Message from the NSDI '23 Program Co-Chairs

Welcome to NSDI '23! This year marks the 20th anniversary of the NSDI conference. In these two decades, networked systems have transformed the way that we live, work, and interact with one another. NSDI papers have spearheaded this revolution, providing many of the key technological advances behind industries such as Cloud Computing, Big Data, Software-Defined Networks, and more. With this latest iteration of NSDI, we hope to extend our community's track record of enabling and accelerating seismic shifts in computing via foundational research.

NSDI '23 received 560 submissions across two deadlines (272 in the Spring and 288 in the Fall), an increase of 40% from NSDI '22. To handle this record number of submissions, we assembled a Program Committee of 99 experts from academia and industry. The reviewing process included two rounds of double-blind review, an online discussion phase, and a two-day online PC meeting for each of the two deadlines. A total of 96 papers were accepted, resulting in an acceptance rate of 17%.

We thank our Program Committee members, who wrote over 1.6 million words of thoughtful, high-quality feedback across 2172 reviews, and discussed the papers extensively online and during the PC meetings. Many thanks to our poster chairs, Francis Yan and Soudeh Ghorbani, for bringing back the poster session to NSDI after a three-year hiatus. We thank our stand-in conflict PC chairs: Ben Y. Zhao, Siddhartha Sen, Indranil Gupta, and Katerina Argyraki. We would also like to thank Ellen Zegura, Rebecca Isaacs, and Matthew Caesar for helping us select the Best Paper award winners this year; and Aditya Akella, Sujata Banerjee, Ranjita Bhagwan, Jon Howell, James Mickens, Amar Phanishayee, George Porter, Vyas Sekar, and Minlan Yu for serving on the Test-of-Time awards committee. We are also grateful to Amar Phanishayee, Vyas Sekar, Arvind Krishnamurthy, Jay Lorch, Aditya Akella, and the rest of the NSDI Steering Committee for their advice and insight from running past NSDI instances. We would like to thank Sudarsanan Rajasekaran of MIT, who helped us immensely with the logistics of the PC meetings. We also thank Casey Henderson, Jasmine Murcia, Ginny Staubach, Jessica Kim, Sarah TerHune, Heidi Sherwood, Liz Markel, Camille Mulligan, Cathy Bergman, Nicole Santiago, Olivia Verneti, Arnold Gatilao, Mo Moreno, and the rest of the USENIX staff for all their hard work behind the scenes. Finally, we would like to thank all the authors for submitting their best work to NSDI.

We look forward to seeing you all in Boston for the 20th iteration of NSDI!

Mahesh Balakrishnan, *Confluent*
Manya Ghobadi, *Massachusetts Institute of Technology*
NSDI '23 Program Co-Chairs

20th USENIX Symposium on Networked Systems Design and Implementation (NSDI '23)

April 17–19, 2023
Boston, MA, USA

Monday, April 17

RDMA

SRNIC: A Scalable Architecture for RDMA NICs 1

Zilong Wang, *Hong Kong University of Science and Technology*; Layong Luo and Qingsong Ning, *ByteDance*; Chaoliang Zeng, Wenxue Li, and Xinchun Wan, *Hong Kong University of Science and Technology*; Peng Xie, Tao Feng, Ke Cheng, Xiongfei Geng, Tianhao Wang, Weicheng Ling, Kejia Huo, Pingbo An, Kui Ji, Shideng Zhang, Bin Xu, Ruiqing Feng, and Tao Ding, *ByteDance*; Kai Chen, *Hong Kong University of Science and Technology*; Chuanxiong Guo

Hostping: Diagnosing Intra-host Network Bottlenecks in RDMA Servers 15

Kefei Liu, *BUPT*; Zhuo Jiang, *ByteDance Inc.*; Jiao Zhang, *BUPT and Purple Mountain Laboratories*; Haoran Wei, *BUPT and ByteDance Inc.*; Xiaolong Zhong, *BUPT*; Lizhuang Tan, *ByteDance Inc.*; Tian Pan and Tao Huang, *BUPT and Purple Mountain Laboratories*

Understanding RDMA Microarchitecture Resources for Performance Isolation 31

Xinhao Kong and Jingrong Chen, *Duke University*; Wei Bai, *Microsoft*; Yechen Xu, *Shanghai Jiao Tong University*; Mahmoud Elhaddad, Shachar Raindel, and Jitendra Padhye, *Microsoft*; Alvin R. Lebeck and Danyang Zhuo, *Duke University*

Empowering Azure Storage with RDMA 49

Wei Bai, Shanm Sainul Abdeen, Ankit Agrawal, Krishan Kumar Attre, Paramvir Bahl, Ameya Bhagat, Gowri Bhaskara, Tanya Brokhman, Lei Cao, Ahmad Cheema, Rebecca Chow, Jeff Cohen, Mahmoud Elhaddad, Vivek Ette, Igal Figlin, Daniel Firestone, Mathew George, Ilya German, Lakhmeet Ghai, Eric Green, Albert Greenberg, Manish Gupta, Randy Haagens, Matthew Hendel, Ridwan Howlader, Neetha John, Julia Johnstone, Tom Jolly, Greg Kramer, David Kruse, Ankit Kumar, Erica Lan, Ivan Lee, Avi Levy, Marina Lipshteyn, Xin Liu, Chen Liu, Guohan Lu, Yuemin Lu, Xiakun Lu, Vadim Makhervaks, Ulad Malashanka, David A. Maltz, Ilias Marinos, Rohan Mehta, Sharda Murthi, Anup Namdhari, Aaron Ogus, Jitendra Padhye, Madhav Pandya, Douglas Phillips, Adrian Power, Suraj Puri, Shachar Raindel, Jordan Rhee, Anthony Russo, Maneesh Sah, Ali Sheriff, Chris Sparacino, Ashutosh Srivastava, Weixiang Sun, Nick Swanson, Fuhou Tian, Lukasz Tomczyk, Vamsi Vadlamuri, Alec Wolman, Ying Xie, Joyce Yom, Lihua Yuan, Yanzhao Zhang, and Brian Zill, *Microsoft*

Learning with GPUs

Transparent GPU Sharing in Container Clouds for Deep Learning Workloads 69

Binyang Wu and Zili Zhang, *Peking University*; Zhihao Bai, *Johns Hopkins University*; Xuanzhe Liu and Xin Jin, *Peking University*

ARK: GPU-driven Code Execution for Distributed Deep Learning 87

Changho Hwang, *KAIST, Microsoft Research*; Kyoungsoo Park, *KAIST*; Ran Shu, Xinyuan Qu, Peng Cheng, and Yongqiang Xiong, *Microsoft Research*

BGL: GPU-Efficient GNN Training by Optimizing Graph Data I/O and Preprocessing 103

Tianfeng Liu, *Tsinghua University, Zhongguancun Laboratory, ByteDance*; Yangrui Chen, *The University of Hong Kong, ByteDance*; Dan Li, *Tsinghua University, Zhongguancun Laboratory*; Chuan Wu, *The University of Hong Kong*; Yibo Zhu, Jun He, and Yanghua Peng, *ByteDance*; Hongzheng Chen, *ByteDance, Cornell University*; Hongzhi Chen and Chuanxiong Guo, *ByteDance*

Zeus: Understanding and Optimizing GPU Energy Consumption of DNN Training 119

Jie You, Jae-Won Chung, and Mosharaf Chowdhury, *University of Michigan*

RPC and Remote Memory

- Remote Procedure Call as a Managed System Service**141
Jingrong Chen, Yongji Wu, and Shihan Lin, *Duke University*; Yechen Xu, *Shanghai Jiao Tong University*; Xinhao Kong, *Duke University*; Thomas Anderson, *University of Washington*; Matthew Lentz, Xiaowei Yang, and Danyang Zhuo, *Duke University*
- Canvas: Isolated and Adaptive Swapping for Multi-Applications on Remote Memory**161
Chenxi Wang, Yifan Qiao, Haoran Ma, and Shi Liu, *UCLA*; Yiyang Zhang, *UCSD*; Wenguang Chen, *Tsinghua University*; Ravi Netravali, *Princeton University*; Miryung Kim and Guoqing Harry Xu, *UCLA*
- Hermit: Low-Latency, High-Throughput, and Transparent Remote Memory via Feedback-Directed Asynchrony** ...181
Yifan Qiao and Chenxi Wang, *UCLA*; Zhenyuan Ruan and Adam Belay, *MIT CSAIL*; Qingda Lu, *Alibaba Group*; Yiyang Zhang, *UCSD*; Miryung Kim and Guoqing Harry Xu, *UCLA*
- NetRPC: Enabling In-Network Computation in Remote Procedure Calls** 199
Bohan Zhao, *Tsinghua University*; Wenfei Wu, *Peking University*; Wei Xu, *Tsinghua University*

Congestion Control

- Bolt: Sub-RTT Congestion Control for Ultra-Low Latency** 219
Serhat Arslan, *Stanford University*; Yuliang Li, Gautam Kumar, and Nandita Dukkkipati, *Google LLC*
- Understanding the impact of host networking elements on traffic bursts** 237
Erfan Sharafzadeh and Sepehr Abdous, *Johns Hopkins University*; Soudeh Ghorbani, *Johns Hopkins University and Meta*
- Poseidon: Efficient, Robust, and Practical Datacenter CC via Deployable INT** 255
Weitao Wang, *Google LLC and Rice University*; Masoud Moshref, Yuliang Li, and Gautam Kumar, *Google LLC*; T. S. Eugene Ng, *Rice University*; Neal Cardwell and Nandita Dukkkipati, *Google LLC*
- Rearchitecting the TCP Stack for I/O-Offloaded Content Delivery** 275
Taehyun Kim and Deondre Martin Ng, *KAIST*; Junzhi Gong, *Harvard University*; Youngjin Kwon, *KAIST*; Minlan Yu, *Harvard University*; Kyoungsoo Park, *KAIST*

Distributed Systems

- Hydra: Serialization-Free Network Ordering for Strongly Consistent Distributed Applications** 293
Inho Choi, *National University of Singapore*; Ellis Michael, *University of Washington*; Yunfan Li, *National University of Singapore*; Dan R. K. Ports, *Microsoft Research*; Jialin Li, *National University of Singapore*
- The Benefit of Hindsight: Tracing Edge-Cases in Distributed Systems** 321
Lei Zhang, *Emory University and Princeton University*; Zhiqiang Xie and Vaastav Anand, *Max Planck Institute for Software Systems*; Ymir Vigfusson, *Emory University*; Jonathan Mace, *Max Planck Institute for Software Systems*
- DiSh: Dynamic Shell-Script Distribution** 341
Tammam Mustafa, *MIT*; Konstantinos Kallas, *University of Pennsylvania*; Pratyush Das, *Purdue University*; Nikos Vasilakis, *Brown University*
- Waverunner: An Elegant Approach to Hardware Acceleration of State Machine Replication** 357
Mohammadreza Alimadadi and Hieu Mai, *Stony Brook University*; Shengsun Cho, *Microsoft*; Michael Ferdman, Peter Milder, and Shuai Mu, *Stony Brook University*

Wireless

- LeakyScatter: A Frequency-Agile Directional Backscatter Network Above 100 GHz** 375
Atsute Kludze and Yasaman Ghasempour, *Princeton University*
- RF-Bouncer: A Programmable Dual-band Metasurface for Sub-6 Wireless Networks** 389
Xinyi Li, Chao Feng, Xiaojing Wang, and Yangfan Zhang, *Northwest University*; Yaxiong Xie, *University at Buffalo SUNY*; Xiaojiang Chen, *Northwest University*
- Scalable Distributed Massive MIMO Baseband Processing** 405
Junzhi Gong, *Harvard University*; Anuj Kalia, *Microsoft*; Minlan Yu, *Harvard University*

DChannel: Accelerating Mobile Applications With Parallel High-bandwidth and Low-latency Channels 419
William Sentosa, *University of Illinois Urbana-Champaign*; Balakrishnan Chandrasekaran, *Vrije Universiteit Amsterdam*;
P. Brighten Godfrey, *University of Illinois Urbana-Champaign and VMware*; Haitham Hassanieh, *EPFL*; Bruce Maggs,
Duke University and Emerald Innovations

Cloud

SkyPilot: An Intercloud Broker for Sky Computing 437
Zongheng Yang, Zhanghao Wu, Michael Luo, Wei-Lin Chiang, Romil Bhardwaj, Woosuk Kwon, Siyuan Zhuang,
Frank Sifei Luan, and Gautam Mittal, *UC Berkeley*; Scott Shenker, *UC Berkeley and ICSI*; Ion Stoica, *UC Berkeley*

Unlocking unallocated cloud capacity for long, uninterruptible workloads 457
Anup Agarwal, *Carnegie Mellon University*; Shadi Noghahi, *Microsoft Research*; Íñigo Goiri, *Azure Systems Research*;
Srinivasan Seshan, *Carnegie Mellon University*; Anirudh Badam, *Microsoft Research*

Invisinets: Removing Networking from Cloud Networks 479
Sarah McClure and Zeke Medley, *UC Berkeley*; Deepak Bansal and Karthick Jayaraman, *Microsoft*; Ashok Narayanan,
Google; Jitendra Padhye, *Microsoft*; Sylvia Ratnasamy, *UC Berkeley and Google*; Anees Shaikh, *Google*; Rishabh Tewari,
Microsoft

Bamboo: Making Preemptible Instances Resilient for Affordable Training of Large DNNs 497
John Thorpe, Pengzhan Zhao, Jonathan Eyolfson, and Yifan Qiao, *UCLA*; Zhihao Jia, *CMU*; Minjia Zhang, *Microsoft
Research*; Ravi Netravali, *Princeton University*; Guoqing Harry Xu, *UCLA*

Internet-Scale Networks

ONEWAN is better than two: Unifying a split WAN architecture 515
Umesh Krishnaswamy, *Microsoft*; Rachee Singh, *Microsoft and Cornell University*; Paul Mattes, Paul-Andre
C Bissonnette, Nikolaj Bjørner, Zahira Nasrin, Sonal Kothari, Prabhakar Reddy, John Abeln, Srikanth Kandula,
Himanshu Raj, Luis Irun-Briz, Jamie Gaudette, and Erica Lan, *Microsoft*

RHINE: Robust and High-performance Internet Naming with E2E Authenticity 531
Huayi Duan, Rubén Fischer, Jie Lou, Si Liu, David Basin, and Adrian Perrig, *ETH Zürich*

Enabling Users to Control their Internet 555
Ammar Tahir and Radhika Mittal, *University of Illinois at Urbana-Champaign*

xBGP: Faster Innovation in Routing Protocols 575
Thomas Wirtgen, Tom Rousseaux, Quentin De Coninck, and Nicolas Rybowski, *ICTEAM, UCLouvain*; Randy Bush,
Internet Initiative Japan & Arrcus, Inc; Laurent Vanbever, *NSG, ETH Zürich*; Axel Legay and Olivier Bonaventure,
ICTEAM, UCLouvain

Tuesday, April 18

Synthesis and Formal Methods

TACCL: Guiding Collective Algorithm Synthesis using Communication Sketches 593
Aashaka Shah, *University of Texas at Austin*; Vijay Chidambaram, *University of Texas at Austin and VMware Research*;
Meghan Cowan, Saeed Maleki, Madan Musuvathi, Todd Mytkowicz, Jacob Nelson, and Olli Saarikivi, *Microsoft Research*;
Rachee Singh, *Microsoft and Cornell University*

Synthesizing Runtime Programmable Switch Updates 613
Yiming Qiu, *Rice University*; Ryan Beckett, *Microsoft*; Ang Chen, *Rice University*

Practical Intent-driven Routing Configuration Synthesis 629
Sivaramakrishnan Ramanathan, Ying Zhang, Mohab Gawish, Yogesh Mundada, Zhaodong Wang, Sangki Yun,
Eric Lippert, and Walid Taha, *Meta*; Minlan Yu, *Harvard University*; Jelena Mirkovic, *University of Southern California
Information Sciences Institute*

Formal Methods for Network Performance Analysis 645
Mina Tahmasbi Arashloo, *University of Waterloo*; Ryan Beckett, *Microsoft Research*; Rachit Agarwal, *Cornell University*

Data Centers

- Flattened Clos: Designing High-performance Deadlock-free Expander Data Center Networks Using Graph Contraction** 663
Shizhen Zhao, Qizhou Zhang, Peirui Cao, Xiao Zhang, and Xinbing Wang, *Shanghai Jiao Tong University*;
Chenghu Zhou, *Shanghai Jiao Tong University and Chinese Academy of Sciences*
- Scalable Tail Latency Estimation for Data Center Networks**..... 685
Kevin Zhao, *University of Washington*; Prateesh Goyal, *Microsoft Research*; Mohammad Alizadeh, *MIT CSAIL*;
Thomas E. Anderson, *University of Washington*
- Shockwave: Fair and Efficient Cluster Scheduling for Dynamic Adaptation in Machine Learning** 703
Pengfei Zheng and Rui Pan, *University of Wisconsin-Madison*; Tarannum Khan, *The University of Texas at Austin*;
Shivaram Venkataraman, *University of Wisconsin-Madison*; Aditya Akella, *The University of Texas at Austin*
- Protego: Overload Control for Applications with Unpredictable Lock Contention**..... 725
Inho Cho, *MIT CSAIL*; Ahmed Saeed, *Georgia Tech*; Seo Jin Park, Mohammad Alizadeh, and Adam Belay, *MIT CSAIL*

Systems for Learning

- TopoOpt: Co-optimizing Network Topology and Parallelization Strategy for Distributed Training Jobs**..... 739
Weiyang Wang, Moein Khazraee, Zhizhen Zhong, and Manya Ghobadi, *Massachusetts Institute of Technology*;
Zhihao Jia, *Meta and CMU*; Dheevatsa Mudigere and Ying Zhang, *Meta*; Anthony Kewitsch, *Telescent*
- ModelKeeper: Accelerating DNN Training via Automated Training Warmup** 769
Fan Lai, Yinwei Dai, Harsha V. Madhyastha, and Mosharaf Chowdhury, *University of Michigan*
- SHEPHERD: Serving DNNs in the Wild** 787
Hong Zhang, *University of Waterloo*; Yupeng Tang and Anurag Khandelwal, *Yale University*; Ion Stoica, *UC Berkeley*
- Better Together: Jointly Optimizing ML Collective Scheduling and Execution Planning using SYNDICATE** 809
Kshiteej Mahajan, *University of Wisconsin - Madison*; Ching-Hsiang Chu and Srinivas Sridharan, *Facebook*;
Aditya Akella, *UT Austin*

Privacy and Security

- Addax: A fast, private, and accountable ad exchange infrastructure** 825
Ke Zhong, Yiping Ma, and Yifeng Mao, *University of Pennsylvania*; Sebastian Angel, *University of Pennsylvania & Microsoft Research*
- SPEEDEX: A Scalable, Parallelizable, and Economically Efficient Decentralized EXchange** 849
Geoffrey Ramseyer, Ashish Goel, and David Mazières, *Stanford University*
- Boomerang: Metadata-Private Messaging under Hardware Trust** 877
Peipei Jiang, *Wuhan University and City University of Hong Kong*; Qian Wang and Jianhao Cheng, *Wuhan University*;
Cong Wang, *City University of Hong Kong*; Lei Xu, *Nanjing University of Science and Technology*; Xinyu Wang, *Tencent Inc.*; Yihao Wu and Xiaoyuan Li, *Wuhan University*; Kui Ren, *Zhejiang University*
- Hamilton: A High-Performance Transaction Processor for Central Bank Digital Currencies** 901
James Lovejoy, *Federal Reserve Bank of Boston*; Madars Virza and Cory Fields, *MIT Media Lab*; Kevin Karwaski and Anders Brownworth, *Federal Reserve Bank of Boston*; Neha Narula, *MIT Media Lab*

Video

- RECL: Responsive Resource-Efficient Continuous Learning for Video Analytics**917
Mehrdad Khani, *MIT CSAIL and Microsoft*; Ganesh Ananthanarayanan and Kevin Hsieh, *Microsoft*; Junchen Jiang, *University of Chicago*; Ravi Netravali, *Princeton University*; Yuanchao Shu, *Zhejiang University*; Mohammad Alizadeh, *MIT CSAIL*; Victor Bahl, *Microsoft*
- Boggart: Towards General-Purpose Acceleration of Retrospective Video Analytics** 933
Neil Agarwal and Ravi Netravali, *Princeton University*

Tambur: Efficient loss recovery for videoconferencing via streaming codes 953
Michael Rudow, *Carnegie Mellon University*; Francis Y. Yan, *Microsoft Research*; Abhishek Kumar, *Carnegie Mellon University*; Ganesh Ananthanarayanan and Martin Ellis, *Microsoft*; K.V. Rashmi, *Carnegie Mellon University*

Gemel: Model Merging for Memory-Efficient, Real-Time Video Analytics at the Edge 973
Arthi Padmanabhan, *UCLA*; Neil Agarwal, *Princeton University*; Anand Iyer and Ganesh Ananthanarayanan, *Microsoft Research*; Yuanchao Shu, *Zhejiang University*; Nikolaos Karianakis, *Microsoft Research*; Guoqing Harry Xu, *UCLA*; Ravi Netravali, *Princeton University*

Data

Fast, Approximate Vector Queries on Very Large Unstructured Datasets 995
Zili Zhang and Chao Jin, *Peking University*; Linpeng Tang, *Moqi*; Xuanzhe Liu and Xin Jin, *Peking University*

Arya: Arbitrary Graph Pattern Mining with Decomposition-based Sampling1013
Zeyang Zhu, *Boston University*; Kan Wu, *University of Wisconsin-Madison*; Zaoxing Liu, *Boston University*

SECRECY: Secure collaborative analytics in untrusted clouds1031
John Liagouris, Vasiliki Kalavri, Muhammad Faisal, and Mayank Varia, *Boston University*

FLASH: Towards a High-performance Hardware Acceleration Architecture for Cross-silo Federated Learning 1057
Junxue Zhang and Xiaodian Cheng, *iSINGLab at Hong Kong University of Science and Technology and Cluster*; Wei Wang, *Cluster*; Liu Yang, *iSINGLab at Hong Kong University of Science and Technology and Cluster*; Jinbin Hu and Kai Chen, *iSINGLab at Hong Kong University of Science and Technology*

Making Systems Learn

On Modular Learning of Distributed Systems for Predicting End-to-End Latency 1081
Chieh-Jan Mike Liang, *Microsoft Research*; Zilin Fang, *Carnegie Mellon University*; Yuqing Xie, *Tsinghua University*; Fan Yang, *Microsoft Research*; Zhao Lucis Li, *University of Science and Technology of China*; Li Lina Zhang, Mao Yang, and Lidong Zhou, *Microsoft Research*

SelfTune: Tuning Cluster Managers 1097
Ajaykrishna Karthikeyan and Nagarajan Natarajan, *Microsoft Research*; Gagan Somashekar, *Stony Brook University*; Lei Zhao, *Microsoft*; Ranjita Bhagwan, *Microsoft Research*; Rodrigo Fonseca, Tatiana Racheva, and Yogesh Bansal, *Microsoft*

CausalSim: A Causal Framework for Unbiased Trace-Driven Simulation1115
Abdullah Alomar, Pouya Hamadani, Arash Nasr-Esfahany, Anish Agarwal, Mohammad Alizadeh, and Devavrat Shah, *MIT*

