100	1.7×	0.08%
	Language Modeling		HuggingFace [2]	69	WikiText-103 [47]	1.8×	-0.13 perplexity

Table 1: Summary of improvements. ModelKeeper improves training execution time without accuracy drop, by reducing the amount of training needed (i.e., GPU Saving). Accuracy difference is defined by $Acc.(Keeper) - Acc.(Baseline)$, and smaller perplexity is better.

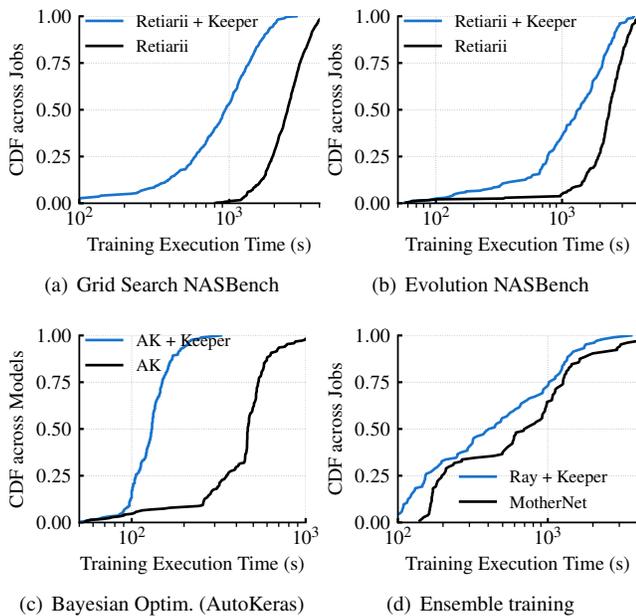

Figure 14: ModelKeeper outperforms existing warmup training.

6.2 End-to-End Performance

In this section, we evaluate how ModelKeeper (Keeper) is complementary to and benefits today’s ML frameworks. Here, we run the NAS task using Microsoft NNI (with Retiarii backend [77]) and AutoKeras, and other training tasks on Ray [49]. Table 1 summarizes the average improvement on each training workload after applying ModelKeeper.

ModelKeeper outperforms existing warmup solutions. ModelKeeper outperforms existing training warmup solutions in Retiarii, AutoKeras, and MotherNet by $1.7\times$ - $4.3\times$ (Figure 14), by saving 43.1%-76.7% total amount of training needed. Their inefficiency is due to two primary reasons:

(i) Suboptimal parent model selection: Retiarii and AutoKeras track the lineage of graph mutation and treat the base model in evolution as the parent model. However, as multiple layers can be modified on the base model in searching

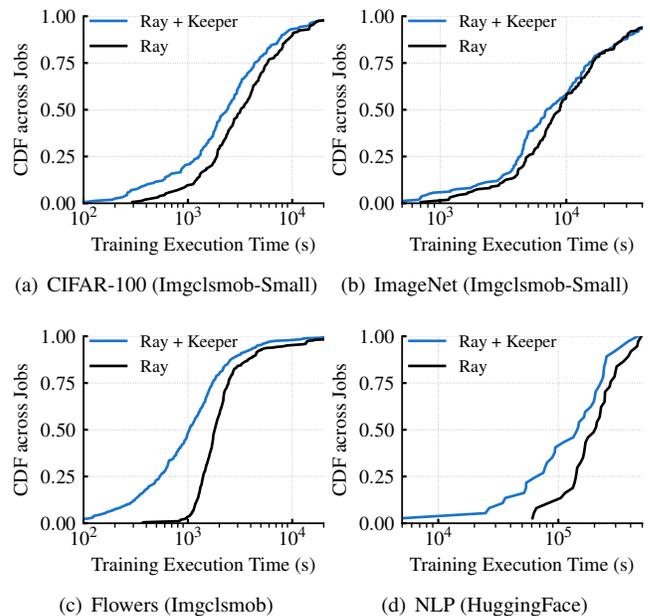

Figure 15: ModelKeeper improves general training tasks.

new models, such rigid parent selection can miss better parent models out of other explored NAS models. Similarly, MotherNet not only requires additional training of the model subnet, but can not repurpose better-trained models on the fly.

(ii) Insufficient weight transformation: Their design, which simply copies the weights from the parent model when two tensors are identical, is lossier than ModelKeeper. For example, inserting randomly initialized prefix tensors can make the copy of subsequent tensors useless.

Meanwhile, they are limited to specific NAS or ensemble training tasks and cannot serve various DNN training jobs on the fly in the cluster wide.

ModelKeeper accelerates ML training for various tasks.

Figure 15 and Table 2 report the performance of individual jobs. Compared to training from scratch, we observe that: (i) ModelKeeper achieves $1.3\times$ - $4.3\times$ faster training, saving 23%-77% training execution, across a wide range of work-

Workload	Time Improvement			Acc.(Keeper) - Acc.(Baseline)		
	25th	50th	75th	25th	50th	75th
NAS-Grid	1.5×	2.0×	3.1×	0.01%	0.25%	0.42%
NAS-Evol	1.2×	1.6×	3.0×	0.03%	0.19%	0.48%
Flowers102	1.2×	2.1×	3.3×	0.0%	0.16%	0.37%
CIFAR-100	1.1×	1.5×	2.0×	-0.04%	0.08%	0.32%
ImageNet32	1.0×	1.2×	1.6×	-0.07%	0.0%	0.11%
V-Ensemble	1.1×	1.5×	1.9×	0.02%	0.07%	0.65%
HuggingFace	1.2×	1.4×	2.1×	0.2 ppl	-1.3 ppl	-3.87 ppl

Table 2: Keeper saves training execution time of individual jobs without accuracy drop. Smaller perplexity (ppl) is better.

loads. This improvement is more pronounced in a larger zoo because of having more trained models to repurpose. (ii) Improvements on different workloads report a positive correlation with the prevalence of model similarity in that model zoo. Here, ModelKeeper achieves larger improvement on NAS-Bench, which is consistent with the fact that this model zoo owns higher inter-model similarities (Figure 2). (iii) Although ModelKeeper starts from an empty zoo and jobs arrive on the fly, we can still save the training execution for 70%-95% individual jobs (Table 2). We note that the 25th percentile improvement of small-scale model zoos (e.g., Imgcsmob) is inferior to others. This is because not all training models are warmed up due to the cold start of this online setting, and the fact that ModelKeeper will not warm start the model that does not have a similar parent (similarity > 0).

ModelKeeper speeds up training without accuracy drop.

Table 1 and Table 2 report that, on average, ModelKeeper can achieve similar (or even slightly better) final model accuracy. Intuitively, ModelKeeper should perform no worse than baseline accuracy, since the rest of the training (e.g., data) remains the same. However, we note that this slightly better model performance is consistent with the observations in ML network morphism [66], which interprets it as the internal regularization ability. Specifically, by transferring from well-trained models, model weights have been placed in a good position in the space, resulting in a more regularized network to reach a better basin of the loss curvature [25, 66]. In contrast, training from scratch can get stuck in local minima.

6.3 Performance Breakdown

In the rest of the evaluations, we refer to the improvement on V-Ensemble as that over training from scratch for brevity.

Breakdown of Components We break down ModelKeeper by disabling Matcher and Mapper respectively: (1) *Keeper w/o Matcher*: remove our Matcher design, and instead resort to a state-of-the-art graph matching strategy [57] to select a parent model with the most pairwise tensor mappings; and (2) *Keeper w/o Mapper*: disable our Mapper design, so only transform the parent model weight if and only if two tensors are identical. Figure 16 reports the improvement of these

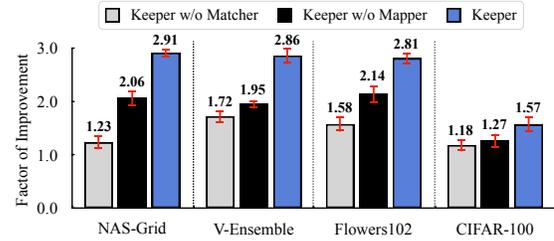

Figure 16: Breakdown of Keeper components.

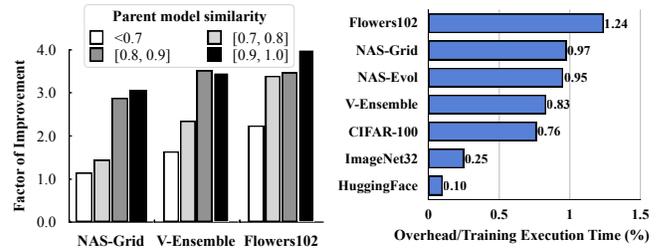

Figure 17: Faster training with higher model similarity.

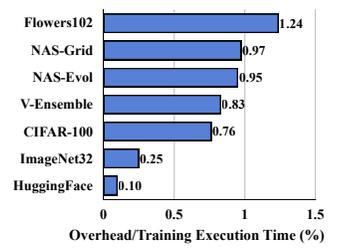

Figure 18: Keeper introduces negligible overhead.

variants. We notice: (i) the classic GED solution, in *Keeper w/o Matcher*, achieves suboptimal performance, since model matching prefers to match prefixes, and partial matching allows better overall similarity. (ii) transforming weights only for identical tensors, in *Keeper w/o Mapper*, is inferior to Keeper information-preserving transformation. (iii) Matcher and Mapper contribute comparable improvements.

Breakdown of Improvement Characteristics Figure 17 reports the average improvement after categorizing training models by their similarity to the parent model. We note that: (1) Keeper tends to achieve better execution saving for models with a higher parent model similarity. This again supports our parent model selection criteria that prioritize models with higher architectural similarity. (2) Improvements of different similarity regimes (e.g., [0.7, 0.8] vs. [0.8, 0.9]) are often distinct, and this becomes vague as similarity over 0.8. Because most layers have been largely warmed up, and deeper layers are too specific to the parent model to be transferable [71].

Overhead Analysis Figure 18 reports Keeper's overhead, i.e., the time taken between initiating the query and starting to train, over the training execution time. We report the average of all jobs, and notice that Keeper introduces less than 1.5% overhead (< 43 s) across all workloads.

6.4 Sensitivity and Ablation Studies

Impact of Low-Accuracy Models As a cluster-wide service, ModelKeeper should be robust to unfavorable settings where the accuracy of user-registered zoo models can be low (e.g., due to insufficient training). We follow the popular early-stop design in ML [44] to simulate unfavorable setups, where model registration takes place when jobs run to at most X minutes. Figure 19 reports the improvement of execution time across different degrees of unfavorable settings. Here, the x-axis value 40% indicates X is set to be the 60th percentile

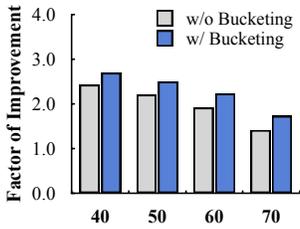

Figure 19: Keeper is robust in the presence of poor performance models (NAS-Grid).

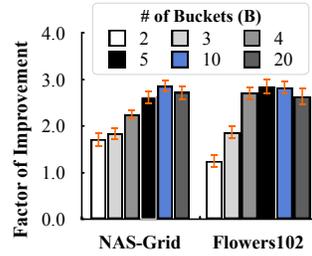

Figure 20: Keeper improves training execution time across the different numbers of buckets.

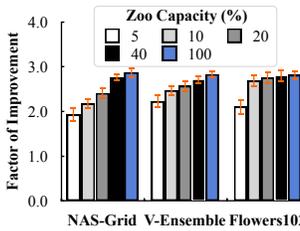

Figure 21: Impact of zoo capacity on execution time. Error bars report standard deviation.

Figure 22: Keeper accelerates model training on CIFAR-100 using ImageNet32 model zoo.

value in execution time distributions, so only 40% zoo models are trained to converge. We observe that: (i) improvement decreases as more zoo models have low accuracy. (ii) Keeper is more robust with our bucketing design as it exploits the similarity-accuracy sweet spot.

Impact of Bucketing Figure 20 reports that ModelKeeper delivers consistent improvement across a wide range of number of buckets B . Meanwhile, we notice that using the most accurate parent model (i.e., $\sim B=2$) or the most architecturally similar parent (i.e., $\sim B=20$) achieves suboptimal improvement, since it respectively undervalues the model similarity and accuracy in selecting the parent model.

Impact of Zoo Capacity Figure 21 reports the average improvement under different zoo capacities. The total size (i.e., 100%) of model zoos in NAS-Grid, V-Ensemble, and Flowers102 are 1.6GB, 17GB, and 31 GB, respectively. We observe that: (i) as expected, the improvement is more pronounced as we allocate more storage to ModelKeeper’s model zoo, but (ii) we can still achieve $\sim 2\times$ improvement under severe capacity limits (e.g., 5% capacity aka < 2 GB storage), since Keeper adaptively evicts suboptimal zoo models.

Cross-Dataset Training Warmup Figure 22 reports that ModelKeeper can benefit DNN training across datasets. Here, we warm start the training of Imgclsmb-small models on CIFAR-100 using zoo models from the ImageNet32 workload, and notice $2.5\times$ faster training on average. This is because front DNN layers capture general input features (e.g., color blobs of images), which are transferable to similar datasets [71]. While picking which dataset as the source for warmup is still an open ML problem [45, 78], ModelKeeper

provides systems support for automated warmup transformation across ML tasks and datasets using the given model zoo.

7 Discussion and Future Work

Support for Hyperparameter Tuning ModelKeeper by default automatically searches and transforms the parent model for various training tasks. Meanwhile, the developer can specify which parent model to repurpose using the tag configuration in their request too (Figure 6), while enjoying the automated weights transformation. For example, we may want the same parent model for hyperparameter tuning jobs to eliminate the comparison bias and/or to ensure reproducibility. Moreover, as the training of the query model will be jump-started, it would be interesting to investigate how to adapt to better job configurations (e.g., scaling the learning rate in terms of the number of transformed layers [56, 66]) to further improve the training convergence.

Model Sharing in the Wild ModelKeeper repurposes a zoo of trained models to warm start the new training job. These zoo models can be maintained by the cluster provider, and/or contributed by users. For example, AWS SageMaker offers hundreds of pre-trained models for tasks like object detection and natural language processing [8]; HuggingFace Model Hub has gathered ~ 70 K models shared by the community [2]. The former is more managed but expensive to include extensive models and tasks, while the latter has good extensibility but can exhibit great uncertainties (e.g., low-accuracy models). To the best of our knowledge, ModelKeeper moves the first step to *automatically* warm start the cluster-wide model training. However, further investigations on how to democratize it in the wild, such as for privacy and security concerns, are needed. To this end, one possible approach is to develop differential privacy-like solutions [11] (e.g., adding noise to the weights of the contributed models), which naturally leads to an interesting trade-off between privacy and the model quality.

8 Related Work

Deep Learning Frameworks Recent ML efforts have made considerable progress toward efficient inter-job scheduling [28, 49, 56, 74], intra-job computation placement [43, 50], communication optimization [40, 55], specialized execution backend [9, 18, 42], and timely inference [29]. However, they are mostly in-execution optimizations, and/or the total amount of training remains the same. Different from transforming tensors for faster computation (e.g., TASO [38] and PET [64]), ModelKeeper operates on model weights, and acts as a complementary service to accelerate cluster-wide DNN training.

AutoML Systems Retarii [77] and AutoKeras [41] rely on the lineage of graph mutation to repurpose trained models, whereas they are limited to NAS tasks within individual jobs. Experiment Graph [22] identifies the reusable ML scripts and artifacts in platforms to speed up repeated executions,

so it focuses on the same job execution. As recent AutoML platforms, such as AzureML [59], Amazon SageMaker [1] and MLflow [75], provide a collaborative environment to simplify ML deployments, reusing artifacts can greatly speed up repeated executions (e.g., reuse scripts [22]). ModelKeeper is the first automated training warmup system to accelerate cluster-wide DNN training jobs across users, and improves Retiarii and AutoKeras further (§6.2).

Transfer Learning Transfer learning today mostly transfers the weight of the same model [71], from one source task to another target to alleviate the need for large training data. For a given parent model, network morphism [17, 66] introduces function-preserving transformation to construct child models while preserving the parent information. MotherNet [65] further applies the network morphism to warm start model training, but is limited to ensemble training tasks. ModelKeeper tackles a more challenging scenario for various tasks in the wild, and achieves better performance (§6.2).

Graph Matching Graph matching is one of the NP-hard fundamental problems in graph analysis [61]. To speed up the matching, DAF [31] decomposes the graph into forests. Similarly, AED [57] divides global matching into local matching, and then aggregates the local matching decisions. However, they are insufficient due to the novel properties of DNN graphs, where pairwise matching prefers ordered alignment and allows partial weights transformation. ModelKeeper outperforms them in training speedup and throughput (§6.3).

9 Conclusion

In this paper, we introduce ModelKeeper to enable automated warmup of DNN training jobs at the cluster scale. ModelKeeper manages a collection of already-trained models from different developers and/or frameworks. Before training a model, it selects a high-quality trained parent model and performs structure-aware transformation of parent model weights to warm up the weights of new training models. Our evaluations across thousands of CV/NLP models show that ModelKeeper achieves $1.3\times$ - $4.3\times$ faster training completion.

Acknowledgments

Special thanks go to the entire CloudLab team for making ModelKeeper experiments possible. We would also like to thank the anonymous reviewers, our shepherd, Neeraja J. Yadwadkar, and SymbioticLab members for their insightful feedback. This work was supported in part by NSF grants CNS-1909067, CNS-1900665, and CNS-2106184.

A ModelKeeper Analysis

A.1 Design Criteria

At its core, ModelKeeper performs informed weight initialization for DNN models by repurposing a well-trained model’s weights. Intuitively, we note that

- This can be viewed as an instance of existing transfer learning (TL), where we transform the weight of a model on one dataset to train on “another” dataset (i.e., the warmup model has not viewed that dataset before its training takes place) [13]. More subtly, it is a simplified and complementary TL scenario under homogeneous data distribution and features, so existing TL theories can be applied to validate our effectiveness too.
- ModelKeeper transformation is an informed weight initialization, thus a special case of random initialization. As the rest of the training remains the same, the model should be able to reach similar final accuracy when the model converges.

Why ModelKeeper Can Help Convergence? We next present the theoretical analysis of model convergence to show why ModelKeeper can achieve faster convergence.

Corollary A.1. (Theorem 1 in [72]). Under widely-used DL assumptions (1) Smoothness: loss function $f(\mathbf{w})$ is L -Lipschitz smooth; (2) Bounded gradient variances: with constants $G > 0$, $\sigma > 0$, we assume $\mathbb{E}[\|\nabla f(\mathbf{w})\|^2] \leq G^2$ and $\mathbb{E}[\|\nabla F(\mathbf{w})\|^2 - \nabla f(\mathbf{w})\|^2] \leq \sigma^2$; and (3) Unbiased estimation: on mini-batch ξ , we have $\mathbb{E}_{\xi|\mathbf{w}}[\nabla f(\mathbf{w})] = \nabla F(\mathbf{w})$.

With learning rate γ to $0 < \gamma \leq \frac{1}{L}$, then for iteration T , the model training convergence rate is:

$$\frac{1}{T} \sum_{t=1}^T \mathbb{E}[\|\nabla f(\mathbf{w}^{t-1})\|^2] \leq \frac{2}{\gamma T} (f(\mathbf{w}^0) - f^*) + 4\gamma^2 T^2 G^2 L^2 + \frac{L}{N} \gamma \sigma^2$$

Where N is the number of workers in synchronized data-parallel training, f^* is the optimal training loss.

From Corollary A.1, we can notice that, for the same model, training achieves faster convergence with a smaller initial loss value $f(\mathbf{w}^0)$ in theory (similar to [53, 71]). Indeed, existing gradient variance reduction techniques in the ML community report a similar theory analysis [12]. Here, we empirically show that the initial training loss of the warmup query model, $f(\mathbf{w}^0)$, will start from some basin of loss curvature (e.g., better accuracy in Figure 3 and smaller gradient variance in Figure 4), and theoretically analyze why this enables starting from the loss basin in Appendix A.2.

Admittedly, weight transformation can be lossy (e.g., due to incomplete matching), which breaks the parent model information. We note that capturing the exact convergence comparison herein is extremely challenging, which indeed is a funda-

mental open problem even in today’s transfer learning [25]. Nevertheless, many empirical analyses have reported consistently encouraging improvement [71], and transfer learning is widely-used. Intuitively, for front tensors that enjoy full information-preserving transformation, we can consider them as a prefix subnet, and this subnet holds the same output as the corresponding parent subnet. Therefore, these tensors can still potentially achieve faster convergence according to Corollary A.1.

How to Select Parent Models? In selecting the parent model, ModelKeeper prioritizes the model with (1) *better model accuracy*: this is because parent models with better accuracy enable smaller initial loss $f(\mathbf{w}^0)$, thus allowing better convergence speed (Corollary A.1); and (2) *larger architectural similarity* and *prefix preference*: If we dive to the fundamental of model training, the output activations of a specific model tensor i is $\mathbf{y}^i = f_i(\mathbf{y}^{(i-1)T} \mathbf{w}_i + \mathbf{b}_i)$. Here, assuming the front $l-1$ tensor are warmup, while \mathbf{w}_i is randomly initialized. The front subnet still enjoys better convergence, so we prefer a model with architectural similarity to maximize this potential. In the forward training propagation, \mathbf{w}_i leads to cascading information loss to subsequent tensors, so we prioritize the match of prefixes to minimize this loss. On the other hand, training front tensors is more difficult but more transferable, because gradient information becomes less informative as it is backpropagated through more subsequent tensors [25], which requires us to match subsequent tensors as many as possible to curb this divergence to the front tensors in backward propagation.

A.2 Information-Preserving Transformation

ModelKeeper employs width and depth operators to perform structure-aware weight transformation, wherein expanding the parent model performs the same to Net2Net [17]. Net2Net theoretically grounds that expanding transformation (e.g., more convolution channels or new convolution tensors) can preserve the parent model information for a wide range of tensors. Specifically, the depth operator tries to deepen a tensor $\mathbf{y}^i = f_i(\mathbf{y}^{(i-1)T} \mathbf{w}_i + \mathbf{b}_i)$ using two tensors $\mathbf{y}^i = f_i(\mathbf{U}^{(i)T} f_i(\mathbf{y}^{(i-1)T} \mathbf{w}_i + \mathbf{b}_i))$, where f_i , \mathbf{w}_i , \mathbf{b}_i are the activation function, tensor weights, and bias vectors, respectively. When matrix \mathbf{U} is initialized to an identity matrix, adding \mathbf{U} preserves the same output of its input tensor if f_i is chosen such that $f_i(\mathbf{U} f_i(\mathbf{v})) = f_i(\mathbf{v})$ for all vectors \mathbf{v} . This property, f_i , holds for widely-used rectified linear activation in today’s DNN models. For example, to insert a new convolution tensor, we should set the convolution kernels to be identity filters. Readers can refer to Net2Net [17] for the theoretical analysis for the width operator. As such, in expanding the parent model, we may preserve the full parent model information.

SHEPHERD: Serving DNNs in the Wild

Abstract

Model serving systems observe massive volumes of inference requests for many emerging interactive web services. These systems need to be scalable, guarantee high system goodput and maximize resource utilization across compute units. However, achieving all three goals simultaneously is challenging since inference requests have very tight latency constraints (10–500ms), and production workloads can be extremely unpredictable at such small time granularities.

We present SHEPHERD, a model serving system that achieves all three goals in the face of workload unpredictability. SHEPHERD uses a two-level design that decouples model serving into planning and serving modules. For planning, SHEPHERD exploits the insight that while individual request streams can be highly unpredictable, aggregating request streams into *moderately-sized groups* greatly improves predictability, permitting high resource utilization as well as scalability. For serving, SHEPHERD employs a novel online algorithm that provides guaranteed goodput under workload unpredictability by carefully leveraging preemptions and model-specific batching properties. Evaluation results over production workloads show that SHEPHERD achieves up to $18.1\times$ higher goodput and $1.8\times$ better utilization compared to prior state-of-the-art, while scaling to hundreds of workers.

1 Introduction

Model inference has grown to become a critical component of many interactive applications [1–11]. Facebook, for instance, serves tens of trillions of inference requests per day [12]. Compared to model training, model inference dominates production costs: on AWS, inference accounts for over 90% of the machine learning infrastructure cost [13]. This has driven significant effort in the design of model serving systems to serve inference requests from several applications with deep neural network (DNN) architectures, often using hardware accelerators like graphics processing units (GPUs) to meet tight per-request latency service-level objectives (SLOs), *e.g.*, 50–500ms. These systems typically group requests with the same SLO and target model into separate request streams, and must make two types of scheduling decisions across them to meet system goals. First, they make request serving decisions to maximize *system goodput*, *i.e.*, the number of requests that meet their SLO deadlines per unit time. Second, they make resource provisioning decisions in order to *scale* to a massive

number of request streams using large pools of GPUs, while ensuring *high utilization* for the GPU pool for cost-efficiency.

We find that meeting these goals is challenging due to *short-term workload unpredictability*: our analysis of both synthetic and production workloads (§2.2) indicates that while the average request arrival rates are predictable over longer timescales (*i.e.*, hours), they are bursty and unpredictable at smaller time granularities (*i.e.*, milliseconds) that must be considered when scheduling requests to meet their SLO deadlines. As such, existing solutions [3–11] fail to meet one or more of the above goals due to two key reasons.

First, existing systems expose a hard tradeoff between resource utilization and scalability under short-term unpredictability, as they typically employ one of two classes of scheduling policies: (1) *periodic per-stream* policies [3–9], which make scheduling decisions (*i.e.*, resource provisioning, batch sizing, load balancing, etc.) for each stream of requests separately in a periodic manner, and (2) *online global* policies, which make scheduling decisions in an online manner by time-multiplexing the entire pool of resources (*e.g.*, GPUs) across all request streams [10, 11]. On one hand, while the periodic and per-stream nature of scheduling for the former permit scaling to many request streams and compute resources, these systems must over-provision resources to handle unpredictable bursts of requests during each period, resulting in poor resource utilization. On the other hand, online global policies can achieve higher resource utilization by adapting the amount of resources allocated to each stream in an online fashion, but scale poorly with the number of request streams and size of the resource pool due to the increased complexity of online scheduling decisions.