HALP: Heuristic Aided Learned Preference Eviction Policy for YouTube Content Delivery Network1149
Zhenyu Song, *Princeton University*; Kevin Chen, Nikhil Sarda, Deniz Altınbüken, Eugene Brevdo, Jimmy Coleman, Xiao Ju, Pawel Jurczyk, Richard Schooler, and Ramki Gummadi, *Google*

IoT Networks

OpenLoRa: Validating LoRa Implementations through an Extensible and Open-sourced Framework1165
Manan Mishra, Daniel Koch, Muhammad Osama Shahid, and Bhuvana Krishnaswamy, *University of Wisconsin-Madison*; Krishna Chintalapudi, *Microsoft Research*; Suman Banerjee, *University of Wisconsin-Madison*

VECARE: Statistical Acoustic Sensing for Automotive In-Cabin Monitoring 1185
Yi Zhang, *The University of Hong Kong and Tsinghua University*; Weiyang Hou, *The University of Hong Kong*; Zheng Yang, *Tsinghua University*; Chenshu Wu, *The University of Hong Kong*

SlimWiFi: Ultra-Low-Power IoT Radio Architecture Enabled by Asymmetric Communication 1201
Renjie Zhao, *University of California San Diego*; Kejia Wang, *Baylor University*; Kai Zheng and Xinyu Zhang, *University of California San Diego*; Vincent Leung, *Baylor University*

SLNet: A Spectrogram Learning Neural Network for Deep Wireless Sensing 1221
Zheng Yang and Yi Zhang, *Tsinghua University*; Kun Qian, *University of California San Diego*; Chenshu Wu, *The University of Hong Kong*

Wednesday, April 19

Programming the Network

- A High-Speed Stateful Packet Processing Approach for Tbps Programmable Switches** 1237
Mariano Scazzariello and Tommaso Caiazz, *KTH Royal Institute of Technology and Roma Tre University*;
Hamid Ghasemirahni, *KTH Royal Institute of Technology*; Tom Barbette, *UCLouvain*; Dejan Kostić and
Marco Chiesa, *KTH Royal Institute of Technology*
- ExoPlane: An Operating System for On-Rack Switch Resource Augmentation** 1257
Daehyeok Kim, *Microsoft and University of Texas at Austin*; Vyas Sekar and Srinivasan Seshan, *Carnegie Mellon University*
- Sketchovsky: Enabling Ensembles of Sketches on Programmable Switches** 1273
Hun Namkung, *Carnegie Mellon University*; Zaoxing Liu, *Boston University*; Daehyeok Kim, *Microsoft Research*;
Vyas Sekar and Peter Steenkiste, *Carnegie Mellon University*
- RingLeader: Efficiently Offloading Intra-Server Orchestration to NICs** 1293
Jiaxin Lin, Adney Cardoza, Tarannum Khan, and Yeonju Ro, *UT Austin*; Brent E. Stephens, *University of Utah*;
Hassan Wassel, *Google*; Aditya Akella, *UT Austin*

Alternative Networks

- STARRYNET: Empowering Researchers to Evaluate Futuristic Integrated Space and Terrestrial Networks** 1309
Zeqi Lai and Hewu Li, *Tsinghua University and Zhongguancun Laboratory*; Yangtao Deng, *Tsinghua University*;
Qian Wu, Jun Liu, and Yuanjie Li, *Tsinghua University and Zhongguancun Laboratory*; Jihao Li, Lixin Liu, and
Weisen Liu, *Tsinghua University*; Jianping Wu, *Tsinghua University and Zhongguancun Laboratory*
- POLYCORN: Data-driven Cross-layer Multipath Networking for High-speed Railway through Composable Schedulerlets** 1325
Yunzhe Ni, *Peking University*; Feng Qian, *University of Minnesota – Twin Cities*; Taide Liu, Yihua Cheng, Zhiyao Ma,
and Jing Wang, *Peking University*; Zhongfeng Wang, *China Railway Gecent Technology Co., Ltd*; Gang Huang and
Xuanzhe Liu, *Key Laboratory of High Confidence Software Technologies, Ministry of Education, Peking University*;
Chenren Xu, *Zhongguancun Laboratory and Key Laboratory of High Confidence Software Technologies, Ministry of
Education, Peking University*
- Augmenting Augmented Reality with Non-Line-of-Sight Perception** 1341
Tara Boroushaki, Maisy Lam, and Laura Dodds, *Massachusetts Institute of Technology*; Aline Eid, *Massachusetts
Institute of Technology and University of Michigan*; Fadel Adib, *Massachusetts Institute of Technology*
- Acoustic Sensing and Communication Using Metasurface** 1359
Yongzhao Zhang, Yezhou Wang, and Lanqing Yang, *Shanghai Jiao Tong University*; Mei Wang, *UT Austin*; Yi-Chao Chen,
Shanghai Jiao Tong University and Microsoft Research Asia; Lili Qiu, *UT Austin and Microsoft Research Asia*;
Yihong Liu, *University of Glasgow*; Guangtao Xue and Jiadi Yu, *Shanghai Jiao Tong University*

Abstract

RDMA is expected to be highly scalable: to perform well in large-scale data center networks where packet losses are inevitable (*i.e.*, high network scalability), and to support a large number of performant connections per server (*i.e.*, high connection scalability). Commercial RoCEv2 NICs (RNICs) fall short on scalability as they rely on a lossless, limited-scale network fabric and support only a small number of performant connections. Recent work IRN improves the network scalability by relaxing the lossless network requirement, but the connection scalability issue remains unaddressed.

In this paper, we aim to address the connection scalability challenge, while maintaining high performance and low CPU overhead as commercial RNICs, and high network scalability as IRN, by designing SRNIC, a Scalable RDMA NIC architecture. Our key insight in SRNIC is that, on-chip data structures and their memory requirements in RNICs can be minimized with careful protocol and architecture co-designs to improve connection scalability. Guided by this insight, we analyze all data structures involved in an RDMA conceptual model, and remove them as many as possible with RDMA protocol header modifications and architectural innovations, including cache-free QP scheduler and memory-free selective repeat. We implement a fully functional SRNIC prototype using FPGA. Experiments show that, SRNIC achieves 10K performant connections on chip and outperforms commercial RNICs by 18x in terms of normalized connection scalability (*i.e.*, the number of performant connections per 1MB memory), while achieving 97 Gbps throughput and 3.3 μ s latency with less than 5% CPU overhead, and maintaining high network scalability.

1 Introduction

Datacenter applications are increasingly driving the demands for high-speed networks, which are expected to provide high

throughput, low latency, and low CPU overhead, with a large number of connections (*a.k.a.*, connection scalability), over a large-scale network (*a.k.a.*, network scalability). Specifically, bandwidth-intensive applications like distributed machine learning training [13, 23] and cloud storage [16, 18], require 100 Gbps and beyond network bandwidth between servers; online services like search [9, 15] and database [25, 29], demand low latency to minimize query response time; most applications desire a network stack with low CPU overhead to reserve as many CPU cores as possible for computations; cloud storage like Alibaba Pangu [18] requires a large number of performant connections per host to provide mesh communications between chunk servers and block servers; last but not the least, high-speed networks tend to be deployed at larger scale as their application footprints expand [19].

Remote Direct Memory Access (RDMA) is emerging as a popular high-speed networking technique, thanks to its high throughput, low latency and low CPU overhead provided by architectural innovations including kernel bypass and transport offload. With these advantages, RoCEv2 (RDMA over Converged Ethernet Version 2) is becoming the de-facto standard for high-speed networks in modern data centers [4, 42].

Despite high performance and low CPU overhead, commercial RoCEv2 NICs (RNICs) suffer from both network scalability and connection scalability issues. On one hand, the network scalability issue arises from PFC (Priority-based Flow Control) which is required by RDMA to implement a lossless network fabric. PFC brings issues such as head-of-line blocking, congestion spreading, occasional deadlocks, and PFC storms in large-scale clusters [18, 19, 21, 34, 42]. As a result, datacenter operators tend to restrict the PFC configurations within a small network scope (*e.g.*, a moderate cluster). On the other hand, the connection scalability issue is the phenomenon that RDMA performance drops dramatically when the number of connections (*a.k.a.*, queue pairs (QPs)) exceeds a certain small threshold (*e.g.*, 256) [24, 28, 39]. Although commercial RNICs are blackbox, the root cause of this performance collapse phenomenon is explained as cache misses due to context switch between connections [24].

* This work is done while Zilong Wang, Chaoliang Zeng, and Xinchun Wan are interns with ByteDance.

To improve network scalability of RNICs, existing work IRN [33] advocates lossy RDMA that eliminates PFC, by replacing go-back-N with more efficient selective repeat (SR). However, the introduction of SR is non-trivial: it adds some SR specific data structures and thus increases memory consumption. To reduce the on-chip memory overhead, IRN makes some RoCEv2 header extensions, but still requires 3-10% more memory than existing RNIC implementations. As a result, IRN achieves high network scalability but leaves the connection scalability issue unaddressed.

In this paper, we propose SRNIC, a Scalable RDMA NIC architecture to address the connection scalability issue, while preserving high performance and low CPU overhead inherited from transport offload as commercial RNICs, and maintaining high network scalability originated from lossy RDMA as IRN. The major insight of SRNIC is that, most on-chip data structures and their memory requirements in RNICs can be eliminated with careful protocol and architecture co-designs, and the connection scalability of RNICs could be, as a result, significantly improved. Guided by this insight, we examine the typical data flow in a lossy RDMA conceptual model (§3.1), analyze all the involved data structures, classify them into two categories: *common data structures* required by RDMA in general, and *selective repeat specific data structures* brought by lossy RDMA, and finally take customized optimization strategies to minimize these two types of data structures respectively to improve the connection scalability (§3.2).

In particular, the cache-free QP scheduler proposed in §4.3 optimizes common data structures for RDMA designs no matter whether the underlying network is lossy or lossless. The optimizations of RDMA header extensions and bitmap onloading introduced in §4.4 are for memory-free selective repeat, hence specific for lossy RDMA.

We have implemented a fully functional SRNIC prototype with FPGA (§5) and evaluated SRNIC’s scalability and performance through the testbed and simulations. Experiments (§6) show that SRNIC achieves high connection scalability, while preserving high performance and low CPU overhead as commercial RNICs, and high network scalability as IRN. Specifically, SRNIC supports 10K¹ connections/QPs without performance degradation, which outperforms Mellanox RNIC CX-5 by 18x in terms of normalized connection scalability (*i.e.*, the number of performant connections per 1MB memory). Meanwhile, SRNIC achieves 97 Gbps line-rate throughput and 3.3 μs latency, with only 5% CPU overhead, which are comparable with Mellanox RNICs. In addition, SRNIC shows its high network scalability via high loss tolerance (3x higher goodput than Mellanox RNICs under 1% loss rate) and predictable performance in large-scale lossy networks.

As a summary, Figure 1 shows the design space of RDMA NICs and makes a comparative analysis between different so-

¹Unless otherwise stated, K is 1024 in measuring the size of memory, data structures and messages, and 1000 in measuring the others.

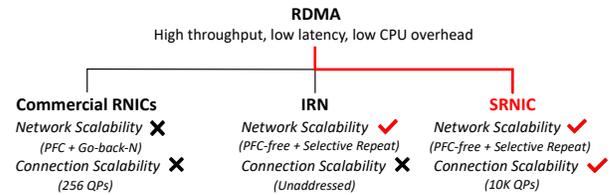

Figure 1: Design space of RDMA NICs.

lutions. Although all RDMA hardware solutions provide high throughput, low latency, and low CPU overhead via transport offload and kernel bypass, their scalability varies. Commercial RNICs suffer from both the network scalability issue caused by the troublesome PFC, and the connection scalability issue caused by unknown blackbox implementations. IRN revisits the network supports for RDMA, and eliminates the need of PFC by introducing selective repeat with 3-10% extra memory overhead. As a result, the network scalability is significantly improved, but the connection scalability is left unsolved. SRNIC leverages the lossy RDMA approach of IRN to improve network scalability, and further addresses the connection scalability issue with the design guiding principle: minimize the on-chip memory requirements of RNICs in a simple yet performant way. As a result, SRNIC achieves both high network scalability and connection scalability.

This paper makes the following major contributions:

- We systematically study and quantify the memory requirements of RDMA NICs, by introducing an RDMA conceptual model (§3).
- We design SRNIC, a scalable and high-performance RDMA NIC architecture, that significantly improves the connection scalability, guided by an insight that the on-chip memory requirements in the conceptual model can be minimized with careful RDMA protocol modifications and architecture innovations, including cache-free QP scheduler and memory-free selective repeat (§4).
- We implement SRNIC using FPGA, with only 4.4 MB on-chip memory. The implementation achieves our design goals on scalability, performance, and CPU overhead (§5 and §6).

2 Background and Motivation

2.1 RDMA Overview

Unlike the traditional software transport TCP, RDMA is a hardware transport that implements the transport functionalities including congestion control and loss recovery entirely in NIC hardware, and provides kernel-bypass and zero-copy interfaces to the user applications. As a result, RDMA achieves high throughput, low latency, and low CPU overhead, compared with software transport TCP [42].

RDMA was originally designed and simplified for lossless Infiniband [1]. To make RDMA work in Ethernet, RoCEv2 relies on PFC [22] to turn Ethernet into a lossless fabric. However, PFC brings management risks and network scalability challenges (e.g., PFC storms and deadlocks) that affect the entire network’s availability and also causes collateral damage to innocent flows due to head-of-line blocking [19, 42]. Besides, with PFC, the lossless network scale is also limited by the switch buffer size. Consequently, datacenters usually limit the scale of RDMA networks [18].

As the network scalability issue of RoCEv2 is mainly caused by PFC, IRN [33] takes the first step to rethink RDMA’s network requirements, eliminates PFC and allows RDMA working well in lossy networks, by replacing the default lossy recovery mechanism go-back-N with more efficient selective repeat. However, it leaves the connection scalability challenge unsolved.

2.2 Connection Scalability Issue

Commercial RNICs face a well-known connection scalability issue [24, 27, 28, 39], i.e., the RDMA performance drops significantly as the number of QPs increases beyond a small value (varies from 16 to 500 in different settings [28]). We demonstrate this issue using off-the-shelf commercial RNICs including Mellanox CX-5 and CX-6 [7, 8] with PFC enabled. As shown in Figure 2a, the aggregate throughput of Mellanox CX-6 drops 46% (from 97 to 52 Gbps) when the QP number increases from 128 to 16384, and there is no obvious improvement of connection scalability from CX-5 to CX-6.

The root cause of RNIC’s performance degradation is commonly explained as cache misses [24, 28, 38]. Commercial RNICs usually take a DRAM-free architecture, which does not have DRAM connected directly to the RNIC chip to reduce cost, power consumption, and area, but just has limited on-chip SRAM. As a result, RNICs can cache only a small number of QPs on chip, while storing the others in host memory. When the number of active QPs increases beyond the on-chip memory size, frequent cache misses and context switches between host memory and RNIC cause performance collapse. Our experiments in Figure 2b verify this in some sense. We observed significant extra PCIe bandwidth² and an increase in ICM cache miss³ during the performance collapse. Both metrics reflect certain kinds of cache misses, causing extra PCIe traffic increase after 256 QPs.

Although on-chip SRAM is limited, it is abnormal in that the performance drops so early. Given the on-chip memory size and the QP Context (QPC) size for a QP, we can estimate the maximum number of performant QPs that could be supported without cache misses and performance collapse as:

$$\max_QPs = \frac{\text{memory_size}}{\text{sizeof}(QPC)}. \quad (1)$$

²Extra PCIe throughput = PCIe throughput - network throughput.

³"ICM Cache Miss" is a counter provided by Mellanox Neohost tool [12].

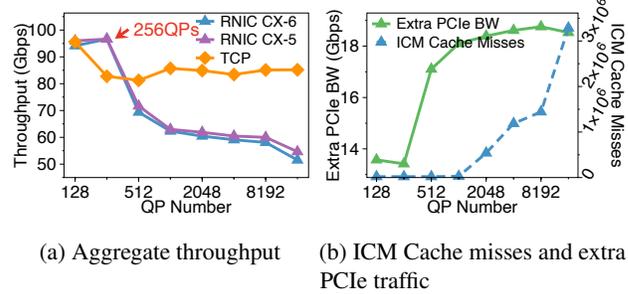

Figure 2: Connection scalability issue of current RNICs. Compared with TCP, the aggregate throughput of current RNICs collapses when the number of QPs exceeds 256.

Let’s take Mellanox CX-5 as an example. Its on-chip memory size is ~ 2 MB [24] and a QPC takes ~ 375 B [24], so that the maximum number of performant QPs supported by CX-5 could be up to 5.6K (2 MB/375 B), which contradicts the fact shown in Figure 2a that CX-5 performance begins to collapse much earlier at 256 QPs. The contradiction implies that there is room to significantly improve the connection scalability.

Motivated by this contradiction, we systematically analyze the memory requirements of RNICs, and improve the connection scalability based on the insights derived from thorough memory analysis.

3 RNIC Memory Analysis

As commercial RNICs are blackbox, we are not able to use their micro-architectures as a reference. Instead, we leverage a lossy RDMA conceptual model with selective repeat to derive the involved data structures (§3.1). Then, we summarize and classify these data structures into two categories: *common data structures* required by RDMA in general, and *selective repeat specific data structures* brought by lossy RDMA, and discuss different optimization strategies to minimize them respectively to improve the connection scalability (§3.2).

3.1 RDMA Conceptual Model

Figure 3 shows an RDMA conceptual model, based on which, a typical RDMA data flow consists of the following steps:

1. Requester: the user posts a work queue element (WQE) into a send queue (SQ) to issue a SEND request. RNIC fetches the WQE from the SQ to a **WQE Cache**.
2. Requester: RNIC gets the virtual address of the data buffer by parsing the WQE, translates it into the physical address through a **Memory Translation Table (MTT)**, and fetches data from the host data buffer using the physical address. RNIC then appends an appropriate RoCEv2 header onto the data and sends out the packet to the responder. The metadata of all outstanding requests is

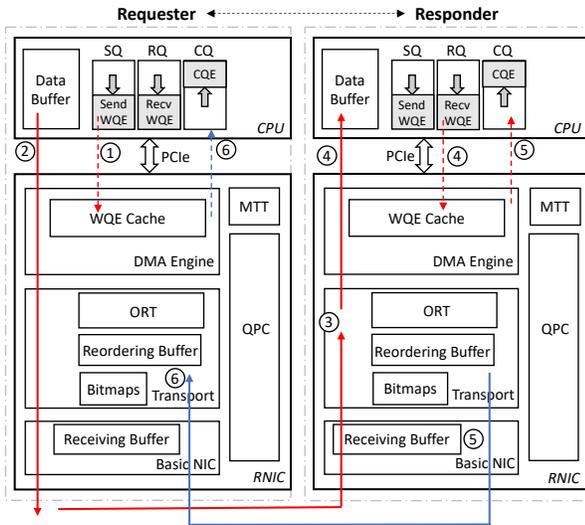

Figure 3: An RDMA conceptual model, and the RDMA data flow using a small SEND message as an example.

stored in an **Outstanding Request Table** (ORT) for fast retransmission in case of packet loss.

3. Responder: the incoming request is first queued in the **Receiving Buffer** and then gets verified. Out-of-order packets will be recorded in **Bitmaps** and reordered using the **Reordering Buffer**.
4. Responder: upon receiving a SEND packet, RNIC fetches a Receive WQE from a receive queue (RQ), queries MTT to get the physical address of the host data buffer, and DMA the reordered data from the **Reordering Buffer** to the host data buffer.
5. Responder: RNIC replies an acknowledgment (ACK) packet to the requester, and notifies the user with a completion queue element (CQE) to indicate the Receive WQE is consumed.
6. Requester: RNIC receives the ACK, and generates a CQE to indicate the Send WQE is consumed.

Besides, RNIC leverages a **QPC** per QP to track QP/connection related contexts for all modules.

3.2 Data Structures

As concluded in Table 1, we classify the involved data structures into two categories: (1) *common data structures*, required by RDMA in general, and (2) *selective repeat specific data structures*, brought by lossy RDMA.

3.2.1 Common Data Structures

Common data structures are essential to RDMA in general, no matter whether the underlying network is lossy or lossless.

Receiving Buffer. The receiving buffer in the Basic NIC module is used to queue all incoming packets. Its major purpose is to absorb bursts caused by the temporal performance gap between the upstream Ethernet port and the whole downstream RNIC processing logic.

QPC. A QPC maintains for a QP all its contexts, including the DMA states (*e.g.*, the start and end addresses, read and write pointers of SQ & RQ), and connection states (*e.g.*, expected and next packet sequence numbers, window or rate for congestion control). The QPC size we allocate for each QP is 210 B, so the total size for 10K QPs is 2.0 MB.

MTT. RDMA uses virtual addresses in the packet while the PCIe system relies on physical addresses to perform DMA transactions. To perform address translation, RNIC maintains an MTT to map virtual pages of memory regions into physical pages. The size of MTT depends on the total size of memory regions and the page size, irrelevant to the number of connections. For example, considering the total memory region size of 4 GB, the page size of 4 KB, and an MTT entry size of 8 B, the MTT size is equal to $4\text{ GB}/4\text{ KB} * 8\text{ B} = 8\text{ MB}$.

WQE Cache. An SQ WQE cache could be used to cache the Send WQEs fetched from an SQ in host memory. Assuming each QP stores 8 WQEs ($64\text{ B} * 8$) in a dedicated cache, 10K QPs consume 4.9 MB on-chip memory. Similarly, RNIC needs to fetch Receive WQEs from the RQ to process incoming SEND requests, and could allocate an RQ WQE cache to store the fetched Receive WQEs. The memory size of the RQ WQE cache is similar to that of the SQ WQE cache.

3.2.2 Selective Repeat Specific Data Structures

These data structures are all introduced by lossy RDMA using selective repeat as the loss recovery mechanism.

Bitmap. Bitmaps are used to track which packets are received or lost [31]. As mentioned in IRN [33], each QP requires five BDP (bandwidth-delay product)-sized bitmaps (500 slots for each bitmap to fit the BDP cap of a network with bandwidth 100 Gbps and RTT $40\ \mu\text{s}$ [5]) and 10K QPs cost 3.0 MB memory in total.

Reordering Buffer. A reordering buffer is used to rearrange the out-of-order packets and ensure in-order delivery to the data buffer in host memory. The reordering buffer is required in a lossy RNIC implementation with the standard RoCEv2 header. As RoCEv2 is designed for the lossless network, its header lacks the necessary information to support out-of-order packet reception without extra reordering buffers.

One option is to allocate a separate reordering buffer for each QP. Each QP requires a BDP-sized (0.5 MB) reordering buffer, so it takes 4.9 GB memory to support 10K QPs. Another option is to maintain a shared reordering buffer for all QPs [31]. However, it does not scale. When multiple QPs experience out-of-order packets, it may soon run out of the shared buffer with limited on-chip SRAM. Hence, we choose the separate reordering buffer option in the analysis.