Second, existing approaches are fundamentally unable to provide any *guarantees on system goodput* under unpredictable workloads. We establish several important theoretical results to show why this is fundamental (§5). First, making the optimal scheduling decisions (*e.g.*, executing, deferring or dropping a request) requires future knowledge of request arrival patterns, and even with perfect knowledge, the problem is NP-complete. Second, no online algorithm can achieve goodput that is even within a constant factor of the optimal with perfect knowledge *without using preemption*. Since existing approaches [10] employ simple heuristics without considering preemption, their performance can be arbitrarily worse than the optimal under unpredictable workloads (§2.2).

This raises the question: *Is it possible to design a model*

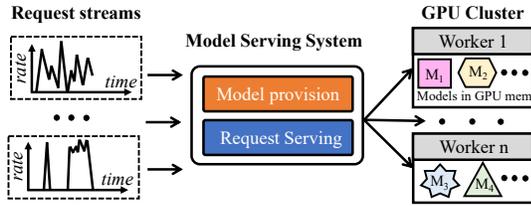

Figure 1: High-level architecture of model serving system

servicing system that is scalable, achieves high utilization, and provides guaranteed high goodput under unpredictable servicing workloads? In this paper, we answer the above question in affirmative with SHEPHERD, a model serving system resilient to workload unpredictability.

To break the utilization-scalability trade-off exposed by existing solutions, we make an important observation: while individual request streams can be highly unpredictable, aggregating them into *groups* permits accurate resource provisioning. Moreover, our analysis show that even moderately-sized groups comprising hundreds to thousands of streams can already offer reasonable predictability (§3.1). SHEPHERD realizes this insight into a *two-level* design that decouples model serving into a *periodic planning* phase and an *online servicing* phase. For the planning phase, we introduce HERD, a planner that periodically classifies inference request streams, DNN models, and GPUs into several *servicing groups*. Then based on the planning results, the servicing phase employs an online algorithm FLEX to serve requests across streams within each servicing group *independently*. HERD solves an ILP to efficiently balance utilization and scalability (§4): on one hand, HERD limits the size of each group, restricting the online scheduling algorithm’s decision space to a limited number of streams and GPUs within each group. On the other hand, HERD provisions a sufficient number of streams and GPU workers for each servicing group to maximize utilization.

To achieve guaranteed high goodput, we design FLEX (§5), an online scheduling algorithm that leverages preemption and model-specific batching properties. First, we note that while preemption permits correcting for sub-optimal scheduling decisions in the online setting, preempting too often can result in significant amount of wasted work. As such, FLEX carefully weighs the utility of the currently running batch of requests against pending candidate requests to decide whether or not the running batch should be preempted. Second, FLEX leverages a model-specific relationship between the batch size in batched inference execution and its execution latency to determine appropriate batch sizes and the order of execution across request streams. We show that both techniques work in concert to achieve SHEPHERD’s goodput guarantee.

We implement SHEPHERD (§6) and evaluate it using a combination of testbed experiments and large-scale emulations with both production and synthetic workloads (§7). Our results show that (1) SHEPHERD achieves up to $18.1\times$ higher goodput and $1.8\times$ higher utilization than periodic per-stream solutions, (2) SHEPHERD achieves up to $5.2\times$ higher goodput

compared to heuristic-based online approaches, and (3) SHEPHERD’s goodput scales linearly with the number of workers.

2 Background and Motivation

We begin with an overview of model serving systems (§2.1) and short-term workload unpredictability (§2.2).

2.1 System Model and Goals

We focus on Deep Neural Network (DNN) model serving systems [3–11] deployed on GPU clusters (Figure 1). Users issue inference requests, which the system must serve using a specific DNN model on one of its GPU workers within a latency SLO specified for the request, typically 10–500ms [6]. Requests for the same model and with the same latency SLO are typically grouped into a *request stream*, with arbitrary request arrival patterns within each stream. In serving these streams, servicing systems can benefit significantly by batching requests on GPUs — on an NVIDIA GTX1080, batching together 32 inference requests improves model serving throughput by $4.7\text{--}13.3\times$ for VGG, ResNet and Inception models relative to serving them individually [6]. Taking the above constraints into account, the system makes two scheduling decisions: *model provisioning* decisions to determine which models should be loaded on which and how many GPUs, and *request serving* decisions to determine:

- *batch size*: how many requests to be executed in a batch,
- *batch priority*: which batch should be executed first, and,
- *target GPU*: which GPU to execute the batch on.

Note that although multiple batches can be executed on one GPU worker concurrently, their execution time becomes non-deterministic due to poor performance isolation on GPUs. As such, most model serving systems [3–11] execute one batch at a time for performance predictability.

The key performance goal for a model serving system is to maximize the system goodput, or the number of served requests that meet their SLO requirements per unit time; requests that fail to meet them often hold no utility for the user. Since servicing systems must cater to thousands of requests streams [1, 12], the system should also scale to large clusters with thousands of GPUs in order to serve them. Finally, since inference pipelines comprise the majority of the machine learning infrastructure costs in production settings [13], servicing systems should target high resource utilization of the GPU clusters to maximize cost-efficiency.

2.2 Short-term Workload Unpredictability

We find that a key challenge in achieving all three of the goals outlined above is *short-term workload unpredictability*¹ — while the average request arrival rates are predictable over longer timescales (*e.g.*, hours), they can be quite unpredictable at smaller time granularities (*e.g.*, milliseconds) that must be

¹Unpredictability in request arrival patterns is orthogonal to *performance predictability* demonstrated in prior works [6, 10], where the execution latency for inference requests on GPUs is often quite predictable.

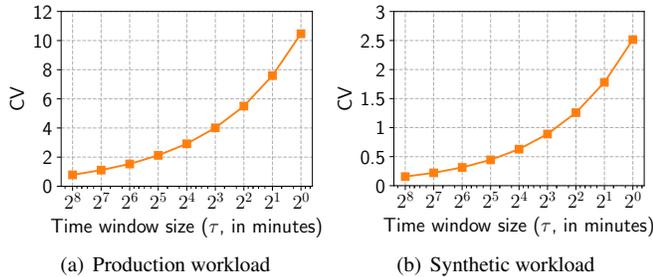

Figure 2: **The coefficient of variance (CV) over the number of request in each time window vs window size (τ , in minutes).** The CV value increases dramatically as time window size decreases.

Solutions	Utilization	Scalability	Goodput
Periodic, per-stream policies [3–9]	✗	✓	✗
Online, global policies [10, 11]	✓	✗	✗
SHEPHERD	✓	✓	✓

Table 1: Existing solutions under short-term unpredictability

considered to meet per-request SLO deadlines. Next, we show the presence of short-term unpredictability and its impact for both production and synthetic application workloads. Since we are unaware of any publicly available production traces for inference workloads, we use Microsoft’s recently released traces for Azure Functions [14] for our production workload, which is noted by recent work to be representative of real-world inference workloads in terms of both diurnal patterns and short-term burstiness [4, 10]. The trace contains the number of function invocations performed at minute granularities across $\sim 46k$ applications over a two-week period. Our synthetic workload simulates $1k$ user request streams as Poisson processes with average arrival rate following an exponential distribution, a commonly-used approach in approximating human-generated invocations [3, 4, 14].

To study workload unpredictability, we divide the entire time period into non-overlapping time windows of size τ , and compute the number of requests $r_{t,s}$ in each time window t for every stream s . We quantify unpredictability in each stream using the coefficient of variance — the ratio of the standard deviation to the mean across $r_{t,s}$. Note that meeting 10–500ms request SLOs requires optimizing scheduling decisions in time window sizes (τ) of hundreds of milliseconds. Figure 2 shows the average coefficient of variance across all streams for different values of τ : for both synthetic and production workloads, coefficient of variance increases drastically as τ decreases. Clearly, while statistical models may be able to estimate average arrival patterns at hours time-scales, the high coefficient of variance at even minute-granularity makes sub-second request arrival patterns nearly impossible to predict.

Under short-term workload unpredictability, existing solutions [3–11] are unable to meet one or more of the three performance goals outlined in §2.1 (Table 1):

Poor resource utilization. Many existing approaches [3–9] make *periodic* provisioning and serving decisions for each user stream *independently*. Within each period (typically a

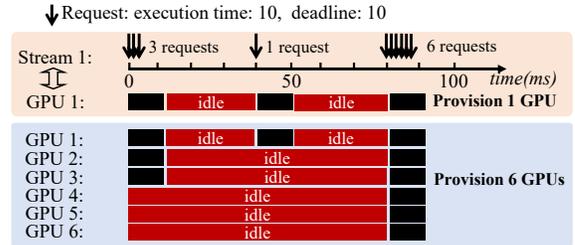

Figure 3: **Periodic per-stream policies observe poor utilization.** Request arrival pattern is shown at the top, with each request’s execution time as well as latency SLO being 10ms. Provisioning one GPU (top) based on average load causes 70% of the requests to miss their deadline. Provisioning six GPUs (bottom) allows all requests to meet their SLOs, but reduces resource utilization to 17%.

few minutes to hours), inference requests are served following a fixed schedule determined at the beginning of the period. Since scheduling decisions are computed per-stream and updated only periodically, such approaches can scale to many streams over massive pools of GPUs. However, these approaches also tend to over-provisioning GPUs in order to maximize the number of request SLOs met in the presence of short-term burstiness, resulting in poor resource utilization.

As a concrete example, Figure 3 shows a user stream with average arrival rate of 1 request every 10ms, with each request’s execution time and latency SLO being 10ms as well. The bursty nature of the workload causes three requests to arrive at $t=0$ ms, one at $t=40$ ms and six at $t=80$ ms. Provisioning one GPU for the stream based on the average load would cause 7 out of 10 requests to miss their SLO deadlines — two from the first burst and five from the last. Provisioning six GPUs permits all request latency SLOs to be met, but reduces the resource utilization to 17%, since the GPUs are collectively idle for 500ms out of 600ms cumulative runtime.

Poor scalability. An alternate approach employed by other serving systems is to time-multiplex the GPU cluster across different user streams to achieve better resource utilization [10, 11]. Instead of provisioning and scheduling request for each stream independently and periodically, the system scales the number of GPUs allocated to each stream in an online manner in response to workload fluctuations. While this results in better resource utilization, it also limits system scalability — scheduling decisions to maximize system goodput grow super-linearly in computational complexity with both the number of request streams as well as the number of GPUs they are served over. Our scalability evaluation of Clockwork [10], a recent model serving system that employs such an approach, shows that its goodput does not scale beyond a hundred GPU workers, saturating at $\sim 50k$ requests/second (§7.1). In contrast, real-world inference serving load at Facebook can be as high as 2.3 billion requests/second [12].

Lack of goodput guarantees. Maximizing goodput is challenging under short-term unpredictability. To see why, consider the example in Figure 4, where a request r with an exe-

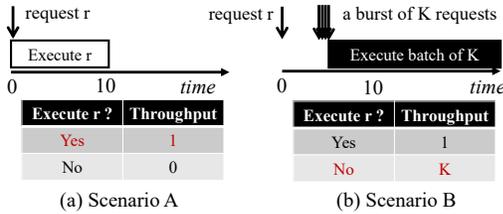

Figure 4: **Example highlighting challenges in online scheduling with short-term unpredictability.** The optimal scheduling decision for request r at time $t = 0$ depends on future arrivals: the performance can be far from optimal depending on the scenario and the scheduling decision to either execute request r or to drop it.

cution duration of 10ms arrives at time $t = 0$. The request has a tight SLO deadline that necessitates its immediate execution for the deadline to be satisfied. The scheduling algorithm has two choices: to schedule the request, or drop it. Unfortunately, the optimal decision to maximize system goodput depends on the future arrival pattern. Specifically, in Scenario A, since no other request arrives during r 's execution, the optimal choice is to serve the request. In scenario B, however, where a large burst of K requests with equally tight deadlines arrive at time $t = 5$, the optimal decision is drop r , since it would prevent K request SLOs from being satisfied in favor of one. Note that if the SLO deadline for r was not as tight, the scheduler would have yet another choice to consider — whether or not to defer r 's execution so that it may be batched with future requests.

Since future arrival patterns cannot be accurately predicted in the short-term, making the right scheduling choice is inherently hard. Existing solutions rely on simple heuristics, which provides no guarantees on how far the performance could be from the optimal. While they perform well on certain workloads, their performance can be arbitrarily worse than the optimal under unpredictable workloads, similar to the above example. We validate this observation experimentally in §7.2.

3 SHEPHERD Design

We now outline SHEPHERD's key design elements.

3.1 Overcoming Short-term Unpredictability

We leverage three key observations to overcome the challenges introduced by short-term unpredictability (§2.2):

Group-level predictability and group multiplexing. We observe that while the short-term arrival pattern for individual request streams are hard to predict, the aggregated arrival pattern across a group of request streams tends to be much more predictable. We validate this observation by considering the same workloads in Figure 2, but randomly classifying the request streams into *serving groups* of different sizes and measuring the coefficient of variance *per-group* instead of *per-stream*. Figure 5 shows that increasing the group sizes drastically reduces the coefficient of variance even at smaller window sizes. Note that the networking community has long made similar observations for bursty network flows, where statistical multiplexing can drastically improve utilization

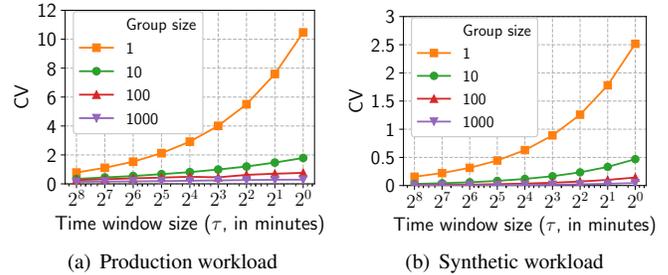

Figure 5: **Coefficient of variance (CV) for groups of streams vs window size (τ , in minutes).** The CV increase with decreasing window sizes is much slower for larger group sizes.

by dynamically sharing a network link across network flows based on their instantaneous demands [15–18].

However, unlike multiplexing a network link across a few flows, multiplexing thousands of GPU workers across tens of thousands of SLO-bound request streams in real time presents a significant scalability challenge. To address it, we observe that even at moderate group sizes (100–1000), the per-group coefficient of variance is small enough to make its arrival pattern highly predictable (Figure 5). This motivates a *group multiplexing* approach that first partitions the GPU cluster and request streams into moderately-sized serving groups (§4), then applies statistical multiplexing per-group to perform online scheduling (§5). This approach offers a means to break the tradeoff between resource utilization and scalability faced by existing systems: moderately sized groups are predictable enough even in the short-term to accurately provision their resources for high resource utilization. At the same time, restricting the online scheduling algorithm's decision space to streams and GPUs assigned to each group drastically limits its computational complexity, allowing the system to scale to much larger number of request streams and GPUs.

Preemption to correct for scheduling errors. As noted in the example from Figure 4, the optimal scheduling decision often depends on future arrival patterns, which can be hard to predict. As such, any non-clairvoyant online algorithm is bound to occasionally make sub-optimal scheduling decisions. We find that the ability to correct such decisions when its sub-optimality becomes apparent via preemptions is *necessary* for achieving performance guarantees for an online scheduling algorithm. For instance, in the example of Figure 4, a solution can correct for a sub-optimal scheduling decision in both scenarios by simply preempting r if a burst of requests arrives later. Preemptions in online scheduling algorithms are not a new concept; they have been used in a variety of scheduling contexts [19, 20] to achieve bounds on the algorithm's *competitive ratio* — the ratio between its performance and that of an optimal offline algorithm. Leveraging insights from recent work on context switching for DNN training on GPUs [21] allows us to realize preemptions efficiently for inference workloads (§6), and combining it with model-specific batch-latency relationships (described next) permits bounding

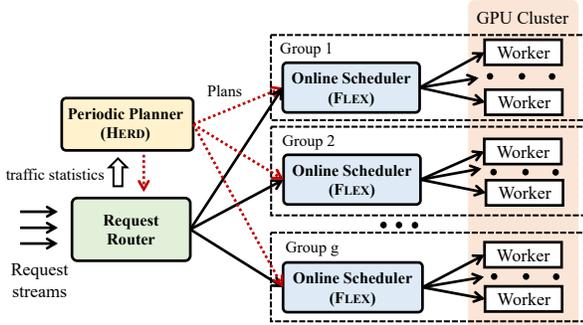

Figure 6: Overview of SHEPHERD design

the competitive ratio for online model serving.

Model-specific batch-latency relationships. Empirical measurements in prior work [6] indicate that a simple linear model can accurately describe the execution latency for varying request batch sizes in model serving workloads. In particular, for a batch B of size $|B|$ being executed on a model m , the execution latency $\ell_m(B)$ is given by:

$$\ell_m(B) = \alpha_m \cdot |B| + \beta_m \quad (1)$$

where β_m is the baseline execution latency for executing an empty batch on the model, while α_m is the latency for each additional request in the batch.

We find exploiting this relationship helps make better scheduling *and* stream grouping decisions. First, larger batches help amortize the fixed cost β_m and achieve higher throughput, but too large a batch may miss the SLO deadline altogether. As such, making scheduling and preemption decisions that leverage the batch-latency relationship to prioritize appropriately large batches that are likely to meet their deadline, permit better performance guarantees for the online scheduling algorithm. Second, when scheduling requests across streams in a serving group of certain models, we find that the online algorithm can achieve better performance guarantees if the models have similar α and β values (§5.2).

We next describe how SHEPHERD incorporates all of these insights into an end-to-end design.

3.2 Design Overview

SHEPHERD leverages group-level predictability in a two-level design that comprises a periodic planning and an online serving component. At a high-level, the periodic planning component leverages long-term load statistics to partition the entire GPU cluster into several serving groups, and determines how models and request streams querying them are mapped to these groups to optimize both resource utilization and system scalability. The online serving component, on the other hand, schedules requests from streams in each serving group across the group’s allocated GPUs, and ensures that its goodput is always within a constant factor of the optimal schedule.

SHEPHERD’s architecture (Figure 6) comprises four key components: a planner (HERD), a request router, a scheduler

(FLEX) per serving group and multiple GPU workers. HERD executes periodic planning, and informs each GPU worker which serving group it belongs to and which models it must serve. HERD also assigns a group-level scheduler to each serving group — the total number of group-level schedulers can be scaled based on the number of models being served by the system and the aggregate load across them. The request router forwards client inference requests to group-level schedulers based on their target model, and collects statistics regarding their arrival patterns that HERD employs to compute group-level mappings. The group-level schedulers, in turn, execute our online scheduling algorithm, FLEX, to schedule inference requests across GPU workers in their own serving group.

HERD (§4). While even random assignment of models and GPU workers to serving groups can achieve decent workload predictability (§3.1), achieving high utilization and guaranteed goodput requires considering a number of additional constraints. To this end, HERD formulates this assignment problem as an Integer Linear Program (ILP) incorporating all such constraints. In particular, as noted in §3.1, colocating models with similar α , β values (Eq. 1) in the same serving group yields better goodput guarantees in FLEX. Consequently, HERD also incorporates model-affinity — a measure of similarity across α , β values — in its ILP.

FLEX (§5). FLEX’s goal is to provide guaranteed high goodput for each group under short-term unpredictability. To this end, we answer three key theoretical and practical questions:

- **What performance guarantees are possible?** We first establish two impossibility results. We show that determining an optimal solution is NP-hard, even in the offline setting. In the online setting, we show that no online algorithm can achieve performance *competitive* with the optimal offline solution without using preemption. Since prior model serving systems do not employ preemption, they are fundamentally unable to provide any performance guarantees.
- **What performance guarantees can FLEX provide?** FLEX ensures that for each serving group, the aggregated goodput achieved is guaranteed to be at most $12.62 \cdot K \times$ worse than the optimal offline schedule with complete knowledge of the future. K is a model-affinity parameter that reduces to one if all models in the serving group have the same α and β , and increases if they diverge (§5.2).
- **How does FLEX achieve this guarantee?** FLEX leverages two key insights outlined in §3.1: preemption to correct for scheduling errors, and model-specific batch-latency relationships. First, preempting a scheduled batch requires carefully weighing the utility brought by the scheduled batch of requests against the utility of the new batch to be scheduled — the threshold beyond which preemption is performed significantly impacts the performance bound FLEX can achieve. Second, FLEX leverages the model-specific relationship in Eq. 1 to determine appropriate batch sizes

Decision variables	Definition
$x_{ij} \in \{0, 1\}$	Is stream i mapped to group j ?
$y_{cj} \in \{0, 1\}$	Is affinity-set c mapped to group j ?
$z_{kj} \in \{0, 1\}$	Is model k mapped to group j ?
$size_j \in \mathbb{N}^+$	# of GPUs allocated to group j
Input parameters	Definition
mem	GPU memory capacity
\bar{G}	Scalability limit for # of GPUs per group
N	# of GPUs in cluster
$h_{ki} \in \{0, 1\}$	Does stream i use model k ?
$q_{ck} \in \{0, 1\}$	Does affinity-set c include model k ?
Optimization goal	Definition
$bt(i)$	The burst tolerance metric for stream i

Table 2: Variables used in HERD’s ILP.

and their order of execution across request streams.

4 Periodic Planner: HERD

HERD operates in two steps. It first determines the number of GPUs n_i that would be needed to sustain the average load $rate_i$ for each request stream separately. To do so, HERD empirically measures the maximum goodput T_i each stream i can achieve on a single GPU, and uses it to compute n_i as $\frac{rate_i}{T_i}$. It uses n_i to define a new *burst tolerance* metric (bt) that captures the increase in load that the stream can tolerate if assigned to a particular serving group relative to the average-load based assignment of GPUs. More formally,

$$bt(i) = \frac{\# \text{ GPUs } i \text{ can use for its peak load}}{\# \text{ GPUs } i \text{ needs for its average load}} = \sum_j \frac{size_j \cdot x_{ij}}{n_i}$$

where x_{ij} is 1 if stream i is assigned to group j (0 otherwise), and $size_j$ is the number of GPUs assigned to group j .

Second, HERD uses an Integer Linear Program (ILP) to combine streams into serving groups to *maximize the minimum burst tolerance across all streams*; this captures the goal of ensuring every stream can tolerate as heavy a burst as possible, subject to a certain set of constraints:

- Cluster-size limit** ensures that the total number of GPUs assigned across all serving groups is no larger than the cluster-size N (in number of GPUs).
- Group-worker limit** ensures that the total number of GPUs $size_j$ assigned to each group j does not exceed the maximum scalability limit \bar{G} of the online algorithm.
- GPU-memory limit** ensures that the sum of model sizes assigned a serving group j does not exceed the GPU memory capacity mem .
- Group surjectivity** ensures that every stream i is assigned to a single group j , and only if its associated model is also assigned to group j .
- Affinity-set surjectivity** ensures that models assigned to the same group j have similar α, β values (as defined in Eq. 1) to ensure better performance guarantees in FLEX.

We capture the divergence in model α, β values as K (defined in §5), and pre-compute affinity-sets c_1, c_2, \dots as a partitioning of models such that K between any two models in an affinity set is $\leq \bar{K}$; this simplifies our ILP constraint to only picking models from the same cluster.

Our ILP is presented below, with variables listed in Table 2:

$$\begin{aligned}
 & \mathbf{maximize} \quad \min_i \{bt(i)\} & (2) \\
 \mathbf{s.t.} \quad & \sum_j size_j \leq N, & \text{(a) Cluster-size limit} \\
 & size_j \leq \bar{G}, \quad \forall j & \text{(b) Group-worker limit} \\
 & \sum_k z_{kj} \cdot |m_k| \leq mem, \quad \forall j & \text{(c) Memory limit} \\
 & \left. \begin{aligned} & \sum_j x_{ij} = 1, \quad \forall i \\ & h_{ki} \cdot x_{ij} \leq z_{kj}, \quad \forall i, j, k \end{aligned} \right\} & \text{(d) Group surjectivity} \\
 & \left. \begin{aligned} & \sum_c y_{cj} = 1, \quad \forall j \\ & q_{ck} \cdot z_{kj} \leq y_{cj}, \quad \forall i, j, k \end{aligned} \right\} & \text{(e) Affinity-set surjectivity}
 \end{aligned}$$

Note that the above formulation is not linear due to the non-linear optimization goal, which contains: (1) a max-min term, and, (2) a product between binary and non-negative variables ($x_{ij} \cdot size_j$). However, both can be linearized using standard techniques [22] — we omit the linearized ILP for brevity. Similar to prior work [6], HERD ensures that all models to be served by a worker in the subsequent online serving phase are present in GPU memory, with some memory set aside for the operation of the online algorithm, FLEX. We discuss additional challenges due to memory constraints in §8.

HERD complexity and periodicity. Since solving HERD’s ILP is NP-hard, and we must scale to millions of streams and thousands of workers, we first aggregate streams using the same model into a single “model-stream”, then apply the ILP to optimize the burst tolerance metric across the model-streams. The burst tolerance metric of the model-stream the lower bound of the burst tolerance metric for each stream in it. Note that different streams in the model-stream may have different SLOs, but this will not affect the correctness of our ILP, since none of the constraints (a) – (e) depend on per-stream SLO. Instead, FLEX incorporates the impact of SLOs across different streams during online serving.

Also, note that we only need to ensure that the ILP solver is much faster than HERD’s periodicity, which, in turn, depends on how frequently the workload characteristics change enough to require recomputing group assignments. Fortunately, our analysis of Microsoft’s Azure Function trace [14] shows that the workloads within moderately-sized serving groups remain stable for tens of minutes or more, while our solver can compute a plan within a few seconds (§7.3).

Input variables	Definition
$S = \{r_1, r_2, \dots\}$	A request stream from one application.
a_r, d_r, m_r	Arrival time, deadline, model for request r .
$a(B), d(B), m(B)$	Arrival time, deadline and model for batch B .
$\mathbb{B} = \{B_1, B_2, \dots\}$	Set of all possible batches.
Decision variables	Definition
$I(B, t, n) \in \{0, 1\}$	Is batch B is executed at time t on GPU n ?

Table 3: Notations for online batch scheduling.

5 Online Serving Algorithm: FLEX

We first formulate the online serving problem (§5.1) and then present the FLEX algorithm to provide guaranteed goodput under short-term unpredictability (§5.2).

5.1 Problem Formulation

Our online serving setting focuses on scheduling inference requests across models and GPUs assigned to a single serving group. Requests within each stream query the same model with the same latency SLO. Each request r has an arrival time a_r , deadline d_r and queries model m_r . Requests are served in batches; for a batch B , arrival time $a(B)$ is the arrival time of the most recent request in B , and deadline $d(B)$ is the earliest deadline of all requests in B . Let \mathbb{B} be the set of all possible batches of requests; the online serving algorithm decides whether to execute batch $B \in \mathbb{B}$ at time t on GPU n , which we capture as the decision variable $I(B, t, n) \in \{0, 1\}$. The goal of online serving is to maximize the overall goodput: the number of requests that meet their SLOs per second. Table 3 summarizes the notations for our problem formulation.

Optimal offline serving algorithm. We find that the offline serving problem where the scheduler has access to the complete future can be formulated as the following Zero-one Integer Linear Program (ZILP):

$$\begin{aligned}
& \text{maximize } \sum_t \sum_n \sum_{B \in \mathbb{B}} |B| \cdot I(B, t, n) & (3) \\
\text{s.t. } & \sum_t \sum_n \sum_{\{B|r \in B\}} I(B, t, n) \leq 1, & \forall r & (a) \\
& \sum_{B \in \mathbb{B}} \sum_{\{t'|t' \leq t \leq t' + \ell_{m_B}(B)\}} I(B, t', n) \leq 1, & \forall t, n & (b) \\
& a(B) \cdot I(B, t, n) \leq t, & \forall B, t, n & (c) \\
& (\ell_{m_B}(B) + t) \cdot I(B, t, n) \leq d(B), & \forall B, t, n & (d) \\
& I(B, t, n) \in \{0, 1\}, & \forall B, t, n & (e)
\end{aligned}$$

Intuitively, the ZILP maximizes the total number of requests that meet their latency SLOs across all selected batches ($I(B, t, n) = 1$), which in turn maximizes the total goodput. The ZILP constraints correspond to:

- Each request can be executed in at most one batch,
- A GPU can only execute one batch at a time,
- No selected batch can start before its arrival time,

Algorithm 1 FLEX Algorithm

```

1: Initialize:
2: for each model  $m$  do
3:    $Q_m \leftarrow$  Priority queue of  $m$ 's requests sorted by deadlines.
4: Event: On completion of a batch on any GPU  $n$ :
5:    $B_{g,n} \leftarrow$  BATCHGEN( $n$ ) # Largest feasible batch across all  $Q_m$ 
6:   Execute  $B_{g,n}$  and dequeue requests in  $B_{g,n}$  from model queue
7:   for each GPU  $n$  do
8:      $B_{g,n} \leftarrow$  BATCHGEN( $n$ ) # Update candidate batch
9: Event: On arrival of request  $r$ :
10: Enqueue  $r$  to corresponding queue
11: for each GPU  $n$  do
12:    $B_{c,n} \leftarrow$  The batch currently being executed on GPU  $n$ 
13:    $B_{g,n} \leftarrow$  BATCHGEN( $n$ )
14:   if  $B_c = \emptyset$  then
15:     Execute  $B_{g,n}$  and dequeue requests in  $B_{g,n}$ 
16:   else if  $|B_{g,n}| \geq \lambda \times |B_{c,n}|$  then # Preemption rule
17:     Preempt  $B_{c,n}$ 
18:     Execute  $B_{g,n}$  and dequeue requests in  $B_{g,n}$ 
19:     Treat requests in  $B_{c,n}$  as new arrivals (go to Line 11)

```

- Every selected batch must finish before its deadline, and
- The decision variable $I(B, t, n)$ must either be 1 or 0.

Clearly, the optimal solution to the above ZILP is also the optimal offline schedule. Obtaining such an optimal is unrealistic — not only is it impractical to have access to the complete future (or even a reasonable prediction of it, §2), computing the optimal solution to the ZILP is NP-hard [23].

Achievable guarantees. However, the optimal offline schedule provides us with a baseline of the best schedule possible, and permits us to reason about how close an online algorithm can get to such a solution. More formally, the performance guarantee an online algorithm can achieve is typically captured by the *competitive ratio*: the worst-case ratio of the ZILP's goodput to the online algorithm's goodput over all possible inputs. Note that our focus is on online request serving decisions, so we assume both algorithms have the same resources provisioned to them. We establish the following important result regarding the competitive ratio:

Theorem 5.1 *No non-preemptive, deterministic algorithm can achieve a bounded competitive ratio for online serving.*

We defer the proof to Appendix A, but note that since existing online serving algorithms [6, 10, 11] are non-preemptive, they are incapable of achieving a bounded competitive ratio.

5.2 FLEX Algorithm

Algorithm 1 presents our FLEX algorithm that achieves a bounded competitive ratio for online serving. During initialization, FLEX creates a priority queue Q_m for each model m , which holds requests sorted by tightness of their deadlines. The algorithm reacts to two key events: (1) *completion event* of a batch on any GPU, and, (2) *arrival event* of a new request.

For a completion event, FLEX simply generates a new batch B_g and executes it; all requests in B_g are dequeued from corresponding model queue Q_m . To generate the new batch, FLEX finds the largest feasible batch across all queues, such that all requests in the batch can meet their latency SLOs.

For an arrival event, FLEX generates a candidate batch for each GPU as outlined above, and compares it with the currently running batch. If the generated batch is λ times larger than currently running batch, the current batch is preempted. If preemption occurs, requests in preempted batch that can still meet their SLOs are re-enqueued to their corresponding priority queues. The re-enqueued requests will be treated as newly arrived requests so they can be scheduled again.

We now dive deeper into salient features of the algorithm.

Choice of λ . The preemption threshold λ plays a crucial role in bounding FLEX’s competitive ratio. A conservative preemption policy with larger λ can result in a poor competitive ratio, while an aggressive preemption policy with smaller λ can waste GPU resources, since the preempted work does not contribute to system goodput. As such, we express the competitive ratio in terms of λ , and formulate the problem of finding the optimal competitive ratio as an optimization problem. Solving this problem yields the optimal value of $\lambda \approx 3.03$ (Theorem 5.2). Note that while a worker may experience cascading preemptions if batches keep arriving with sizes $\lambda \times$ than the currently executing batch, our choice of λ ensures that the total wasted work is always much less than the additional useful work performed post-preemption. In practice, the effect of cascading preemptions is bounded due to our maximum batch size limit (128 by default). We defer the description of our preemption implementation to §6.

Prioritizing batches for a single model. Online job scheduling algorithms [19, 20, 24–27] tend to consider one of two key metrics as optimization goals: a job’s *value*, and its *value density*. In the online model serving context, the value of a job (batch) corresponds to the number of requests it contains (i.e., its batch size), while the value density corresponds to its contribution to system goodput (i.e., $\frac{\text{batch size}}{\text{batch latency}}$). Traditional online job scheduling algorithms often fail to achieve a bounded competitive ratio since optimizing these two goals are often at odds with each other, i.e., optimizing total value density comes at the cost of optimizing total value across jobs, and vice versa. Fortunately, Eq. 1 establishes a linear relationship between value density and value for batches of inference requests: for a single model, *larger batches always contribute more to system goodput*. As such, our preemption and batch generation criteria always favor larger batches to maximize total value and value density simultaneously, enabling FLEX to achieve a bounded competitive ratio. In contrast, prior slack-based prioritization schemes (e.g., tightest deadline first [10]) are unable to provide such guarantees. In fact, our evaluation (§7) shows that prioritizing larger batches over those with tighter deadlines leads to higher goodput under high load.

Extending FLEX to multiple models. While the above prioritization scheme is straightforward when a single model is involved, extending FLEX’s competitive ratio analysis to a multi-model scenario is challenging, since the linear relationship between batch value and value density no longer holds *across* models. However, the batch-latency relationship in Eq. 1 still allows us to bound the batch value and value density across models using the model-specific parameters α and β . More precisely, we define an affinity metric $A(m_i, m_j)$ between two models m_i and m_j as:

$$A(m_i, m_j) = \begin{cases} \frac{\alpha_i + \beta_i}{\alpha_j}, & \text{if } \alpha_j + \beta_j - \beta_i \leq 0 \\ \min\left(\frac{\alpha_i + \beta_i}{\alpha_j}, \max\left(\frac{\alpha_i}{\alpha_j + \beta_j - \beta_i}, \frac{\alpha_i}{\alpha_j}\right)\right), & \text{otherwise} \end{cases}$$

where $\alpha_i, \alpha_j, \beta_i$ and β_j are the model-specific parameters for models m_i and m_j respectively. While its specific formulation is devised to establish FLEX’s competitive ratio (Theorem 5.2), we note that $A(m_i, m_j)$ is close to 1 if m_i and m_j have similar α and β , and deviates from 1 as the α and β values for the models diverge. For a set of models \mathbf{M} , we show that the competitive ratio is a multiple of K , the largest affinity value $A(m_i, m_j)$ across all pairs of models (m_i, m_j) in \mathbf{M} , i.e.,

$$K = \max_{i, j \in \mathbf{M}} A(m_i, m_j) \quad (4)$$

FLEX properties. Our analysis in Appendix B shows that:

Theorem 5.2 *Algorithm 1 is $12.62 \cdot K$ -competitive with preemption threshold $\lambda \approx 3.03$, with K defined in Eq. 4.*

We note that FLEX is the first algorithm that achieves guaranteed performance for online model serving to the best of our knowledge. We validate FLEX’s performance empirically over a wide range of representative workloads in §7. Finally, while we defer the complexity analysis to Appendix C the following result establishes FLEX’s complexity:

Theorem 5.3 *FLEX has a worst-case complexity of $O(G)$, where G is the number of GPUs in the serving group.*

6 SHEPHERD Implementation

Our SHEPHERD implementation follows the architecture described in Figure 6. The periodic planner (HERD), request router and online scheduler are implemented as C++ processes, while the GPU workers support configurable model execution runtimes like PyTorch [28] and Apache TVM [29].

Supporting preemptions. While recent hardware-based preemptions on newer GPUs [31] may enable better performance, we opt for software-based preemptions adapted from Pipeswitch [21] in SHEPHERD due to its general applicability to commodity GPUs. Pipeswitch supports preemption of DNN training tasks by inserting exit points between the training phases of different DNN layers: when a preemption is requested, the execution of the current training task can be terminated at the next exit point. Since PipeSwitch currently supports preemptions for PyTorch only, we use the PyTorch

Model	α (ms)	β (ms)	# Exit points
ResNet18 (RN18)	0.22	3.74	40
ResNet34 (RN34)	0.38	5.78	46
ResNet50 (RN50)	0.75	7.96	46
ResNet101 (RN101)	1.25	13.57	39
ResNet152 (RN152)	1.77	18.98	84
ResNeSt50 (RS50)	1.18	15.39	78
ResNeSt101 (RS101)	1.91	29.21	57
ResNeSt200 (RS200)	3.35	45.43	96
ResNeSt269 (RS269)	4.37	74.20	128
DenseNet121 (DN121)	0.69	19.96	129
DenseNet161 (DN161)	1.74	23.10	171
DenseNet169 (DN169)	0.83	27.47	120

GoogLeNet (GN)	0.25	8.41	44
Inception v3 (I3)	0.96	11.77	122
R-CNN (RCNN)	2.59	14.90	51
BERT (BERT)	40.98	5.67	43

Table 4: DNN Models evaluated in SHEPHERD. BERT [30] is a popular NLP model, while the rest are popular CV models from six different model families.

runtime by default in our implementation, although the same approach could be implemented for Apache TVM as well.

Adapting the preemption approach from training to inference pipelines introduces a key challenge: while the overhead for preemption is not a major concern for long-running model training tasks, it is quite crucial to minimize preemption overheads for model inference. On one hand, adding too few exit points to an inference task introduces unacceptable *preemption delay* — the time between from the preemption being requested and actually being completed — since the preempted task may still execute for tens of milliseconds before the reaching next exit point. On the other hand, adding too many exit points slows down the normal execution of inference tasks, as each exit point introduces non-negligible *execution delay*. To better navigate the trade-off, we evaluate the preemption and execution delay overheads with different number of exit points for different DNN models via comprehensive profiling, and determine the optimal number of exit points for each individual model (§7.3). Table 4 shows the DNN models used in SHEPHERD, with their α , β values (Eq. 1) and the number of exit points. Note that adding exit points incurs a one-time offline profiling cost during model registration; this can be implemented as a part of the DNN framework, making it completely transparent to users.

7 Evaluation

We evaluate SHEPHERD to answer the following questions:

- How does SHEPHERD compare against state-of-the-art schemes for real-world workloads? (§7.1)
- How does each design component in SHEPHERD contribute to its performance gains? (§7.2)
- What overheads do SHEPHERD’s preemption and periodic planning components introduce? (§7.3)

Setup. All our experiments were run on Amazon EC2. For GPU workers, our testbed experiments use 12 p3.2xlarge instances each with 8 vCPUs, 61GB RAM, and one NVIDIA Tesla v100 GPU with 16GB memory, while our large-scale emulations use m4.16xlarge instances with 64 vCPUs and 256GB RAM. The request router, periodic planner, and online schedulers are deployed on separate m4.16xlarge instances.

Metrics. We focus on goodput, utilization and scalability as our key metrics. Goodput and utilization values are averaged over 5 runs, while scalability is measured as the increase in system goodput on increasing the number of workers.

Compared schemes. We compare SHEPHERD against Clockwork [10] and Nexus [6]. Clockwork is representative of online global scheduling policies, while Nexus is a representative of the periodic per-stream approach (§1). We implement all evaluated policies in our SHEPHERD prototype and use a PyTorch-based runtime to ensure that the performance differences are solely due to the scheduling decisions rather than choices in system implementation or the underlying runtime.

For Nexus, we set the reconfiguration period to 60 seconds as recommended in [6]. Moreover, since Nexus is designed for predictable workloads, we adapt their algorithm to provision for the peak demand in every 60-second window of the workload to ensure it can sustain the provided load. For SHEPHERD, we set the GPU group-worker limit to 12, since we found it to be large enough to ensure workload predictability (due to a large enough group size) while being well within our scheduler’s scalability limit. The GPU memory limit for p3.2xlarge instances is large enough to fit all 13 DNN models. Finally, we place all the models in a single affinity-set.

DNN Models. We evaluate SHEPHERD with 17 DNN models widely used for model inference (Table 4), taken from PyTorch Hub [32]. For Clockwork and Nexus, we use models without any exit points (needed for preemption in SHEPHERD, §6) to ensure they do not suffer any performance penalties for execution delays. We ensure the models remain in GPU memory for the duration of all our experiments to eliminate performance impacts of loading models into GPU memory.

Workloads. Similar to prior work [10], we use the Microsoft’s publicly-released production traces from Azure Functions (MAF) [14] as a representative production model serving workload. MAF interleaves a wide range of workloads, including heavy-sustained, low-utilization, bursty and fluctuating workloads. For our 13 profiled DNN models, we assign the 46,000 streams from MAF to models in a round-robin manner, and configure all streams with a default SLO of 250ms², unless otherwise specified. The MAF trace only contains the aggregated number of requests per one-minute interval for each request stream. Therefore, we generate two request ar-

²We use a relatively relaxed SLO compared to [10] since the PyTorch runtime used in our implementation observes longer inference latencies compared to the TVM runtime used in [10].

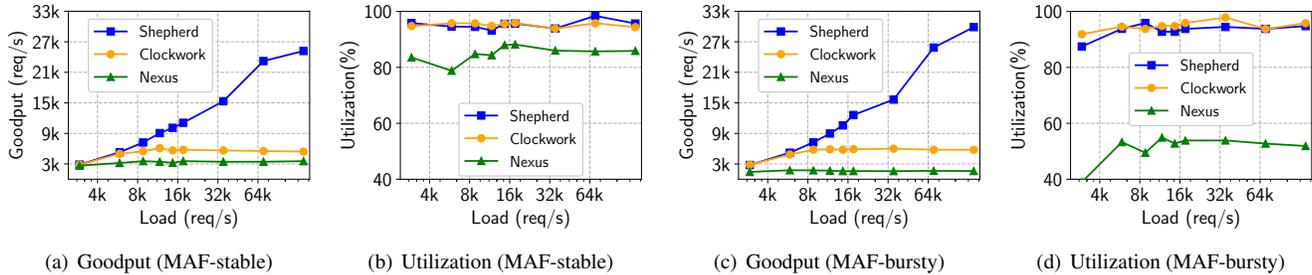

Figure 7: **Performance variation with load.** Under high load, SHEPHERD achieves 4.6 (5.2) \times and 7.1 (18.1) \times higher goodput than Clockwork and Nexus under the MAF-stable (MAF-bursty) workload, respectively. SHEPHERD and Clockwork achieve high system utilization while Nexus’s utilization remains under 89% (55%) across different arrival rates under the MAF-stable (MAF-bursty) workload.

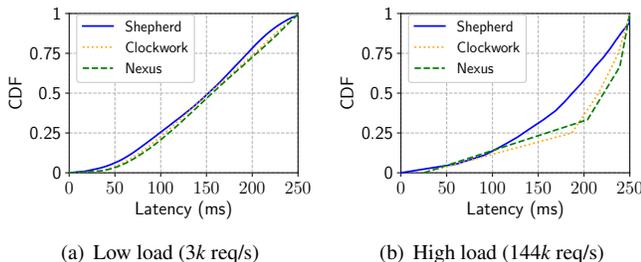

Figure 8: **Latency CDFs for MAF-stable workload with 250ms SLO.** The latency CDF is presented for the set of requests admitted by each approach. At high load, large portions of Clockwork and Nexus request latencies are close to the SLO, while SHEPHERD’s request latencies are distributed more evenly. See §7.1 for details.

arrival patterns within each one-minute interval: (1) a Poisson process to model stable workloads, similar to [10] (“MAF-stable”), and (2) a more bursty Markov-modulated Poisson process (MMPP) similar to [9] (“MAF-bursty”).

7.1 SHEPHERD in the Wild

We first evaluate the compared systems for real-world workloads on a testbed comprising 12 GPU workers and large-scale emulations that mimic work done by a GPU on CPU cores.

Performance variation with load (Figure 7). For the MAF-stable workload, with a low request arrival rate (*e.g.*, at $\sim 3k$ requests/second), all systems can meet the SLO deadlines for most requests in the workload. As such, both SHEPHERD and Clockwork achieve high system utilization (over 95%) and high goodput. At higher loads, while both systems are consistently busy serving requests (resulting in high utilization) neither SHEPHERD nor Clockwork can satisfy all request deadlines; however, since Clockwork prioritizes requests based on how close their deadline is, it greedily schedules many small batches of requests with tight deadlines, resulting in a reduced goodput. In contrast, SHEPHERD always prioritizes execution of larger batches, while the use of preemption ensures that large batches never get blocked by small batches scheduled before them. SHEPHERD can therefore efficiently utilize limited GPU resources to maximize goodput under high load, and while Clockwork’s goodput starts to saturate beyond a load of 6k requests/second, SHEPHERD’s goodput keeps in-

creasing, outperforming Clockwork by up to 4.6 \times at 144k requests/second. We confirm that SHEPHERD’s gains stem from its preemption and prioritization design choices in §7.2. We observe similar trends for Clockwork and SHEPHERD under the MAF-bursty workload.

For Nexus, we find that the goodput largely remains the same as we increase the load under both MAF-stable and MAF-bursty workloads, with a goodput that is up to 7.1 \times and 18.1 \times lower than SHEPHERD. Moreover, Nexus’s utilization remains under 89% for the MAF-stable workload and 55% for the MAF-bursty workload — even under high load. These observations can largely be attributed to Nexus’s offline approach — during its periodic planning phase, Nexus takes the arrival rate as input and calculates the number of GPU workers required along with an offline schedule for each worker. With a fixed number of workers, Nexus can only make its planning decision assuming a specific arrival rate that it can completely satisfy, which ends up being much lower than the applied load. Moreover, during online serving phase, Nexus is unable to adjust its planning decisions dynamically based on the increased arrival rates. This impact is even more severe for the MAF-bursty workload, where predetermined execution plan is unable to adapt to periodic bursts of requests, resulting in even lower utilization (1.8 \times worse than SHEPHERD) and goodput relative to the MAF-stable workload.

Figure 8 plots per-request latency CDFs for SHEPHERD, Clockwork, and Nexus at low (3k requests/second) and high load (144k requests/second) for the MAF-stable workload. Note that while Figure 7(a) shows the proportion of requests admitted by each system, the CDF only depicts the latency of requests admitted by each solution. All systems observe similar latency distributions at low load (Figure 8(a)). At high load, however, a large portion of requests in Clockwork observe latency close to the SLO, since Clockwork prioritizes serving requests closer to their deadlines. Nexus also shares a similar CDF pattern, as its periodic scheduler tries to batch together as many requests as it can based on request deadlines. In contrast, SHEPHERD’s request latencies are distributed more evenly; this is because SHEPHERD prioritizes requests based on their batch sizes rather than their deadlines, and the evaluated workload results in batches of widely varying sizes at different times. We observe similar trends under the

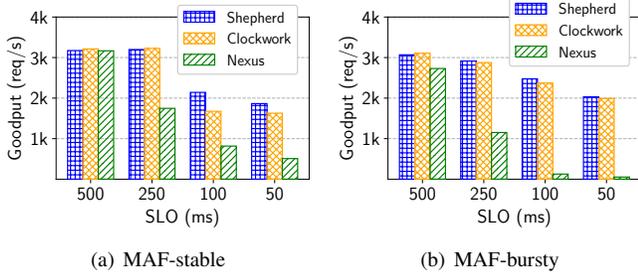

Figure 9: **Goodput with varying request SLOs.** SHEPHERD outperforms Nexus and Clockwork by up to $38\times$ and $1.3\times$, respectively, under tight SLOs. We omit SLOs ≤ 10 ms since some of our evaluated models have higher execution latencies (Table 4).

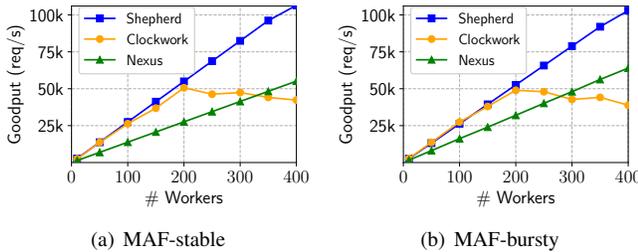

Figure 10: **Scheduler scalability with emulated workers.** For both workloads, Clockwork does not scale beyond 200 workers; Nexus scales linearly but observes 40–50% lower goodput than SHEPHERD. SHEPHERD observes both high goodput and linear scaling.

MAF-bursty workload.

Goodput with varying request SLOs (Figure 9). To understand the impact of request SLOs, we fix the arrival rate to $\sim 3k$ requests/second and measure the goodput for the compared approaches with varying SLO values. All approaches achieve high goodput with 500ms SLO, since almost all request deadlines can be met with a relaxed SLO. On reducing SLO from 500ms to 50ms, all approaches observe reduced goodput; Clockwork’s reduction is smaller due to its online algorithm that prioritizes requests with tighter deadlines, while Nexus observes higher reduction, especially for the MAF-bursty workload. This is because its periodically computed static execution plan is unable to adapt to small bursts of requests, resulting in even fewer requests meeting their deadlines. However, SHEPHERD’s online FLEX algorithm is able leverage prioritization and preemption to maximize the number requests that meet the stringent SLOs, outperforming both Clockwork and Nexus by up to $1.3\times$ and $38\times$ respectively.

Scheduler scalability (Figure 10). Due to the limited number of GPUs in our testbed, we were unable to evaluate the scalability of SHEPHERD and existing systems beyond a point. We therefore complement our testbed experiments with large-scale emulations with up to 400 *emulated* workers. As in prior work [10], an emulated worker is identical to a real SHEPHERD worker, except an inference request triggers no meaningful work; instead, they wait for a period of time determined by the corresponding model’s batch-latency characteristics (Table 4), before returning a response. We run the

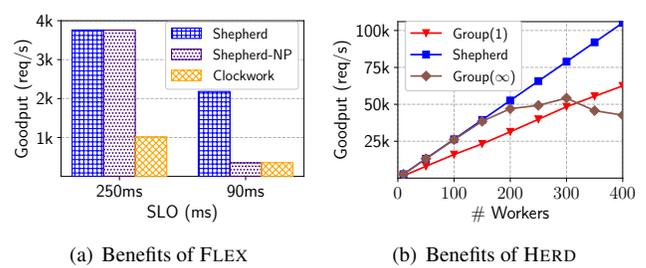

Figure 11: **Understanding SHEPHERD benefits.** (a) Prioritization and preemption in SHEPHERD results in $3.7\times$ and $6.2\times$ improvement in goodput, respectively; SHEPHERD-NP refers to a non-preemptive variant of SHEPHERD. (b) SHEPHERD achieves both high goodput and scalability with group-worker limit $\bar{G} = 12$.

MAF-stable and bursty workloads with varying number of emulated workers (N), scaling up the total load applied to the system with the number of workers. We apply a low enough load per worker to ensure any requests dropped in SHEPHERD and Clockwork are solely due to the scheduler’s failure to scale to large number of workers.

Clockwork’s goodput scales linearly with smaller N , slows down around $N = 150$, and saturates at 50k request/second around $N = 200$ since its centralized scheduler becomes the bottleneck³ (Figure 10(a)). Nexus goodput, on the other hand, scales almost linearly with N ; this is expected since Nexus’s scheduling decisions are computed per-stream and updated only periodically. However, its periodically computed schedule results in $\sim 40\%$ lower goodput than SHEPHERD. This is because Nexus’s computed schedule conservatively provisions for a load that a given number of workers can sustain without adapting to any changes due to workload unpredictability, as discussed in the results for Figure 7. Finally, SHEPHERD observes both consistently high goodput and linear scaling. The linear scaling is attributed to SHEPHERD dividing its workers into groups, each with a group-worker count of 12, which is below the scalability limit of our online scheduler. The high goodput, on the other hand, is attributed to each group being large enough for efficient multiplexing across request streams. As such, SHEPHERD outperforms Clockwork and Nexus by $2.5\times$ and $1.8\times$ respectively in terms of goodput at $N = 400$ workers. We note, however, that SHEPHERD employs multiple schedulers — specifically, $\lceil \frac{N}{12} \rceil$ schedulers for N workers — in contrast to Clockwork’s single centralized scheduler to achieve its linear scaling. We observe similar trends with the MAF-bursty workload in Figure 10(b).