Category	Data structures	Typical sizes	Optimization ideas	Sizes after optimization
Common	Receiving Buffer	0.6 MB	None	0.6 MB
	QPC	2.0 MB	None	2.0 MB
	MTT	8 MB	Cache (§4.5)	1.2 MB
	WQE Cache	9.8 MB	Cache-free QP scheduler (§4.3)	0
SR Specific	Bitmap	3.0 MB	Bitmap onloading (§4.4.2)	0
	Reordering Buffer	4.9 GB	Header extensions (§4.4.1)	0
	Outstanding Request Table	114.4 MB	Header extensions (§4.4.1)	0

Table 1: Data structures in the RDMA conceptual model. The first three columns show the typical data structures and their memory requirements with 10K QPs. The last two columns summarize our ideas to minimize the on-chip memory requirements of these data structures, and show the memory size after optimization.

Outstanding Request Table. Outstanding request table is used to maintain the mapping between outstanding request packets and their metadata, which are used to quickly locate and retransmit the lost packets. These metadata include (1) packet sequence number (PSN), used to track packet sequences, (2) message sequence number (MSN), used to track message sequences and to locate the WQE associated with that message quickly, and (3) packet offset (PSN_OFFSET), used to locate the data offset inside the corresponding data buffer. With these fields, the outstanding request table size for each QP is 11.7 KB (given the entry size 24 B, entry number 500 sized to BDP), and 10K QPs consume 114.4 MB in total.

In summary, all the data structures derived from the RDMA conceptual model could be classified into two categories: *common data structures* required by RDMA in general, and *selective repeat specific data structures* brought by lossy RDMA. Table 1 summarizes the memory requirements of these data structures in the third column. Both categories require significant memory sizes, and thus need to be optimized to improve connection scalability.

To this end, we make different optimization strategies to minimize these two types of data structures respectively. In particular, all the common data structures required by RDMA should be optimized in a generic way, with architectural innovations that are not specific to lossless or lossy RDMA. The cache-free QP scheduler proposed in §4.3 falls into this strategy. On the other hand, all the selective repeat specific data structures brought by lossy RDMA, could be optimized based on the lossy network assumption. The header extensions and bitmap onloading approaches in the memory-free selective repeat architecture in §4.4 follow this strategy.

4 SRNIC Design

4.1 Design Goal and Guiding Principles

In the design space of RDMA NICs, Mellanox RNICs represent the state-of-the-art in terms of high performance and low CPU overhead, and IRN is the state-of-the-art in network scalability. The design goal of SRNIC is to maximize the con-

nection scalability, while preserving high performance and low CPU overhead as Mellanox RNICs, and maintaining high network scalability as IRN.

To achieve this goal, we follow three design guiding principles: (1) keep as many RDMA functionalities as possible in hardware to achieve high performance and low CPU overhead; (2) handle packet loss as efficient as possible to allow discarding PFC and thus to support large-scale lossy networks; and (3) reduce the on-chip memory requirements as much as possible to support a large number of performant QPs with a limited amount of memory.

4.2 Architecture Overview

Guided by the above principles, we design a scalable RDMA NIC architecture SRNIC, as shown in Figure 4.

The server CPU allocates and manages QPs in the RNIC driver, and runs applications in user space over these QPs. Besides, a software retransmission module resides in user space to maintain the memory-consuming retransmission states collected by hardware and assist packet loss processing (§4.4). A pair of control queues (CtrlQs) is used as the communication channel between the software retransmission module and RNIC hardware.

RNIC hardware consists of three layers: DMA Engine, Transport, and Basic NIC. The *DMA Engine* layer leverages a *QP scheduler* to schedule tens of thousands of QPs from host memory, decides which QP to send data next, and then fetches WQEs and data from that SQ via *data mover*. The *Transport* layer realizes most of RDMA transport functionalities (except for the *software retransmission* in CPU), including a *congestion control* module that implements a hardware-friendly DCTCP [14], and a *hardware retransmission* module that implements the hardware part of selective repeat. The *Basic NIC* layer implements the primary functions of the Ethernet NIC, responsible for sending and receiving RoCEv2 packets via the *100GE MAC*. In addition to these three layers, there are two major data structures: QPC, which maintains all QP-related contexts, and MTT, which stores the mapping between virtual and physical addresses.

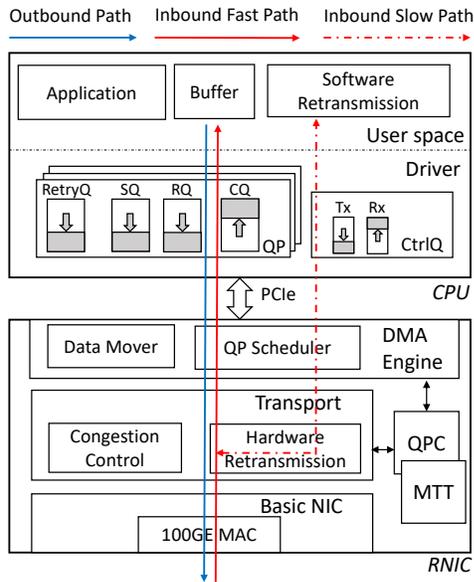

Figure 4: SRNIC architecture.

In order to balance performance and scalability, the data path of SRNIC is divided into a fast path and a slow path (§4.4), which handle sequential and out-of-order (OOO) packets, respectively. The fast path wholly implemented in RNIC processes the majority of traffic consisting of sequential packets, and thus provides hardware-level high performance with low CPU overhead for most packets. The slow path implements software retransmission, processes very little traffic consisting of OOO packets, and onloads bitmaps to host memory for connection scalability.

The overhead of the data path separation is very low for two reasons. First, the average packet loss rate in data centers is low (less than 0.01% [20, 41, 43]), and the resulting OOO packets form a very small fraction of traffic. Second, SRNIC only transmits loss events (*i.e.*, metadata of the OOO packets) over PCIe, further reducing the PCIe overhead. For example, the extra PCIe overhead is only 2.46% even with 1% loss rate.

Based on the above architecture, we further make two critical design optimizations: cache-free QP scheduler (§4.3) and memory-free selective repeat (§4.4) to optimize RDMA common data structures and lossy RDMA specific data structures, respectively, in order to address the scalability issues while preserving high performance.

4.3 Cache-free QP Scheduler

4.3.1 SQ Scheduler

An SQ is either *active* when it contains WQEs or *inactive* otherwise. The SQ scheduler (as modeled in Figure 5a) chooses one active SQ each time from tens of thousands of SQs in host memory to send messages next. The design challenges

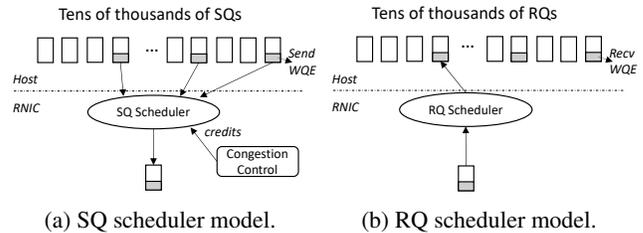

Figure 5: The QP scheduler models.

of the SQ scheduler are as follows:

- **Challenge #1:** Active SQs cannot be scheduled blindly, as they are also subject to congestion control, as shown in Figure 5a. Once an SQ is scheduled, if it is not allowed to send messages due to the lack of credits granted by congestion control, the scheduling does not take effect but just wastes time and degrades performance.
- **Challenge #2:** The PCIe round-trip latency between RNIC and host memory is high (around 1 μ s in FPGA based RNIC), and it takes at least two PCIe transactions (one WQE fetch and one message fetch), to execute one scheduling decision. Without careful design, the high latency between scheduling iterations will significantly degrade the performance.
- **Challenge #3:** There are tens of thousands of SQs in host memory but very limited on-chip memory within RNIC. It is prohibitive to have separate WQE caches for different SQs in the RNIC.

To address these challenges, SQs should be scheduled when they are both active and have credits (to address Challenge #1), with appropriate batch transactions to hide PCIe latency (to address Challenge #2), and in a WQE-cache-free way (to address Challenge #3).

Guided by these principles, we propose a cache-free SQ scheduler (as shown in Figure 6) that can do fast scheduling among tens of thousands QPs with minimal on-chip memory requirements. It consists of three major components:

Event Mux (EMUX): The EMUX module handles all scheduling related events, including (1) SQ doorbell⁴ from the host to indicate which SQ has new WQEs and messages to send; (2) credit update from the *congestion control* module to indicate window or rate adjustment for a connection/SQ; and (3) dequeue event from the *schedule queue* to indicate an SQ is scheduled.

Upon receiving an event, EMUX changes the scheduling states in QPC. There are three scheduling states: an *active* state indicating the SQ has WQEs; a *credit* value indicating

⁴Doorbell is the mechanism for the driver to notify RNIC that a SEND WQE has been posted into an SQ [26]. It is usually implemented by updating the write pointer of the SQ into an RNIC register.

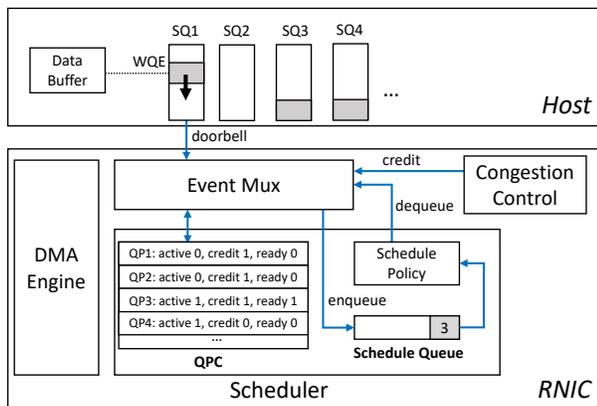

Figure 6: The cache-free SQ scheduler.

the bytes of messages allowed to send, and a *ready* state indicating the SQ is in the *schedule queue* and ready for scheduling. An SQ is ready for scheduling only when it is both active and has available credits, which addresses **Challenge #1**.

Scheduler: The scheduler leverages a *schedule queue* to maintain a list of SQs ready for scheduling. The scheduler implements a round-robin strategy in the *schedule policy* module, by popping a single ready SQ from the head of the *schedule queue* each time, and fetching from that SQ a given amount of WQEs and messages. After this scheduling iteration, if the SQ is still ready for scheduling, it will be pushed back into the *schedule queue* by the EMUX. Other scheduling strategies (e.g., weighted round-robin and strict priority) can be implemented by modifying the *schedule policy* module.

DMA Engine: When an SQ is being scheduled, the DMA engine fetches from that SQ up to n WQEs and $\min(\text{burst_size}, \text{credit})$ bytes of messages to address **Challenge #2**. After a scheduling iteration, there could be unused WQEs left in RNIC, if the total message size associated with the n WQEs is over $\min(\text{burst_size}, \text{credit})$ bytes. Unused WQEs are dropped instead of being cached in RNIC, and they will be fetched again next time when its SQ is scheduled. This *fetch-and-drop* strategy enables us to achieve cache-free scheduling to address **Challenge #3**.

There are two critical parameters (n and *burst_size*) to balance tradeoffs. n is the maximum number of WQEs, and *burst_size* is the maximum bytes of messages allowed to fetch in each scheduling iteration. n reflects the tradeoff between PCIe bandwidth usage and PCIe latency hiding. A smaller n would lead to less PCIe bandwidth waste in the *fetch-and-drop* strategy, but be harder to hide the PCIe latency or saturate the PCIe bandwidth with small messages, while a larger n would perform inversely. In SRNIC, n is set to 8 to balance the PCIe bandwidth utilization and latency hiding. With this setting, the maximum message rate of a single QP is 8 million requests per second (Mrps) (i.e., 8 messages per $1\ \mu\text{s}$). As for *burst_size*, it reflects the tradeoff between PCIe bandwidth utilization and scheduling granularity. A

smaller *burst_size* would enable finer scheduling granularity and hence less HoL, but be harder to saturate PCIe bandwidth, while a larger *burst_size* would perform inversely. Based on this analysis, we set *burst_size* to the PCIe BDP, i.e., 16 KB, to balance performance and scheduling granularity.

In summary, the SQ scheduler adopts a cache-free architecture to do fast scheduling among a large number of SQs with minimal on-chip memory. Specifically, the width of the schedule queue is 2 bytes, i.e., the QPN (QP Number) size, and a schedule queue of 19.5 KB can support 10K SQs.

4.3.2 RQ Scheduler

The RQ scheduler is modeled as shown in Figure 5b. Upon receiving a packet, RNIC gets its QPN by parsing the packet header, fetches a Receive WQE from the RQ indicated by that QPN, and places the packet payload into the data buffer associated with that Receive WQE.

This process seems straightforward, but there is one design decision affecting connection scalability: *do we prefetch and cache Receive WQE in RNIC before the packet arrives?*

If Receive WQEs are prefetched and cached, the incoming packet could hit the WQE cache, reducing the latency by one PCIe round-trip time (i.e., around $1\ \mu\text{s}$). However, it is hard to predict from which RQ to prefetch Receive WQEs before packets arrive, and thus the cache hit ratio largely depends on the traffic pattern and the cache size. Therefore, we decide to take the cache-free approach without prefetching or caching Receive WQEs, thus improving the connection scalability. Given that the typical RDMA network latency for small messages is tens of microseconds in data centers (e.g., for 1KB messages, RDMA P50 and P99 latency is 24us and 40us, respectively [5]), the increased $1\ \mu\text{s}$ latency is generally negligible. For latency-sensitive scenarios where $1\ \mu\text{s}$ matters, like in rack-scale deployments, a shared Receive WQE cache can be brought back to optimize the latency.

4.4 Memory-free Selective Repeat

The introduction of selective repeat into RNICs increases the challenge to achieve high connection scalability. As analyzed in §3.2.2, the extra data structures brought by selective repeat include outstanding request tables, reordering buffers, and bitmaps, whose memory requirements in total exceed the typical on-chip SRAM sizes of RNICs.

To minimize the memory requirements introduced by selective repeat, SRNIC eliminates the need for outstanding request tables and reordering buffers via RDMA protocol header extensions (§4.4.1), and onloads bitmaps into host memory without sacrificing performance via careful software-hardware co-designs (§4.4.2).

4.4.1 Header Extensions

As described in §3.2, the *outstanding request table* is used to maintain for each QP the mapping between outstanding request packets and their metadata including PSN, MSN, and PSN_OFFSET for fast selective retransmission. We eliminate the need for this data structure, by carrying these per-packet metadata on packet headers, instead of storing them in the on-chip memory. Specifically, we let all outstanding request packets carry these metadata on their headers, and let their response packets echo the same metadata back. In this way, the requester can locate the WQE and its message quickly with metadata in the response packet header.

The *reordering buffer* is used by each QP to rearrange the OOO packets and ensures in-order delivery to the data buffer of user applications. To get rid of the per-QP reordering buffer, our approach is *in-place reordering*, *i.e.*, leveraging the user data buffer pinned in host memory as the reordering buffer. To achieve this, all incoming packets should be placed directly into the user buffer at correct addresses. We make the following header extensions so that RNIC can derive the address for each packet by parsing its header: (1) all SEND packets carry send message sequence number (SSN) and the aforementioned PSN_OFFSET, which can be used by the RNIC responder to locate the corresponding receive WQE and the offset in its associated receive buffer. (2) all WRITE packets carry their target remote addresses [33].

As to RDMA READ, we add acknowledgements to READ requests and responses respectively to add self-clocking for RDMA READ, and schedule RDMA READ at the responder side similar to RDMA WRITE. By doing so, we can apply similar header extensions of SEND and WRITE for READ request and response packets, and more importantly, we can apply window-based congestion control for RDMA.

With these modifications, both sequential and out-of-order packets can be placed directly into the user buffer at the correct address, thus achieving *in-place reordering* and eliminating per-QP reordering buffer in the on-chip memory.

The aforementioned extensions add 8 to 20 bytes of headers to packets. In particular, the header is increased from 58 to 66 bytes for SEND and from 58 to 78 bytes for WRITE, which will decrease the application goodput by 0.7% and 1.8%, respectively, given 1024 byte RoCE MTU.

4.4.2 Bitmap Onloading

As mentioned in §3.2.2, each QP requires five BDP-sized bitmaps, and 10K QPs need 3.0 MB memory to store bitmaps, which alone may exceed the RNIC on-chip memory size (*e.g.*, 2 MB in Mellanox RNIC [24]), thus increasing the challenge to achieve high connection scalability.

We observe that, when there is no packet loss, packets from the same QP are sent and received in order, and an expected PSN (ePSN) in the responder and a last acknowledged PSN

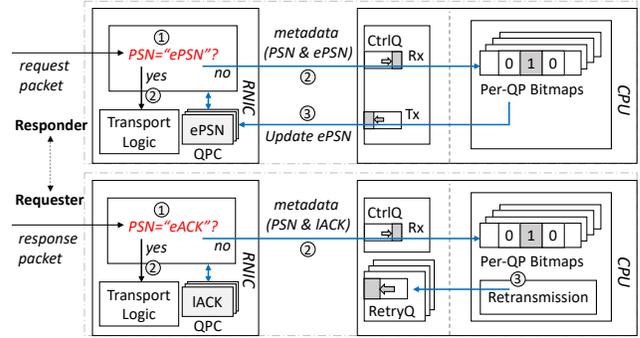

Figure 7: Selective repeat with bitmap onloading.

(IACK) in the requester are enough to track the sequential reception of request and response packets, respectively, without the need of bitmaps; when there is packet loss, OOO packets appear, and bitmaps are only required to track OOO packets.

Based on the above observation, for each QP we maintain an ePSN and a IACK in QPC to process sequential packets in hardware, and onload all bitmaps into host memory to track OOO packets. Assume packet loss rate is low and sequential packets are the majority, most traffic is handled by hardware directly, and little traffic containing the OOO packets is handled by software with the memory-consuming bitmaps in host memory. In this way, we achieve a balance between high performance and high connection scalability.

Figure 7 shows the software-hardware co-designed selective repeat architecture with bitmap onloading. On the responder side, the PSN of an inbound request packet is compared against the ePSN (①). If they match (②), it is a sequential packet and will be handled in the RNIC; otherwise (②), it is an OOO packet and the responder enters into the loss recovery state. In this state, the metadata (PSN and ePSN) of all incoming OOO packets is sent to software, which then fills the bitmaps in host memory to track received packets. After lost packets are received and bitmaps are filled accordingly, a new ePSN is updated (③), and the RNIC exits from the loss recovery state. On the requester side, the PSN of an inbound response packet is compared against an eACK (*i.e.*, a coalesced ACK greater than the IACK) (①). If they match (②), the IACK is updated in hardware; otherwise (*e.g.*, upon receiving NACK or SACK) (②), the requester enters into the loss recovery state. In this state, the metadata of all incoming OOO response packets including PSN and IACK is sent to the software retransmission module, which then manipulates the bitmaps in host memory to track which packets are received by the responder, and makes retransmission decision accordingly. The retransmitted requests are submitted through a Retry Queue (RetryQ) associated with each QP (③). After all retransmitted packets are successfully delivered (indicated by ACKs), the requester exits from the loss recovery state. Another option is to keep bitmaps only in the responder and make the requester stateless. Then, the responder should notify the requester exactly which packets to be retransmitted.

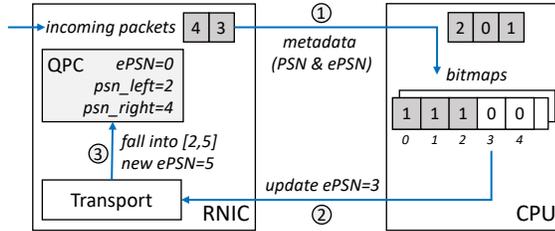

Figure 8: Fast exit from the loss recovery state.

A race condition may arise in the responder when exiting from the loss recovery state. Specifically, when the software updates the new ePSN, there might be inflight metadata of OOO packets with newer PSN between RNIC and CPU. In this case, the updated ePSN is not the latest, and thus the exit fails. To address the race condition problem while preserving high performance, RNIC records the range of the most advanced sequential packets (via $[psn_left, psn_right]$) after it enters the loss recovery state. A QP can exit from the loss recovery state if the updated ePSN falls into $[psn_left, psn_right + 1]$ range, and the ePSN in QPC will be updated to $psn_right + 1$, as illustrated in Figure 8.

4.5 Other Design Considerations

With the cache-free QP scheduler and memory-free selective repeat, all data structures shown in Table 1 are eliminated, except for the receiving buffer, QPC, and MTT.

Receiving Buffer is a shared packet buffer among all QPs and its size is small, so it is not optimized in this paper.

QPC is essential to maintain the per-QP states, and is involved in per-packet processing. To support a large number of performant QPs, we have to store their QPCs entirely in on-chip memory. Therefore, this part is not eliminated, and we preserve as much on-chip memory as possible for QPC to maximize the number of performant QPs.

MTT is memory-consuming as analyzed in §3.2 (e.g., 4 GB memory region requires 8 MB MTT size). Therefore, MTT is maintained in the host memory, and an MTT cache is implemented inside the RNIC by leveraging traffic locality. The cache size does not increase with the number of QPs, and its performance is highly related to traffic patterns. In addition, adopting hugepages (e.g., 2MB/1GB) is a classical optimization to reduce the memory size of address translation tables [24, 40], but requires modification to the applications.

4.6 Design Summary

The last two columns of Table 1 summarize our ideas to minimize the RDMA related data structures, and show the memory requirements after optimizations. Specifically, we eliminate the WQE cache through a cache-free QP scheduler, eliminate all SR-related data structures in on-chip memory through SR-friendly header extensions and bitmap onloading,

Resource Usage				
LUT	Register	BRAM	URAM	
101102	140816	621	48	
Memory Breakdown (MB)				
QPC	MTT	Receiving Buffer	SQ Scheduler	Total
2.3	1.2	0.6	0.3	4.4

Table 2: Resource usage of the SRNIC prototype.

and minimize the on-chip memory requirements of MTT with a cache, while keeping the large MTT table in host memory.

5 Implementation

We build a fully functional prototype of SRNIC using a Xilinx FPGA board with a PCIe Gen3 x16 interface and a 100 Gbps Ethernet port, running at a clock frequency of 300 MHz.

Congestion Control. Since SRNIC introduces ACK based self-clocking for RDMA READ, we therefore can use window-based congestion control for RDMA. Window-based approach in general is more friendly for hardware implementation than rate-based congestion control due to its self-clocking mechanism. More specifically, window-based design is event-driven: congestion window update events are triggered by inbound acknowledgement packets, and window based congestion control for each flow is applied at QP scheduling events. These events are naturally serialized and can be processed one by one. On the other hand, rate-based congestion control is timer-driven. It is challenging to support a large number of timer-based rate limiters in parallel for many concurrent flows. In SRNIC, we use DCTCP.

Memory Consumption. We realize 10K QPs in SRNIC and the resource consumption is broken down in Table 2. SRNIC consumes 4.4 MB on-chip SRAM in total. The QPC table, whose size increases linearly with the QP number, occupies 2.3 MB⁵ for 10K QPs. The remaining memories are used by QP-irrelevant data structures, including MTT cache, receiving buffer, and SQ scheduler, which consume constant memories when the QP number increases.

Per Table 2, the precious on-chip SRAM of SRNIC is mainly partitioned between the two most memory-consuming data structures: the QPC table and the MTT cache. A larger QPC table would support more performant QPs, while a larger MTT cache could provide a higher cache hit rate during address translation thus better performance. The best on-chip memory partition strategy between the QPC table and the MTT cache highly depends on scenarios, and it's an interesting problem to explore in the future.

⁵This is slightly larger than 2 MB calculated in Table 1 due to memory alignment overhead, e.g., each memory depth should be a power of 2 in FPGA implementation.

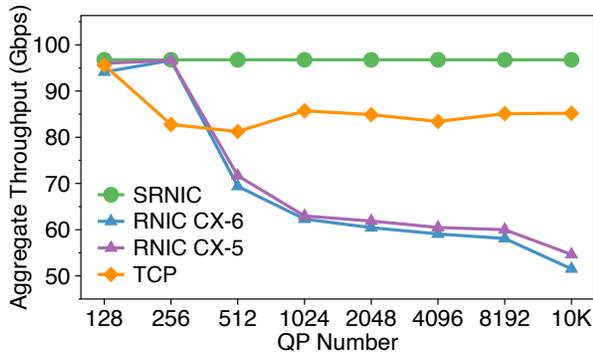

Figure 9: Connection scalability. SRNIC maintains constant high throughput as the number of QPs increases, while the performance of commercial RNICs (Mellanox CX-5 & 6) drops dramatically when the QP number exceeds 256.

6 Evaluation

We evaluate SRNIC using both testbed experiments and large-scale ns-3 simulations [10], and compare it with Mellanox RNICs, IRN, and TCP. Our results reveal that:

- SRNIC achieves high connection scalability: it supports 10K performant QPs, outperforming Mellanox RNIC CX-5 by 18x in terms of normalized connection scalability.
- SRNIC achieves high throughput (97 Gbps), low latency (3.3 μ s), and low (5%) CPU overhead.
- SRNIC achieves high network scalability: it is loss-tolerant (up to 75 Gbps goodput under 1% loss rate) and maintains predictable performance over large-scale lossy networks.

6.1 Connection Scalability

We compare SRNIC with Mellanox RNIC CX-5, CX-6, and TCP in terms of connection scalability. The settings of the testbed experiments are as follow. We connect two RNICs directly and launch 16 threads on each side, with each thread executing 512 B send operations. We set the RoCE MTU to 1024 bytes, and use the standard *perftest* benchmarks [11] in all experiments. With the above settings, we measure the aggregate throughput of these solutions while increasing the number of QPs from 128 to 10K, as shown in Figure 9.

SRNIC preserves the highest aggregate throughput almost unchanged at around 97 Gbps when the QP number increases from 128 to 10K. This is expected, as SRNIC keeps the QPC of 10K QPs entirely in the on-chip memory while eliminating or minimizing all other data structures.

TCP also preserves relatively high performance (from 81 to 96 Gbps), as it maintains the contexts of 10K connections in the large host memory, demonstrating high connection scalability but lower and unpredictable performance.

In contrast, the aggregate throughput of Mellanox RNICs

CX-5 and CX-6 drops dramatically when the QP number exceeds 256 due to frequent cache misses, as explained in §2.2.

In summary, SRNIC provides much higher connection scalability than commercial RNICs. Specifically, SRNIC realizes 10K QPs with 4.4 MB memory, while Mellanox CX-5 supports 256 QPs with 2 MB memory. To make a fair comparison, we define *normalized connection scalability* as the number of performant connections per 1 MB on-chip memory. SRNIC outperforms Mellanox CX-5⁶ by 18x (10 K QPs/4.4 MB vs. 256 QPs/2 MB) in terms of normalized connection scalability.

6.2 Performance and CPU Overhead

We compare SRNIC with CX-6⁷ and TCP in terms of throughput, latency, and CPU overhead using a single connection, with the same settings as above (*i.e.*, 1024-byte RoCE MTU, two NICs are connected directly).

Throughput. The throughput comparison is shown in Figure 10a. When the message size exceeds 4 KB, SRNIC and CX-6 both achieve line-rate throughput (97 Gbps), whereas TCP can only achieve up to 37 Gbps since the single CPU core becomes the bottleneck. In our experiments, the maximum message rate that SRNIC can achieve is 6.6 Mrps, comparable to that of the CX-6 (6.3 Mrps). This confirms that RNIC can achieve a high message rate without WQE cache. As mentioned in §4.3.1, the message rate of SRNIC depends on the batch size of the SQ scheduler. In our implementation, the SQ scheduler can request at most 8 WQEs at a time and the average PCIe RTT we measured is 1.1 μ s, therefore our result is close to the upper bound of 7.2 Mrps.

Latency. We measure the latency for transmitting 64 B small messages. As Figure 10b shows, the latency of SRNIC is about 3.3 μ s, slightly higher than that of CX-6 (1.16 μ s). We believe this gap comes from the extra 1 μ s added by the cache-free QP scheduler and the clock frequency difference between FPGA (300MHz) and ASIC (GHz) implementations. The latency would be decreased if SRNIC adopts the shared Receive WQE cache or is implemented in ASIC. In contrast, TCP has the highest latency of 24 μ s, indicating that bypassing kernel and offloading transport in RDMA is vital for significant latency reduction.

CPU overhead. As shown in Figure 10c, the CPU overhead of SRNIC and CX-6 both maintains at a low level (< 5%) thanks to transport offload and kernel bypass. TCP consumes much more CPU cycles at both the client and server sides (around 100% CPU utilization, not shown in the figure).

6.3 Network Scalability

Finally, we evaluate the network scalability of SRNIC. We show the efficiency of loss recovery in SRNIC with testbed

⁶We know the on-chip memory size (*i.e.*, 2 MB) of CX5 [24] but not CX6, so we only compare with CX-5 in terms of normalized connection scalability.

⁷CX-5 and CX-6 behave similarly, so we only show CX-6 thereafter.

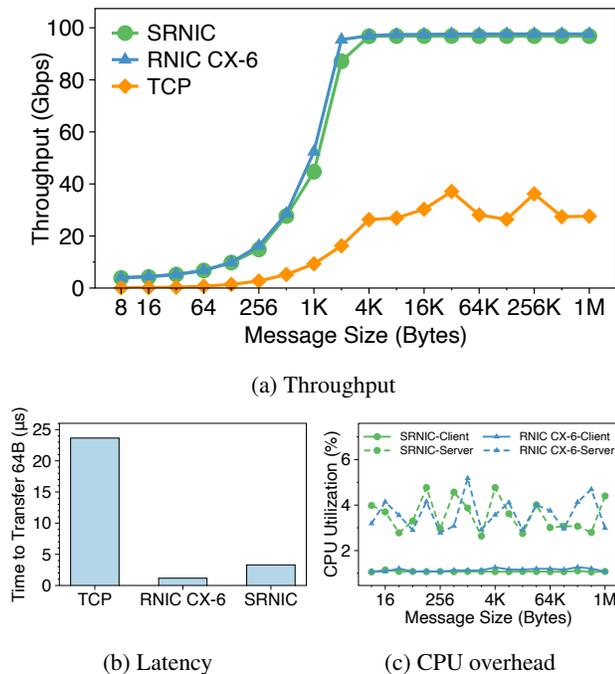

Figure 10: Performance and CPU overhead. SRNIC achieves high throughput, low latency, and low CPU overhead, similar to CX-6.

experiments, and the performance of SRNIC over large-scale lossy networks via simulations.

Loss tolerance. We compare the goodput of SRNIC with CX-6 at different packet loss rates, which are emulated by placing an FPGA between two RNICs and letting the FPGA randomly drop packets at given rates. We use *perftest* to generate 4 KB messages continuously. We disable congestion control here to exclude the influence of congestion control on loss tolerance, and only compare the loss recovery efficiency between selective repeat in SRNIC and go-back-N in CX-6.

Figure 11 compares SRNIC with CX-6 in terms of goodput under different loss rates. The goodput of CX-6 drops rapidly when the loss rate exceeds 0.1%. In particular, the CX-6 goodput is down to 25 Gbps when the loss rate exceeds 1%. Meanwhile, we monitor the MAC statistics counters in CX-6 and get its raw throughput of ~ 97 Gbps, which indicates that most of the RNIC bandwidth is wasted on retransmission caused by go-back-N. The goodput of SRNIC drops much slower than that of CX-6. When the loss rate exceeds 1%, the goodput is still 75 Gbps, 3x higher (75 vs. 25 Gbps) than that of CX-6.

The good loss tolerance of SRNIC comes from both the efficiency of selective repeat and its careful software-hardware co-designs in §4.4.2.

Performance in large-scale lossy networks. We use ns-3 to simulate the transport behavior of SRNIC, and compare it with CX-6 and IRN in large-scale lossy networks. We simulate

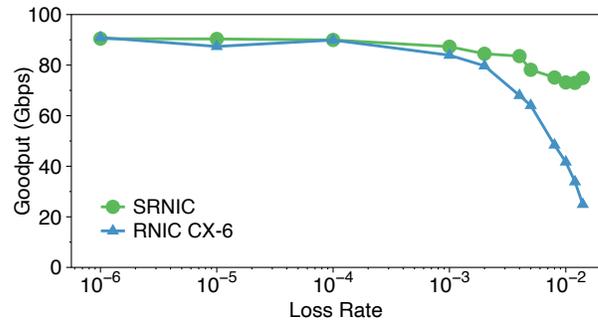

Figure 11: Loss tolerance. SRNIC achieves higher goodput than CX-6 when loss rate increases, as the number of retransmitted packets with selective repeat is much fewer than that with go-back-N.

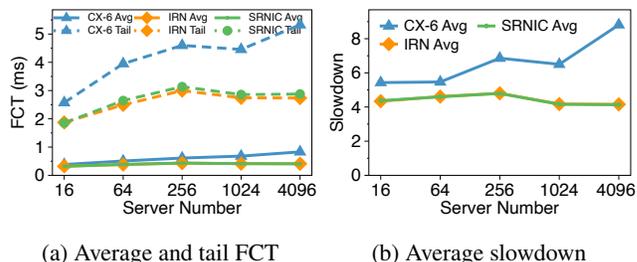

Figure 12: Performance at different network scales.

the fat-tree topologies with the server number ranging from 16 to 4096, with the (ToR, Aggregate, Core) switch number varying among five settings: (1, 0, 0), (4, 4, 0), (8, 8, 0), (64, 64, 16) and (128, 128, 64). The subscription ratio is 1:1 in all topologies. We equip each server with one 100 Gbps NIC connected to one ToR. ToR, Aggregate, and Core switches are connected via 400 Gbps links. The propagation delay of each link is 1 μ s.

PFC is enabled for CX-6 but disabled for SRNIC and IRN. We use the traffic trace in Cache_Follower [36], where 53% of the flows are sized between 0 - 100 KB, 18% between 100 KB - 1 MB, and the rest are larger than 1 MB. We set the network load at 0.7 utilization, and configure other algorithm parameters based on their papers.

We primarily focus on three metrics, *i.e.*, average FCT, P99 tail FCT, and average slowdown [33]. The average FCT and tail FCT describe the performance of throughput-intensive flows, while the average slowdown shows the performance of latency-sensitive flows.

As shown in Figure 12, the performance of SRNIC is 1.9 - 2.2x better than CX-6 across all three metrics. As the cluster scale increases, SRNIC maintains stable performance, while the performance gap between SRNIC and CX-6 widens. Meanwhile, SRNIC and IRN perform similarly well as they use the same loss-recovery mechanism (selective repeat) and similar congestion control schemes (DCTCP vs. DCQCN).

7 Discussion

RDMA Protocol for lossy Ethernet. The RDMA protocol was originally designed and simplified for lossless Infiniband, and it *"does not support selective packet retransmission nor the out-of-order reception of packets"*, written in the Infiniband RDMA specification [1]. As a result, the current RDMA, by design, requires a lossless fabric to perform well.

Based on this requirement, when RDMA is introduced into Ethernet-based data centers, Ethernet is turned from lossy to lossless by introducing PFC, rather than re-designing an Ethernet-native or loss-friendly RDMA protocol.

A lossless Ethernet network, however, is inherently difficult to scale and hard to maintain for high availability. It is therefore desirable to look into the other end of the design spectrum: revising the RDMA protocol for a lossy network. This is the path taken by the pioneering work of IRN [33], and SRNIC. We hope these early attempts can inspire the re-design of a new RDMA specification for lossy network, which supports out-of-order packet reception and selective packet retransmission natively and efficiently, and ensures compatibility and interoperability among different protocol versions and RNIC vendors.

SRNIC vs. RoCEv2, iWARP and ToE. There exists a long debate [3, 6] between RoCE and iWARP [35] (ToE [2] is similar to iWARP in the sense of TCP offload). The former takes a bottom-up strategy: start from a minimal, hardware-friendly yet working transport (*e.g.*, go-back-0, no congestion control) and incrementally add more advanced mechanisms (*e.g.*, go-back-N/selective repeat, DCQCN/DCTCP) to make RoCE work better over various networks. The latter takes a top-down strategy: offloading the fully-compatible TCP/IP stack (which is already proven to work well over various networks at scale), and gradually reduce unnecessary complexity to improve hardware friendliness.

SRNIC takes a more balanced approach: it inherits the hardware friendliness (and thus high performance) from RoCE, and introduces only necessary features from TCP such as selective repeat and DCTCP.

SRNIC demonstrates that high network scalability and hardware friendliness can be achieved simultaneously with careful architecture and protocol co-designs. We believe that the best of both RoCE (hardware friendliness) and iWARP/TCP (high network scalability) can coexist as we have shown in SRNIC.

8 Related Work

Several works [30, 32, 42] aim at improving RDMA's network scalability via bringing advanced congestion control algorithms to RNICs. They control the queue length at switches and thus improve RDMA's performance at scale. Note that these works are orthogonal to ours and can be integrated into SRNIC if they are hardware-friendly.

Mellanox tries to improve RNIC's connection scalability via DCT [17] technology, which restricts the number of active connections and avoids QP exhaustion via dynamically creating and destroying QPs. However, such behavior may cause frequent flips of connections, resulting in increased latency and bandwidth waste [27]. StaR [39] improves RNIC's connection scalability at one side by letting the other side save states for it. However, this strategy highly relies on the asymmetric communication pattern, where the client with low concurrency can share its resources with the server with high concurrency, to improve the overall connection scalability.

Other software based transport solutions or DPDK-style NICs, *e.g.*, eRPC [24], FaSST [27], 1RMA [38], and Nitro [37], expect NICs to provide scalable connection-less service including packet transmission and reception, and leverage CPU to implement connection-related semantics. In these solutions, it is the CPU's responsibility to handle most of the transport-related tasks, including packet order maintenance, congestion control, and loss recovery. Though the scalabilities of these approaches are comparable to the software transport TCP, the heavy involvement of CPU results in higher CPU overhead, higher latency, and higher jitter than that of hardware-based transport. In contrast, SRNIC handles almost everything in hardware but leaves only part of retransmission in software, resulting in hardware-level performance in most cases when there is no packet loss, and software-level loss tolerance when packet loss happens.

9 Conclusion

This paper presents the design and implementation of SRNIC, a scalable RDMA NIC architecture, which addresses the connection scalability challenge, while achieving high network scalability, high performance, and low CPU overhead at the same time. Our key insight in SRNIC is to minimize RNIC's memory requirement, by eliminating as many on-chip data structures as possible in a simple yet performant way. Guided by this insight, we make a few RDMA protocol header extensions and architectural innovations to achieve the design goal. Our experiences in SRNIC tell us that existing RDMA header formats originally designed for a lossless environment, are not suitable for much large-scale, lossy data center networks. SRNIC therefore is our first attempt towards more scalable and performant, next-generation RoCE/RDMA designs.

Abstract

Intra-host networking was considered robust in the RDMA (Remote Direct Memory Access) network and received little attention. However, as the RNIC (RDMA NIC) line rate increases rapidly to multi-hundred gigabits, the intra-host network becomes a potential performance bottleneck for network applications. Intra-host network bottlenecks may result in degraded intra-host bandwidth and increased intra-host latency, which can severely impact network performance. However, when intra-host bottlenecks occur, they can hardly be noticed due to the lack of a monitoring system. Furthermore, existing bottleneck diagnosis mechanisms fail to diagnose intra-host bottlenecks efficiently. In this paper, we analyze the symptom of intra-host bottlenecks based on our long-term troubleshooting experience and propose Hostping, *the first bottleneck monitoring and diagnosis system dedicated to intra-host networks*. The core idea of Hostping is conducting loopback tests between RNICs and endpoints within the host to measure intra-host latency and bandwidth. Hostping not only discovers intra-host bottlenecks we already knew but also reveals six bottlenecks we did not notice before.

1 Introduction

RDMA has been applied to many applications [14] [17] [28] [30] [42] [46] in data centers to achieve high throughput and ultra-low latency. As the last hop of network communication, intra-host networking can significantly impact the performance of network applications. However, the intra-host network is far from flawless, and intra-host bandwidth may degrade due to sudden link failures or occupation by other traffic. Previously, the intra-host bandwidth was much greater than the RNIC line rate (e.g., ~63 Gb/s PCIe Gen 3 x8 for 25 Gb/s RNIC), providing sufficient bandwidth redundancy for RNIC traffic. Therefore, the intra-host network rarely became

an obstacle to network communication, and bottlenecks in the host network received little attention.

However, bottlenecks in the host network are on the rise. With the increasing demand for high throughput and ultra-low latency, the RNIC line rate increases rapidly (from 25 Gb/s to 200 Gb/s). In contrast, the intra-host bandwidth does not improve equally (e.g., PCIe bandwidth increases from ~63 Gb/s to ~252 Gb/s). As a result, when intra-host bandwidth degrades, traffic on the RNIC is more likely to be throttled. What is worse, both the topology and traffic patterns within the host become much more complicated, making bandwidth degradation caused by sudden link failures or traffic contention happens more frequently. Besides, as intra-host services become more complex, configuration items in the host also increase considerably, leading to a high probability of misconfigurations. Some of them, such as enabling Access Control Service, will redirect GDR (GPU Direct RDMA) traffic to the CPU, leading to a drastic increase in intra-host latency and severe degradation of intra-host bandwidth.

Intra-host bottlenecks¹ may significantly degrade network performance. In our distributed machine learning system, one single intra-host bottleneck can significantly degrade the whole system and may even block the training process. This phenomenon is common in our data center. When it occurs, operators may need hours to days to diagnose the root cause.

Why do intra-host bottlenecks have such a severe impact? If the intra-host bandwidth is lower than the RNIC receiving rate, the RNIC receive buffer may accumulate or even be saturated. When this occurs in a lossy environment (without PFC) [39], RNIC may drop packets. Since RDMA is vulnerable to packet drops, even a low drop rate will result in drastic throughput degradation [24]. While in a lossless environment, RNIC will send PFC pause frames (Tx pause frames) to the upstream switch's egress port to stop its traffic. If the RNIC sends pause frames continually, it may eventually lead to a PFC storm [21] [24] [36], which may bring down the whole network.

The first two authors contributed equally to this paper. This work is done while Kefei Liu, Haoran Wei, and Xiaolong Zhong are doing a joint research project at ByteDance. (*Jiao Zhang is the corresponding author.)

¹In the following, we use "intra-host bottleneck" as the bottleneck in the host network and "network bottleneck" as the bottleneck in the inter-host network, i.e., switches and cables.

Therefore, when an intra-host bottleneck occurs, it should be discovered, diagnosed, and resolved as soon as possible.

However, due to the lack of an efficient intra-host bottleneck monitoring system, bottlenecks can hardly be noticed when they occur. When customers complain to the network team about performance degradation, the upper layer service usually has been severely influenced by the bottleneck. In addition, the phenomena caused by intra-host and network bottlenecks may be similar. Thus, when network performance degrades, operators need first to judge whether the host or the network should be blamed. Furthermore, when finding the bottleneck lies in the host, operators need to log in to the host, execute a series of test cases and conduct some profiling tools to infer the bottleneck. The whole process is time-consuming. What is worse, existing profiling tools could only be used for specific devices, such as Intel PCM [2] for Intel CPUs, AMD uProf [1] for AMD CPUs, and Nvidia SMI [9] for Nvidia GPUs. As each host may have devices from different vendors, operators may need different toolsets for each diagnosis, which brings additional learning and execution overhead.

To solve the limitations above, we propose Hostping, *the first bottleneck monitoring and diagnosing system dedicated to intra-host networks*. It could be deployed on all RDMA servers with low overhead and adapt to devices from different vendors. When intra-host bottlenecks occur, Hostping could quickly discover them and automatically diagnose their root causes. Thus, when network performance degrades, we can rapidly judge whether the host or the network should be blamed.

We need to address three challenges to achieve these design targets. Firstly, we need to find and measure metrics that could effectively discover and diagnose intra-host bottlenecks. Secondly, we need to keep responsive to intra-host bottlenecks with low overhead. Finally, we need to efficiently diagnose intra-host bottlenecks based on measured data.

Based on our long-term troubleshooting experience, we realized that leveraging intra-host bandwidth and latency as metrics could effectively discover and diagnose most intra-host bottlenecks. This guides the core idea of Hostping: conduct loopback tests between RNICs and endpoints (GPUs and memory nodes [33]) within the host to measure intra-host latency and bandwidth. By registering memory regions in different endpoints, Hostping could evaluate the latency and bandwidth of any intra-host path that a message received by an RNIC can take. To keep Hostping responsive to intra-host bottlenecks without degrading application performance, we design a hardware monitor to determine when to launch it. Finally, we propose an efficient diagnosing mechanism that could effectively identify the root cause of intra-host bottlenecks even under the interference of service traffic on RNICs.

We evaluate Hostping on over 300 servers in our distributed machine learning system. During the deployment, Hostping not only discovers intra-host bottlenecks we already knew but also reveals six bottlenecks we did not notice before, such

as CPU root port failures and memory channel flapping. To summarize, this paper makes the following contributions:

- We analyze the symptom of intra-host network bottlenecks based on our long-term troubleshooting experience and realize that most intra-host bottlenecks have one or both of the following symptoms: intra-host bandwidth degradation and intra-host latency increase.
- We design Hostping, the first bottleneck monitoring and diagnosing system dedicated to intra-host networks.
- We propose an efficient diagnosing mechanism that could effectively identify the root cause of intra-host bottlenecks even under the interference of service traffic on RNICs.

2 Background & Motivation

2.1 Intra-host Bottlenecks

When sending/receiving a message, the RNIC will read/write it from/to an intra-host endpoint (e.g., memory node, GPU) through multi-hops in the host network, such as PCIe links, memory channels, and inter-socket buses (e.g., Intel QPI [51]/UPI [11] and AMD xGMI [12]). We refer to the round-trip latency and the maximum available bandwidth between the RNIC and the endpoint as *intra-host latency* and *intra-host bandwidth*², respectively.

Previously, intra-host bandwidth was much greater than the RNIC line rate, providing sufficient bandwidth redundancy. Therefore, the host rarely became an obstacle to network communication, and intra-host bottlenecks received little attention. In recent years, with the increasing demand for high throughput and ultra-low latency from applications, the RNIC line rate has increased rapidly. In contrast, the intra-host bandwidth does not improve equally. As a result, when intra-host bandwidth degrades due to link failures or contention from other intra-host traffic, it is more likely to trigger network performance degradation.

What is worse, both the topology and traffic patterns within the host become much more complex, making the intra-host bandwidth degradation commonplace [13] [16] [19] [35] [37]. To satisfy the ever-increasing demand for computation capability, more GPUs and RNICs are integrated into one single host. For example, the latest Nvidia DGX-A100 [5] server incorporates 8 Nvidia A100 GPUs and 4 Mellanox 200 Gb/s RNICs. This leads to much more complicated intra-host traffic patterns and more bandwidth contention. In addition, as the number of root ports [43] on the CPU socket is limited, more PCIe switches are required to interconnect these devices. As a result, the intra-host topology becomes more complex, leading to more frequent intra-host link failures.