7.2 Understanding SHEPHERD Benefits

We now dig deeper into how each design component in SHEPHERD contributes to its overall performance gains.

Benefits of FLEX (Figure 11(a)). To demonstrate the effective

³This trend is consistent with the scalability results reported in the Clockwork paper [10] albeit with a higher peak goodput due to differences in the system implementation and execution runtime.

tiveness of batch prioritization and preemption in FLEX, we create a synthetic workload with two streams. Stream A is bursty and issues requests to the low-latency model ResNet18 ($\sim 4\text{ms}$ for batch size = 1, $\sim 32\text{ms}$ for batch size = 128). Requests in stream A arrive periodically in bursts of 1024 requests at $t = 5\text{ms}, 125\text{ms}, 245\text{ms}, \dots$, i.e., with a period of 120ms. Stream B is stable and issues requests to the high-latency model ResNet269 (79ms for batch size = 1), and has individual requests arriving at $t = 0\text{ms}, 1\text{ms}, 2\text{ms} \dots$; note that in the absence of other queued requests from stream B, any approach would schedule batches of size 1 for it every 1ms.

We provision one GPU worker for both streams, and compare the performance for SHEPHERD and Clockwork for this workload. To decouple the contributions of preemption from prioritization, we also evaluate a non-preemptive variant of SHEPHERD that retains all the properties of FLEX except preemption. We run the experiments under two different SLOs (250ms and 90ms) to separate the contributions of prioritization and preemption in SHEPHERD, as described next.

For 250ms SLO, both SHEPHERD and non-preemptive SHEPHERD outperform Clockwork by $3.7\times$. Since Clockwork prioritizes requests with tighter deadlines, it always ends up prioritizing high-latency requests of stream B over low-latency requests of stream A. In contrast, SHEPHERD’s batch generation prioritizes larger batches — since stream A’s low-latency requests can accumulate much larger batches under the 250ms SLO (e.g., 128 sized batches with 32ms latency) and achieve much higher goodput. Prioritizing stream A’s requests allows SHEPHERD to leverage the limited GPU resource to complete more requests in the same time span. In more detail, after a batch of stream B (comprising a single request) scheduled at time $t = 1\text{ms}$ completes after 79ms, SHEPHERD prioritizes stream A’s queued requests over the remaining requests of stream B. With an SLO of 250ms, most requests in stream A can meet their SLO deadlines, permitting SHEPHERD to achieve high goodput even without preemption.

However, with a reduced SLO of 90ms, non-preemptive SHEPHERD cannot complete executing larger batches of stream A’s requests within their SLO deadline since it *waits* for stream B’s batch to finish (i.e., at $t = 80\text{ms}$). Thus, the performance for non-preemptive SHEPHERD is similar to Clockwork — most of stream A’s requests fail to meet their deadline. With preemption, a large batch of stream A’s requests preempts the scheduled (much smaller) batch of stream B’s requests, allowing most requests of stream A to finish within the deadline. As such, SHEPHERD outperforms both its non-preemptive variant and Clockwork by $6.2\times$. Note that the performance for heuristic-driven and non-preemptive approaches can be made arbitrarily worse than SHEPHERD by increasing stream A’s burst size and reducing its request execution latency, as discussed in §2.2 and Theorem 5.1, respectively.

Benefits of HERD (Figure 11(b)). We use the same setting as the large-scale emulation in §7.1 and vary the number of group-worker limit \bar{G} for HERD (§4). With a group-worker

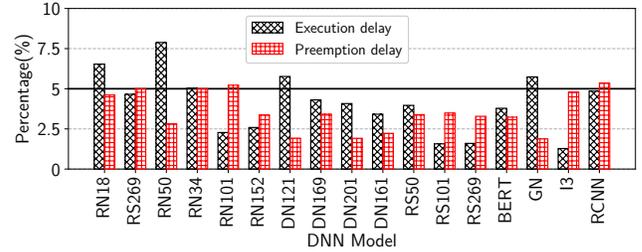

Figure 12: **Preemption overheads.** The preemption delay and additional execution delay relative to the normal batch executions for most of our evaluated models remains below 5%.

# streams	# models	# workers	solver	network	loading
200,000	200	200	0.55	0.19	0.71
400,000	400	400	2.51	0.35	1.23
600,000	600	600	4.28	0.51	1.84
800,000	800	800	8.53	0.62	2.41
1,000,000	1,000	1,000	13.26	0.90	3.14

Table 5: Components of the periodic planning latency (in seconds).

limit of $\bar{G} = \infty$, SHEPHERD always chooses a group size equal to the number of workers. As such, it reduces to the online global approach, observing the same scalability limit as Clockwork (Figure 10). With a group-worker limit of $\bar{G} = 1$, SHEPHERD cannot efficiently multiplex across streams, leading to constantly lower goodput compared to SHEPHERD with multiple workers. As such, HERD allows SHEPHERD to achieve a goodput that is $2.5\times$ and $1.7\times$ higher than the two grouping alternatives, respectively, at 400 workers.

7.3 Understanding SHEPHERD Overheads

Finally, we evaluate the preemption and periodic planning overheads in SHEPHERD to show that neither impact SHEPHERD’s performance benefits in any significant manner.

Preemption overheads (Figure 12). As discussed in §6, efficient preemption should minimize two overheads: (1) *preemption delay*, or the time between from the preemption being requested and actually being completed, and (2) *execution delay*, the additional latency introduced by exit points for normal batch execution. We achieve a reasonable trade-off between these two overheads by specifically tailoring appropriate number of exit points for each model listed in Table 4.

We measure the *relative* preemption overheads introduced by SHEPHERD, i.e., the preemption and execution delay relative to normal batch execution time, averaged over batch sizes 1–128. For most models, both the preemption delay and the extra execution delay are well below 5%.

Periodic planning overheads in HERD (Table 5). The periodic planning latency in HERD consists of three parts: (1) the solver latency for solving the ILP (Eq. 2), (2) the network latency for broadcasting the plan to schedulers and workers, and, (3) the loading latency for loading the models from CPU memory to GPU on each worker. We run large-scale emula-

tion to divide the system into 10 serving groups, and measure these latencies with different number of streams, models, and emulated workers. The solver latency accounts for most of the planning time, taking 13.26 seconds for 1 million streams and 1k workers. Network latency is always less than a second, while model loading time increases with the number of models. Even so, the total planning latency is always much smaller than HERD’s scheduling period, which is tens of minutes. Moreover, the solver and network latency for the next planning phase can be pipelined with the current online serving phase, ensuring that planning is never a bottleneck.

8 Discussion and Caveat

We now outline avenues of future research in SHEPHERD.

Group predictability under different workloads. Although we have demonstrated group predictability using two representative workloads, we note that the number of streams (i.e., group size) to achieve sufficient group predictability may be different for real-world workloads. With insufficient predictability, HERD may under or overprovision resources for some groups, although FLEX would still provide the same performance guarantee within each group since it does not rely on predictability. Moreover, group predictability itself is rooted in statistical multiplexing theory, and holds when a large enough number of request streams in the workload have statistical independence [33–35]. While well-exploited in the networking community to achieve high utilization under bursty network traffic patterns [15–18], more in-depth quantitative analysis of group predictability for real-world inference serving workloads is important future work.

Model affinity vs. degree of multiplexing. Recall from §4 that HERD includes an affinity-set surjectivity constraint, which requires that models assigned to the same group j have divergence less than \bar{K} . With a small \bar{K} , HERD will break models into more groups, with each group containing fewer but more similar models, i.e., models with similar model affinity values. While this enables tighter performance guarantees in FLEX, it also reduces the degree of multiplexing within each group, since GPU workers in each group can serve streams across a smaller set of models. Although a single affinity group (i.e., $\bar{K}=\infty$) yields a looser competitive ratio, our evaluation shows that it still results in high empirical performance for the MAF workload. Finding an optimal value of \bar{K} is promising future work.

Fairness across request streams. Similar to prior serving system designs [6, 10], we focus on the isolated GPU cluster settings where fairness across request streams and models is not a major concern. Fairness can be an important metric to extend our design to multi-user or cloud scenarios.

Dynamic model swapping. Similar to prior work [6], SHEPHERD only loads models onto GPU memory at the start of a planning period. An alternative solution is to dynamically swap models between GPU and CPU memory on-demand dur-

ing online serving [10]. However, since such swaps are likely to take much longer than serving a request, its cost must be weighed against the potential performance gains from swapping in a new model. We leave incorporating this decision as a part of online serving as future work.

Large DNN models. If a DNN model is so large that it cannot be co-located with other models in GPU memory, HERD must place it in an isolated group with reduced degree of multiplexing. It is possible, however, to break such large models into smaller partitions [36] to group them with other models for better multiplexing.

9 Related Work

We discussed existing model serving systems in §2; we now discuss prior work related to SHEPHERD in other areas.

Preemption for ML workloads. PipeSwitch [21] allows preempting a training tasks to execute an inference task. Irina [11] applies preemption to improve average latency for inference tasks. LazyBatching [8] is an inference system that can preempt and stall the currently ongoing batch. SHEPHERD leverages preemption approaches outlined in these works to achieve guaranteed high goodput. Concurrent to our work, REEF [31] leverages ISA support for preemptions [37, 38] in recent AMD GPUs to enable μ s-scale preemptions. While our current implementation still implements preemptions in software, it can readily incorporate hardware-based preemptions. Future improvements in this space will only improve SHEPHERD’s performance further.

Online job scheduling. The theory community has long considered issues of prioritization and preemption in online job scheduling [19, 20, 24–27]. Its adaptation to model serving, however, has a few nuances — the scheduler for model serving must also decide how to optimally execute requests across batches while taking into account model-specific batch-latency relationships. Our scheduling algorithm exploits both to achieve strong performance guarantees.

10 Conclusion

We have presented SHEPHERD, a distributed a DNN model serving system. SHEPHERD employs a periodic planner that aggregates request streams into moderately-sized groups for high utilization and scalability, and an online scheduler that employs a novel online algorithm to provide guaranteed goodput. Evaluation over production workloads shows that SHEPHERD achieves $17.2\times$ higher goodput and $1.8\times$ higher utilization than prior approaches and scales to hundreds of workers.

A Competitive Ratio without Preemption

Theorem A.1 *No non-preemptive, deterministic algorithm can achieve a bounded competitive ratio for online serving.*

Proof Consider a batch X_1 with $|X_1| = 1$, $\ell_{X_1} = 1$ and $d_{X_1} = 1$ that arrives at time $t = 0$. A deterministic non-preemptive algorithm \mathcal{B} serves X_1 with probability $p = \{0, 1\}$. We consider two scenarios after the scheduling decision at $t = 0$: (A) no request arrives afterwards, and therefore, the optimal solution has a total value of 1, and algorithm \mathcal{B} has a total value of p ; (B) another batch X_2 arrives at time $t = \varepsilon$ with $|X_2| = \omega \rightarrow \infty$, $\ell_{X_2} = 1$ and $d_{X_2} = 1 + \varepsilon$: the optimal solution can achieve a total value of ω by ignoring X_1 , and algorithm \mathcal{B} has a total value of $p + (1 - p) \cdot \omega$, since it is non-preemptive.

Note that the competitive ratio should be no less than the ratio between the optimal solution over algorithm \mathcal{B} in either scenario. As such, by combining both cases we show the competitive ratio c of algorithm \mathcal{B} should be no less than:

$$c \geq \max_{p \in \{0,1\}} \left(\frac{1}{p}, \frac{\omega}{p + (1-p) \cdot \omega} \right) \rightarrow \infty \quad (5)$$

which completes the proof \blacksquare

B Competitive Ratio Analysis for FLEX

We define a *schedule* σ to be a sequence of batch executions (B, t_B) , where t_B is the start time of batch B in the schedule σ . Note that since we allow preemption, some batches may get preempted and never complete; we use $\sigma^c \subset \sigma$ to denote the set of completed batches in σ and $\sigma^p \subset \sigma$ to denote the set of preempted batches. We say a schedule σ is *feasible* if (1) at any time, at most one batch $B \in \sigma$ is executing, and, (2) a request is completed (i.e., executed without being preempted) in at most one batch $B \in \sigma^c$. Let $v(\sigma) = \sum_{B \in \sigma} v(B, t)$ denote the aggregated value of all batches in σ . We have,

$$v(\sigma) = v(\sigma^c) + v(\sigma^p) \quad (6)$$

We use standard competitive analysis to evaluate our algorithm. We denote the schedule due to an algorithm \mathcal{A} as $\sigma_{\mathcal{A}}$, and the optimal schedule constructed by a computationally unbounded offline algorithm as σ_* . We say that algorithm \mathcal{A} is *c-competitive* if for any request stream we have:

$$c \cdot v(\sigma_{\mathcal{A}}^c) \geq v(\sigma_*^c) \quad (7)$$

To better differentiate batch sequences (B, t) between schedule $\sigma_{\mathcal{A}}$ and σ_* , we denote the batch sequences in $\sigma_{\mathcal{A}}$ as (I, t_I) and batch sequences in σ_* as (J, t_J) . Moreover, for a batch $I \in \sigma_{\mathcal{A}}$, we denote its (1) start time as t_I ; (2) value (batch size) as $|I|$; and (3) duration as ℓ_I . The same notation rules apply to $J \in \sigma_*$.

We prove our main result in Theorem 5.2 in three steps. First, we consider a simplification of the online batch scheduling algorithm that only considers online batch scheduling for

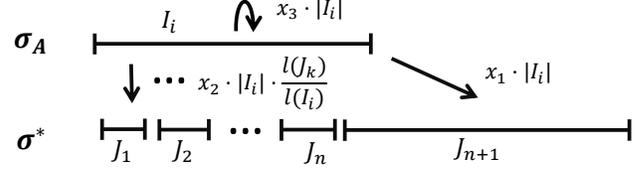

Figure 13: The value assignment rule from one $I \in \sigma_{\mathcal{A}}$ to $J_s \in \sigma_*$.

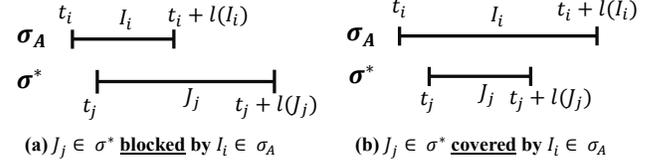

Figure 14: The block and cover relationship between batches in $\sigma_{\mathcal{A}}$ and σ_* . Note that if J is identical to I then J is covered by I (by our definition of blocking).

a single model running on a single GPU (§B.1). We then extend the setting to include multiple models deployed on a single GPU (§B.2), and finally consider the general case of multiple models deployed across multiple GPUs (§B.3).

B.1 Single-GPU Single-Model Setting (sgsm)

For the single GPU, single model setting our key result is: **Theorem B.1** *Algorithm 1 is 10.81-competitive with a single model on a single GPU with preemption threshold $\lambda \approx 2.38$.*

Proof To prove the above theorem, we bound the value of batches in the optimal schedule (σ_*) by the value of completed batches in \mathcal{A} 's schedule ($\sigma_{\mathcal{A}}^c$). To this end, our analysis builds on the *value assignment approach* employed in [19, 20]. This approach operates in two steps:

1. Mapping. First, we *map* each batch in $\sigma_{\mathcal{A}}$ to a set of batches in σ_* in a manner that ensures each batch in σ_* is matched to at least one batch in $\sigma_{\mathcal{A}}$. This mapping identifies batches in σ_* that are related to batches in $\sigma_{\mathcal{A}}$, either because they overlap in their execution durations, or the batches contain common requests. More formally we define three relationships to compare a batch $J \in \sigma_*$ with a batch $I \in \sigma_{\mathcal{A}}$ (Figure 14):

- M1.** J is *blocked* by I if $t_I \leq t_J < t_I + \ell_I \leq t_J + \ell_J$.
- M2.** J is *covered* by I if $t_I < t_J$ and $t_I + \ell_I > t_J + \ell_J$.
- M3.** J is *intersected* by I if neither **R1** or **R2** hold, and $\exists r$ such that, $r \in I$ and $r \in J$.

We say J is temporally related to I if either **R1** or **R2** holds, and spatially related if **R3** holds.

2. Assignment. We assign values from each batch $I \in \sigma_{\mathcal{A}}$ to its mapped batches $J \in \sigma_*$, which we denote as $v_a(I, J)$. This assignment must satisfy two properties. First, it should be *feasible*, i.e., for any $I \in \sigma_{\mathcal{A}}$ its total assignment to all batches in σ_* should be equal to the value of I :

$$\sum_{J \in \sigma_*} v_a(I, J) = |I|, \quad \forall I \in \sigma_{\mathcal{A}} \quad (8)$$

Second, the assignment should be bounded, i.e., the total value assigned from all $I \in \sigma_{\mathcal{A}}^c$ to all $J \in \sigma_*$ must be greater than or equal to a constant portion of the aggregated value of $J \in \sigma_*$:

$$\sum_{J \in \sigma_*} \sum_{I \in \sigma_{\mathcal{A}}^c} v_a(I, J) \geq r \cdot \sum_{J \in \sigma_*} |J| \quad (9)$$

where $r \in [0, 1]$ is a constant. Note that for an assignment that is both feasible and bounded, we have:

$$\begin{aligned} v(\sigma_{\mathcal{A}}^c) &= \sum_{I \in \sigma_{\mathcal{A}}^c} |I| \\ &= \sum_{I \in \sigma_{\mathcal{A}}^c} \sum_{J \in \sigma_*} v_a(I, J) \\ &= \sum_{J \in \sigma_*} \sum_{I \in \sigma_{\mathcal{A}}^c} v_a(I, J) \\ &\geq \sum_{J \in \sigma_*} r \cdot |J| \\ &\geq r \cdot v(\sigma_*) \end{aligned} \quad (10)$$

Based on the definition of competitive ratio in Eq. 7, Eq. 10 suggests a competitive ratio of $c = \frac{1}{r}$.

The key tasks that remain are defining a feasible and bounded assignment v_a , and quantifying the bound r achieved by this assignment.

Defining the value assignment v_a : We are now ready to define our value assignment; as Figure 13 shows, a batch I in $\sigma_{\mathcal{A}}$ may cover n batches J_{c1} to J_{cn} (see **M2**), block at most one batch J_b (see **M1**) and intersect m batches J_{i1} to J_{im} (see **M3**). Our value assignment rules are as follows:

- **A1.** For a batch J_b that I blocks, $v_a(I, J_b) = x_1 \cdot |I|$.
- **A2.** For a batch J_c that I covers, $v_a(I, J_c) = x_2 \cdot |I| \cdot \frac{\ell_{J_c}}{\ell_I}$, i.e., the assigned value is proportional to the duration of J_c . Moreover, since the total duration of all covered batches J_{c1} to J_{cn} is no more than ℓ_I , the total assignment across J_{c1}, \dots, J_{cn} is no more than $x_2 \cdot |I|$.
- **A3.** For a batch J_i that I intersects, we assign a value of x_3 to J_i for every request that is common between I and J_i , i.e., $v_a(I, J_i) = x_3 \cdot |I \cap J_i|$. Since each request will be executed at most once in σ_* , the total assigned value from I across all J_i is no larger than $x_3 \cdot |I|$.
- **A4.** If the total assigned value from I is less than $|I|$, we assign the residual value of I to any arbitrary $J \in \sigma_*$.

It is clear to see that the above assignment ensures that the total assignment from any batch $I \in \sigma_{\mathcal{A}}$ to all $J \in \sigma_*$ equals $|I|$, i.e., satisfies the feasibility constraint Eq. 8, if $(x_1 + x_2 + x_3) \leq 1$. Next, we quantify for each batch $J \in \sigma_*$, the lower-bound r to satisfy the boundedness constraint (Eq. 9).

3. Determining the bound r : A key challenge in determining the bound r for value $|J|$ relative to the value assigned to it, as per the boundedness constraint Eq. 9, is that a batch $I \in \sigma_{\mathcal{A}}$ and a batch $J \in \sigma_*$ can be related both temporally and spatially as outlined in our mapping step. As such, each such

case requires analysis for the bound. As a concrete example, consider a batch J blocked by a batch I (as per **M1**). One possible reason J is not executed in $\sigma_{\mathcal{A}}$ is because a subset $J^E \subset J$ of requests may already have been dequeued from Q_m in $\sigma_{\mathcal{A}}$ and thus will not be executed again. Based on the dequeue condition in Algorithm 1, J^E is the subset of all requests in J that have already completed in $\sigma_{\mathcal{A}}$ at time t_J . On the other hand, it may be the case that J is not executed in $\sigma_{\mathcal{A}}$, because the value added by subset of requests $J^R \subset J$ that still remain to be executed (i.e., $J^R = J \setminus J^E$) is less than twice the value of the batch executed by $\sigma_{\mathcal{A}}$ in its place, namely I .

To accurately capture the impact of both of the above effects in determining the bound r , we define *virtual batches* J^R and J^E for each batch $J \in \sigma_*$ as above (see Figure 15). We denote the fraction of requests in J which belong to J^R as p , so that J^E contains the remaining $1 - p$ fraction of requests. Note that p can take different values in $[0, 1]$ for different J in σ_* . Since the value of a batch equals batch size, we have:

$$\begin{aligned} |J^R| &= p \cdot |J| \\ |J^E| &= (1 - p) \cdot |J| \end{aligned} \quad (11)$$

Our next step is to determine the bound r based on J^R and J^E independently (r_R and r_E , respectively), and take the tighter of the two as our final lower bound, i.e., $r = \max(r_R, r_E)$.

Determining r_R based on J^R : We first consider the lower-bound bound imposed on the value of J by only considering the virtual batches J^R . To this end, we confine ourselves to assignment rules **A1** and **A2** corresponding to blocked and covered batches, respectively.

- **Case 1:** $I \in \sigma_{\mathcal{A}}$ blocks J^R . Since J^R is blocked by I , it must be the case that $|J^R| \leq \lambda \cdot |I|$; otherwise J^R would have preempted I in $\sigma_{\mathcal{A}}$ at time t_J . Combined with the assignment rule **A1**, this gives us:

$$\begin{aligned} \sum_{I \in \sigma_{\mathcal{A}}} v_a(I, J) &\geq x_1 \cdot |I| \\ &\geq x_1 \cdot \left(\frac{1}{\lambda} \cdot |J^R|\right) \\ &= x_1 \cdot \frac{1}{\lambda} \cdot p \cdot |J| \end{aligned} \quad (12)$$

- **Case 2:** $I \in \sigma_{\mathcal{A}}$ covers J^R . To determine the lower bound in this case, we exploit two properties. First, since I covers J^R , $\ell_I > \ell_{J^R}$, i.e.,

$$\ell_I > \ell_{J^R} \quad (13)$$

Second, we exploit the property that a given model can always execute larger batches with smaller latency per record. Since I covers J^R ,

$$\frac{|I|}{\ell_I} > \frac{|J^R|}{\ell_{J^R}} \quad (14)$$

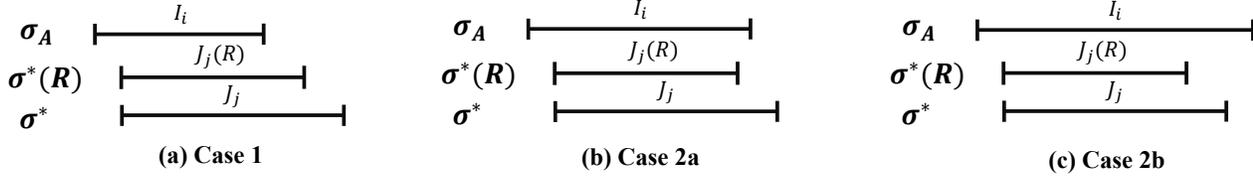

Figure 15: All possible conditions in $\sigma_{\mathcal{A}}$ for a batch $J \in \sigma_*$. Here schedule $\sigma_*(R)$ denotes the batch sequence of $(J(R), t_J)$.

Finally, as Figure 15(b)-(c) shows, this case can be further broken down into the following two sub-cases based on the relation between I and the real batch J :

– **Case 2a: I blocks J .** Assignment **A1** gives us:

$$\begin{aligned}
 \sum_{I \in \sigma_{\mathcal{A}}} v_a(I, J) &\geq x_1 \cdot |I| \\
 &> x_1 \cdot \frac{|J^R|}{\ell_{J^R}} \cdot \ell_I \\
 &= x_1 \cdot \frac{p \cdot |J|}{\ell_{J^R}} \cdot \ell_I \\
 &> x_1 \cdot p \cdot |J|
 \end{aligned} \tag{15}$$

– **Case 2b: I covers J .** Assignment **A2** combined with Eqs. 13 and 14 applied to J gives us:

$$\begin{aligned}
 \sum_{I \in \sigma_{\mathcal{A}}} v_a(I, J) &\geq x_2 \cdot |I| \cdot \frac{\ell_J}{\ell_I} \\
 &> x_2 \cdot \frac{|J|}{\ell_J} \cdot \ell_I \cdot \frac{\ell_J}{\ell_I} \\
 &> x_2 \cdot |J|
 \end{aligned} \tag{16}$$

Note that in this case we do not need consider J^R to determine the bound since I directly covers J .

• **Case 3:** If neither of the above cases occur, then $\sigma_{\mathcal{A}}$ must be idle at time t_J . This implies that J^R must have been empty (i.e., $p = 0$), otherwise J^R would have been scheduled in $\sigma_{\mathcal{A}}$. Therefore, the following trivial bound holds:

$$\sum_{I \in \sigma_{\mathcal{A}}} v_a(I, J) \geq p \cdot |J| = 0 \tag{17}$$

Combining all the cases (Eq. 12, Eq. 15, Eq. 16 and Eq. 17), we have for any $J \in \sigma_*$:

$$\sum_{I \in \sigma_{\mathcal{A}}} v_a(I, J) \geq \min\left(\frac{p \cdot x_1}{\lambda}, x_2\right) \cdot |J| \tag{18}$$

Note that we omit the term from **Case 3**, since the corresponding inequality is dominated by $\frac{1}{2} \cdot x_1 \cdot p$ with $x_1 \leq 1$. Similarly, the term from **Case 2a** is also omitted since it is dominated by Case 1.

Aggregating both sides of Eq. 18 over all $J \in \sigma_*$, we get:

$$\begin{aligned}
 \min\left(\frac{p \cdot x_1}{\lambda}, x_2\right) \cdot \sum_{J \in \sigma_*} |J| &\leq \sum_{J \in \sigma_*} \sum_{I \in \sigma_{\mathcal{A}}} v_a(I, J) \\
 &= \sum_{I \in \sigma_{\mathcal{A}}} \sum_{J \in \sigma_*} v_a(I, J) \\
 &= \sum_{I \in \sigma_{\mathcal{A}}} |I| \\
 &= v(\sigma_{\mathcal{A}})
 \end{aligned} \tag{19}$$

Next, we show how we can upper-bound $v(\sigma_{\mathcal{A}})$ by $v(\sigma_{\mathcal{A}}^c)$. Note that batches in $\sigma_{\mathcal{A}}$ can form a chain based on the preemption relation. For each chain, the next batch on the chain preempts the previous one, and each chain must end with a batch in $\sigma_{\mathcal{A}}^c$. We denote the chain which ends with batch $|I|$ as $chain(I)$. Denote $v(chain(I))$ as the value of all the batches in $chain(I)$, since each batch in $\sigma_{\mathcal{A}}$ will be covered by exactly one chain, we have

$$\sum_{I \in \sigma_{\mathcal{A}}^c} v(chain(I)) = \sum_{I \in \sigma_{\mathcal{A}}} |I| = v(\sigma_{\mathcal{A}}) \tag{20}$$

Moreover, based on the preemption rule we have that for each chain, the value of the i th batch in the chain must be no less than $\lambda \times$ the value of the $i - 1$ th batch. As such, $v(chain(I))$ must be no higher than $\frac{\lambda}{\lambda - 1} \times |I|$, which indicates that:

$$\begin{aligned}
 v(\sigma_{\mathcal{A}}^c) &= \sum_{I \in \sigma_{\mathcal{A}}^c} |I| \\
 &\geq \sum_{I \in \sigma_{\mathcal{A}}^c} \frac{\lambda - 1}{\lambda} \cdot v(chain(I)) \\
 &= \frac{\lambda - 1}{\lambda} \cdot \sum_{I \in \sigma_{\mathcal{A}}} |I| \\
 &= \frac{\lambda - 1}{\lambda} \cdot v(\sigma_{\mathcal{A}})
 \end{aligned} \tag{21}$$

Combined with Eq. 6, we have,

$$\begin{aligned}
 v(\sigma_{\mathcal{A}}) &\leq \frac{\lambda}{\lambda - 1} \cdot v(\sigma_{\mathcal{A}}^c) \\
 &= \frac{\lambda}{\lambda - 1} \cdot \sum_{I \in \sigma_{\mathcal{A}}^c} |I| \\
 &= \frac{\lambda}{\lambda - 1} \cdot \sum_{J \in \sigma_*} \sum_{I \in \sigma_{\mathcal{A}}} v_a(I, J)
 \end{aligned} \tag{22}$$

Combining Eqs. 19 and 22, we get:

$$\sum_{J \in \sigma_*} \sum_{I \in \sigma_A} v_a(I, J) \geq \frac{\lambda - 1}{\lambda} \cdot \min\left(\frac{p \cdot x_1}{\lambda}, x_2\right) \cdot \sum_{J \in \sigma_*} |J| \quad (23)$$

This gives us a bound $r_R = \frac{\lambda - 1}{\lambda} \cdot \min\left(\frac{p \cdot x_1}{\lambda}, x_2\right)$.

Determining r_E based on J^E : Note that all requests in J^E must have been completed in σ_A . So based on our assignment rule **A3**, any request in J^E must have been assigned a value of x_3 from one *completed* batch from σ_A^c (the set of completed batches in σ_A). The above observation permits bounding $|J|$ based on J^E as follows:

$$\begin{aligned} \sum_{I \in \sigma_A^c} v_a(I, J) &\geq \sum_{I \in \sigma_A^c} x_3 \cdot |I \cap J| \\ &\geq x_3 \cdot |J^E| \\ &= (1 - p) \cdot x_3 \cdot |J| \end{aligned} \quad (24)$$

Aggregating both sides of Eq. 24 over all $J \in \sigma_*$, we get $r_E = (1 - p) \cdot x_3$.

4. Determining the optimal competitive ratio: Combining the bounds r_R and r_E , we get the final competitive ratio:

$$\begin{aligned} c_{sgsm} &= \frac{1}{\max(r_R, r_E)} \\ &= \frac{1}{\min_{p \in [0, 1]} \{ \max\left\{ \frac{\lambda - 1}{\lambda} \cdot \min\left\{ \frac{p \cdot x_1}{\lambda}, x_2 \right\}, (1 - p) \cdot x_3 \right\} \}} \end{aligned} \quad (25)$$

To minimize the value of c_{sgsm} , we can select appropriate values of x_1 , x_2 and x_3 subject to the feasibility constraint $x_1 + x_2 + x_3 \leq 1$, and select appropriate value of $\lambda \in (1, \infty)$. Note, however, that we cannot select p — it can take arbitrary values in $[0, 1]$; as such, we have to consider the worst-case value for p to compute the competitive ratio. This provides us the following optimization problem:

$$\begin{aligned} \min_{x_1, x_2, x_3, \lambda} \quad & c_{sgsm} \\ \text{s. t.} \quad & x_1 + x_2 + x_3 \leq 1 \\ & 1 < \lambda < \infty \end{aligned} \quad (26)$$

Solving the above optimization problem (via numerical methods [39]) yields the minimal value for $c_{sgsm} \approx 10.81$ with preemption threshold $\lambda \approx 2.38$. ■

B.2 Single-GPU Multi-Model Setting (sgmm)

We now extend our analysis to the setting with k models $\{m_1, \dots, m_k\}$ deployed on a single GPU. The competitive analysis for the multi-model case also leverages the linear relationship between batch size and batch execution latency: for model m_i , the execution latency for a batch B is $\alpha_i \cdot |B| + \beta_i$, where α_i and β_i are model-specific constants

Theorem B.2 *Algorithm 1 is $10.81 \cdot K$ -competitive with multiple models on a single GPU, with preemption threshold $\lambda \approx 2.38$ and K defined in Eq. 4*

Proof The proof shares a similar structure with the single-GPU, single-model case, and is identical until we determine r_R based on J^R . Even so, the analysis for **Case 1** is still the same, since the preemption rule remains unchanged. For **Case 2**, however, Eq. 14 no longer holds, since with multiple models, a batch with larger length may have a smaller value density than a batch for a different model. However, with Eq. 1 we can replace Eq. 14 with:

$$K \cdot \frac{|I|}{\ell_I} > \frac{|J^R|}{\ell_{J^R}} \quad (27)$$

Now we show why Eq. 27 always holds. Assume I and J are batches for models m_1 and m_2 respectively. We have

$$\begin{aligned} \frac{|J^R|}{\ell_{J^R}} \cdot \frac{\ell_I}{|I|} &= \frac{|J^R|}{\alpha_2 \cdot |J^R| + \beta_2} \cdot \left(\alpha_1 + \frac{\beta_1}{|I|}\right) \\ &\leq \frac{|J^R|}{\alpha_2 \cdot |J^R| + \beta_2} \cdot (\alpha_1 + \beta_1) \\ &= \frac{|J^R| \cdot (\alpha_1 + \beta_1)}{\alpha_2 \cdot |J^R| + \beta_2} \\ &\leq K \end{aligned} \quad (28)$$

Note that Line 1 to Line 2 is based on the implicit constraint that $|I| \geq 1$ since it can only take integer values.

To further improve the bound, we notice that as $\ell_I > \ell_{J^R}$ always holds in Case 2, with Eq. 1 we have

$$\begin{aligned} \alpha_1 \cdot |I| + \beta_1 &> \alpha_2 \cdot |J^R| + \beta_2 \\ \rightarrow |I| &> \frac{\alpha_2 \cdot |J^R| + \beta_2 - \beta_1}{\alpha_1} \end{aligned} \quad (29)$$

On one hand, if $\alpha_2 + \beta_2 - \beta_1 > 0$, we have $\alpha_2 \cdot |J^R| + \beta_2 - \beta_1 > 0$. Then we can replace I in the first line of Eq. 28 with Eq. 29:

$$\begin{aligned} \frac{|J^R|}{\ell_{J^R}} \cdot \frac{\ell_I}{|I|} &= \frac{|J^R|}{\alpha_2 \cdot |J^R| + \beta_2} \cdot \left(\alpha_1 + \frac{\beta_1}{|I|}\right) \\ &< \frac{|J^R|}{\alpha_2 \cdot |J^R| + \beta_2} \cdot \left(\alpha_1 + \frac{\beta_1 \cdot \alpha_1}{\alpha_2 \cdot |J^R| + \beta_2 - \beta_1}\right) \\ &= \frac{|J^R|}{\alpha_2 \cdot |J^R| + \beta_2} \cdot \left(\frac{\alpha_1 \cdot (\alpha_2 \cdot |J^R| + \beta_2 - \beta_1) + \beta_1 \cdot \alpha_1}{\alpha_2 \cdot |J^R| + \beta_2 - \beta_1}\right) \\ &= \frac{|J^R|}{\alpha_2 \cdot |J^R| + \beta_2} \cdot \left(\frac{\alpha_1 \cdot \alpha_2 \cdot |J^R| + \alpha_1 \cdot \beta_2}{\alpha_2 \cdot |J^R| + \beta_2 - \beta_1}\right) \\ &= \frac{|J^R|}{\alpha_2 \cdot |J^R| + \beta_2} \cdot \left(\frac{\alpha_1 \cdot (\alpha_2 \cdot |J^R| + \beta_2)}{\alpha_2 \cdot |J^R| + \beta_2 - \beta_1}\right) \\ &= \frac{\alpha_1 \cdot |J^R|}{\alpha_2 \cdot |J^R| + \beta_2 - \beta_1} \\ &\leq K \end{aligned} \quad (30)$$

Then for Case 2a we will have:

$$\begin{aligned} \sum_{I \in \sigma_A} v_a(I, J) &\geq x_1 \cdot |I| \\ &> \frac{x_1 \cdot p \cdot |J|}{K} \end{aligned} \quad (31)$$

For Case 2b we have:

$$\begin{aligned} \sum_{I \in \sigma_{\mathcal{A}}} v_a(I, J) &\geq x_2 \cdot |I| \cdot \frac{\ell_J}{\ell_I} \\ &> \frac{x_2 \cdot |J|}{K} \end{aligned} \quad (32)$$

The analysis for Case 3 and J^E is the same as the single model case. Similar to Eq. 25, by combining all cases we can calculate the competitive ratio c_{sgmm} for the multi-model case:

$$c_{sgmm} = \frac{1}{\min_{p \in [0,1]} (\max(\frac{\lambda-1}{\lambda} \cdot \min(\frac{p \cdot x_1}{\lambda}, \frac{p \cdot x_1}{K}, \frac{x_2}{K}), (1-p) \cdot x_3))} \quad (33)$$

Since $K \geq 1$, combining Eqs. 33 and 25 gives us:

$$c_{sgmm} \leq K \cdot c_{sgsm} \quad \forall x_1, x_2, x_3, p, \lambda \quad (34)$$

As such, Algorithm 1 can always achieve a competitive ratio of $10.81 \cdot K$ for the single-GPU, multi-model setting. ■

B.3 Multi-GPU Multi-Model Setting (mgmm)

Finally, we extend our analysis to the general case with k models $\{m_1, \dots, m_k\}$ and N GPUs. The major difference lies in the per-GPU preemption rule for the request arrival event — the new preemption rule ensures that at any time, no available batch will have a value $\lambda \times$ higher than the value of the currently running batches on *any* GPU. Moreover, the modified dequeue rule ensures that in the multi-GPU case, a request is completed in *at most one* batch in $\sigma_{\mathcal{A}}$.

We have the following theorem for the general case.

Theorem B.3 *For the multi-GPU, multi-model case, Algorithm 1 is $12.62 \cdot K$ -competitive with preemption threshold $\lambda \approx 3.03$, with K defined in Eq. 4.*

Proof The proof follows the same structure as the single-GPU, single-model setting as well. Define the schedule $\sigma_{\mathcal{A}}(u)$ as the schedule of Algorithm \mathcal{A} on GPU $u \in [1, N]$ and $\sigma_*(v)$ as the optimal schedule on GPU $v \in [1, N]$. We have $\sigma_{\mathcal{A}} = \bigcup_u \sigma_{\mathcal{A}}(u)$ and $\sigma_* = \bigcup_v \sigma_*(v)$. Moreover, we define (u, v) as a GPU pair between the schedule $\sigma_{\mathcal{A}}(u)$ and $\sigma_*(v)$.

Value assignment rule between GPU pair (u, v) We apply a similar value assignment rule in the basic case for *each GPU pair (u, v)* in the general case. The major difference lies in assignment rules **A1** and **A2**, where we evenly spread the value for I from each $\sigma_{\mathcal{A}}(u)$ to all $\sigma_*(v)$ with different v .

- **A1.** For a batch $J_b \in \sigma_*(v)$ that $I \in \sigma_{\mathcal{A}}(u)$ blocks, $v_a(I, J_b) = \frac{x_1}{N} \cdot |I|$.
- **A2.** For a batch $J_c \in \sigma_*(v)$ that $I \in \sigma_{\mathcal{A}}(u)$ covers, $v_a(I, J_c) = \frac{x_2}{N} \cdot |I| \cdot \frac{\ell_{J_c}}{\ell_I}$.
- **A3.** For a batch $J_i \in \sigma_*(v)$ that $I \in \sigma_{\mathcal{A}}(u)$ intersects, we assign a value of x_3 to J_i for every request that is common between I and J_i , i.e., $v_a(I, J_i) = x_3 \cdot |I \cap J_i|$.

- **A4.** If the total assigned value from $I \in \sigma_{\mathcal{A}}(u)$ is less than $|I|$, we assign the residual value of I to a random $J \in \sigma_*(v)$.

Similar to the basic case, the above pair-wise assignment rule ensures the following property:

Feasibility: For any GPU $u \in [1, N]$, with $(x_1 + x_2 + x_3) \leq 1$, the total assignment from any batch $I \in \sigma_{\mathcal{A}}(u)$ to all J in all $\sigma_*(v)$ equals $|I|$. That is:

$$\sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} v_a(I, J) = |I|, \quad \forall I \in \sigma_{\mathcal{A}}(u) \quad (35)$$

Boundedness: Similar to the basic case (Eq. 9), the assignment should be bounded. Here we want to show that the total value assigned from all I in all $\sigma_{\mathcal{A}}(u)$ to all batches J in all $\sigma_*(v)$ must be greater than or equal to a constant portion of the aggregated value of J in all $\sigma_*(v)$. That is:

$$\sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}^c(u)} v_a(I, J) \geq r \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} |J| \quad (36)$$

where $r \in [0, 1]$ is a constant. Note that similar to the basic case (Eq. 10), for an assignment that is both feasible and bounded, we have:

$$\begin{aligned} v(\sigma_{\mathcal{A}}^c) &= \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}^c(u)} |I| \\ &= \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}^c(u)} v_a(I, J) \\ &\geq \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} r \cdot |J| \\ &\geq r \cdot v(\sigma_*) \end{aligned} \quad (37)$$

Eq. 37 suggests a competitive ratio of $c = \frac{1}{r}$.

Determining the bound r : The key task that remains is to quantify the bound r achieved by the assignment. Similar to the basic case, this is done by bounding the values of J for each $\sigma_*(v)$ by values of I for each $\sigma_{\mathcal{A}}(u)$, based on both the J^E and J^R parts.

Determining r_R based on J^R : We can apply the same analysis as in the basic case for each GPU pair (u, v) . Note that for **Case 1**, the modified preemption rule ensures that at any time, no available batch in $\sigma_{\mathcal{A}}$ will have a value $\lambda \times$ higher than the value of the currently running batches on *any* GPU. As such, the J^R from any GPU u must have a value no higher than $\lambda \times$ the value of the I blocks it in any u , which indicates:

$$\begin{aligned} \sum_{I \in \sigma_{\mathcal{A}}(u)} v_a(I, J) &\geq \frac{x_1}{N} \cdot |I| \\ &\geq \frac{x_1}{N} \cdot \left(\frac{1}{\lambda} \cdot |J^R|\right) \\ &= \frac{x_1}{N} \cdot \frac{1}{\lambda} \cdot p \cdot |J| \end{aligned} \quad (38)$$

Moreover, the analysis for **Case 2** and **Case 3** follows the same logic. Formally, for any u and $J \in \sigma_*(v)$ we have:

$$\sum_{I \in \sigma_{\mathcal{A}}(u)} v_a(I, J) \geq \begin{cases} \frac{x_1 \cdot p}{\lambda} \cdot \frac{|J|}{N}, & \text{Case 1} \\ \frac{x_1 \cdot p \cdot |J|}{K \cdot N}, & \text{Case 2a} \\ \frac{x_2 \cdot |J|}{K \cdot N}, & \text{Case 2b} \\ p \cdot |J|, & \text{Case 3} \end{cases} \quad (39)$$

Since the above equation holds for each $\sigma_{\mathcal{A}}(u)$, we have:

$$\sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}(u)} v_a(I, J) \geq \min\left(\frac{x_1 \cdot p}{\lambda}, \frac{x_1 \cdot p}{K}, \frac{x_2}{K}\right) \cdot |J| \quad (40)$$

Aggregating both sides of Eq. 39 over all J in all $\sigma_*(v)$, we get:

$$\begin{aligned} & \min\left(\frac{x_1 \cdot p}{\lambda}, \frac{x_1 \cdot p}{K}, \frac{x_2}{K}\right) \cdot \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} |J| \\ & \leq \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}(u)} v_a(I, J) \\ & = \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}(u)} |I| \\ & = v(\sigma_{\mathcal{A}}) \end{aligned} \quad (41)$$

Next, we bound $v(\sigma_{\mathcal{A}})$ by $v(\sigma_{\mathcal{A}}^c)$. We apply the same chain analysis as we did for the basic case for each $\sigma_{\mathcal{A}}(u)$. More specifically we have:

$$\sum_{I \in \sigma_{\mathcal{A}}^c(u)} v(\text{chain}(I)) = \sum_{I \in \sigma_{\mathcal{A}}(u)} |I| \quad \forall u \in [1, N] \quad (42)$$

Then based on the preemption rule we have:

$$\begin{aligned} v(\sigma_{\mathcal{A}}^c) &= \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}^c(u)} |I| \\ &\geq \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}^c(u)} \frac{\lambda - 1}{\lambda} \cdot v(\text{chain}(I)) \\ &= \frac{\lambda - 1}{\lambda} \cdot \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}(u)} |I| \\ &= \frac{\lambda - 1}{\lambda} \cdot v(\sigma_{\mathcal{A}}) \end{aligned} \quad (43)$$

Combining Eqs. 41 and 43, we get:

$$\begin{aligned} & \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}^c(u)} v_a(I, J) \\ & \geq \frac{\lambda - 1}{\lambda} \min\left(\frac{x_1 \cdot p}{\lambda}, \frac{x_1 \cdot p}{K}, \frac{x_2}{K}\right) \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} \cdot |J| \end{aligned} \quad (44)$$

This gives us a bound $r_R = \frac{\lambda - 1}{\lambda} \min\left(\frac{x_1 \cdot p}{\lambda}, \frac{x_1 \cdot p}{K}, \frac{x_2}{K}\right)$.

Determining r_E based on J^E : Note that based on the dequeue and preemption rule in Algorithm 1, some request in J^E may not have been completed in $\sigma_{\mathcal{A}}$. Instead, it only ensures that for any $J \in \sigma_*(v)$, all requests in the corresponding J^E must

have been (or being) executed in some $\sigma_{\mathcal{A}}(u)$. Since each of the requests in J^E gets assigned a value of x_3 (based on **A3**), we have the following bound:

$$\begin{aligned} \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}(u)} v_a(I, J) &\geq \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}(u)} |I \cap J^E| \\ &\geq x_3 \cdot |J^E| \\ &= (1 - p) \cdot x_3 \cdot |J| \end{aligned} \quad (45)$$

Note that Eq. 45 is in the exact same form as Eq. 40. So following the same procedure from Eq. 41 to Eq. 44 we can get:

$$\begin{aligned} & \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} \sum_{u \in [1, N]} \sum_{I \in \sigma_{\mathcal{A}}^c(u)} v_a(I, J) \\ & \geq \frac{\lambda - 1}{\lambda} (1 - p) \cdot x_3 \sum_{v \in [1, N]} \sum_{J \in \sigma_*(v)} \cdot |J| \end{aligned} \quad (46)$$

This gives us a bound $r_E = \frac{\lambda - 1}{\lambda} (1 - p) \cdot x_3$.

Determining the optimal competitive ratio c_{mgmm} : Combining the bounds r_R and r_E , we get the final competitive ratio:

$$\begin{aligned} c_{sgsm} &= \frac{1}{\max(r_R, r_E)} \\ &= \frac{1}{\frac{\lambda - 1}{\lambda} \cdot \min_{p \in [0, 1]} \{ \max\{ \min\left(\frac{p \cdot x_1}{\lambda}, \frac{p \cdot x_1}{K}, \frac{x_2}{K}\right), (1 - p) \cdot x_3 \} \}} \end{aligned} \quad (47)$$

Similar to the basic case, we can select appropriate values of x_1, x_2, x_3 and λ to minimize c_{mgmm} .

$$\begin{aligned} & \min_{x_1, x_2, x_3, \lambda} c_{mgmm} \\ & \text{s. t. } x_1 + x_2 + x_3 \leq 1 \\ & 1 < \lambda < \infty \end{aligned} \quad \blacksquare$$

Solving the above optimization problem yields the maximal value for $c_{mgmm} \approx 12.62 \times K$ with preemption threshold $\lambda \approx 3.03$.

C Complexity Analysis for FLEX

Theorem C.1 FLEX has a worst-case complexity of $O(G)$, where G is the number of GPUs in the serving group.

Proof Batch generation (Algorithm 2) has a complexity of $O(|\mathbb{M}| \cdot |Q|)$ where $|\mathbb{M}|$ is the number of models queues with newly enqueued requests since last update, and $|Q|$ is the largest queue size among these model queues. For each request arrival event, batch generation is triggered $O(G)$ times. Moreover, between every two invocations, at most one model queue changes. Therefore, $|\mathbb{M}|$ is at most 2 for each invocation (Line 2 in Algorithm 2). In addition, since each preemption will increase the size for the running batch by at least $\lambda \times$, each GPU can only be preempted by at most $O(\log_{\lambda}(|Q|))$ times.

Algorithm 2 Batch generation algorithm in FLEX

```
1: procedure BATCHGEN( $n$ )
2:    $\mathbb{M} \leftarrow$  models with newly enqueued requests or currently
   running on GPU  $n$ 
3:   for each model  $m \in \mathbb{M}$  do
4:     Dequeue requests passing their deadlines from  $Q(m)$ 
   # Line 5-13: Find largest feasible batch  $B_g(n, m)$  for model  $m$ 
5:     Candidate request set  $\mathbb{S} \leftarrow Q(m)$ 
6:     if  $B_c(n)$  uses model  $m$  then
7:        $\mathbb{S} \leftarrow Q(m) \cup B_c(n)$ 
8:        $B_g(n, m) \leftarrow \emptyset$ 
9:       for request  $r$  in  $\mathbb{S}$  with ascending deadline do
10:        if  $r$  can meet SLO with batch size  $|B_g(n, m)|$  then
11:          Add  $r$  to  $B_g(n, m)$ 
12:        else
13:          Break
14:      $B_g(n) \leftarrow B_g(n, m)$  with largest batch size among all models
15:   Return  $B_g(n)$ 
```

As such, the re-enqueue event (Line 19 and 11) will be triggered by at most $O(\log_\lambda(|Q|))$ times for each GPU. The complexity of enqueue operation is $O(\log(|Q|))$ (Line 10), and the complexity of re-enqueue operation is $O(|Q| + |B_c(n)|)$ (Line 19). Note that $|B_c(n)|$ can never be larger than $|Q|$ by definition. Note that $|Q|$ and λ are constants. Based on the above analysis, the total complexity for each request arrival event and batch completion event is $O(G)$. Similar analysis applies for each batch completion event. Taken together, FLEX has an overall complexity of $O(G)$. ■

Better Together: Jointly Optimizing ML Collective Scheduling and Execution Planning using SYNDICATE

Kshiteej Mahajan^{*}, Ching-Hsiang Chu[†], Srinivas Sridharan[†], Aditya Akella[§]
University of Wisconsin - Madison^{}, Facebook[†], UT Austin[§]*

Abstract: Emerging ML training deployments are trending towards larger models, and hybrid-parallel training that is not just dominated by compute-intensive all-reduce for gradient aggregation but also bandwidth-intensive collectives (e.g., all-to-all). These emerging collectives exacerbate the communication bottlenecks despite heterogeneous network interconnects with ample multipath opportunities. In this work, we propose SYNDICATE, a systematic, general framework to minimize communication bottlenecks and speed up training for both state-of-the-art and future large-scale models and interconnects. SYNDICATE proposes a novel abstraction, the motif, to break large communication work as smaller pieces as part of execution planning. SYNDICATE also does joint optimization of scheduling and execution planning by rethinking the interfaces in the networking systems stacks used for ML training. Motifs afford greater flexibility during scheduling and the joint optimizer exploits this flexibility by packing and ordering communication work so as to maximize both network utilization and overlap with compute. This improves the speed of training state-of-the-art large models by 21-74%.