²It could be further divided into sending bandwidth from the endpoint to the RNIC and receiving bandwidth from the RNIC to the endpoint. If not explicitly mentioned, it indicates the minimum value of the sending and receiving bandwidth.

Furthermore, as intra-host services become more complicated, configuration items in the host also increase considerably, leading to a high probability of misconfigurations. Among them, some misconfigurations may lead to severe intra-host bottlenecks. For example, ACS (Access Control Service) is a PCIe configuration used in IO virtualization. GDR is a widely used communication method in machine learning, which uses the GPU to communicate directly with the RNIC without any involvement of the CPU and host memory. However, all GDR traffic will be redirected to the CPU with ACS enabled, leading to a drastic increase in intra-host latency and severe degradation of intra-host bandwidth.

2.2 The Impact of Intra-host Bottlenecks

When bottlenecks appear in the host, the intra-host bandwidth may be lower than the RNIC receiving rate, and the RNIC receive buffer may accumulate. If the receive buffer is saturated in a lossy environment (without PFC) [39], the RNIC will drop packets. Since RDMA is vulnerable to packet drops, even a low drop rate will result in drastic throughput degradation [24]. While in a lossless environment, when the RNIC receive buffer exceeds a threshold, it will send pause frames to the upstream switch’s egress port to stop its traffic. If the RNIC sends pause frames continually, it may finally lead to a PFC storm, which may bring down the whole network.

One single intra-host bottleneck may significantly degrade the distributed machine learning system. To achieve better training performance, developers aggregate more and more servers in a distributed system. However, this leads to more frequent performance bottlenecks. In data-parallel training, before updating the neural network parameters, all involved GPUs need to aggregate their local gradients [16] [28] [45]. In this process, GPUs may communicate in one or several rings [22] [38] [41] consisting of intra-host links (e.g., NVLinks [8], PCIe links) and network links to achieve optimal bandwidth utilization. This ring-based communication is extremely sensitive to network and intra-host bottlenecks. A single RNIC suffering from degraded intra-host bandwidth may significantly slow down the aggregation process of the whole system. We conducted a ring-based nccl all-reduce test [7] with eight hosts, and each host has a 200 Gb/s RNIC for network communication. Fig. 1 shows the throughput of each host during the test. In this scenario, an RNIC’s PCIe link has degraded bandwidth due to a link failure, leading to a slow sending/receiving rate. As a result, the throughput for all the hosts drops drastically to 50 Gbps (~70% lower than the ideal).

Frequent intra-host bottlenecks bring more challenges for performance bottleneck diagnosis. When packet drops or bandwidth degradation occur on a path, how to diagnose the root cause? This problem generally lies in the network when few intra-host bottlenecks appear, and operators only need to check each link and switch on the path in sequence. However, as intra-host bottlenecks occur much more frequently,

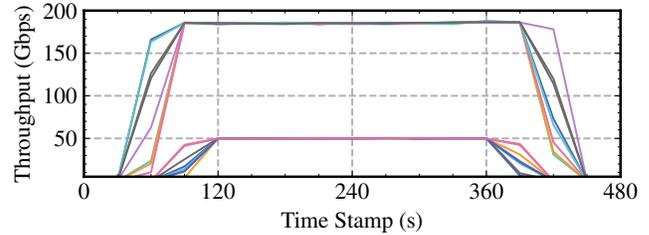

Figure 1: One single bottleneck degrades the throughput of the entire machine learning system by 70%. The upper lines are ideal, and the lower lines are abnormal. The throughput of each host is calculated every 30 seconds.

the same phenomenon may also be caused by the degraded intra-host bandwidth. As a result, operators must first distinguish whether the host or the network should be blamed, which brings more challenges for bottleneck diagnosis.

2.3 Limitations of Existing Intra-host Bottleneck Diagnosis Mechanisms

When an intra-host bottleneck occurs, it must be discovered, diagnosed, and resolved as soon as possible. Unfortunately, as far as we know, there are currently no monitoring and diagnosing systems dedicated to the host network in data centers, and intra-host bottleneck diagnosis is inefficient.

Unresponsive. When bottlenecks occur in a host, they can hardly be noticed in time due to the lack of an efficient intra-host bottleneck monitoring system. However, when customers (e.g., the machine learning team) complain to the network team about performance degradation, the upper layer service has usually been severely influenced. Thus, operators require a responsive monitoring system to quickly discover intra-host bottlenecks, avoiding application performance degradation.

Time-consuming. When a system suffers from degraded performance, operators usually need to run benchmark tests, such as perfest [10] and nccl-test [7], to narrow down the problem. However, these tests reflect “end-to-end” performance, including senders, networks, and receivers. Thus, they cannot quickly determine whether the bottleneck occurs in the network or the host. When finding the bottleneck lies in the host, root cause diagnosis is still challenging due to the complex intra-host topology. Operators need to log in to the host, execute a series of test cases, and conduct some profiling tools to evaluate all intra-host links. The entire process above needs to be conducted manually, which is time-consuming.

Fragmented. When an intra-host link has anomalous performance, operators may need to run some profiling tools to determine whether the link is occupied by other traffic. However, these tools are usually vendor-specific, such as Intel PCM for Intel CPUs, AMD uProf for AMD CPUs, Nvidia SMI for Nvidia GPUs, and Mellanox Neohost [4] for Mellanox RNICs. Unfortunately, each host in data centers may have a different combination of equipment, such as different

network adapters (Mellanox, Broadcom, or Intel), different CPUs (Intel or AMD), and different GPUs (Nvidia or AMD). As a result, when diagnosing bottlenecks in the host, operators need to utilize different combinations of tools, which brings additional learning and execution overhead.

2.4 Targets of Hostping

Considering the limitations above, we desire to develop a dedicated intra-host bottleneck monitoring and diagnosing system, which could be deployed on all RDMA servers with little overhead and adapt to devices from different vendors. When intra-host bottlenecks appear, the system can quickly discover them and automatically diagnose their root causes. Thus, when network performance degrades, we can rapidly judge whether the bottleneck lies in the host or the network. In conclusion, this system should have the following characteristics:

- **Responsiveness:** It should quickly discover intra-host bottlenecks and diagnose their root causes.
- **Deployability:** It should be implementable with commodity hardware.
- **Scalability:** It should be compatible with equipment from different vendors.
- **Lightweight:** It should have negligible interference with services in the host.

3 Hostping Overview

In this section, we will first introduce the challenges we should address to achieve the targets of Hostping (3.1). Then we will analyze the symptoms of intra-host network bottlenecks based on our long-term troubleshooting experience, which guides the core idea of Hostping (3.2). Finally, we will briefly illustrate the framework of Hostping (3.3).

3.1 Challenges

To realize the targets of Hostping, there are three main challenges to be solved:

Find and measure metrics that could effectively discover and diagnose intra-host bottlenecks. As the topology and traffic patterns within the host become much more complex, the root causes of intra-host performance bottlenecks are heterogeneous. We need to find some unified metrics that could effectively uncover intra-host bottlenecks and precisely infer their root causes. Besides, since the intra-host network is like a black box, measuring these metrics with high accuracy is also challenging.

Be responsive to intra-host bottlenecks with low overhead. Diagnosing intra-host performance bottlenecks requires evaluating all the links in the host. Due to the complexity of the

host topology, this is not an easy task and will have a non-negligible impact on the applications within the host. For example, active probing consumes CPU memory, GPU video memory, and bus bandwidth. How can we quickly perceive intra-host bottlenecks with low overhead to the performance of applications running in the host?

Effectively diagnose intra-host performance bottlenecks based on measured data. During the operation of Hostping, we will collect many performance data through active probing and monitoring. However, the complex intra-host topology makes it challenging to infer intra-host bottlenecks from scattered data. Besides, the data measured by active probing may be influenced by the service traffic on the RNIC. In this scenario, the degraded performance data does not necessarily mean the emergence of an intra-host bottleneck. We need to find an efficient bottleneck diagnosis mechanism to determine whether there is an intra-host bottleneck and find its root cause effectively based on scattered performance data.

3.2 Symptoms of Intra-host Bottlenecks

As mentioned above, intra-host bottlenecks are varied. How to use the least number of metrics to uncover most intra-host bottlenecks? Based on our long-term troubleshooting experience, we realize that although different root causes may be blamed, most intra-host bottlenecks have one or both of the following symptoms: **intra-host bandwidth degradation** and **intra-host latency increase**. Furthermore, leveraging intra-host bandwidth and latency as metrics could effectively discover and diagnose most intra-host bottlenecks. This guides the core idea of Hostping: conduct loopback tests between RNICs and endpoints within the host to measure intra-host latency and bandwidth. Next, we will introduce these two symptoms and their possible causes.

3.2.1 Bandwidth Degradation

Intra-host bandwidth degrades when an intra-host link is failed or is occupied by other traffic in the host. The RNIC receive buffer will accumulate when the intra-host bandwidth is lower than the RNIC receiving rate. If this situation continues, it will finally trigger packet drops (in lossy environments) or PFC pause frames (in lossless environments), leading to severe network performance degradation.

As the host topology becomes more complicated, the possibility of link failures in the host boosts. In addition, due to the large number of data center hosts, even if link failures are unusual on a particular host, they frequently occur throughout the data center. We encounter abnormal servers even daily in severe cases. What is worse, the locations of failures are varied, requiring a great deal of time for debugging. The host topology inside one of our most used training machines is shown in Fig. 2, which has two Intel Xeon CPUs connected through Intel UPI (Intel UltraPath Interconnect). Each CPU

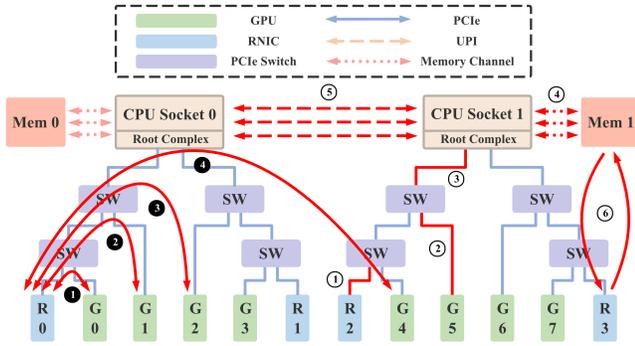

Figure 2: The host topology in one of our most used training machines. ①-④ show the GDR distance between an RNIC and a GPU. ①-⑤ show the link failures we encountered in practice, and ⑥ shows intra-host bandwidth degradation due to bandwidth contention.

root complex [43] is attached with four Nvidia A100 GPUs³ and two Mellanox CX6-DX 200 Gb/s RNICs through multiple PCIe switches. As shown in Fig.2, we have encountered failures of ① RNIC PCIe links, ② GPU PCIe links, ③ CPU root ports, ④ memory channels, and ⑤ UPI in practice. Some issues cannot be detected via static commands such as *lspci* and can only be discovered through benchmark tests.

Furthermore, services in the host are becoming more complicated, leading to more bandwidth contention. When the host bandwidth is occupied by other traffic, traffic on the RNIC may be congested (Fig.2 ⑥). Here, we give two practical examples. First, as RDMA devices are far from flawless, TCP and RDMA traffic may co-exist in the same host to meet high availability and a Service-Level Agreement [21]. However, the processing of TCP in the Linux kernel may consume a lot of memory bandwidth, leading to a slow receiving rate for RDMA traffic. Besides, in the training scenario, a physical machine is usually split into multiple Virtual Machines (VMs) to fully utilize host resources. In this case, communication between two VMs in the same host may trigger loopback traffic, which consumes the RNIC PCIe bandwidth and slows down the receiving rate from other hosts [32]. As shown in Fig.3, both link failures and bandwidth contention may throttle RNIC throughput and trigger a large number of PFC pause frames.

3.2.2 Latency Increase

When sending/receiving a message, the RNIC will read/write it from/to an endpoint (e.g., memory node, GPU) through multi-hops in the host network, such as PCIe links, memory channels, and inter-socket buses. We refer to the round-trip latency from the RNIC receive buffer to the endpoint as *intra-host latency*. Intra-host latency increases when there are too

³GPUs are connected via NVLinks and NVSwitches [8] for intra-host GPU-to-GPU communication (not shown in Fig.2).

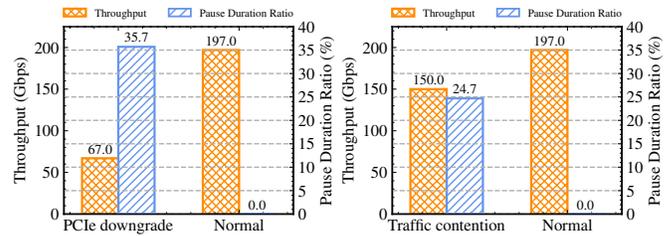

Figure 3: Both link failures (①-⑤) and bandwidth contention (⑥) will lead to intra-host bandwidth degradation, which may throttle RNIC throughput and trigger a large number of PFC pause frames.

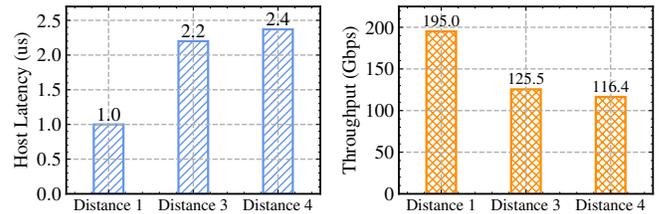

Figure 4: As the GDR read distance increases (from ① to ④), the intra-host latency rises, especially when going through the CPU root complex. Accordingly, the throughput degrades due to limited outstanding read request TLPs.

many hops between the RNIC and the endpoint. High intra-host latency hurts application latency and may significantly degrade intra-host bandwidth. When an RNIC needs to read from an endpoint, it sends PCIe read request TLPs (Transaction Layer Packets) [34] to the endpoint, and the endpoint will respond data to the RNIC after receiving the request. Therefore, when intra-host latency increases, the RNIC needs to send more read requests to sustain the line rate. However, RNICs limit the maximum outstanding read requests. As a result, intra-host bandwidth degrades when intra-host latency increases significantly.

Next, we leverage GDR traffic to illustrate the impact of high intra-host latency on intra-host bandwidth. GDR has been widely used in data centers to improve training performance in distributed machine learning systems. With GDR, the RNIC can write and read GPU video memory directly without using host memory, effectively improving the intra-host latency and intra-host bandwidth. However, GDR suffers from high latency when traffic traverses the CPU root complex. As shown in Fig.2, there are four types of communication distances between an RNIC and a GPU: ① traversing a single PCIe switch, ② traversing multiple PCIe switches without traversing the CPU root complex, ③ traversing the CPU root complex without traversing the UPI, and ④ traversing the UPI.

In the experiment, we use GDR read to test the impact of different communication distances on intra-host latency and bandwidth. We leverage Mellanox Neohost to measure

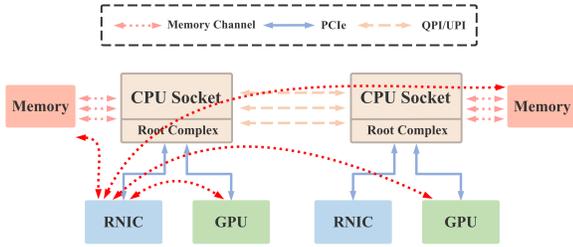

Figure 5: The core idea of Hostping: conduct loopback tests between RNICs and endpoints (GPUs and memory nodes) within the host to measure intra-host latency and bandwidth.

the intra-host latency. Since the latency of ❶ and ❷ is almost the same, we only compare the intra-host latency and the GDR bandwidth of ❶, ❸, and ❹ in the experiment. As shown in Fig.4, when the RNIC communicates with the closest GPU (distance ❶), the host latency is 1 μ s, and the RNIC can achieve almost the line rate. For distance ❸, when GDR packets need to pass through the CPU root complex, the host latency rises dramatically to 2.2 μ s, and the throughput drops sharply to 125.5 Gbps. As for distance ❹, traversing the UPI bus brings an additional 200 ns delay, and the throughput degrades to 116.4 Gbps. Just 1.4 μ s of additional intra-host latency results in a 40% drop in intra-host bandwidth.

3.3 Framework of Hostping

As shown in Fig.5, the core idea of Hostping is conducting loopback tests between RNICs and endpoints within the host to measure intra-host latency and bandwidth and leveraging the measured data to infer intra-host bottlenecks. Hostping is implemented based on commodity RNICs. Thus, it could run on all RDMA servers in data centers.

In the loopback test, the RNIC will read messages from one endpoint to its buffer and then write them back directly. In this process, all communication occurs inside the host without any network participation. Therefore, we could leverage the loopback latency and bandwidth to reflect intra-host latency and bandwidth. Furthermore, by conducting loopback tests between an RNIC and all endpoints in the host, we could evaluate the latency and bandwidth of all intra-host paths that a message received by the RNIC can take. When network performance degrades, if RNICs find no anomalies in loopback tests, we infer that the bottleneck occurs in the network. On the contrary, when the loopback test to an endpoint shows anomalous results, we confirm that a bottleneck exists on the path between the RNIC and the endpoint.

Fig.6 shows the framework of Hostping. The Hostping agent is deployed on RDMA servers and consists of three components: hardware monitor, Hostping engine, and data analyzer. The Hostping engine implements the core logic of Hostping and consists of two functions: (1) leverage RNICs to measure intra-host latency and bandwidth; (2) monitor bus utilization (PCIe links, inter-socket buses, and memory

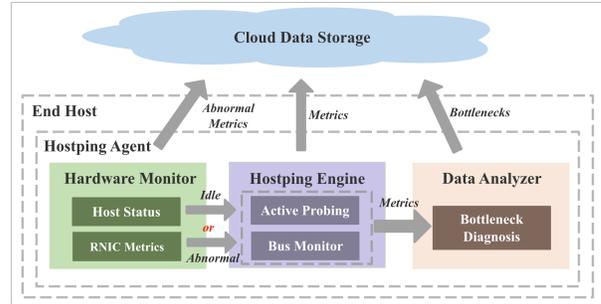

Figure 6: The framework of Hostping.

channels). The hardware monitor judges when to run the Hostping engine based on host status and abnormal metrics on RNICs. The data analyzer is responsible for diagnosing intra-host bottlenecks based on the data collected by the Hostping engine. All these modules will upload the information they collect to the cloud, which will be the basis for subsequent bottleneck diagnosis.

4 Hostping Design

In this section, we will first illustrate the functions of the Hostping engine and how to measure intra-host latency & bandwidth with the loopback test (4.1). Then, we will introduce how to utilize the hardware monitor to keep Hostping highly responsive to intra-host bottlenecks with low overhead (4.2). Finally, we will present how to diagnose intra-host bottlenecks with the data analyzer (4.3).

4.1 Hostping Engine

4.1.1 Measure Intra-host Latency & Bandwidth

Next, we will illustrate how to measure intra-host latency and bandwidth in the Hostping engine. Fig.7 demonstrates the process of the loopback test. First, the Hostping engine leverages `ibv_reg_mr` [3] to register two memory regions (read and write) in an endpoint for sending and receiving, respectively. Next, the Hostping engine uses `ibv_post_send` [3] to post a write WQE (Work Queue Element. Tell the RNIC to read the message of a specified *size* from the read region and write it to the write region) and doorbell the RNIC to fetch the WQE. Then the RNIC will send a request to read the message from the read region. Since the receiver is the same RNIC as the sender, the RNIC will directly write the message back to the write region instead of sending it to the network. Finally, after all PCIe write packets are sent out, the RNIC will generate a completion notification and inform the Hostping engine that the transmission is finished. By measuring the span between the call of `ibv_post_send` and the polling of completion, the Hostping engine could figure out the loopback latency. Moreover, by registering memory regions in different endpoints, we could get the loopback latency between the

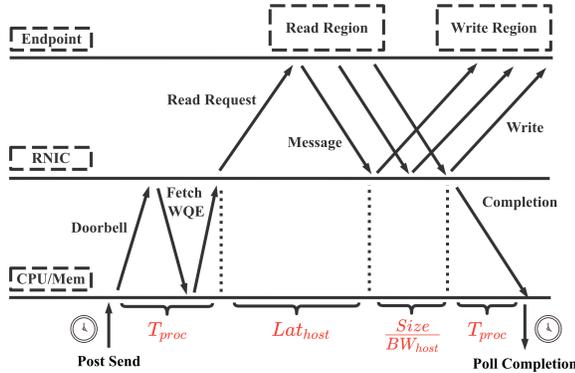

Figure 7: The process of the loopback test. Hostping engine figures out loopback latency by measuring the span between the call of `ibv_post_send` and the polling of completion.

RNIC and any intra-host endpoint. The measured loopback latency could be approximated⁴ as follow:

$$Lat = T_{proc} + Lat_{host} + \frac{Size}{BW_{host}} \quad (1)$$

T_{proc} contains two periods: (1) the duration between the call of `ibv_post_send` in the Hostping engine and the RNIC sending the first read request, and (2) the duration between the RNIC sending out all the PCIe write packets and the CPU polling the completion. The intra-host bandwidth (BW_{host}) is determined by the minimum bandwidth in PCIe read and write. Besides, the measured latency also includes intra-host latency (Lat_{host}). When we leverage a small message, the measured latency is close to:

$$\lim_{size \rightarrow 0} Lat = T_{proc} + Lat_{host} \quad (2)$$

It is hard to measure T_{proc} on commodity RNICs. Nevertheless, T_{proc} generally remains the same when the RNIC is underutilized and does not suffer from intra-host bottlenecks. In this case, we could leverage the change of small message latency to reflect the variation of intra-host latency. Thus, when the measured latency of a small message increases drastically, we could infer that there is an intra-host bottleneck leading to abnormal intra-host latency. On the contrary, when we use a very large message, the measured latency is close to:

$$\lim_{size \rightarrow \infty} Lat = \frac{Size}{BW_{host}} \quad (3)$$

Then the latency reflects intra-host bandwidth. Actually, we do not need to use a very large message in practice. We could use the difference between the latency of large and small messages (Equation 1 - Equation 2) to obtain Equation 3. In practice, our large message size is 128K bytes for 200 Gb/s RNICs, and our small message size is 1 byte.

⁴Here *size* refers to the message size. For simplicity, we do not consider PCIe encapsulation overhead (e.g., TLP header).

4.1.2 Monitor Bus Utilization

While the loopback test could reveal anomalous intra-host paths and links, it fails to diagnose the root cause of anomalies in some scenarios. For example, when the loopback test shows a memory channel has degraded bandwidth, how to further determine whether the root cause lies in traffic contention or a link failure?

To solve this problem, we implement a monitoring module in the Hostping engine to monitor bus utilization (PCIe links, inter-socket buses, and memory channels). Therefore, when the loopback test shows an intra-host link has degraded bandwidth, we could further check its utilization. If the link is overloaded, we infer that the root cause lies in traffic contention. Otherwise, the link is possibly failed. Unlike previous vendor-specific tools, our monitor could automatically adapt to devices from different vendors, and operators no longer need to learn and use various tools for different devices.

4.2 Responsiveness with Low Overhead

When performance bottlenecks occur in the host network, we hope Hostping can automatically, quickly, and accurately locate their root causes. However, high responsiveness and low overhead are usually a trade-off. We can frequently run loopback tests to judge whether there are performance bottlenecks in the host. However, loopback tests consume CPU/GPU memory and intra-host bandwidth, leading to contention with service traffic. Thus, frequent loopback tests will have a non-negligible impact on applications in the host. How could we ensure responsiveness to bottlenecks with low overhead to application performance?

Generally, data center hosts keep switching between busy and idle status. When the host is idle (little traffic on RNICs and all GPUs are inactive), we could frequently run loopback tests to keep responsive to intra-host bottlenecks, regardless of the overhead. When the host is busy with services and the network performance is degraded due to intra-host bottlenecks, abnormal metrics on the RNIC, such as packet drops and Tx pause frames, will usually appear. These metrics are indicators of intra-host bottlenecks. Therefore, we could execute loopback tests when these abnormal metrics appear. This way, Hostping keeps responsive to intra-host bottlenecks with low overhead to application performance.

We implement a hardware monitor in the Hostping agent to achieve the targets above. It (1) monitors host status and abnormal metrics on RNICs and (2) determines when to run the Hostping engine. In general, it has two functions:

- Monitor RNIC throughput and GPU status periodically. If the throughput of all RNICs is less than the threshold Thp_{low} , and all GPUs are idle, execute the Hostping engine to detect if there are intra-host bottlenecks. Otherwise, skip this execution.

- Monitor abnormal metrics on all RNICs. If the Tx pause duration ratio is larger than PFC_{high} or packet drops appear, execute the Hostping engine immediately to diagnose intra-host bottlenecks.

4.3 Bottleneck Analysis

In this section, we will demonstrate how the data analyzer leverages the data collected by the Hostping engine to determine whether there is a bottleneck within the host and diagnose its root cause. We first discuss how to diagnose intra-host bottlenecks when the host is idle. In general, the analyzer determines intra-host path status (normal or abnormal) by comparing the measured intra-host path bandwidth with the baseline and leverages path status to infer anomalous links. This idea is inspired by *binary network tomography* [15] [18] [27]. Besides, the analyzer compares measured intra-host path latency with the baseline to assist in root cause diagnosis. The baseline path bandwidth and path latency are obtained via loopback tests on a batch of idle hosts with the same devices and configurations.

$$y_j = \prod_{i: \text{link}_i \in \text{path}_j} x_i, \forall j, \quad (4)$$

The measured path bandwidth reflects the minimum link bandwidth on it. As shown in Equation 4, $y_j, x_i \in \{0, 1\}$, represents the status of path j and link i , respectively (1 for normal and 0 for abnormal). If the measured path bandwidth is lower than the baseline by $Abnormal_{th}$, we infer that one or more links on this path suffer from degraded bandwidth and mark this path as abnormal. However, a path with the expected bandwidth is not necessarily bottleneck-free. It depends on whether the RNIC can reach the line rate on this path. For affinitive endpoints of the RNIC (memory nodes⁵, GPUs under the same root port as the RNIC), the path bandwidth could reach the RNIC line rate. If the bandwidth of these paths is as expected, we consider them normal. However, as demonstrated in Section 3.2.2, the RNIC could not reach the line rate for GPUs under different CPU root ports due to high intra-host latency. In this case, if the bandwidth of a link degrades but is still higher than the RNIC rate, the measured bandwidth is still close to the baseline. For these paths, we only judge whether they are abnormal based on the baseline.

With adequate path status, we can judge the status of each link within the host. Our algorithm is shown in Algorithm 1. In a symmetric topology like Fig. 2, conducting loopback tests between RNICs and their affinitive endpoints could evaluate all intra-host links. Nevertheless, we do full-mesh tests when the host is idle to improve the accuracy of bottleneck inference. If no abnormal paths could be found, we conclude that there is no bandwidth bottleneck. Otherwise, we will

⁵We draw this conclusion from the server introduced in Section 3.2.1. For some types of servers, the RNIC cannot reach the line rate when communicating with the memory in remote NUMA nodes.

Algorithm 1 Detect Links with Bandwidth Degradation

Input: *normal* and *abnormal paths*

Output: *abnormal* and *gray links*

```

1: function DETECTABNORMALLINKS()
2:   InitLinkStatus()
3:   for  $\text{path}_j$  in normal paths do
4:     for  $\text{link}_i$  in  $\text{path}_j$  do
5:        $\text{link}_i.\text{status} \leftarrow \text{normal}$ 
6:   for  $\text{path}_j$  in abnormal paths do
7:     if  $\exists \text{links} \in \text{path}_j$  in uncertain status then
8:       for  $\text{link}_i$  in all these links do
9:          $\text{link}_i.\text{status} \leftarrow \text{abnormal}$ 
10:         $\text{link}_i.\text{abnormal\_cnt} ++$ 
11:     if  $\exists \text{links} \in \text{path}_j$  in abnormal status then
12:       for  $\text{link}_i$  in all these links do
13:         if marked abnormal by a new RNIC then
14:            $\text{link}_i.\text{abnormal\_cnt} ++$ 
15:         if  $\forall \text{links} \in \text{path}_j$  in normal status then
16:           for  $\text{link}_i$  in  $\text{path}_j$  do
17:              $\text{link}_i.\text{status} \leftarrow \text{gray}$ 
18:   return abnormal links and gray links
19: function INITLINKSTATUS()
20:   for  $\text{link}_i$  in all links do
21:      $\text{link}_i.\text{status} \leftarrow \text{uncertain}$ 
22:      $\text{link}_i.\text{abnormal\_cnt} \leftarrow 0$ 

```

diagnose anomalous links based on Algorithm 1. First, we mark all intra-host links as uncertain. Next, we traverse all normal paths and mark all links on them as normal. Then, we traverse all abnormal paths. If an abnormal path has uncertain links, we mark all these links as abnormal, and *abnormal_cnt* records how many RNICs mark a link as abnormal. If all the links on an abnormal path are normal, some links may be flapping. Then we set all the links on this path to gray.

When the host is idle, most bottlenecks could be attributed to *link failures* or *misconfigurations*. The analyzer first judges whether the RNIC is a bottleneck. If the path status between an RNIC and all its affinitive endpoints is abnormal, then the RNIC PCIe link may be failed. If the PCIe link connected to a GPU is marked as abnormal, the analyzer will further check the path latency between the GPU and its affinitive RNIC. If the latency is also abnormal, a misconfiguration (e.g., enabling ACS) may be the root cause. Otherwise, a link failure should be blamed. For other abnormal links, the analyzer diagnoses them as failed links. In addition, links marked as gray in three consecutive loopback tests will be identified as flapping links. All abnormal links and their possible root causes will be reported to operators for further operations, such as hardware inspection and reconfigurations.

When abnormal metrics on an RNIC trigger the Hostping engine, the host is usually busy with services, and some RNICs, especially the abnormal RNIC, may have heavy ser-

vice traffic. In this case, the path bandwidth measured by these RNICs will degrade due to the contention of service traffic, even if there is no bottleneck. Thus, we cannot judge the status of these paths according to the bandwidth baseline.

Nevertheless, these RNICs could still indicate abnormal paths. In the server introduced in 3.2.1, applications usually use an RNIC to communicate with its affinitive endpoints (memory nodes, GPUs under the same root port) to achieve optimal performance. Furthermore, memory channels and inter-socket buses generally provide considerable bandwidth redundancy. Therefore, the measured bandwidth between the RNIC and its affinitive endpoints is usually identical if no bottleneck occurs, no matter how much influenced by service traffic on the RNIC. Thus, among the RNIC's affinitive endpoints, if the measured path bandwidth to one endpoint is significantly lower than that to the other endpoints (by $Abnormal_{th}$), we infer this path is abnormal. However, we have no idea whether other paths are normal due to degraded RNIC loopback bandwidth, leading to reduced diagnosis accuracy. As a workaround, we could check whether there are idle RNICs on the host, which could still judge path status according to the baseline.

As applications usually use an RNIC to communicate with its affinitive endpoints, bottlenecks generally occur on the paths between the abnormal RNIC and its affinitive endpoints. Thus, we could focus on finding bottlenecks on these paths. When triggered by abnormal metrics, the Hostping engine only conducts loopback tests between RNICs and their affinitive endpoints. First, this method is sufficient to diagnose the status of the memory channel and the inter-socket bus with low overhead to service traffic. In addition, the service traffic may affect the measured bandwidth between the affinitive GPU of the abnormal RNIC and the RNIC under other root ports. As a result, the analyzer may incorrectly judge these paths as abnormal, leading to an inaccurate diagnosis. Thus, for the links under the same root port as the abnormal RNIC, we only use this abnormal RNIC to judge their status.

The inference of abnormal links is still based on Algorithm 1. However, as RNICs with heavy traffic cannot judge whether a path is normal, some normal links may be marked as abnormal. In this case, links with the highest $abnormal_cnt$ are most likely abnormal and should receive more attention. When abnormal metrics trigger the Hostping engine, abnormal links are usually fully loaded. Based on this, we can infer the root cause by monitoring these links. Links with utilization higher than $Util_{high}$ will be diagnosed as *overloaded links*, while *link failures* or *misconfigurations* may be the root cause of other abnormal links. However, as the abnormal RNIC suffers from intra-host bottlenecks, the latency measured by it will rise anomalously. Thus, we cannot judge whether the degraded GPU PCIe link is caused by a link failure or a misconfiguration. Operators then need to do a further inspection. Notably, if no abnormal link could be found, the RNIC PCIe link may be the bottleneck, and the analyzer will further check

if it is overloaded with loopback traffic to determine whether traffic contention or a link failure should be blamed.

5 Implementation

For the hardware monitor, throughput and abnormal metrics are provided by our RNIC vendors, and GPU status is obtained based on Nvidia Management Library (NVML) [6]. For the threshold, Thp_{low} is 5% of the RNIC line rate to judge whether the RNIC is idle. PFC_{high} is 3% (every second, transmission is paused by 30ms) to trigger the Hostping engine. During the deployment, the monitor checks the host status every five minutes⁶ and collects abnormal metrics every second to decide whether to start the Hostping engine.

For the Hostping engine, we implement the probing module with the verbs API and rdma-core libraries [3]. The bus monitor is implemented based on the API and metrics provided by our vendors: Intel's and AMD's API for CPU root ports, memory channels, and inter-socket buses, NVML for GPU PCIe links, and Mellanox's metrics for RNIC PCIe links.

The data analyzer takes the metrics collected by the Hostping engine as input and infers the most susceptible root causes for intra-host bottlenecks. $Abnormal_{th}$ is 20% to judge whether the latency or bandwidth of a path is abnormal, and $Util_{high}$ is 90% to judge whether a bus is overloaded.

The cloud data storage is implemented based on our time-series database. Every time the Hostping engine starts, all the information collected and deduced by the Hostping agent will be uploaded to the cloud. These data help us better understand the frequency and root causes of bottlenecks. Moreover, operators may need historical data to determine the root causes in some scenarios.

6 Evaluation & Intra-host Bottlenecks Found

We evaluate Hostping on over 300 servers in our distributed machine learning system. The host topology is shown in Fig.2 and introduced in Section 3.2.1, which is the most complex intra-host topology in our data center servers. In this section, we will summarize the bottlenecks we found during the deployment of Hostping. For known bottlenecks, Hostping could effectively diagnose their root causes. In addition, Hostping also reveals six bottlenecks we did not notice before. We roughly classify the bottlenecks found by Hostping into three scenarios according to their root causes.

Scenario 1: Intra-host bandwidth degrades due to link failures. As the host topology becomes more complex, link failures occur frequently. During the deployment, we encountered dozens of instances where failed links resulted in degraded intra-host bandwidth, including failures of #1 RNIC PCIe links (Fig.8 (a)), #2 GPU PCIe links (Fig.8 (b) & Fig.10

⁶As link failures and misconfigurations infrequently appear in a host, 5 minutes is a fine granularity.

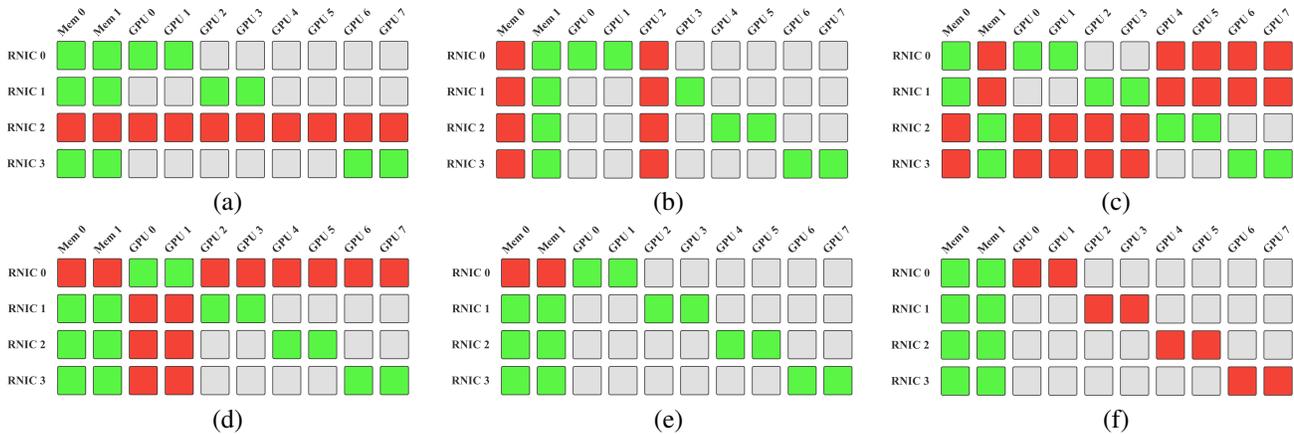

Figure 8: The intra-host end-to-end bandwidth matrices measured by the Hostping engine when hosts are idle. The topology between RNICs and endpoints is shown in Fig.2. (a)-(e) show intra-host bandwidth degradation due to link failures. (f) shows the impact of inappropriate configurations. Green, red, and gray indicate that the path status is normal, abnormal, and uncertain, respectively.

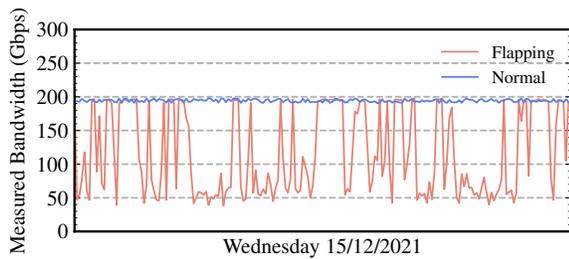

Figure 9: Memory channel flapping on the server. When this occurs, the bandwidth of the memory channel switches between normal and abnormal.

(a)), #3 memory channels (Fig.8 (b)), and #4 UPI (Fig.8 (c)). For the sake of space, Fig.8 (b) contains #2 and #3. Their problem may be loose PCIe interfaces, dust on connecting fingers, or hardware failures and requires further troubleshooting. Based on the matrix, the analyzer could accurately infer abnormal links. Note that in Fig.10 (a), although RNIC2 has a large amount of service traffic, it could still judge that the path to GPU4 is abnormal according to other measured paths. With Hostping, operators could quickly discover and deal with link failures, avoiding application performance degradation.

[New] #5 CPU root port failures. Before deploying Hostping, we only knew four kinds of link failures (#1 to #4). During the deployment, we found that the CPU root port may also experience hardware bandwidth degradation. When this happens, the bandwidth between the RNIC and the GPU under the failed root port is normal. While traffic passes through the failed root port may suffer from degraded bandwidth. The corresponding bandwidth matrix is shown in Fig.8 (d) and (e). They have the same root cause, except that (e) has slight bandwidth degradation, and RNICs under other root ports cannot find anomalies. Nevertheless, Hostping could still accurately diagnose the root cause in this case.

[New] #6 Memory channel flapping. With the assistance

of Hostping, we found a host suffers from degraded memory channel bandwidth due to a link failure. However, no performance issues could be discovered in subsequent manual testing. By continuously running Hostping and collecting measured data, we found that the root cause lies in the flapping memory channel. As shown in Fig.9, the bandwidth of the host memory channel switches between normal and abnormal. With historical data, we could understand the causes of intra-host bottlenecks more clearly. This case shows the necessity to run Hostping periodically.

Scenario 2: Inappropriate configurations lead to degraded performance. #7 Enabling ACS results in high PCIe latency. We have mentioned this case in 2.1. With ACS enabled, all GDR traffic will be guided to the CPU instead of directly to the GPU, resulting in drastic performance degradation. As shown in Fig.8 (f), all PCIe bridges are configured as ACS enabled in this case. As a result, both the latency and bandwidth between the RNIC and the GPU under the same root port turn abnormal. Hostping could accurately diagnose this bottleneck and remind operators to check the configuration.

[New] #8 Disabling ATS results in high PCIe latency. We found this case in a virtualized environment. In IO virtualization, if Address Translation Service (ATS) is disabled on the RNIC, all GDR packets will be directed to the CPU root complex for address translation. Similar to #7, with ATS disabled, the latency between the RNIC and the GPU under the same root port increases, leading to drastic bandwidth degradation. By enabling ATS, the translation can be finished in the RNIC to achieve optimal GDR performance.

[New] #9 Enabling "slow start" on the RNIC. This is a lossy feature provided by our RNIC vendor. When enabled on an RNIC, the RNIC sending rate will start from a small value instead of the line rate. Although "slow start" could alleviate congestion under Incast scenarios, it increases the completion time of short flows. Thus, it usually remains disabled in most

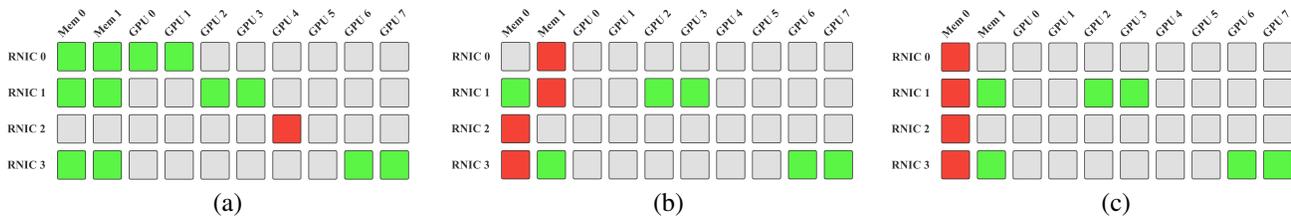

Figure 10: The bandwidth matrices measured when hosts are busy with services. (a) shows hardware bandwidth degradation due to the GPU PCIe link failure. (b) and (c) show degraded intra-host bandwidth caused by traffic contention.

scenarios. When "slow start" is enabled, the RNIC bandwidth to all intra-host endpoints will be lower than the baseline (similar to Fig. 8 (a)). At first, Hostping diagnosed the root cause as the RNIC PCIe link failure. However, we found no bottlenecks during continuous bandwidth tests. After configuration inspection, we finally uncovered the root cause.

[New] #10 Setting "Tx window" too small on the RNIC. This is also a lossy feature. "Tx window" will limit the maximum in-flight bytes of each queue pair on an RNIC. Therefore, "Tx window" influences the maximum bandwidth a QP could achieve and needs to be set reasonably to alleviate network congestion without degrading throughput. Similar to #9, when an RNIC's "Tx window" is too small, its bandwidth to all intra-host endpoints will be lower than the baseline.

Scenario 3: Intra-host bandwidth degrades due to traffic contention. [New] #11 Overloaded Inter-socket buses. During the deployment, we found some malfunctioning applications overloaded the UPI of a host, and cross-socket receiving traffic on RNIC0 triggered a large number of Tx pause frames. Fig. 10 (b) shows the corresponding bandwidth matrix measured by Hostping. In this case, RNIC0 and RNIC2 have a large amount of service traffic. Nevertheless, they could still judge that two paths (RNIC0 to mem1 and RNIC2 to mem0) are abnormal according to other measured paths. With the help of the other two idle RNICs, the analyzer infers that the UPI is most likely to be abnormal (with the highest *abnormal_cnt*). Furthermore, leveraging the bus monitor, it diagnoses the root cause as the overloaded UPI. The operator then will find out the traffic source that overloads the UPI.

#12 Overloaded memory channels. TCP and RDMA traffic may co-exist in the same host to keep high availability [21]. In this case, the processing of TCP may consume a lot of memory bandwidth, leading to a slow receiving rate for RDMA traffic. However, we did not discover this case in A100 servers during the deployment of Hostping. As a supplement, we conduct an experiment to evaluate how Hostping behaves when the memory channel is overloaded. We use several processes to overload the channel of mem0. Besides, RNIC0 and RNIC2 receive traffic writing to mem0 and mem1, respectively. Fig. 10 (c) shows the corresponding bandwidth matrix. Although RNIC0 and RNIC2 have a large amount of receiving traffic, they could still judge that their paths to mem0 are abnormal. Similar to #11, in this case, the analyzer infers that the channel of mem0 is most likely abnormal and diagnoses

the root cause as the overloaded memory channel.

In this scenario, we evaluate the performance of Hostping when intra-host links are overloaded. Furthermore, the results show that Hostping could still effectively diagnose intra-host performance bottlenecks under the interference of service traffic on RNICs.

7 Experiences Learned

Conduct Hostping before running applications. As the intra-host topology becomes more complex, the likelihood of link failures in the host network boosts. Based on our experience, some failures may already exist when the server leaves the factory. Thus, it is essential to evaluate the intra-host network performance before delivering the server to customers. In addition, as intra-host services become more complicated, configuration items in the host also increase considerably, and the configuration methods are varied. For example, the setting of Address Translation Service requires a reboot to take effect. In contrast, Access Control Service is enabled by default and needs to be disabled after each reboot. Furthermore, configurations may not be completed successfully for some reason. Therefore, misconfigurations occur occasionally. We recommend conducting Hostping after each reboot to ensure proper configurations before running applications.

Perceive intra-host bottlenecks with VoQ ECN marking. Although intra-host bottlenecks should be addressed in a targeted manner (e.g., hardware replacement, reconfigurations), we argue that *congestion control mechanisms should be able to perceive intra-host bottlenecks*. Thus, they could alleviate the triggering of packet drops and Tx pause frames to provide better network performance before the bottleneck could finally be resolved. Generally, packets could only be ECN-marked in a switch's egress port, and ECN-based congestion control mechanisms could only perceive network congestion. Fortunately, some latest RNICs provide a new function called VoQ (Virtual Output Queuing) ECN marking, enabling the receiver RNIC to ECN-mark packets when its receive buffer exceeds a threshold. By enabling this function, ECN-based congestion control mechanisms, such as DCQCN [50], can also perceive intra-host bottlenecks. Thus, the sender could timely slow down its sending rate to alleviate the triggering of packet drops or Tx pause frames.

Pay attention to intra-host topologies. Although GDR is

supported at any distance within the host, it is highly recommended not to conduct GDR across CPU root ports. When this occurs, the GDR bandwidth degrades severely, which may lead to a large number of Tx pause frames or packet drops. Furthermore, when testing some AMD servers, we found a large number of Tx pause frames and drastic throughput degradation when the RNIC (200 Gb/s) writes to the memory in the remote socket. This is due to the low cross-socket hardware bandwidth on these servers, and the root cause lies in the host architecture. Thus in these servers, we should avoid using RNICs to communicate with the memory in the remote socket for optimal performance.