1 Introduction

Training machine learning (ML) models is a common-case workload at any data-driven enterprise. To keep up with evolving data and maintain a competitive edge, enterprises are employing more sophisticated features and more complex model architectures, and attempting to train faster at ever larger scales and to deploy high-quality models frequently.

These trends are exemplified by the deep learning recommendation model (DLRM). DLRM is used in recommendation systems at several large organizations. These models use a mixture of continuous and categorical features obtained from user data. The model architectures, which are themselves rapidly evolving, uses a mixture of multi-layer perceptrons and embedding table lookups. The model capacity and compute is increasing exponentially year-on-year [24].

At production scale, such state-of-the-art models use a mixture of data and model parallelism to efficiently scale-out to a large number of machines in the training cluster. This induces rich communication collectives such as all-reduce, all-to-all, collective-permute, and all-gather [21, 24]. The resulting communication operations (comm-ops) are a major bottleneck to end-to-end training performance [24].

Evolution in networking infrastructure in training clusters [32, 35] (to include faster interconnects such as NVLink/NVSwitch, RoCE, Infiniband and support faster

transports such as Remote Direct Memory Access (RDMA)) does not in itself help address these bottlenecks. These advancements need to be coupled with effective computation-communication scheduling and execution planning optimizations. These optimizations hide communication by maximizing overlap with compute and help maximize utilization of the networking infrastructure.

Unfortunately, existing scheduling optimizations [16, 18, 29] and execution planners [10, 11, 20, 33, 34] fall short. These works make several restrictive assumptions limiting their applicability to simplistic models, training settings, and networks. Communication schedulers make assumptions about the model and training architecture (simple layer-by-layer models [29] with data-parallel training) or deployment mode (Parameter Server-based [16, 18]), and the execution planners make simplifying assumptions about the nature of comm-ops (only all-reduce [10, 11, 20, 33, 34] or only push-pull [20]).

Moreover, existing solutions are point solutions in the optimization space and fail to *jointly* optimize scheduling and execution planning concerns. Schedulers today are unaware of the optionality during execution planning, such as parallel execution of two comm-ops over non-overlapping network communication channels, and might impose orders that fail to leverage such opportunities during execution planning. As a result, they leave significant room for optimization.

We seek a comm-op optimization framework that jointly optimizes planning and scheduling, applies to state-of-the-art large models with complex communication patterns, is generalizable to future large models and arbitrary network interconnects. Our framework should also encapsulates all possible optimization axes, and enables a systematic, thorough, automatic search through the space for optimal strategies.

Enabling systematic joint optimization of scheduling and execution planning is challenging. First, the communication systems stacks used for ML training today place scheduling and execution planning concerns in two different layers. The scheduler is co-located with ML training frameworks (such as PyTorch, TensorFlow) and the execution planner is co-located with communication libraries (such as NCCL, MPI). These are governed by two different developer communities and the scheduler interacts with the execution planner via a narrow, one-way API to just submit comm-ops. Moreover, the scheduler and the execution planner only accommodate fast, deterministic procedures so as to enable tight co-ordination across worker processes that peer with each other using parallel programming frameworks (such as MPI) during training.

Second, scheduling happens at the very coarse granularity of collectives submitted by the training application which limits scheduling flexibility as it leads to fewer opportunities to reorder communication work in time and efficiently pack communication work in space, i.e., over the heterogeneous mix of communication channels and bandwidth available in the networking infrastructure.

We propose SYNDICATE, a system for joint optimization of scheduling and execution planning with several innovations:

- SYNDICATE proposes a novel abstraction, the motif, to break large communication work in comm-ops into smaller units of communication work. Motifs afford greater flexibility, by helping pack and order communication work so as to maximize network multipath utilization and to maximize overlap with compute.
- Similar to query optimization backed by a well-defined relational algebra, we present a novel algebra atop motifs that systematically codifies the search space of correct, composable motif operators used to transform comm-ops into motifs and enables comm-op optimization.
- SYNDICATE rethinks the interfaces in the communication stack and enables joint optimization via the joint action of a control plane and a data plane. The former executes a time-intensive, non-deterministic joint optimization out-of-band without blocking the latter which enables fast execution of tightly co-ordinated motifs.
- We blend techniques used for optimal tensor operator fragmentation [19], DAG scheduling [15] and query replanning [22] to probabilistically search the joint optimization space to yield near-optimal comm-op optimization plans. We also introduces a novel shim-layer above existing communication libraries to enforce these plans.

We implement the enforcer atop existing communication libraries by extending the `torch-ucc` interface; the joint optimizer as a separate python process; and enable safe interaction between the central optimizer and the enforcer via a two phase commit protocol. We present the evaluation of several state-of-the-art models on a 128-GPU cluster with rich multipath opportunities. SYNDICATE demonstrates 21–74% faster training than the closest state-of-the-art [29] and is better than hand-optimized trainers.

2 Background

The compute and capacity of models has been increasing exponentially [1], with model training compute approaching 1000s of petaflop/s-days [9] and model capacity approaching trillions of parameters [24]. To train ever larger models, training clusters are scaling up to thousands of devices [21].

In this section, we give a short primer on the compute parallelization strategies used for ML training and the accompanying communication operations (comm-ops) that are issued. We also discuss how training network infrastructure is evolving to deal with higher network loads.

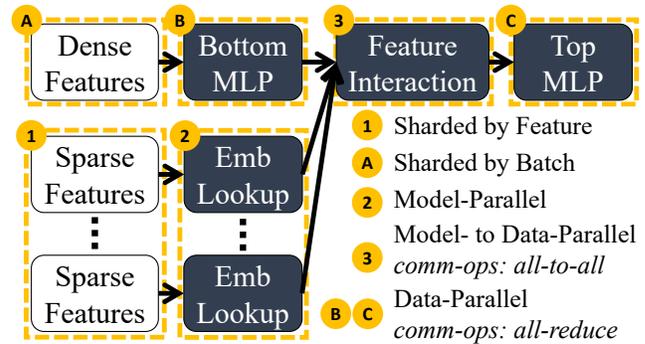

Figure 1: DLRM Model

2.1 Parallelization Strategies

We exemplify the different parallelization strategies via the Deep Learning Recommendation Model (DLRM). The largest DLRM used in production has trillions of parameters [12, 24, 26], making DLRM training especially challenging. DLRM uses a hybrid mix of parallelization strategies for different model parts (similar to BERT [13], Megatron [30], GPT [9]).

Figure 1 shows the DLRM model architecture. The training data comprises a mixture of dense continuous features and sparse categorical features (one-hot encoded or multi-hot encoded data), which are first mapped to a common embedding space using the bottom multi-layer perceptron (MLP) and the embedding table lookups respectively. The output embeddings go through a feature interaction phase and are then fed to the top MLP to get the recommender model output.

Data-Parallelism: With data-parallelism, all the model parameters are replicated across all the training devices and each device has a worker process computing parameter gradients in parallel. In the case of DLRM, the bottom MLP and top MLP use data-parallelism for training in production. These MLPs are compute intensive but not memory intensive and the MLP parameters fit within a single device memory.

Model-Parallelism: Data-Parallelism does not work for models with large capacity and with input datasets that cannot be trivially sharded into batches. With Model-Parallel training, the model is partitioned (and not replicated) across different devices. For DLRM, the embedding table lookup models and the input tables are large and memory-intensive, and as a result are partitioned across different devices during training resulting in model-parallel training.

Hybrid-Parallelism: As seen so far, different portions of DLRM training use different parallelization strategies. This is known as hybrid-parallelism. In the most general case, models can be replicated or partitioned in several different ways during training [19, 21, 25], resulting in hybrid-parallelism.

FSDP: Fully Sharded Data Parallelism [8] is a memory-efficient version of data-parallelism. It shards the model state (weights, gradients, optimizer state) for each layer of the model. During forward- or backward-propagation of a layer it enables data-parallel computation by first doing an all-gather of all the model state at all the devices and reshards the updated state post-computation by doing a scatter. This leads

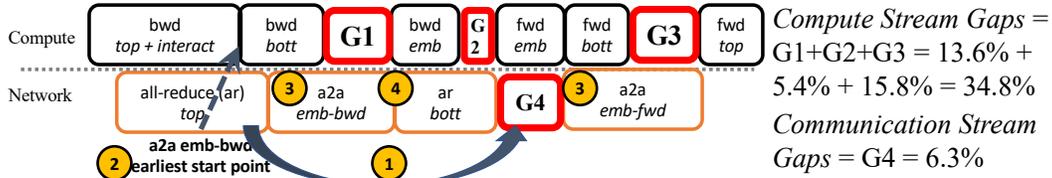

Figure 2: Gaps in DLRM Training Trace

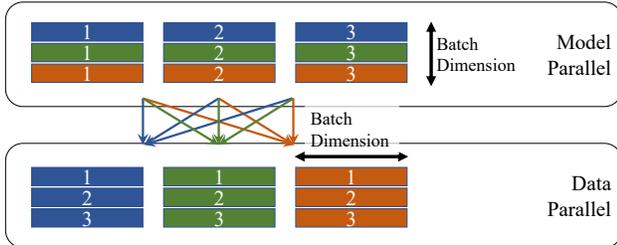

Figure 3: Illustration of all-to-all collective in DLRM

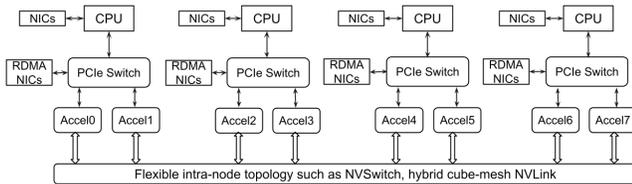

Figure 4: State-of-the-art system architecture of training cluster such as Nvidia DGX/HGX-like systems [24, 28]

to memory-efficiency and as a result allows to pack larger models in the same cluster resources.

2.2 Communication Operations (Comm-Ops)

Different parallelism strategies induce different comm-ops.

With data-parallel training, gradients computed at each worker process are aggregated layer-by-layer (during backward pass). Each aggregation yields an **all-reduce** collective.

After the embedding lookups in DLRM (2) in Figure 1), each device has a vector for the table lookup models resident on those devices for all the samples in the batch, which needs to be reorganized and sharded along the batch dimension. This induces an **all-to-all** pattern of collective communication, as shown in Figure 3.

Collectives from the MPI standard [23]: In the general case, hybrid-parallel or FSDP model training [8, 14, 21] results in several types of comm-ops, ranging from all-reduce, all-to-all, collective-permute, all-gather, reduce-scatter to any collective defined in the MPI standard [23].

2.3 Evolving Network Infrastructure

The aforementioned comm-ops push increasing amounts of network traffic and the network infrastructure is adapting with fatter topologies and faster interconnects to ensure the needed throughput and latency. The network infrastructure in a state-of-the-art training cluster [24, 28] is shown in Figure 4. Each node has multiple CPU cores and accelerators such as GPUs, with frontend Network Interface Controllers

(NICs) connected to the host CPUs and a dedicated RDMA NICs such as InfiniBand and RDMA over Converged Ethernet (RoCE) for each of the GPUs connected via PCIe switches. The RDMA NICs from across nodes can be connected with a dedicated network. The extensible design of this node allows to scale-out the network to interconnect thousands of nodes, forming a data-center scale training cluster. This cluster has heterogeneous mix of networking interconnects and protocols with varying throughput and latency guarantees. There are multiple communication channels between any two endpoints. At an intra-node level, a pair of GPUs can communicate via shared memory, NVLink, PCIe or the external network. At an inter-node level, any two GPUs can communicate via GPUDirect RDMA [27] or TCP/IP over Ethernet.

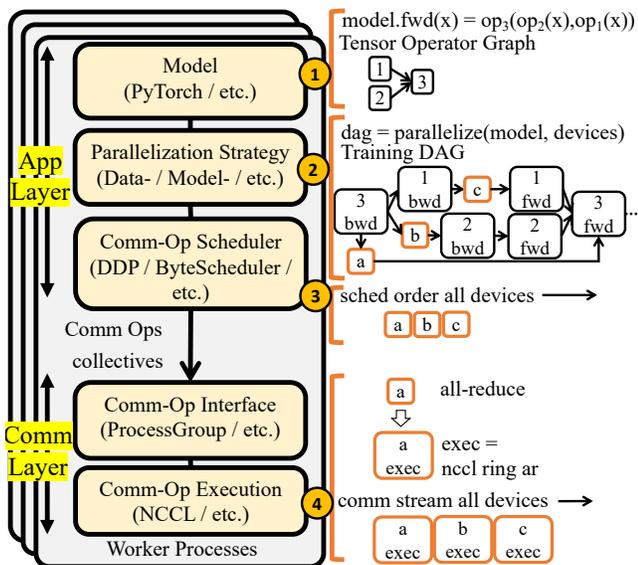

3 Motivation

Communication Bottleneck: Despite the networking infrastructure upgrades, the execution of comm-ops are a source of excessive delays in training. As an example of the issues that can arise in large model training, Figure 2 shows the execution of CUDA stream kernels on a randomly chosen GPU during a single iteration of production scale DLRM training¹. The training creates a compute and a communication stream for serialized execution of tensor operator kernels and comm-op kernels, respectively. We note that there are several gaps during execution. A gap on a stream occurs when the stream is waiting for the result of kernel execution on the other stream. The compute stream gaps are wider (34.8%) and cumulatively larger than those in the communication stream (6.3%). This means that communication is a training bottleneck as it blocks compute for a third of the iteration. We now show that there are several opportunities to optimize comm-ops.

Better Scheduling Opportunity: Reordering of comm-ops improve compute/communication overlap. As shown in Figure 2 – 1: the top MLP all-reduce comm-op can be split judiciously and partially executed later to occupy the gap G4; 2: as a result the all-to-all backward comm-op can be pulled up to begin as soon as possible to reduce the gap G1.

Better Execution Planning Opportunity: Existing comm-ops do not efficiently utilize multiple communication channels available in heterogeneous network interconnects. We highlight this in Fig.2 – 3: both the all-to-all’s can be broken up into smaller fragments of communication work and executed one fragment at a time to reduce incast and improve through-

¹We show accurate percentages and hide low-level details.

Existing System Stack
Figure 5: ML Training Communications Stack

put to reduce gaps G1 & G3; ④: all-to-all and all-reduce can be executed in parallel over communication channels with non-overlapping interconnects to start all-reduce sooner and drive higher network throughput to reduce gap G2.

Existing works to reduce communication overheads are optimal for specific training scenarios (PS architecture [16], layer-by-layer models [29], all-reduce collectives [20,34]; §7); and the scheduling and execution planning techniques proposed therein make restrictive assumptions, making it unclear as to how to compose and apply these different techniques towards hybrid-parallel training of large DLRM-like models.

A fundamental shortcoming of these works is that they do not explore *joint optimization* (§3.1) mainly because *existing interfaces in the communication stack used for ML training are not naturally amenable* (§3.2). We also note that *a collective is often too coarse-grained* to schedule communication work; breaking it up improves communication optimization flexibility (§3.3). We describe these issues next.

3.1 Disjoint Scheduling, Execution Planning

3.1.1 Communication Stack Overview

Figure 5 shows the two sets of layers in the communication stack used for ML training – the application (app) layer and the communication (comm) layer – and the four steps leading to execution of a comm-op over the network –

- ① **Model Definition:** The user defines a model by composing various tensor operations. The example shows a model declaration with three operators and its tensor operator graph.
- ② **Parallelization Strategy:** The `parallelize` module (e.g., `nn.DistributedDataParallel` in PyTorch) takes the model and the set of devices and converts the computation to a training DAG. The vertices are compute-ops or comm-ops and edges capture dependencies. Above we show the training DAG for a single iteration; the ops in the DAG are managed

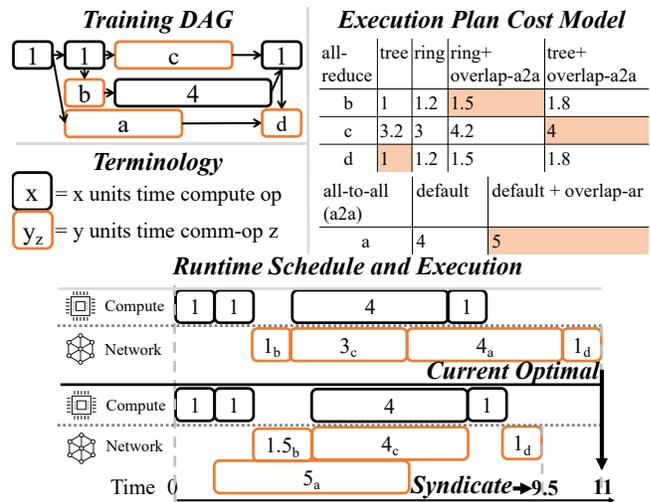

Figure 6: Motivating Example

by spawning several worker processes on all the devices by using a parallel programming library such as MPI.

③ **Comm-Op Scheduling:** The communication scheduler takes the training DAG as input and decides a ordering for the comm-ops that maximizes compute/communication overlap. The scheduling procedure is deterministic and executes on all the worker processes so that the comm-ops are issued (and executed) every training iteration in *the same order on all the devices*. The default PyTorch order is FIFO.

④ **Comm-Op Execution Planning:** The comm layer at all the devices receive the comm-op from the app layer via an interface with a well-defined API (e.g., `ProcessGroup` in PyTorch). The execution planner on receiving each comm-op, assigns it an execution plan and queues it in the same order on the devices’ i.e., GPU’s communication stream for serialized execution. The example shows an all-reduce collective which binds to NCCL’s ring all-reduce implementation during execution. Each collective typically has several options for its execution plan (e.g., ring or tree for all-reduce collective) and execution planners, such as NCCL, have network topology aware cost models that estimate the execution time for different options. Current execution planners are greedy and select the execution plan option with the least execution time. All worker processes bind to the same execution plan.

Thus, scheduling is an app-layer concern today, governed by schedulers in ML training frameworks as PyTorch, while execution planning is a comm-layer concern governed by execution planners in communication libraries as NCCL. As these are not jointly optimized, several inefficiencies arise, which we exemplify next.

3.1.2 Example to highlight suboptimality

Figure 6 illustrates the lost opportunities due to a lack of joint optimization of scheduling and execution planning. The network topology is similar to that illustrated in Figure 4. The training DAG in this example has four collectives: a is an all-to-all collective and b, c, d are all-reduce collectives.

There are several execution plan options for each collective. There is a cost associated with each option which measures the execution time over the network. For all-reduce, the execution plan options are tree all-reduce or the ring all-reduce, both using NVLink and GPUDirect RDMA. For all-to-all, there are two options: pairwise exchange between all processes either using NVLink and GPUDirect RDMA or using PCIe complex and TCP/IP over ethernet. With the latter option for all-to-all, all-to-all and all-reduce can be overlapped. We compare the iteration time of the current solution against SYNDICATE.

Current Solution: The execution planner greedily selects the fastest option for each collective resulting in a training iteration time of 11 units.

SYNDICATE Solution: SYNDICATE realizes that by jointly making changes to the scheduling order and execution plan choices there is opportunity to overlap all-to-all with all-reduce and speed-up communication by utilizing network heterogeneity. The current solution’s scheduling order executes all-to-all last and does not allow overlap. SYNDICATE’s scheduling order executes all-to-all collective at the very beginning and allows overlap. The execution plan choices made by SYNDICATE are shaded in the execution plan cost model in Figure 6. SYNDICATE’s execution planner is not greedy and chooses a slower execution plan for all-to-all so as to allow for parallel execution of all-to-all and all-reduce over non-overlapping interconnects in the network. Overall, this results in a training iteration time of 9.5 units.

Joint optimization is beneficial but current interfaces are not amenable as we discuss next.

3.2 Interface constraints Joint Optimization

The training DAG scheduler in the ML processing frameworks is unaware of optionality (e.g., an all-reduce can be executed by as a ring all-reduce or a tree all-reduce) present lower down the stack during execution planning. A trivial extension of the existing interface is to expose the training DAG to the comm layer and push the scheduling concern down the stack to co-locate it with the execution planner. Exposing the training DAG down the stack is necessary to ensure that any reordering of comm-ops down the stack does not lead to *dependency violations*: a child comm-op cannot be ordered before a parent comm-op as otherwise it can lead to a *deadlock*. This enables joint optimization without dependency violations. However, the joint optimization problem is NP-hard and the joint optimization procedure requires a time-intensive, randomized algorithm (§4.3). As a result, this procedure can delay comm-op execution due to its time-intensive nature. To make matters worse, this randomized procedure, may lead to divergent scheduling orders across different processes. This can lead to *out-of-sync* issues, wherein if the collectives are not submitted in the same order across two different processes then it results in a *deadlock* where each process waits for the other process to issue the same collective as itself. As a result, the existing interfaces are unable to trivially accommodate

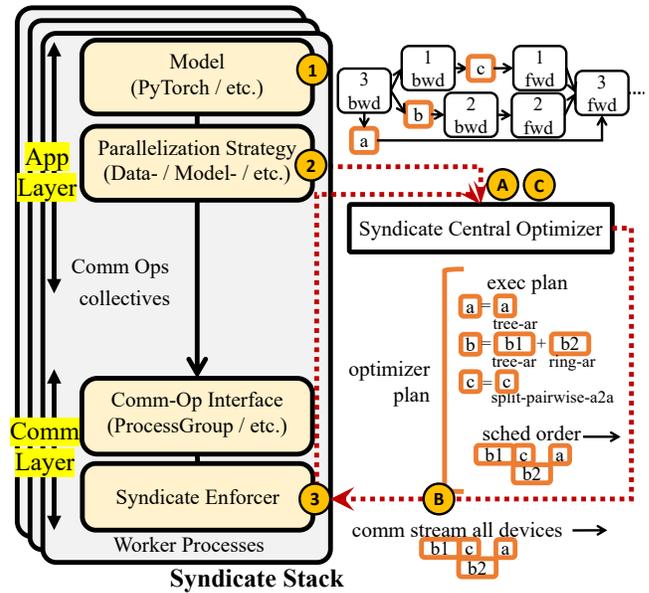

Figure 7: Overview of SYNDICATE’s ML training Communication Stack

joint optimization of these concerns.

3.3 Issues with Coarse-Grained Scheduling

Scheduling today happens at the granularity of user-submitted comm-ops i.e., collectives. Communication libraries such as NCCL, submit each comm-op as a kernel on the GPU communication stream and a kernel cannot be context-switched during execution. This means that once a comm-op is scheduled for execution it cannot be stopped mid-execution. This leads to limited scheduling flexibility in space and time.

If the payload is very large then each network transfer in the comm-op, once scheduled for execution, occupies the network links for a long time. Likewise, if the pattern of network transfers is large (e.g., a clique of network transfers) then the comm-op gang schedules transfers on a large fraction of network interconnects. Comm-ops, if scheduled as-is, thus have large communication work orders and limit the ability to both context switch and efficiently pack communication work over available heterogeneous interconnects.

4 SYNDICATE Design

SYNDICATE changes the interfaces in the communication stack to enable joint optimization of scheduling and execution planning. It builds on the *motif* abstraction to enable deconstructing comm-ops into smaller work units along a few dimensions and allow finer-grained scheduling. In this section, we start with an overview of the new interfaces and the new modules in SYNDICATE’s communication stack and how it enables joint optimization (§4.1). We then explain the motif abstraction (§4.2), the joint optimizer design (§4.3), and enforcement of the joint optimizer’s decisions (§4.4).

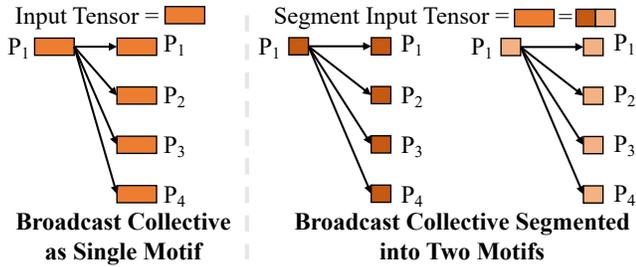

Figure 8: Example showing segmentation of broadcast collective. Left half shows the broadcast collective as a single motif. Right half shows broadcast collective segmented into two motifs, where each motif broadcasts one half of the bytes from the original tensor.

4.1 Overview

Figure 7 shows SYNDICATE’s communication stack. Notably, we propose two new entities: a central optimizer and an enforcer. SYNDICATE co-locates scheduling and execution planning concerns in the centralized joint optimizer. The central optimizer generates an optimizer plan. This plan contains instructions on how to execute as well as how to schedule the comm-ops during training and is conveyed to the enforcer on each worker process. In this regards, *the central optimizer is the control plane while the enforcer is the data plane*. We propose interfaces (A, B, C) between the central optimizer and the communication stack. These interfaces are out-of-band and asynchronous, meaning that the data plane does not, in any circumstances, block execution of a comm-op waiting for control plane instructions.

We now go over the workflow in SYNDICATE. We divide it into control plane workflow and the data plane workflow.

Stepping through the control plane workflow –

A Joint Optimization: The central optimizer pulls the training DAG from the app layer and the network topology from the comm layer. The optimizer uses these inputs to construct the execution plan cost model and does joint optimization to yield the optimizer plan (§4.3).

B Optimizer Plan Distribution: The joint optimizer plan is sent to the enforcer on all the worker processes (§4.3).

C Feedback: The central optimizer pulls comm-op performance statistics from the enforcer to help refine the execution plan cost model and potentially redo joint optimization (§4.4).

Stepping through the data plane workflow –

1 Model Definition: The user defines a model by composing tensor operators. This yields a computation graph (§3.1).

2 Parallelization Strategy: The computation graph is converted to a training DAG (§3.1). The comm-ops from the training DAG are submitted every training iteration as-is to the comm layer in the default FIFO order without applying any scheduling optimizations.