8 Related Work

Bottlenecks in the RNIC and intra-host network. With the increasing RNIC line rate, the intra-host network and the RNIC have become potential performance bottlenecks in network communication. Some literature has studied these bottlenecks. Kong et al. [32] implement a tool to help data center operators uncover potential performance bottlenecks in the RNIC. Martinasso et al. [37] analyze congestion behaviors in PCIe fabric and develop a congestion-aware performance model for PCIe communication. Zhang et al. [49] study RDMA sharing characteristics and analyze performance isolation anomalies in RDMA. Neugebauer et al. [40] study the performance impact of PCIe in the host network. Dong et al. [16] analyze different types of traffic congestion in the host network and propose a new server architecture to alleviate intra-host congestion. Faraji et al. [19] show the implication of distance between GPUs on the GPU-to-GPU communication performance in the host network. Farshin et al. [20] study when Intel Data Direct I/O (DDIO) technology becomes a bottleneck in multi-hundred-gigabit networks and how to optimize DDIO-enabled systems for I/O intensive applications. These studies help us better understand the potential bottlenecks in the RNIC and intra-host network.

Bottleneck diagnosis tools. Diagnosis tools could be broadly classified as system-based tools and intra-host tools. System-based tools aim to diagnose performance bottlenecks in the whole system. Pingmesh [25] implements an end-to-end connectivity and latency monitoring system for network troubleshooting and SLA tracking. Netbouncer [44] leverages the IP-in-IP technique to probe designated paths and then diagnoses device and link failures in data center networks. Deepview [48] builds a near-real-time system for virtual disk failure localization. Microscope [23] leverages queuing information at network functions to identify the root causes of performance bottlenecks. SNAP [47] collects network information such as TCP statistics and socket-call logs to pinpoint the problem in data center network applications. In contrast, intra-host tools are dedicated to diagnosing bottlenecks in the host. Haecki et al. [26] implement a latency diagnosis tool to identify the source of network latency in end-host stacks.

Mellanox Neohost [4] provides plenty of diagnosis counters on Mellanox RNICs. Nvidia SMI [9] provides the status of Nvidia GPUs. Intel PCM [2] and AMD uProf [1] provide the internal resource utilization of the CPU, including the utilization of buses and interfaces connected to the CPU, such as inter-socket buses, memory channels, and CPU root ports.

9 Conclusion & Future Work

Intra-host networking has become a potential bottleneck for RDMA networks, and intra-host bottlenecks can severely degrade network performance. This paper proposes Hostping to monitor and diagnose intra-host bottlenecks. We analyze the symptom of intra-host bottlenecks based on our long-term troubleshooting experience and realize that most intra-host bottlenecks have one or both of the following symptoms: intra-host bandwidth degradation and intra-host latency increase. Thus, Hostping measures intra-host bandwidth and latency as performance metrics to detect and diagnose intra-host bottlenecks. Furthermore, we propose an efficient diagnosing mechanism that could effectively identify the root cause of intra-host bottlenecks even under the interference of service traffic on RNICs. During the deployment, Hostping not only discovers performance bottlenecks we already knew but also reveals six bottlenecks we did not notice before.

The deployment of Hostping makes us realize that more work needs to be done. Firstly, when the host is busy with services, due to the influence of service traffic, it is challenging to accurately diagnose intra-host link status based on binary path status. If the end-to-end traffic information within the host can be obtained, it will provide more insights into intra-host bottlenecks. Secondly, after finding an overloaded link, we hope Hostping could automatically identify the traffic source, such as malfunctioning applications. Finally, in addition to intra-host network bottlenecks, RNIC bottlenecks, such as scalability problems [29] [30] [31], can also lead to severe network performance degradation. Thus, it is also important to diagnose bottlenecks in the RNIC.

Abstract

Recent years have witnessed the wide adoption of RDMA in the cloud to accelerate first-party workloads and achieve cost savings by freeing up CPU cycles. Now cloud providers are working towards supporting RDMA in general-purpose guest VMs to benefit third-party workloads. To this end, cloud providers must provide strong performance isolation so that the RDMA workloads of one tenant do not adversely impact the RDMA performance of another tenant. Despite many efforts on network performance isolation in the public cloud, we find that RDMA brings unique challenges due to its complex NIC microarchitecture resources (e.g., the NIC cache).

In this paper, we aim to systematically understand the impact of RNIC microarchitecture resources on performance isolation. We present a model that represents how RDMA operations use RNIC resources. Using this model, we develop a test suite to evaluate RDMA performance isolation solutions. Our test suite can break all existing solutions in various scenarios. Our results are acknowledged and reproduced by one of the largest RDMA NIC vendors. Finally, based on the test results, we summarize new insights on designing future RDMA performance isolation solutions.

1 Introduction

Multiplexing workloads from different tenants on a shared computing infrastructure enables the modern cloud computing era. The global cloud infrastructure revenue has already surpassed 400 billion US dollars and is forecast to grow to reach around 1 trillion US dollars in the next decade [7].

It is well known that having different tenants' workloads share computing resources can lead to unpredictable application performance interference [12, 18, 66] and privacy leakage [32, 39]. This drives plenty of studies focusing on performance isolation in the cloud, especially for performance-critical applications that have stringent service-level objectives [11, 12, 18, 41, 63, 66, 70]. The state of the art in practice has also significantly advanced: CPU vendors even implement hardware mechanisms to control and isolate access to CPU caches [20]. Side channels through shared resources are

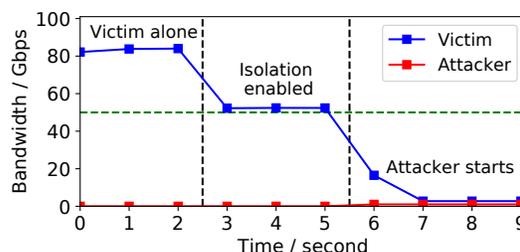

Figure 1: Violations of performance isolation under existing methods being patched over time [39].

In this paper, we visit one particular hardware device, the RDMA NIC (RNIC). RDMA offloads the network stack from OS kernel to NIC hardware to provide high throughput and ultra-low processing latency with near-zero CPU overhead. RDMA has been deployed in datacenters at scale to improve performance and free up CPU cores for first-party workloads like storage and ML [14, 17, 38, 51]. Now cloud providers are working towards supporting RDMA in general-purpose guest VMs to benefit third-party workloads. To this end, cloud providers must provide strong performance isolation for tenants sharing the same RNIC.

Many efforts have been made to improve network performance isolation in the public cloud, with a special focus on bandwidth and packet processing capacity [3, 15, 16, 25, 34, 62, 64]. However, RDMA brings new challenges due to its unique and complex NIC *microarchitecture resources* (e.g., NIC caches and processing units). Their existence and impact on performance are already known to the research community [29, 33]. To avoid performance anomalies, developers carefully design RDMA systems to avoid exhausting these microarchitecture resources [5, 9, 10, 27, 30, 50, 61]. Our study is from a different angle: we look at how these microarchitecture resources affect RDMA performance isolation from a public cloud provider's perspective. The cloud provider has no knowledge and control of tenants' RDMA applications, and tenants can consume RNIC microarchitecture resources in arbitrary manners.

To demonstrate RNIC microarchitecture resources' significant impact on performance isolation, we test the state-of-the-art approach: using SR-IOV with separated hardware traffic class (HW TC). Both SR-IOV and HW TC are hardware mechanisms available on commodity RNICs. HW TC leverages multiple hardware queues (usually 8 queues) in RNICs. We can assign each tenant application to use one queue. We run one victim traffic between two virtual machines using `ib_write_bw`, a standard RDMA bandwidth testing tool in `Perftest` [56]. Each virtual machine is on a different server, and the two servers are equipped with 100 Gbps NVIDIA ConnectX-5 RNICs. Figure 1 shows the bandwidth. The bandwidth test achieves 80 Gbps. We start one virtual machine on each server to represent an attacker (i.e., a buggy or malicious tenant application) and enable performance isolation to grant half of the total bandwidth to the victim and the attacker. The victim traffic reduces to 50 Gbps, which is expected. However, when we start a carefully designed attacker traffic of only 1 Gbps to intentionally exhaust one of the RNIC microarchitecture resources, the victim immediately drops to 2 Gbps, violating the performance isolation guarantee (i.e., 50 Gbps of guaranteed network bandwidth for the victim).

We develop a set of experiments to study how RNIC microarchitecture resources are used by different types of RDMA operations. Our experiments surface several interesting findings, including: (1) Exception or error handling pauses the RNIC's pipelines and causes other tenants' performance to drop drastically. (2) Control verbs cause a severe increase in cache misses and impair other tenants' performance. (3) Data verbs can exhaust different types of microarchitecture resources and violate performance isolation. To the best of our knowledge, we are the first to systematically study the impact of all types of control verbs and exceptions on RDMA microarchitecture resource consumption.

We leverage these findings to create an RDMA operation model to describe the relationship between the RDMA verb operations and the microarchitecture resources consumed. Our model allows us to understand how to exhaust each of the RNIC resources. Using the operation model, we create the first test suite, *Husky*, to systematically test and evaluate RNIC performance isolation solutions. Unfortunately, running our test suite on commodity RNICs reveals bad news: *there is currently no solution that can provide RNIC performance isolation*. We have already reported all of our findings to three major RNIC vendors, NVIDIA, Chelsio, and Intel. Our results are fully reproduced and acknowledged by NVIDIA, one of the largest RDMA NIC manufacturers. Finally, we present new insights on how future performance isolation solutions should be built. We hope these insights can benefit future RNIC design and RDMA software development.

This paper makes the following contributions:

- We identify multiple interactions between RDMA operations and the RNIC microarchitecture resources, including the previously unknown impact of error handling and

control operations.

- We introduce the first RDMA operation model to describe how RNIC microarchitecture resources are consumed in verb operations (the standard RDMA programming API) and why these microarchitecture resources affect performance isolation.
- We build the first test suite to systematically test and evaluate RNIC performance isolation solutions. We show that none of the existing performance isolation solutions can pass our test suite. *Husky* test suite is available at <https://github.com/host-bench/husky>.

This work demonstrates that providing performance isolation for RDMA in the public cloud is much more difficult than one may think. There must be a higher standard for future RDMA performance isolation solutions: they should carefully consider RNIC microarchitecture resources and be evaluated by systematic benchmarks.

2 Background and Motivation

We first present the background knowledge of the network performance isolation in the public cloud. Then we introduce RDMA and discuss new challenges presented by the RDMA network performance isolation.

2.1 Network Performance Isolation in the Public Cloud

Tenants in the cloud mainly cause contention on two types of network resources. The first the most obvious one is the bandwidth in the network fabric. To mitigate bandwidth contention among tenants, one line of work [58, 60, 62] statically limits per-tenant bandwidth. Another line of work [1, 3, 4, 6, 16, 24, 25, 37, 58, 59, 68] gives each tenant a minimum bandwidth guarantee and allows tenants to use spare bandwidth capacity. The second type of resource is the packet processing resources at the end host. Per-packet processing costs depend on many factors, such as cache misses and operations to perform. Recently, *PicNIC* [34] provides isolation for such software packet processing. People also leverage specialized hardware to achieve the same goal [64].

It is worthwhile to note that network performance isolation is very different from network virtualization. Network virtualization orchestrates network resources to provide each tenant with an illusion of an independent network. A tenant should not impact the connectivity of the network of another tenant. The goal of network virtualization is to achieve low overhead [19, 31, 57]. In comparison, network performance isolation focuses on how to manage resource contentions to ensure that tenants can achieve guaranteed performance.

2.2 RDMA Overview

RDMA allows the NIC to directly transfer data between the wire and the application memory. The networking protocol is implemented in the NIC. Figure 2 presents the overview of

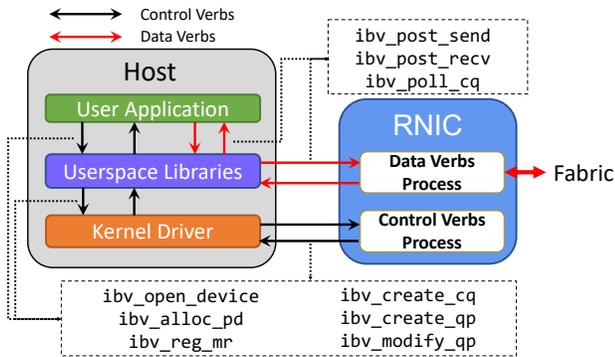

Figure 2: Overview of RDMA workflow. Verbs processing logics are heavily offloaded to the RNIC.

the RDMA workflow. It classifies standard RDMA programming interface, a.k.a., verbs, into two categories: control and data. An application first needs to call several *control verbs* to allocate necessary objects, such as queue pair (QP) and completion queue (CQ), to set up a reliable connection (RC), an unreliable connection (UC), or an unreliable datagram (UD) transmission endpoint. Then the application needs to register a memory region (MR). This registration essentially pins the memory in the host DRAM and obtains the mapping from virtual addresses to physical addresses, which enables the RNIC to directly read from or write to this memory region. All these control verbs are processed by the following procedure: RDMA’s userspace libraries and kernel drivers process the verb request, generate a request command, put the command in a negotiated command queue, and ring the RNIC’s doorbell (e.g., memory-mapped registers). The RNIC fetches the command from the command queue, processes it, and pushes the response back to the queue. The drivers then process the response and return the object to the application.

After the above initialization, the application can start data transmissions between local and remote memory. There are several types of operations that applications can use, such as SEND/RECV, WRITE, READ, and ATOMIC. We name these operations as *data verbs*. To issue a data verb, the application generally posts a request to its send queue and rings the RNIC’s doorbell through userspace libraries. The RNIC then parses the request, reads data from the host memory, segments data into packets, and transmits packets. This procedure bypasses the kernel. There are certain differences in processing different types of requests. For example, for SEND/RECV messages, the receiver should post enough RECV requests before the sender issues SEND requests. Otherwise, the incoming SEND requests may be dropped or need retransmissions because the receiver RNIC lacks receive requests to process them, which is known as the receive not ready (RNR) error. For WRITE/READ data to/from the remote end or execute ATOMIC operations, the sender should specify correct remote virtual addresses and memory keys. An invalid address or a wrong key will trigger a memory protection error and cause the QP to transition into the error state.

2.3 Why RDMA Performance Isolation is Hard?

As shown above, RDMA offloads many host network functionalities to the RNIC, which has many invisible hardware components, and each component may individually become a performance bottleneck. Figure 3 shows the hardware components of a commodity RNIC. We draw this figure based on publicly available documents from NVIDIA [44, 46, 48]. In addition to the packet buffers (TX/RX Buffer), the RNIC also has multiple processing units (PU) and many types of internal caches. Each internal cache is used to store a specific type of metadata. For example, in NVIDIA RNICs, the Interconnect Context Memory (ICM) cache stores QP contexts; the Memory Translation Table (MTT) and Memory Protection Table (MPT) store entries for memory address translation and protection information; and the Work Queue Entry (WQE) cache stores prefetched send WQEs and posted receive WQEs. As these caches are derived from the design needs, other RNICs include similar components. We name these RNIC hardware components *microarchitecture resources* based on the analogy for CPU hardware. CPUs are designed to conform to a standard instruction set architecture (e.g., ARM, x86), but the CPU designers can make the microarchitecture-level decisions, such as how many levels of caches and the cache sizes. RNICs are similar because RNIC vendors have to provide the same programming interface for RDMA application developers, but the vendors can decide on these microarchitecture-level details, e.g., RNIC caches.

Many previous efforts have already identified some impacts of these microarchitecture resources on RDMA application performance. For example, [5, 29, 50] find that an RNIC caches QP contexts. A QP context cache miss can trigger an additional PCIe round trip for the RNIC to fetch the context from the host DRAM, thus degrading application performance. For example, 200 connections can cause a 90% request rate drop on NVIDIA ConnectX-3 NIC [5]. However, these efforts study microarchitecture resources from the perspective of an *application developer*. After a performance degradation, they identify the bottleneck resource, seek more efficient methods to use data verbs, and modify their applications correspondingly.

However, in public clouds, cloud providers have no control over tenants’ applications. Tenants thus can consume RNIC’s microarchitecture resources as they wish, even maliciously. Therefore, from the perspective of the *cloud provider*, we need to understand the microarchitecture resource consumption of most of (if not all) RDMA verbs, not just common data verbs. Only with this knowledge can we properly allocate RNIC’s microarchitecture resources to different tenants to deliver predictable performance.

3 RNIC Microarchitecture Resources

In this section, we present a study on all the RNIC microarchitecture resources that we are currently aware of. Prior works have already identified several particular forms of resource

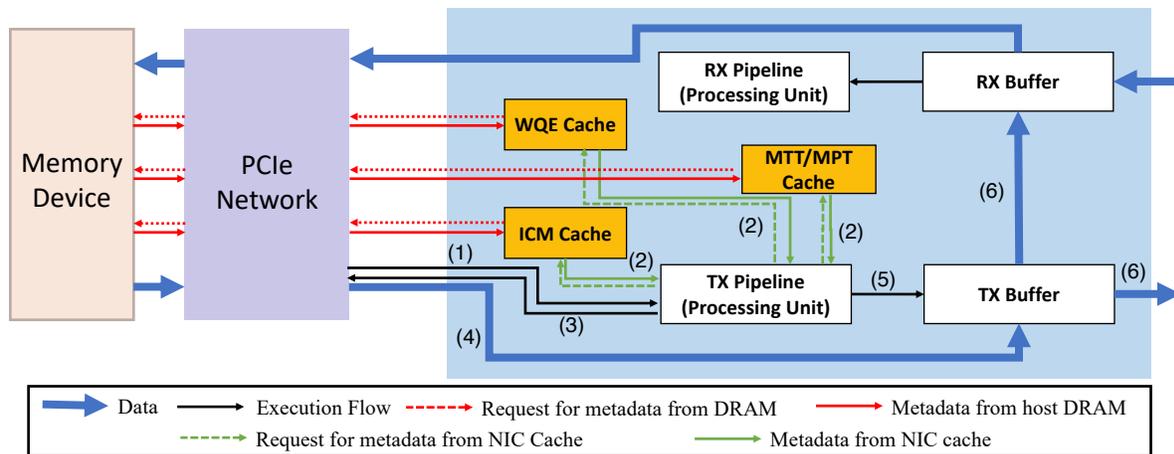

Figure 3: RDMA NIC microarchitecture hardware details: when the doorbell is rung, the RNIC first fetches the control/data verbs request from the host DRAM. (1) To fetch and process this request, the RNIC may need several metadata (e.g., QP contexts) and there are different types of caches inside the RNIC that can store this metadata. The RNIC can get the metadata directly from these caches, (2) or fetch them from DRAM if a cache miss happens (red lines in the figure). Then the RNIC processes the request and (3) sends the response back to the host DRAM for control verbs or issues DMA requests to read payload for data verbs. After (4) reading data from the host DRAM, the RNIC (5) processes the data into network packets and (6) sends them to the fabric. The symmetric receiver side is not shown for simplicity.

contention. But our goal here is to systematically study all possible types of resource contention. For each microarchitecture resource, we study how it is consumed by three categories of RDMA operations: (1) control verbs that allocate objects for applications (e.g., `ibv_create_qp`), (2) data verbs that initiate data transfer (e.g., `ibv_post_send`), and (3) exception handling operations that handle exceptions or errors (e.g., RNR errors). Due to space limitations, we first present a few *key findings* that have significant implications on RNIC performance isolation. After that, we summarize several other findings. We present a detailed analysis of NVIDIA’s responses to these findings in [Appendix B](#).

3.1 Methodology

Our findings center around how to exhaust RNIC microarchitecture resources through the verbs interface [21], the standard RDMA programming API. For each key finding, we demonstrate it with a concrete setting, which consists of a victim workload and an attacker workload. *Although we use the terminology attacker, the attacker tenant does not get unauthorized access to other tenants through vulnerabilities. Instead, the attacker is just a normal RDMA application that issues standard RDMA verbs.* Each tenant has one client and one server. The clients of the victim and the attacker locate on the same physical machine and share the same RNIC. The servers of the victim and the attacker are colocated on a different physical server. During the measurement, we do not enable any isolation mechanism. We will study existing performance isolation solutions in §5.

We focus on the performance interference between the victim and the attacker through the exhaustion of microarchitecture resources. We first run only the victim to saturate the link bandwidth capacity (bits per second) or the RNIC’s

maximum request rate (requests per second). We then start the attacker and measure the two metrics for both the victim and the attacker. If there is no microarchitecture resource contention, the sum of the performance metrics of the two tenants should match the RNIC’s limit in the specification. Modern RNICs specify their bandwidth capacity and request rate limits. If the sum of the two tenants’ performance metrics falls below both specified limits, we attribute this to the contention of microarchitecture resources. For example, assume there is no attacker, and the victim can achieve 100 Gbps. However, with an X Gbps attacker, the victim reduces to Y Gbps, and $X + Y < 100$. Let us also assume the total request rate is below the RNIC specification. In this situation, we conclude that some microarchitecture resource is bottlenecked. The traffic is using RC connection unless otherwise noted.

We test four types of 100 Gbps RNICs: NVIDIA ConnectX-5 EN and ConnectX-6 Dx, Chelsio T62100-LP-CR, and Intel E810. NVIDIA NICs runs RoCE, and the Chelsio NIC runs iWARP. Intel E810 supports both RoCE and iWARP, but we currently only test its RoCE implementation. RoCE and iWARP are two standard ways to run RDMA over Ethernet-based networks. Our testbed consists of two servers, each equipped with an RNIC, and the two RNICs are connected via a 100 Gbps switch. For NVIDIA RNICs, we have access to their hardware counters, e.g., cache miss counters, through their network adapter management tool NEO-Host [44]. These hardware counters allow us to pinpoint which resource is oversubscribed. For example, when the ICM cache miss counter increases quickly with a certain application workload, we learn that this workload heavily uses this cache, making it oversubscribed. Since other RNICs do not expose such counters, we experiment other RNICs based on their end-to-end performance metrics (e.g., bandwidth).

Scenarios	Alone	Registration	Deregistration
BW / Gbps	96.6	95.9	48.0
Miss Rate	17.2%	22.9%	49.1%

Table 1: MR control verbs exhaust the MTT cache and reduce bandwidth.

3.2 NIC Caches

We are aware that an RNIC has at least three types of caches, as shown in Figure 3. The RNIC stores several types of metadata in these caches to accelerate the request processing, such as the QP contexts in the ICM cache. Prior works have identified some RNIC cache contention problems caused by data verbs with particular patterns. For example, transmitting small messages across many RC QPs simultaneously and random accesses to a large number of memory regions can cause certain types of severe cache misses (e.g., ICM and MTT/MPT) [29, 53]. ScaleRPC [5] found that this scalability problem can reduce the WRITE request rate by 90%.

In addition to these well-known problems, we observe a new, and even more severe way to exhaust caches:

Key finding #1: control verbs can cause excessive cache misses and a drastic performance reduction. Control verbs (e.g., `ibv_reg_mr`) are used to create and destroy objects like MRs and QPs, which will be used by data verbs to transfer data. To the best of our knowledge, there is no study on how control verbs consume RNIC microarchitecture resources. We find that control verbs can easily trigger excessive cache misses, thus degrading bandwidth and request rate.