3 Optimizer Plan Enforcer: The comm-ops are executed as instructed by the central optimizer (§4.3).

4.2 Motif Abstraction

A motif is a logical grouping of several point-to-point transfers over the network. The enforcer schedules and executes

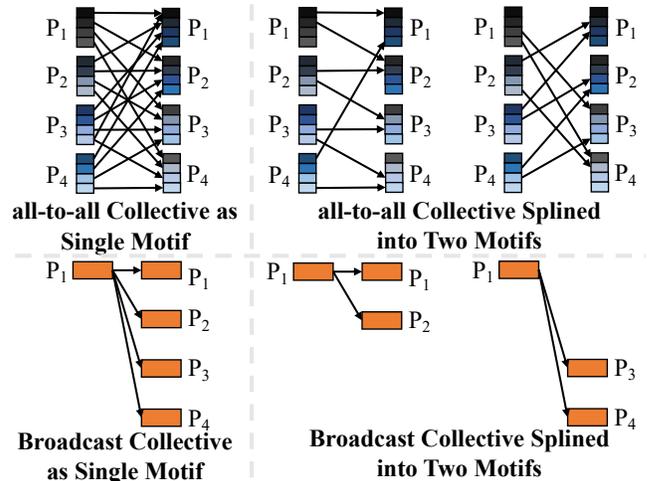

Figure 9: The left half shows all-to-all and broadcast collective as a single motif that bundles the transfers from all the source processes to all the destination processes. The right half shows both the collectives splined into two motifs, where each motif transfers the same payload from the source process to one half of the destination processes.

communication work at the granularity of motifs. A motif once issued to the device e.g., as a kernel on GPU communication stream is non-preemptible and occupies network resources until its communication work is completed.

Conversion of comm-op to motifs: Each comm-op i.e., a collective has two attributes: a payload (typically tensors) and a pattern of network transfers. We propose two transformation operators to slice a comm-op either along the payload dimension or the pattern dimension into one or more motifs. As compared to the original comm-op, each motif represents a smaller unit of communication work (with reduced payload size and/or smaller pattern). Since SYNDICATE does scheduling at the granularity of motifs, this enables finer-grained scheduling with increased opportunities for making more frequent scheduling decisions in time to enable better overlap of compute/communication and packing smaller units of communication work more efficiently over the network resources.

4.2.1 Motif Transformation Operators

Segmentation and Splining: SYNDICATE proposes two transformation operators: segmentation and splining. Segmentation splits the payload into smaller payload segments. Splining splits the pattern of network transfers into smaller patterns. Figure 8 and Figure 9 illustrates these operators.

Transformation Operator Algebra: We now formalize the algebra for the motif transformation operators. The goal of this algebra is to state concrete rules for transforming comm-ops into motifs. This formalization succinctly encodes: (1) correct and admissible motif transformations, (2) correct and admissible transformation combinations, and (3) a structured space for all possible operator compositions. We denote the segmentation operator by $\underline{\text{S}}$ and the splining operator by $\underline{\text{P}}$. These rules are by no means exhaustive and are extensible.

We first present the symbols used in the algebra.

\parallel : Parallel Execution Permitted
 $\underline{\underline{S}}$: Segmentation Transformation
 $\underline{\underline{P}}$: Splining Transformation
 N : Total number of Processes
 $PG[IDs]$: Process IDs involved in a Collective
 $T_i[0:N, 0:D]$: N Tensors of size D on Process P_i with
 $T_i[j, 0:D]$ destined for Process P_j
 $M_{AA}(T_i[0:N, 0:D], PG[0:N])$: collective with all-to-all pattern of transfers
 with tensor T_i as payload
 executing on each Process P_i for all i in $0:N$
 $M(T_i[a_i:b_i, x_i:y_i], PG[IDs])$: Motif M
 executing on each Process P_i for all i in IDs
 with payload = tensor $T_i[j, x_i:y_i]$ from Process P_i
 destined to Process P_j for all j in $a_i:b_i$

Next, we present the algebraic rules that we use in the context of DLRM to transform all-to-all into motifs. The algebra for other comm-ops is in the Appendix §A.1.

Segmented All-To-All:

$$M_{AA}(T_i[0:N, 0:D], PG[0:N]) \stackrel{\underline{\underline{S}}}{=} \parallel_{s=0}^{\frac{D}{d}-1} M(T_i[0:N, s*d:(s+1)*d], PG[0:N])$$

With segmentation, the payload to be sent from a source process to all the destination processes is split into segments of size d ($= T_i[0:N, s*d:(s+1)*d]$). Segmentation of all-to-all in this way, yields $\frac{D}{d}$ motifs where each motif sends a payload of size d from a source process keeping the set of destination processes the same. d is a parameter and controls the number of motifs associated with the input all-to-all.

Splined All-To-All:

$$M_{AA}(T_i[0:N, 0:D], PG[0:N]) \stackrel{\underline{\underline{P}}}{=} \parallel_{c=0}^{\frac{N}{n}-1} M(T_i[(i+c*n)\%N:(i+(c+1)*n)\%N, 0:D], PG[0:N])$$

With splining, the pattern of network transfers in the all-to-all with each source process sending the payload to all the N destination processes is broken down into smaller patterns, where each source process P_i sends the same payload as before to n destination processes ($= (i+c*n)\%N:(i+(c+1)*n)\%N$). Splining of all-to-all in this way, yields $\frac{N}{n}$ motifs. Here, n parameterizes the all-to-all splining operator with larger n breaking the all-to-all into fewer motifs with larger sub-patterns.

Composition of Operators: Note that the all-to-all collective, $M_{AA}(\cdot)$, is in fact a special case single motif (with $d = D$ and $n = N$). These operators can be composed and recursively break a motif into several more finer-grained motifs. While fine-grained motifs are beneficial for scheduling flexibility, there is a fixed overhead associated with dispatching a motif as a kernel on GPU communication stream and launching it during execution and too fine-grained motifs are not desirable as these overheads can slow-down communication.

Physical Plan for Motif: Each motif bundles together several network transfers. Physical plan determines the physical interconnects that each network transfer is assigned to. Figure 10

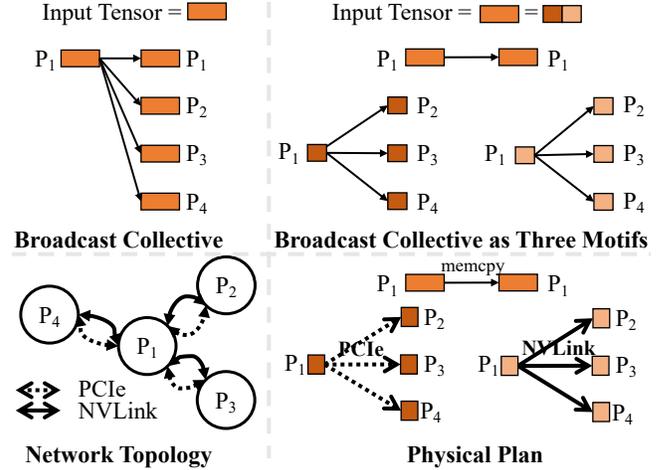

Figure 10: Physical Plan for Broadcast Collective

shows an example of a physical plan for the broadcast collective. The broadcast collective is first broken into three motifs. The physical plan maps the motif to point-to-point network transfers over various interconnects available in the network. The figure also shows a toy network topology where the GPU for process $P1$ connects to all other GPUs via both PCIe and NVLink interconnects. The three motifs can be multiplexed over different interconnects. The physical plan for the first motif does a memcopy on process $P1$. The physical plan for the remaining two motifs use PCIe and NVLink in a mutually exclusive manner. This allows the point-to-point transfers in the three motifs to execute in parallel, maximizing utilization of multipath opportunities available in the network.

4.3 Central Optimizer

The central joint optimizer is responsible for minimizing training iteration time by minimizing communication overheads. The optimizer determines the optimizer plan by systematically navigating the vast space of potential schedules.

The optimizer plan has two pieces: the execution plan and the scheduling order, containing instructions regarding how to execute and how to schedule comm-ops respectively. The execution plan transforms each comm-op in the training DAG into one or more motifs. The scheduling order decides the order of execution of motifs.

Exponential Search Space: There is a lot of optionality in the execution plans for each comm-op. The transformation operators can be composed to break a comm-op into motifs in several different ways. Let us say that there are at least O execution plan options for each comm-op and there are C comm-ops in the training DAG, then this results in O^C unique execution plan options for all the comm-ops in a DAG.

Cost of each Execution Plan: For a particular execution plan, there is an optimal scheduling order for the motifs that maximizes overlap of compute/communication and minimizes training iteration time. This training iteration time with the optimal scheduling order is the cost of the execution plan.

Problem Statement: The centralized joint optimizer takes a

29: end procedure
```

training DAG G and the network topology as inputs. We take a training DAG that unrolls compute-ops and comm-ops across two training iterations to enable cross-iteration optimizations. The aim of the joint optimizer is to take these inputs and find the execution plan with minimal cost. The joint optimizer outputs the optimizer plan, which has the execution plan and the scheduling order that minimizes overall cost.

4.3.1 Joint Optimization Procedure

The key idea in SYNDICATE is to do *probabilistic search* over the exponentially large search space. We use MCMC search as outlined in Pseudocode 1.

MCMC Search: The joint optimizer starts with the default execution plan for the training DAG (denoted by G_*), wherein all the comm-ops are greedily assigned the execution plan choice with the minimum possible execution time. Thereafter, a comm-op is chosen at random and it is assigned a random execution plan option. This changes the motifs associated with this particular comm-op, keeping all the other motifs constant and yields a temporary execution plan for the training DAG (denoted by G_{temp}). The cost i.e., the execution time of this training DAG is calculated using the optSched (line 11 in Pseudocode 1) procedure which is a greedy scheduling heuristic to always dequeue motifs on the critical path in the DAG to maximize overlap of communication motifs with compute tasks or other communication motifs (in case the two communication motifs have non-overlapping physical plans). This update to the execution plan is probabilistically sampled using the Metropolis-Hastings algorithm [17] and retained in G_* (line 8 in Pseudocode 1). This tends to behave as a greedy search over the search space with an ability to escape local minimas [17, 19].

Pseudocode 2 Distributed Optimizer Plan Enforcer

```
1: Exec Plan  $\mathbb{E}_{colls} = \{\dots, coll^m : \{\text{motif}_{i,j}^{fout}\}, \dots\}$  ▷ optimal execution plan
2: Scheduling Order  $\mathbb{S} = \{\dots, \text{motif}_{i,j}^{fout} : \text{seq}_{i,j}^{num}, \dots\}$  ▷ optimizer scheduling order
3: Progress Queue  $pq$  ▷ thread-safe priority queue containing ready motifs

4: procedure ENFORCEEXECPLAN( $coll^m$ ) ▷ app submits comm-op to comm layer
5:   $\{\text{motif}^{fout}\} = \mathbb{E}_{colls}[coll^m]$  ▷ comm-op is deconstructed into motifs
6:  for all  $\text{motif}^{fout} \in \{\text{motif}^{fout}\}$  do
7:     $\text{seq}^{num} = \mathbb{S}[\text{motif}^{fout}]$ 
8:     $pq.INSERT(\text{priority}=\text{seq}^{num}, \text{motif}^{fout})$ 
9:  end for
10: end procedure

11: procedure ENFORCEORDER ▷ runs in a separate thread and enforces order
12:   $\text{nextMotifSeqNum} = 0$ 
13:  while true do
14:    while  $pq.TOP().priority \neq \text{nextMotifSeqNum}$  do
15:      ▷ busy loop until next in order motif is ready
16:    end while
17:     $\text{nextMotifSeqNum} += 1$ 
18:     $\{\text{motif}\} = pq.POP()$ 
19:     $\{\text{motif}_{ensors}\} = \{\text{motif}\}.EXECUTE()$ 
20:     $REPACK(\{\text{motif}_{ensors}\})$ 
21:  end while
22: end procedure
```

Search Termination: MCMC search is terminated if the search procedure exceeds the time budget assigned for search or if the search procedure does not find a better joint optimizer plan for more than half of the total elapsed search time.

4.4 Enforcer

The central optimizer commits the same joint optimizer plan, comprising of the execution plan and the scheduling order to the enforcer on each worker process. The enforcer is responsible for *tightly co-ordinating this plan across all the worker processes during training* so as to avoid deadlocks and out-of-sync issues (§3.2). The application thread spawned by the ML processing framework at each worker process submits comm-ops to the comm layer every training iteration. With SYNDICATE, these comm-ops are submitted one-at-a-time in FIFO order. These comm-ops are intercepted by the enforcer. The enforcer is responsible for execution of these comm-ops and preparing the result of these comm-ops (tensors) to unblock the next application thread operation (compute-op or comm-op typically waiting on a CUDA stream) that is waiting on these tensors.

The enforcer takes the responsibility of executing these comm-ops as per the instructions of the optimizer plan and preparing the output tensors once ready. It does so in three steps. First, on intercepting a comm-op, it enforces the execution plan by breaking it into motifs. Second, it enforces the desired scheduling order of execution of motifs. Third, as and when motifs complete, it checks for completion of comm-ops and packages the output of individual motifs into the comm-ops output tensors. Pseudocode 2 shows the procedure to enforce the execution plan and the scheduling order contained in the joint optimizer plan. The repacking of tensors to comm-op output tensors happens after successful execution of each motif (line 20 in Pseudocode 2).

Enforcing Execution Plan: The enforcer is layered as a shim on top of existing comm-op execution layer i.e., differ-

Compute (TFLOPS)	120 (FP32)/ 1000 (FP16)

DDR	1.5 TB, 200 GB/s
Scale-up bandwidth	1.2 TB/s (uni-directional)
Scale-out bandwidth	8 x 100 Gbps (uni-directional)
Host NW	2 x 100 Gbps

Table 1: Configuration of each node in our cluster

ent communication libraries such as NCCL, MPI, UCX. The app layer submits comm-ops to the comm layer using the interface between them and is immediately trapped by the `enforceExecPlan` procedure (line 4 in Pseudocode 2). This procedure deconstructs the comm-op to one or more motifs, each assigned a sequence number that captures the priority of this motif in the current training iteration. This sequence number is contained in the scheduling order of the joint optimizer plan. These motifs are enqueued into a priority queue using the sequence number as the priority.

Enforcing Scheduling Order: The `enforceOrder` procedure (line 11 in Pseudocode 2) enforces the scheduling order and runs in a thread separate from the `enforceExecPlan` procedure. This procedure maintains a priority counter that is incremented sequentially and is reset at the end of each training iteration. This counter maintains the priority of the next expected motif(s). In case of overlapping motifs, two or more motifs can be assigned the same priority. The `enforceOrder` procedure busy loops until the priority of the motif at the top of the priority queue matches the value in the priority counter. It busy loops until the `enforceExecPlan` enqueues the next expected motif. This ensures that the enforcer on all the worker processes executes motifs in the same order.

Replanning: We measure the wait time in the busy loop and send it as feedback to the central optimizer. If wait times in every iteration consistently add up to more than a threshold ($= 5\%$ of iteration time), then we redo joint optimization at the optimizer to explore a different optimizer plan.

5 Implementation

We implement the central optimizer as a separate module in python. The central optimizer simulates the execution of different execution plan choices as part of the MCMC search procedure until the search procedure terminates and yields a joint optimizer plan. The central optimizer runs on one of the machines in the training cluster and interacts with the various enforcers on the worker processes via RPCs. We build a two-phase commit (2PC) protocol using RPCs so that the same joint optimizer plan is safely committed by the central optimizer to all the enforcers. After the 2PC protocol is complete, the enforcers switch to the new joint optimizer plan from the subsequent training iteration. This ensures that out-of-sync issues are avoided whenever transitioning to a new joint optimizer plan.

We implement the enforcer in the Unified Collective Communication (UCC) library interface [6]. We implement the enforcer routines: `enforceExecPlan` routine in the `main`

6 Evaluation

6.1 Testbed

We experimented with our prototype on a production-scale cluster using off-the-shelf NVIDIA HGX-2 based systems. Specifically, each node hosts dual-socket CPUs, 8 NVIDIA V100 GPUs that are fully-connected using NvSwitch, 2 front-end host NICs, and 8 back-end RoCE NICs to allow RDMA communication between GPUs across nodes. Table 1 summarizes the node configuration; we deployed 16 such nodes.

The testbed runs CentOS-8 and CUDA 11.4 with NVIDIA driver 470.57.02. For distributed training of DLRM models, we used PyTorch 1.11 (nightly) with the extension of Process Group UCC [5] and the latest UCC library [6], which can take advantage of various transports such as NCCL 2.10.3 [2] and UCX-based collectives [31] for dynamically selecting optimal execution planing of collective operations.

6.2 Workloads

We tested SYNDICATE in production across a breadth of scenarios; see Table 2.

Vary Model Architectures: We experiment with three different model architecture families. A1-A4 are Recommendation Models (DLRM [24]), A5 is an NLP Model (XLM-R-XL [14]), A6 is a CV Model (RegNetZ [7]).

Vary Model Sizes: We have progressively wider MLPs and higher number of embedding tables from model A1 to A3.

Vary Parallelization Strategies: Models A1-A3 are Hybrid Parallel. Model A4 is Hybrid Parallel with Fully Sharded Data Parallel (FSDP) for data parallelism [8]. Model A5 is Model Parallel. Model A6 is Data Parallel.

Vary Topologies: We vary the number of nodes (and hence GPUs) used from our testbed.

6.3 Metrics

We measure the following metrics

(1) **Training Throughput:** We measure the training throughput in terms of recommendation queries per second (A1-A4) or words per sec (A5) or images per sec (A6). Higher throughput is desirable.

(2) **Compute Idling:** We measure the idle gaps in the

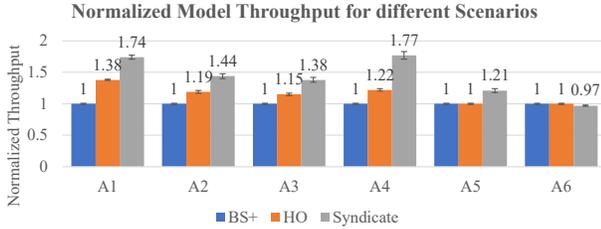

Figure 11: Training performance for SYNDICATE compared against baselines

GPU’s compute stream and report it as a percentage of the total iteration time. Lower compute idling is desirable.

(3) **Normalized Metric:** We normalize the metric (such as throuput) against baseline using the formula – $\frac{\text{Metric with SYNDICATE}}{\text{Metric with Baseline}}$.

We run each experiment 5 times and plot the mean and standard deviation.

6.4 Baselines

We compare SYNDICATE against the following baselines.

- **ByteScheduler+ (BS+):** ByteScheduler [29] proposes LIFO scheduling policy for maximizing overlap of compute and communication. Their implementation only supports all-reduce in layer-by-layer models and does not have support for all-to-all collectives. We emulate ByteScheduler (BS) via our own implementation that is co-located with PyTorch framework. To emulate the bayesian optimizer used in ByteScheduler for tensor partitioning, we aid our BS scheduler with an oracle (BS+) that optimally segments tensors in all collectives.
- **Hand Optimized Model (HO):** Existing execution planners do not optimize all-to-all collectives and existing schedulers do not have support for DLRM-like models. We hand optimize both the scheduling policy in PyTorch (and also provide it the benefit of the segment oracle) and the choice of execution plan for each collective (including all-to-all) in the UCC library. In this regards, HO models the best possible solution with today’s placement of scheduling and execution planning concerns in exiting stacks.
- **SYNDICATE-Exec (S-Exec):** We disable scheduling optimizations in SYNDICATE. We do so by using PyTorch’s default scheduler that does FIFO scheduling to estimate the cost of each execution plan during joint optimization.
- **SYNDICATE-Sched (S-Sched):** We disable execution planning optimizations in SYNDICATE. We do so by disabling the MCMC search procedure and find the optimal scheduling order using SYNDICATE’s scheduling heuristic (and also provide it the benefit of the segment oracle to optimally segment collectives).

6.5 Evaluation on Testbed

Figure 11 compares training performance for SYNDICATE against the BS+ and HO baselines for all the models. The

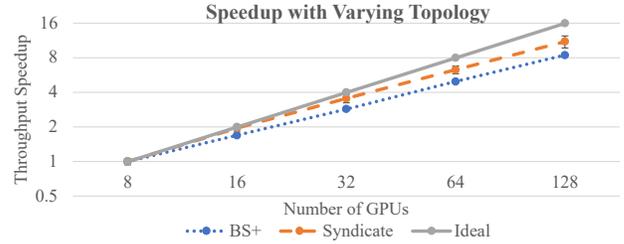

Figure 12: Speedup with varying topology sizes

Y-axis measures the model throughput normalized against that of BS+.

Vary Model Sizes: SYNDICATE outperforms BS+ by a factor of 1.74x, 1.44x, 1.38x for Models A1, A2, A3, respectively. SYNDICATE outperforms HO baseline by a factor of 1.26x, 1.21x, 1.2x for Models A1, A2, A3, respectively. Note that gains diminish with increased model sizes. The embedding tables are not compute-intensive and do not contribute to increasing the MFLOPs per sample and do not contribute to increasing the MFLOPs per sample but have a high memory footprint (and contribute to higher number of parameters) and induce progressively more communication bandwidth-hungry all-to-all’s to transfer a large number of embeddings. On the other hand, MLPs are compute intensive and increase the model compute (MFLOPs per sample). On detailed analysis, we found that the larger embedding table sizes amplify the amount of time spent in all-to-all in a training iteration to a higher degree than the contribution of increased MLP compute time; which skewed the overall ratio of communication to compute and diminished the opportunity to overlap communication and compute with SYNDICATE.

Vary Model Architectures and Parallelization Strategies: SYNDICATE is effective across a range of parallelization strategies and outperforms the BS+ baselines for A2 (hybrid-parallel, recommendation model) by 1.44x, A4 (FSDP, recommendation model) by 1.77x, and A5 (model-parallel, NLP model XLM-R-XL) by 1.21x. SYNDICATE is slightly worse-off for A6 (data-parallel, RegNetZ) by 0.97x. For this model there are no opportunities to overlap comm-ops as they have linear dependency and BS+ solution (LIFO with oracle tensor partitions) is the optimal solution (similar to other CV model families, e.g., ResNet [29]). SYNDICATE is slightly worse-off due to the overheads of SYNDICATE’s enforcer. The gains are for A4 are significantly higher than that for A2 despite both the models having similar model sizes and model architecture. We found that FSDP parallel strategy for A4 offers a richer set of collectives: reduce-scatter and all-gather in addition to all-to-all and all-reduce. This allows SYNDICATE to find a schedule and an execution plan that overlaps atmost three comm-ops for A4 at the same time (compared to atmost two for A2). For Model A5, we find that BS+’s LIFO schedule is optimal and hence HO does not yield any improvements. For A5, the 1.21x gains with SYNDICATE are due to better execution plan with overlap of allgather and reduce-scatter during backward pass. For Model A6, we observe no improvements with SYNDICATE. This is primarily because A6 is data

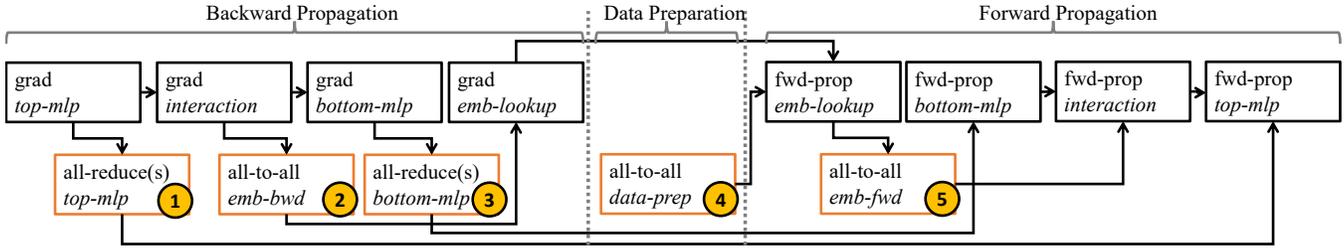

Figure 13: DLRM Training DAG. The numbers represent the order in which the PyTorch modules (`nn.DistributedDataParallel` and `nn.EmbeddingBag`) submit these collectives.

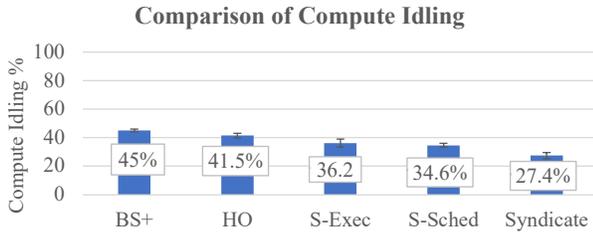

Figure 14: Comparison of Compute Idling

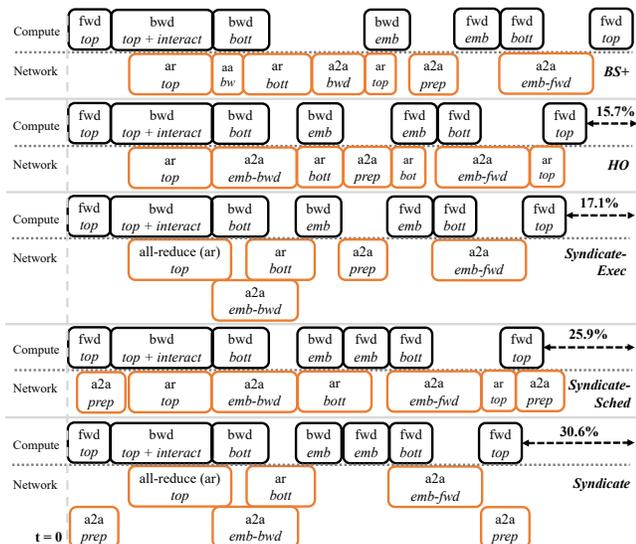

Figure 15: Zooming in on every DLRM iterations for different systems

parallel and BS+ LIFO schedule is optimal for data parallel models. Furthermore, the collectives in training DAG for A6 have serial dependencies across themselves with no room to optimize execution plan by overlapping collectives.

Vary Topologies: Figure 12 compares throughput speedup for Model A2 with SYNDICATE against BS+. We report the speedup relative to throughput on a single node. We note that SYNDICATE scales better than BS+ and is closer to ideal speedup line. SYNDICATE is better at opportunistically utilizing the increasing communication bandwidth as the cluster size scales out.

6.5.1 Sources of Improvement

Compute Idling:

Figure 14 compares the compute idling metric for SYNDICATE against baselines for Model A2. We observe that compute idling with SYNDICATE is 27.4% and is 1.64x, 1.51x, 1.32x, 1.26x less than the BS+, HO, S-Sched, S-Exec baselines, respectively. This shows that SYNDICATE is better at overcoming communication bottlenecks and achieves higher overlap of compute and communication than any other baseline. It also highlights that joint optimization is beneficial as it outperforms the S-Sched and S-Exec baselines. Next, we zoom-in on each training iteration to better understand the reasons for lesser compute idling.

Zooming in on an Iteration: We collect traces for execution of DLRM with different systems using PyTorch Kineto [4]. We illustrate these traces² to zoom-in on the execution of compute and communication events on the GPU streams for a single training iteration for Model A2 in Figure 15. We also show the training DAG in Figure 13 for reference. We explain these traces one system at a time.

BS+: BS+ prioritizes the execution of the most recently submitted collective (LIFO). For reference, Figure 13 shows the order of submission of collectives by DLRM PyTorch trainer. To achieve LIFO, tensors in collectives need to be optimally segmented and as explained before, we use a segment oracle to do so. BS+ is the worst-performing baseline. BS+ prioritizes execution of a2a-emb-bwd over ar-top-mlp³, which is beneficial. However, to its detriment, it also prioritizes execution of ar-bottom-mlp over a2a-emb-bwd despite a2a-emb-bwd being on the critical path. Delaying a2a-emb-bwd also delays bwd-emb compute, which delays a2a-data-prep.

HO: To amend the drawbacks of BS+, we hand optimize the scheduling order to prioritize the execution of a2a-emb-bwd as well as a2a-data-prep before ar-bottom-mlp. We also add support for greedy execution planning for a2a collective (ar greedy optimization is available out-of-the-box). We observe that HO improves the iteration time by 15.7% as compared to BS+. We observe that the key reason for this improvement is that HO unblocks bwd-emb and fwd-emb compute sooner

²We hide low-level events and absolute timing information for confidentiality and legal reasons.

³We use a2a and ar as short hand for all-to-all and all-reduce, respectively.

and enables better overlapping of ar-bottom-mlp with these compute blocks.

S-Exec: With S-Exec, we observe that the iteration time is further improved and is 17.1% better as compared to BS+. We observe that despite placing limiting constraints on scheduling (default FIFO scheduling), the joint optimizer in SYNDICATE finds an execution plan that assigns two different communication channels to a2a and ar and enables better communication-communication overlap by leveraging heterogeneity in the network. The ar’s use a communication channel over NVLink (for intra-node) and GPUDirect RDMA (for inter-node). The a2a’s use a non-intersecting communication channel over PCIe (for intra-node) and TCP/IP over Ethernet (for inter-node). Such communication-communication overlap is not possible with HO and BS+ as they use traditional communication stack and interfaces therein only permit one-at-a-time execution of comm-ops with greedy execution plan.

S-Sched: With S-Sched, we observe that iteration time is further improved and is 21.9% faster than BS+, despite the constraints on execution planning (we also handicap S-Sched with choosing the default execution plan option, which is sub-optimal, for a2a). The primary reason for the improvement is that SYNDICATE’s scheduler finds a superior comm-op scheduling order and SYNDICATE’s enforcer enables enforcing of this order. SYNDICATE’s scheduling order moves a2a-data-prep from the i^{th} iteration and moves it back in time as to overlap it with the fwd-top-mlp and bwd-top-mlp compute blocks in the $(i-1)^{th}$ iteration. The enforcer design enables this ordering due to the presence of busy loop in the `enforceOrder` procedure in Pseudocode 2. The enforcer blocks execution of all the comm-ops in the very first training iteration until a2a-data-prep collective for the next batch is submitted by the application layer. This increases the training iteration time only for the first iteration but significantly improves the training iteration time for all the subsequent iterations by unlocking pipelining.

SYNDICATE: With SYNDICATE, we observe that iteration time is faster than all the baselines and is 30.6% faster than BS+. We observe that as compared to S-Sched, SYNDICATE is able to hide the overheads of ar-top-mlp by completely overlapping it with compute. SYNDICATE enables this by leveraging network heterogeneity and enabling communication-communication overlap of ar-top-mlp and a2a-emb-bwd. S-Sched, due to its execution planning constraints is unable to do so and in its scheduling order has to partially push ar-top-mlp to the very end where it cannot be overlapped with compute. In this way, SYNDICATE’s joint optimizer maximizes compute-communication overlap by leveraging the benefits of communication-communication overlap.

SYNDICATE’s Optimizer Plan for DLRM: Here, we summarize the key highlights of the optimizer plan that SYNDICATE finds for DLRM Model A2. In our study, we find that these observations also hold for Model A1 and Model A3.

Data Prefetch The scheduling order proposed by the optimizer

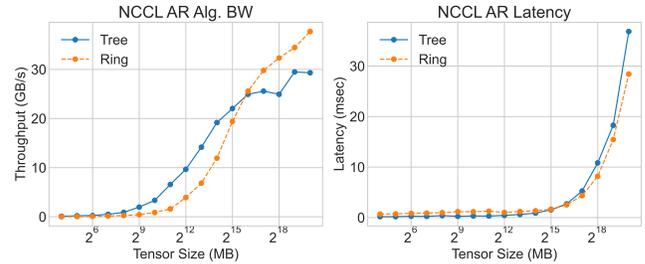

Figure 16: Effect of different execution plans on all-reduce performance

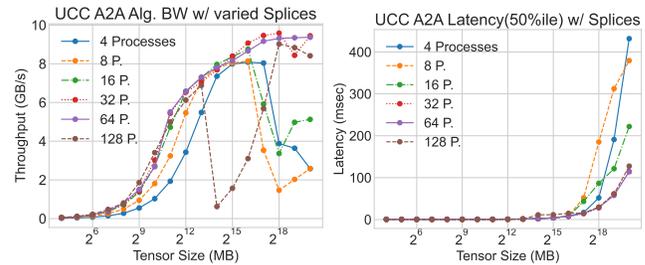

Figure 17: Effect of different execution plans on all-to-all performance

moves a2a-data-prep back in time from the i^{th} iteration to the $(i-1)^{th}$ iteration. As mentioned before, this is made possible by SYNDICATE’s enforcer.

a2a-ar Overlap The execution plan proposed by the optimizer overlaps all-to-all collective with all-reduce collective over two separate communication channels as explained before. SYNDICATE binds both the a2a’s to the 4-way splined execution plan, the ar-bottom-mlp to the ring all-reduce execution plan and the ar-top-mlp to the tree all-reduce execution plan. This maximizes multipath network utilization and also enables greater communication-compute overlap.

6.6 Microbenchmarks

We use the communication microbenchmark, PARAM [3] to systematically understand the space of execution plans for different collectives to better understand the choices made by SYNDICATE’s optimizer plan. SYNDICATE uses these microbenchmarks as a cost model for its joint optimizer. We highlight a subset of these microbenchmarks and explain the various choices made by SYNDICATE for Model A2.

Execution planning options for all-reduce: Figure 16 shows the effect of different all-reduce execution planning options in our testbed. We see that the optimal execution plan depends on the input message size. The optimal plan at small message sizes is tree all-reduce motif whereas the optimal plan at large message sizes is ring all-reduce motif. Bottom MLP is wider and induces larger ($O(100$ ’s of MB) vs. top MLPs $O(MB)$) all-reduce collectives and explains choice of ring all-reduce and tree all-reduce for ar-bottom-mlp and ar-top-mlp, respectively.

Execution planning options for all-to-all:

Figure 17 shows the effect of different all-to-all execution planning options. We note that the optimal plan at small mes-

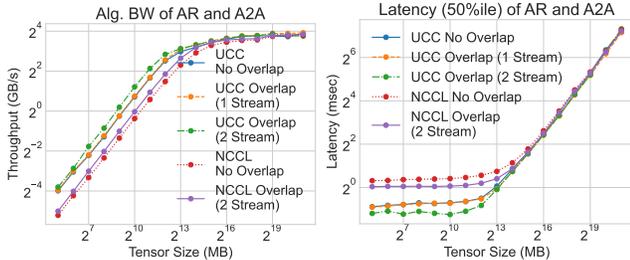

Figure 18: Effect of different execution plans for all-to-all and all-reduce overlap

message sizes is the 1-way splined motif (simultaneous transfers to 128 destination processes from all source processes), at intermediate message sizes is the 2-way splined motif (64 Processes), and at large message sizes is the 4-way splined motif (32 Processes). The effects of incast are significant as we increase the message sizes and more splining helps reduce incast. DLRM training induces large a2a’s (O(GB) message size) and SYNDICATE chooses the 4-way splined execution plan.

Execution planning options for overlap of all-reduce and all-to-all: Figure 18 shows that the optimal execution plan is the one where all-reduce uses NCCL implementation and all-to-all use UCC implementation over non-overlapping communication channels (i.e., 2 streams). With this implementation all-to-all is CPU-driven and uses the PCIe complex and TCP/IP over Ethernet, while all-reduce is GPU-driven and uses NVLink complex and GPUDirect RDMA. This choice is optimal (as opposed to vice versa) as all-reduce also does compute (gradient aggregation) which is faster with GPUs. SYNDICATE uses this execution plan for overlap of all-to-all and all-reduce.

7 Other Related Work

Several works speed-up training by optimizing two main concerns of communication operations: scheduling and execution. Table 3 shows comparison of SYNDICATE against several state-of-the-art systems.

Scheduling concerns looks at reordering communication operations to maximize overlap of compute and communication. The optimal scheduling policy is dependent on factors such as the model architecture, and the parallelization strategy/framework.

Execution concerns look at accelerating individual commu-

nication operations through efficient transport over all communication links. These optimizations propose optimal batching to improve link utilization, propose multipath in collectives to make better use of heterogeneous links in the network, and enable preemption to enable scheduling optimizations.

Existing scheduling works fall short in generalizing optimally to all scenarios and they exercise only a subset of optimizations as highlighted in Table 3. Crucially, unlike SYNDICATE, existing works do not jointly optimize both these concerns.

8 Conclusion

We propose SYNDICATE that rethinks communication scheduling granularity and the interfaces in the communication stack for ML training to enable joint optimization of scheduling and execution planning. Using the novel notion of motifs and a split control/data plane architecture SYNDICATE achieves improvements of 21-74% for production scale large-model training as it better utilizes the network multipath opportunities in emerging training clusters.

A Appendix

A.1 Transformation Operator Algebra

We now present the algebra for the motif transformation operators. We denote the segmentation operator by $\underline{\underline{S}}$ and the splining operator by $\underline{\underline{P}}$. Note that the algebraic rules presented below are not exhaustive and are extensible. Here, we present the algebraic rules that we use in the context of DLRM to transform all-reduce and all-to-all collectives into motifs. We first go over the various symbols used in the algebra.

N : Total number of Processes
 $PG[0:N]$: Process IDs involved in a Motif
 $T_i[0:D]$: Tensor of size D on Process P_i
 $T_i[0:N, 0:D]$: N Tensors of size D on Process P_i with first dimension indicating destination Process ID
 \parallel : Parallel Execution
 \rightarrow : Sequential Execution
 $\underline{\underline{S}}$: Segmentation Transformation
 $\underline{\underline{P}}$: Splining Transformation
 AR : all-reduce motif
 AA : all-to-all motif
 RE_r : reduce motif with root Process P_r
 RS : reduce-scatter motif
 BC_r : broadcast motif with root Process P_r
 AG : all-gather motif
 $COLL(T_i[:], PG[IDs])$: Motif $COLL$ with input tensor T_i executing on each Process P_i for all i in IDs

We now present the algebraic rules for transforming the all-reduce motif using the segment and spline operators.

Segmented All-Reduce: First, we show application of the segment operator which splits the input tensor at all the processes and converts an all-reduce motif into smaller all-reduce motifs over the splits. Each smaller all-reduce motif are independent and can execute at the same time in parallel.

$$AR(T_i[0:D], PG[0:N]) \stackrel{\underline{\underline{S}}}{=} \parallel_{s=0}^{\frac{D}{s}-1} AR(T_i[s*d:(s+1)*d], PG[0:N])$$

Ring All-Reduce: Next, we show an instance of the spline operator that divides the pattern in original all-reduce into two sub-patterns: reduce-scatter motif followed by the all-gather motif. The reduce-scatter motif does aggregation and the all-gather motif broadcasts the aggregated result. The reduce-scatter and all-gather motifs induce a pattern of communication over a ring, where the processes are arranged in a ring and the tensor is divided into N pieces. Each process P_i does a point-to-point transfer of the $(i+r) \% N$ piece to its neighboring process in the ring in the r^{th} round for N rounds.

$$AR(T_i[0:D], PG[0:N]) \stackrel{\underline{\underline{P}}}{=} RS(T_i[0:D], PG[0:N]) \rightarrow AG(T_i[0:D], PG[0:N])$$

$RS(T_i[0:D], PG[0:N]) =$ ring pattern of communication
 $AG(T_i[0:D], PG[0:N]) =$ ring pattern of communication

Tree All-Reduce: Next, we show an instance of the spline operator that divides the pattern in the original all-reduce into three smaller sub-patterns: reduce motif followed by a smaller all-reduce motif followed by broadcast motif. The same spline operator algebraic can be recursively applied to the smaller all-reduce motif. Recursive application results in a hierarchical tree pattern of communication where several

reduce motifs first aggregate results in a tree like fashion at a single root process and several broadcast motifs broadcast the aggregated result from the root process in a tree like fashion until it is updated at all the processes. Each reduce motif results in a convergent pattern of communication where all the processes involved in the reduce send their tensors to the root process where it is aggregated. Each broadcast motif results in a divergent pattern of communication where the root process sends its tensor to all the processes involved in the broadcast motif.

$$AR(T_i[0:D], PG[0:N]) \stackrel{\underline{\underline{C}}}{=} \parallel_{c=0}^{\frac{N}{c}-1} RE_{c*n}(T_i[0:D], PG[c*n:(c+1)*n]) \rightarrow AR(T_i[0:D], PG[\cup_{c=0}^{\frac{N}{c}-1} c*n]) \rightarrow \parallel_{c=0}^{\frac{N}{c}-1} BC_{c*n}(T_i[0:D], PG[c*n:(c+1)*n])$$

$RE_j(T_i[0:D], PG[j:j+n]) =$ convergent pattern of communication
 $BC_j(T_i[0:D], PG[j:j+n]) =$ divergent pattern of communication
 $AR(T_i[0:D], PG[\cup_{c=0}^{\frac{N}{c}-1} c*n]) =$ recursive application of $\underline{\underline{C}}$ induces tree pattern of communication

Segmented and Splined All-To-All: Next, we show examples of segmenting and splining an all-to-all collective into smaller motifs. With segmentation, the tensor at all the processes is split and the original all-to-all is deconstructed into several smaller all-to-all motifs over the split tensors. With splining, the pattern of communication in the original all-to-all motif with a clique of point-to-point transfers between all the processes is broken down into smaller all-to-all motifs with smaller patterns where each process P_i initiates point-to-point transfers to a subset of destination processes (with ids in the range $(i+c*n) \% N : (i+(c+1)*n) \% N$). Here, n parameterizes the all-to-all splining operator with larger n resulting in breaking the original all-to-all into fewer all-to-all motifs with larger sub-patterns.

$$AA(T_i[0:N, 0:D], PG[0:N]) \stackrel{\underline{\underline{S}}}{=} \parallel_{s=0}^{\frac{D}{s}-1} AA(T_i[0:N, s*d:(s+1)*d], PG[0:N])$$

$$AA(T_i[0:N, 0:D], PG[0:N]) \stackrel{\underline{\underline{C}}}{=} \parallel_{c=0}^{\frac{N}{c}-1} AA(T_i[(i+c*n) \% N : (i+(c+1)*n) \% N, 0:D], PG[0:N])$$

Addax: A fast, private, and accountable ad exchange infrastructure

Ke Zhong* Yiping Ma* Yifeng Mao* Sebastian Angel*†

*University of Pennsylvania †Microsoft Research

Abstract. This paper proposes Addax, a fast, verifiable, and private online ad exchange. When a user visits an ad-supported site, Addax runs an auction similar to those of leading exchanges; Addax requests bids, selects the winner, collects payment, and displays the ad to the user. A key distinction is that bids in Addax’s auctions are kept private and the outcome of the auction is publicly verifiable. Addax achieves these properties by adding public verifiability to the affine aggregatable encodings in Prio (NSDI’17) and by building an auction protocol out of them. Our implementation of Addax over WAN with hundreds of bidders can run roughly half the auctions per second as a non-private and non-verifiable exchange, while delivering ads to users in under 600 ms with little additional bandwidth requirements. This efficiency makes Addax the first architecture capable of bringing transparency to this otherwise opaque ecosystem.

1 Introduction

Ad exchanges such as DoubleClick and OpenX are key players in online advertising; their role is to auction ad space on a publisher’s website in real time to advertisers. When a user visits a publisher’s page, the user’s browser contacts a server that triggers an auction on an exchange. The exchange gives advertisers information about the publisher (e.g., URL, ad size and type, category of site) and the user (e.g., demographic, metadata for syncing cookies across sites) in real time, and collects bids from interested parties. The exchange then runs an auction (e.g., second-price auction), delivers to the user the ads of the winning advertisers, and credits the publisher. Finally, technologies like header bidding [4] and Google’s open bidding platform [30] allow publishers to auction users across many exchanges (essentially an exchange of exchanges), increasing competition and improving publishers’ revenue.

While ad networks and exchanges serve as the financial backbone of the free web, their centralized nature means that: (1) they are privy to sensitive information, including user’s browsing habits and the preferences and valuations of advertisers; and (2) they are opaque and hard to audit. The former has received considerable attention [39, 45, 56, 71, 77, 89, 91]; the lack of auditing mechanisms and the knowledge of advertisers’ valuations is becoming a serious sociotechnical issue. A recent antitrust lawsuit alleges that Google used insider knowledge of past bids submitted by advertisers to gain unfair advantages whenever its subsidiaries participated in auctions [63]. Further, it is alleged that Google convinced Facebook to not participate in header bidding—a technology considered an “existential threat” to Google’s business [28, 81, 84]. According to disclosed reports, in return for Facebook choosing to participate

instead in Google’s open bidding platform, “Google provided Facebook with special information and speed advantages to help [Facebook’s exchange] succeed in the auction [over other bidders]—even including a guaranteed win rate” [84].

Regardless of the merits of these cases, the key issue—and the crux of this paper—is that there are no ways for exchanges to *prove* to their customers and to regulators that they are not abusing their position. To address this, we present Addax, an online advertising architecture that achieves 4 goals:

- *Auction integrity.* Auctions should be publicly verifiable to allow the ad exchange to prove that it is not biasing auctions towards particular bidders or lying about their outcome.
- *Auction privacy.* The bids of losing bidders should be hidden from all parties—even the exchange itself! This ensures that the exchange cannot abuse or share this information.
- *High performance.* Addax should handle the stringent performance requirements of the ad ecosystem.
- *Better tracking.* Addax should work with recent tracking efforts such as Google’s Topics API [16] and Microsoft’s PARAKEET [13] that allow targeted ads but collect less information about individuals.

Overview. In Addax, browsers track users’ histories with existing privacy-preserving client-side techniques [57, 58, 80, 89], and kickstart verifiable and private auctions whenever the user navigates to an ad-supported site. Auctions in Addax proceed in three steps. First, the browser invites relevant bidders (e.g., demand-side platforms) by finding their information (e.g., URL of their ad server) on a database. In existing header bidding platforms [2] such databases are currently maintained by publishers; Addax preserves this model, but we additionally experiment with a more decentralized approach where the database is maintained in a public append-only log and discuss how to reduce the cost of lookups in this model (§7). As part of the invitation, the browser supplies to bidders information about the site being visited and a variable amount of user information based on the user’s configuration of Addax (ranging from fully targeted to generic ads).

Second, bidders submit encrypted bids to the publisher and one or more *auxiliary servers*. The auxiliary server helps the publisher run a new lightweight secure auction computation over the encrypted bids (§4). The role of an auxiliary server could be taken up by today’s exchanges or it can be a separate entity propped up by the industry at large. Under the *anytrust model* [88] (either the publisher or any of the auxiliary servers is honest), the secure auction computation returns the winning bidder’s identity and bid, and the auction’s sale price, but no other information.

Last, Addax produces an *audit trail* that is uploaded to a public log and that allows any auditor to verify that the auction was conducted with integrity (§5). At the conclusion of the auction, the browser fetches the ad from the winning bidder (or a content distribution network) and the publisher learns which bidder and how much to bill for the ad impression.

Technical contributions. To maintain good performance, Addax cannot use expensive cryptography (e.g., homomorphic encryption, multiparty computation) in order to achieve the integrity and privacy goals. Indeed, our evaluation of such baselines confirms that they are far too inefficient to meet online advertising’s low latency and communication requirements (§9). Instead, Addax makes three contributions:

Secure auction protocol. Addax introduces a new auction protocol based on Prio’s *affine-aggregatable encodings* (AFE) [51]. Addax’s auction is simple and lightweight and allows two or more parties to run the auction over secret-shared bids without revealing anything beyond the auction’s outcome.

Verifiable AFEs (V-AFEs). Addax extends Prio’s AFEs to provide public verifiability for *outputs* (Prio has mechanisms to verify inputs). Addax then uses V-AFEs to allow anyone (e.g., an auditor) to confirm that an auction was conducted correctly without learning any of the input bids.

Integration with Algorand and Chrome. Addax implements mechanisms to interact quickly with the public log (we use Algorand [3, 55]) and smart contracts to manage the registration of advertisers and the collection of audit materials. Addax also leverages Chrome native messaging to launch auctions.

Our implementation of Addax can complete auctions over WAN with twice the average number of bidders reported in production ad exchanges [92] in 440–580 ms (for first and second-price auctions), and requires only 1.2 MB of communication between the publisher and the auxiliary server (§9.2). This is fast enough for ads to be loaded asynchronously without affecting page load time for the overwhelming majority of websites today [1, 7, 20, 87]. In terms of throughput, Addax can handle around 250–360 auctions per second per core (for second and first-price auctions), which is roughly 40% of what our non-private and unverified baseline can achieve. Creating the audit trail requires additional computation on the part of bidders but adds negligible overhead to users’ browsers and publishers. In contrast, the same auction implemented in existing state-of-the-art cryptographic frameworks (MPC and FHE) requires over 4 GB of communication and over 100 sec.

Limitations. Ad exchanges do more than just run auctions and deliver ads. They vet advertisers to ensure users do not receive malware; mitigate fraud; and provide powerful analytics. Addax does not yet address these complementary and critical aspects, but Section 11 discusses concrete directions to incorporate such features into Addax’s architecture. Finally, Addax can achieve better performance (optionally) at the expense of revealing the existence of winning ties (§4.4).

2 Background and goals

Ad exchanges are platforms that auction *impressions* (the display of a text, image, or video ad) on a publisher’s website or mobile application in real time. Exchanges support highly targeted advertising whereby bidders (advertisers or their representatives, called demand-side platforms) get a chance to evaluate the publisher and the user to whom the ad will be shown to decide how much they would be willing to pay (if at all). This type of programmatic *real-time bidding* (RTB) advertising accounts for over a third of all digital ad spending today [22, 27]. Some of the largest ad exchanges include DoubleClick, PubMatic, OpenX, and Facebook.

To participate in an ad exchange, a publisher inserts a *supply-side platform’s* (SSP) iframe or JavaScript snippet into their page. An SSP is a service that sells the publisher’s ads on an exchange (publishers can also run their own SSP). When a user’s browser fetches the publisher’s site and executes the provided JavaScript, it sends an HTTP GET request to the SSP supplying the user’s cookie, and awaiting for an ad to be returned. At this point, the SSP can identify the user and publisher, and start an RTB auction. During this process, the exchange invites dozens of potentially interested bidders to bid on the user [92], supplying them with demographic information, and relevant details about the publisher and the ad space (size, type, location within the page). To facilitate the valuation of the user, exchanges and bidders synchronize cookies [19, 23] to allow bidders to learn the identity of the user in their respective platforms (if applicable). Based on this information, bidders return a bid in CPM (cost per 1000 impressions), which ranges from cents to tens of dollars [32].

Upon receiving all bids, the exchange runs an auction where it selects the winning bidder and charges them the auction’s sale price based on the type of auction. Two common types are *first-price* (winner pays what they bid) and *second-price* [83] (winner pays second highest bid) auctions. Finally, the exchange notifies the SSP with the result of the auction, who then responds to the user’s GET requests with the information that the browser needs to retrieve the ads (images, videos, etc.) from a storage server.

2.1 Header bidding

Header bidding [4] is a recent advertising paradigm where the publisher (or its SSP) works with multiple exchanges to sell its ad slot in real time. It is called “header bidding” because the publisher supplies JavaScript code that runs in the `<header>` part of the page (which loads as soon as the page starts opening in the user’s browser), and this code triggers the process of contacting the exchanges. The exchanges then internally run their own auctions (first or second-price) and send back the winning bids to the browser. The browser then sends the winning bids to the publisher (or its SSP), which runs another auction (typically first-price), selects the highest bid as the winner, and forwards the winner’s ad tag to the user’s browser. Google’s Open Bidding platform is similar [30].

2.2 Concerns with existing exchanges

We highlight three areas of concern with existing ad exchanges. First, there is no visibility into the auction process. VEX [35] argues that this opens the door to a variety of issues—including those that are mentioned by the antitrust lawsuits [28, 63, 84]. Second, exchanges observe all submitted bids in the clear. These bids represent how valuable different users and publishers are to bidders, which reveals information about bidder’s trading algorithms, finances, and future plans. Last, users lack agency and have no say over which types of ads they receive or what information is shared with bidders. One might imagine a different world in which users can express an opinion on the types of ads they consume (e.g., no ads for kids toys to avoid children exploitation), and what information about themselves they reveal in order to receive targeted ads.

2.3 Goals