We demonstrate this finding with a simple experiment on NVIDIA ConnectX-5 RNICs. We let the victim tenant use 6 cores, 16 connections per core, to issue 512B WRITE requests to exhaust the bandwidth capacity of the RNIC (i.e., 100 Gbps). Table 1 shows the results. The victim can achieve 96.6 Gbps with 17.2% MTT cache miss rate. The victim can still achieve line rate under such cache miss rate because QP multiplexing and the RNIC pipeline design can mask the overhead of cache misses to some degree. We let a single-threaded attacker keep registering memory regions (MRs) using `ibv_reg_mr` (~5K registration per second) on the victim’s sender side. In this scenario, the victim’s bandwidth is almost not affected, staying at 95.9 Gbps with the miss rate slightly increased to 22.9%. However, if the attacker keeps deregistering MRs, we can see a significant impact on the victim: the cache miss rate increases to 49.1%, and the bandwidth degrades to 48 Gbps. The overhead under such a high cache miss rate becomes significant and can no longer be masked by the RNIC processing pipeline. It is worthwhile to note that the attacker does not need to issue any data verbs, so the attacker consumes no network bandwidth or request rate at all. Fortunately, we observe that such interference is negligible at the receiver side.

Compared with data verbs, we find that control verbs are

easier to cause performance interference. To overfill cache resources, we need to launch enough in-flight data verbs and force them to randomly access a large number of objects (e.g., MRs). For example, on NVIDIA ConnectX-5 RNIC, we find that it takes 6 threads to access more than 18K MRs with 96 QPs to cause serious enough MTT cache misses that can degrade bandwidth by 40.1%. We believe cache misses due to data verbs will become less serious since RNIC vendors keep increasing on-chip cache resources. In contrast, control verbs impact cache resources by their special semantics instead of simply consuming them, and thus the impact from control verbs can be hard to mitigate. For example, we speculate that the MR deregistration may invalidate the entire MTT/MPT cache to avoid accessing outdated MRs. This causes cache misses for accessing other MRs.

We also conduct the same experiments on Chelsio and Intel NICs, and we observe similar results.

3.3 Processing Units

The RNIC has several processing units (PUs) to process verbs requests. Due to the lack of public available counters to monitor the status of PUs, we use the request rate as the metric to measure how PUs are consumed by different verbs. We summarize the following two key findings:

Key finding #2: performance interference between different data verbs depends on the complexity of verbs. Different data verbs have different complexities. Simple verbs, like `send` and `read`, only copy data between machines. Complex verbs, such as `fetch_and_add`, atomically add a 64-bit value to the memory of a remote address. This operation leverages PCIe features (e.g., read-modify-write transactions), and may also acquire a lock on the target address. These complex verbs consume more PU resources, resulting in a lower request rate [29]. Our new discovery here is that this difference in resource consumption can also open a new pathway for performance interference through resource exhaustion: a victim’s performance can be substantially penalized when colocated with an attacker that uses complex verbs intensively.

To understand this effect, we first measure the data verbs request rate when competing with other data verbs. We begin with the NVIDIA 100 Gbps ConnectX-5 RNIC. We set up two workloads for each test, and each workload runs 8 QPs across 8 dedicated CPU cores to saturate the RNIC’s rate. To avoid RNIC severe cache misses, we only use 128 QPs in total and 16 MRs. We observe less than 1% cache miss in all the PU tests. To avoid reaching the bandwidth capacity limit, we use 8B as the request size of all data verbs. We first set up one workload (victim) using a particular type of data verbs, and then set up the attacker workload with different types of data verbs. We show their request rate results in Figure 4.

Our first takeaway is that in addition to the ATOMIC operations [29], the READ operations are also more expensive than SEND/RCV and WRITE. When they are running alone (as victim traffic), FAA and CAS only achieve 5.2 Mrps and 4.8

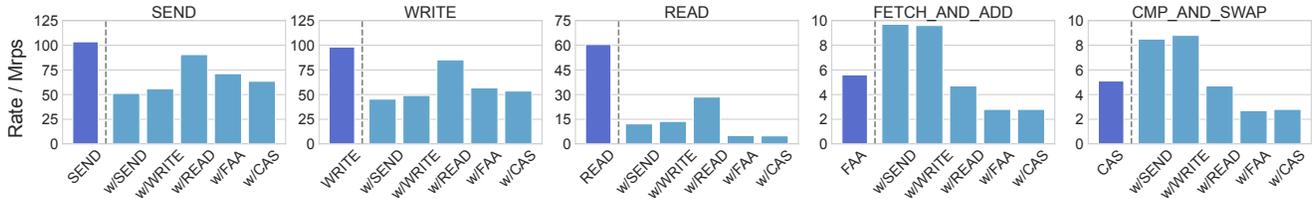

Figure 4: The contention of different data verbs on PU (NVIDIA). The leftmost bar on each subfigure is the request rate of running the victim only. The right 5 bars of each subfigure are the victim’s rate when the attacker is running.

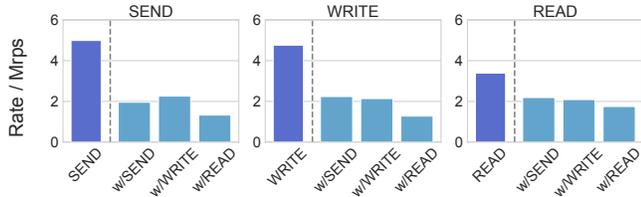

Figure 5: The contention of different data verbs on PU (Chelsio). The leftmost bar on each subfigure is the request rate of running the victim only. The right 3 bars of each subfigure are the victim’s rate when the attacker is running.

Mrps respectively. READ achieves approximately 60 Mrps. SEND and WRITE can achieve more than 90 Mrps.

The second and the more important takeaway is that the contention behavior between different combinations of data verb operations can vary. For example, when the victim runs a READ workload alone, it can achieve 60 Mrps. If the attacker runs a CAS workload, the victim’s request rate immediately drops to 3 Mrps. If the attacker runs a READ workload, the victim’s request rate only drops to 30 Mrps. This means the complex verbs (e.g., CAS) can consume more resources and penalize other colocated verb workloads. One non-intuitive behavior we want to highlight is that the request rate of the victim running FAA or CAS can actually increase if the attacker runs a SEND or WRITE workload under this setting¹.

We also conduct similar tests on 100 Gbps Chelsio T62100-LP-CR RNIC, and the results are shown in Figure 5. This iWARP RNIC does not support ATOMIC operations. We observe that the iWARP RNIC’s request rate for all types of data verbs is lower compared with RoCE RNICs, which matches findings from previous works [8, 49, 71]. We find that the contention among data verbs on Chelsio’s RNIC also varies. For example, the victim with WRITE workload can achieve 4.76 Mrps without interference. The attacker can cause the victim’s request rate to drop 55.0% with SEND workload and 73.1% with READ workload. The specific patterns are different from NVIDIA RNIC, but this result still demonstrates our key finding: the PU overhead of different data verbs varies.

Key finding #3: error handling can stall RNIC processing units and hang all the applications. RNICs need to handle a few types of errors, including transport timeout (the responder side does not send an ACK or NACK), Receive Not Ready

¹We report this to the RNIC vendor and this observation is acknowledged. However, the root cause currently has not been figured out yet.

Scenario	Victim Bandwidth	SEND Bandwidth
Victim Only	97.07	-
w/o RNR	93.53	4.01
w/ RNR	0.018	0

Table 2: The impact of RNR errors on bandwidth. The unit is Gbps.

(RNR) error (the responder does not have enough receive requests for arriving send requests), local or remote protection error (the posted request does not reference a valid local or remote memory region), and local operation error (an opcode is operated on the wrong type of QP). Handling these errors require resources from RNIC processing units and some errors can be expensive for RNICs to handle.

On NVIDIA ConnectX-5 and ConnectX-6 RNICs, we find handling RNR errors can *completely* stall the RNIC processing units. For the victim, we use Perfctest [56] to keep 128 outstanding 64KB WRITE requests on a single QP to saturate the bandwidth capacity. For the attacker, we only use a single QP (i.e., the SEND application in the table) to keep only one in-flight 4KB SEND request to consume a small amount of bandwidth. As shown in Table 2, if the SEND application generates traffic normally (e.g., the responder posts enough receive requests), it consumes 4 Gbps bandwidth, and the bandwidth for the victim only drops approximately 3.5 Gbps. However, when the SEND application triggers RNR errors (e.g., the responder side does not post any receive requests), both the SEND application and the victim are *stalled*. We test this RNR errors with both directions and see the same results. The reason is that the RNIC of the RNR receiver is stalled, and the RNIC cannot even process the ACK packet. The victim therefore is stalled even when they are sending traffics in the opposite direction.

We conduct the same experiments using both Intel and Chelsio NICs. We observe that the victim’s QP connections are also terminated unexpectedly during data transfer for Intel E810. Fortunately, we do not see such RNR issue for Chelsio T62100-LP-CR. Our best guess is that the iWARP is designed on the top of TCP and aimed at running on a lossy fabric, so it may have a more effective error handling mechanism.

3.4 PCIe Bandwidth

The RNIC is connected to the PCIe controller and transfers data from/to the CPU using PCIe lanes. The impact of PCIe

on the networking stacks has been studied by several prior works [29, 34, 52]. Based on existing PCIe models, we further study how RDMA verbs consume and even use up the PCIe bandwidth. Previous works have already identified how RDMA loopback traffic can exhaust PCIe bandwidth [26, 33]. We therefore focus on the normal RDMA TX and RX traffic. To transfer an RDMA message, PCIe introduces the following types of extra bytes: (1) an MMIO to ring the doorbell on the RNIC (64B, depending on cache line size), (2) a Work Queue Element (WQE) (36B or 64B), (3) the PCIe protocol overhead (e.g., TLP headers), and (4) extra PCIe operations triggered by cache misses. Our key observation for PCIe bandwidth is:

Key finding #4: PCIe bandwidth will only become the bottleneck when the request size is in a specific range. We only need a single tenant to demonstrate this key finding. We run the experiment on NVIDIA 100 Gbps ConnectX-5 RNIC. The PCIe bandwidth capacity is 128 Gbps (PCIe Gen 3.0 x16). We use 96 QPs across 6 cores to saturate the PCIe TX bandwidth. Each QP keeps 256 outstanding WRITE requests. We vary the request size and collect both the NIC and the PCIe bandwidth consumption by reading the RNIC’s counters. The result is shown in Figure 6. We first observe that when the payload size is small, the commodity RNIC can mitigate the WQE overhead by embedding the small message in the WQE. As shown in the green rectangle, when the request size is smaller than 28B, increasing the request size does not cause more PCIe bandwidth consumption because the payload is embedded in the same MMIO operation with the WQE.

Our second observation is that PCIe TX bandwidth may only become the bottleneck when the payload size of the request is in a specific range. The reason is that short requests are first throttled by the request rate before exhausting PCIe bandwidth while large requests are always throttled by the RNIC’s bandwidth capacity. We confirm this observation through a theoretical PCIe consumption model and we present two concrete examples. We assume the network MTU is 4096B and the maximum payload per PCIe transaction is 128B (the worst setting to maximize the PCIe overhead). The TLP overhead depends on the implementation [52] and we assume it as 20B, a typical size for a PCIe 3.0 device. Transmitting a 29-byte message will consume at most 127 network bytes and at least 189 PCIe bytes [29, 69]. Therefore, to saturate the link bandwidth (100 Gbps), we need at least 148.8 Gbps PCIe bandwidth, which is much larger than the PCIe 3.0x16 capacity. Appendix A includes the detailed computation. Our measurement shows that the actual consumption can be even higher, as shown in Figure 6. The consumption model for PCIe RX bandwidth (i.e., the RNIC to the host) is similar to that of TX. Additionally, too many cache misses may also cause high PCIe bandwidth consumption due to lots of PCIe reads to fetch metadata. However, in most scenarios, the large number of cache misses will first slow down the RNIC execution (e.g., introduce extra latency) and the PCIe bandwidth is therefore less consumed. In our measurement

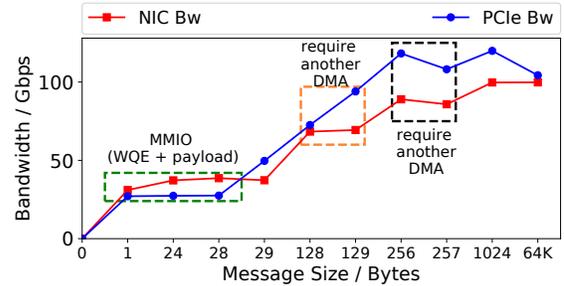

Figure 6: The PCIe bandwidth and RNIC bandwidth consumed by the application.

of cache misses, we do not observe cases where PCIe TX bandwidth is exhausted.

Both the theoretical model and our experimental results demonstrate that the PCIe bandwidth can become the bottleneck, but only for a particular request size range.

3.5 Other findings

We also have several other interesting findings. In the interest of space, we only briefly present them here. However, we do use these findings to guide our test suite design in §4.

Other finding #1: Data verbs contend for different RNIC caches. We conduct the scalability test using different data verbs, and observe different types of cache contention. For example, a large number of RC QPs that issue READ and WRITE will mainly cause ICM cache misses. A large number of UD QPs that issue SEND/RECV requests or many RC QPs that issue ATOMIC requests can cause severe RECV WQE cache misses. This observation indicates that data verbs contend for cache differently, similar to the contention on RNIC PUs.

Other finding #2: Wide range access across many objects (QP, CQ, MR) causes ICM cache misses. The scalability issue has been well studied, but our measurement reveals new observations. In addition to QP and MR, the context of the completion queue (CQ) is also stored in the ICM cache. Thus, accessing a large number of CQs can also trigger severe ICM cache misses. In addition, allocating a large number of these objects does not necessarily cause severe ICM cache misses. Wide range access across the objects (i.e., poor locality) is the key to triggering severe ICM cache misses and performance degradation.

Other finding #3: The impact of control verbs is restricted by its kernel involvement. We observe that all control verbs are first processed by the kernel drivers, thus causing expensive context switch. The execution rates of these control verbs are usually throttled by the kernel instead of RNIC processing. Therefore, control verbs have a limited impact on exhausting RNIC PUs. However, they can still cause significant performance interference and affect the other applications by triggering severe cache misses, as our key finding #1 shows.

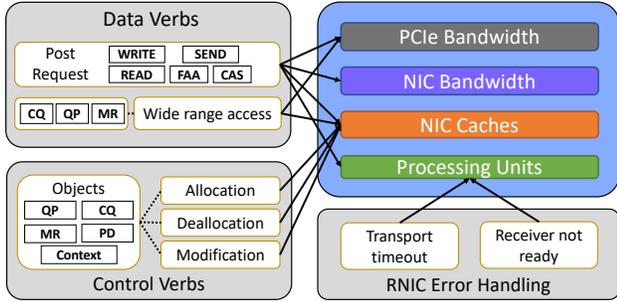

Figure 7: The relationship between verbs and microarchitecture resources. The arrow indicates heavy resource consumption.

3.6 The Resource Consumption Model

We summarize our findings in an RDMA operation model shown in Figure 7. This model describes which microarchitecture resource a verb operation consumes *heavily*. Note that a verb operation can also use other microarchitecture resources that are not captured by our experiments. This is because the usages of these resources are low and do not lead to resource contention. This model is *qualitative*: we do not try to understand the exact resource usage since we have no visibility into proprietary RNIC hardware. For example, we know a certain traffic pattern can trigger a certain type of cache misses, but we does not figure out the total size of the cache or how much of the cache an operation consumes. Even so, we show that this model is sufficiently powerful for us to create the first test suite for RNIC performance isolation, and it can capture a wide range of workloads that can break existing performance isolation solutions.

4 The Husky Test Suite

After we understand how different RDMA operations use these microarchitecture resources, we can design a test suite to evaluate performance isolation solutions. Our goal is the following: given an RNIC hardware and a performance isolation solution, we want to find a set of workloads combinations for an attacker and a victim that can break the performance isolation. We need to check different victim workloads for completeness because different victim workloads are sensitive to exhaustion of different microarchitecture resources.

Our test suite must be general: we will use it to test various RNIC performance isolation solutions on different RNICs. This means we cannot rely on tools and features from specific vendors, such as Mellanox Neo-Host [44]. In addition, different RNICs have different amounts of microarchitecture resources. And existing performance isolation solutions may only be able to mitigate contention on specific resources.

To this end, we build Husky to systematically test and evaluate RNIC performance isolation solutions. Husky targets at four types of resources: NIC bandwidth, PCIe bandwidth, NIC PU, and NIC cache. For each type of resource, we design synthetic workloads with different types of behaviors (e.g., control verbs) to exhaust this resource. More specifi-

cally, we exhaust NIC BW with long messages using different opcodes (e.g., WRITE); we exhaust PCIe bandwidth with loopback traffic and specific message patterns (from key finding #4); we exhaust NIC PU with expensive data verbs (key finding #2), small messages, or error handling behaviors (key finding #3); we exhaust different types of RNIC cache with intensive control verbs (key finding #1) and a wide range access of data verbs. We vary parameters (e.g., connection types) of some synthetic workloads to be more inclusive. In all, Husky includes 52 attacker synthetic workloads (6 for NIC BW, 4 for PCIe BW, 14 for NIC PU, and 28 for NIC cache) and 20 synthetic victim workloads. Many of the attacker workloads cannot be directly generated with existing RDMA traffic engines. We therefore extend Collie [33]’s traffic engine, the most flexible one to the best of our knowledge, to generate these synthetic RDMA traffics, including flexible control verbs workloads and error handling workloads.

Husky’s framework can also easily allow running real applications as additional victim workloads. Husky currently contains two real applications, including the OSU benchmark [54] and eRPC-based Masstree key-value store [27, 40]. The OSU benchmark contains workloads such as allreduce and allgather. Note that we can integrate any RDMA applications into Husky. We test all the (victim, attacker) workload pair exhaustively from our test suite.

One key question is how to define a violation of performance isolation. Our definition of violation depends on the concrete isolation solution. Husky uses a user-specified predicate to compute the expected performance results when isolation is enabled. Husky compares the actual performance with the expected performance to identify violation. For example, most of existing performance isolation solutions only provide bandwidth guarantee. The expected performance for these isolation solutions therefore is a guaranteed bandwidth, B_g . We assume the application can consume bandwidth of B_a when running alone. The bandwidth of this application should be at least $(1 - \alpha) \min(B_a, B_g)$ under *any* attacker workload, where α is a tolerance level. A lower α means stricter isolation. We use an example to demonstrate how this definition works: let us assume that attacker and the victim are configured to share the same 100 Gbps network and we set α to be 25%. If the victim can achieve 60 Gbps when running alone, it should be able to achieve at least $(1 - 25\%) \min(60, 50) = 37.5$ Gbps under the attacker’s workload. If the victim can only achieve 10 Gbps when running alone, its consumed bandwidth should not be less than $(1 - 25\%) \min(10, 50) = 7.5$ Gbps. In practice, we find all existing performance isolation solutions for commodity RNICs are bandwidth guarantee or can be translated into bandwidth guarantee. We use this definition for performance isolation violation in §5 and set α to be 25%.

5 Evaluation

We use a NVIDIA testbed to evaluate existing RDMA performance isolation solutions. There are two servers in the testbed,

Resource Isolation Mechanism	Processing Units			RNIC Cache		PCIe BW
	Error Handling (RC)	Error Handling (UD & UC)	Data Verbs	Control Verbs	Data Verbs	Data Verbs
SR-IOV	✓	✗	✗	✗	✗	✗
HW TC	✗	✗	✗	✗	✗	✗
SR-IOV + HW TC	✓	✗	✗	✗	✗	✗
Justitia	✗	✗	✓	✗	✗	✗
Justitia + HW TC	✗	✗	✓	✗	✗	✗

Table 3: Performance isolation violation caused by exhausting microarchitecture resource. Justitia can only provide isolation among applications using the same function, so cannot be combined with SR-IOV. ✓ means performance isolation is properly enforced. ✗ means Husky can find a workload pair (attacker, victim) to violate performance isolation by exhausting microarchitecture resources.

and each is equipped with one 100 Gbps NVIDIA ConnectX-5 RNIC. The server is equipped with Intel Xeon Gold 5215 CPUs, and the RNICs are connected to the server through PCIe 3.0 x16. The RNICs are connected to a 100 Gbps NVIDIA switch. We use Ubuntu 20.04 and the kernel version is 5.11. For NVIDIA NICs, the kernel drivers and verbs libraries are both from 5.4-OFED. The firmware version is 16.31.1014. We also conduct all the experiments also on NVIDIA ConnectX-6 RNICs and the result is similar.

We evaluate 3 different isolation solutions provided by RNIC vendors and prior work: (1) *NVIDIA separate hardware traffic class (HW TC)*. Cloud operators can set separate TCs for different tenants to use, which separate the RNIC bandwidth and packet buffers [47] to enforce performance isolation. Modern RNICs typically only have 8 traffic classes. This means we cannot use HW TC when we want to colocate more than 8 tenants in a physical server. (2) *NVIDIA SR-IOV*. Though the SR-IOV technique is designed for hardware virtualization, it provides separate virtual functions with some separated resources to different tenants and actually achieves some degrees of performance isolation [45]. (3) *Justitia, a software-based performance isolation solution* [71]. Justitia implements data verbs rate-limiting and pacing in RDMA userspace libraries to enforce performance isolation. This means Justitia has no security: malicious applications can easily circumvent the userspace library. Although Justitia’s software architecture does not target a multi-tenant public cloud environment, we still use Husky to evaluate the effect of its isolation policy (e.g., its token-based algorithm). We also evaluate all the possible combinations of the above solutions². Unfortunately, though we have a testbed with Chelsio T62100-LP-CR and Intel E810 NICs, we did not enable their hardware-based isolation mechanisms. Justitia also does not support Chelsio or Intel drivers. We therefore are not able to conduct the same evaluation on Chelsio or Intel NICs.³

²We do not test Justitia with SR-IOV because Justitia only isolates traffic through the same device. When SR-IOV is enabled, tenants are using different devices (i.e., VF) and Justitia does not work for that scenario.

³We contact the NIC vendors and have multiple rounds of conversations with their experts. However, we still fail to enable any hardware isolation solution for RDMA on both NICs. In addition, we are not aware of any prior work that can set up such RDMA isolation.

5.1 Testing Existing Performance Isolation Solutions

Based on the types of verbs and the exhausted resources, we categorize the workloads generated by Husky into 6 groups. We distinguish the error handling of RC from UD & UC because they cause different behaviors of RNIC PU, and we observe some isolation solution (e.g., SR-IOV) provides different degrees of isolation on these PU behaviors.

We first take a look at the hardware-based isolation mechanism provided by NVIDIA. For *NVIDIA SR-IOV*, we enable two virtual functions (VF) and assign both the victim tenant and the attacker tenant with one VF. We also enable the VF-based rate limiter and restrict the maximal TX bandwidth of each tenant to be 50 Gbps, which is a typical fair sharing setting for the public multi-tenant environment. Given this configuration, we therefore define the isolation violation for *NVIDIA SR-IOV* as the victim’s consumed bandwidth (in terms of bits per second) being reduced by the attacker to less than $(1 - \alpha) \min(50, B_a)$, where α is 25% and B_a is the victim’s bandwidth without attack. For *NVIDIA HW TC*, we assign each tenant with a dedicated TC. For example, the victim exclusively uses TC 0 and the attacker exclusively uses TC 3. We configure TC 0 and TC 3 to equally share the RNIC bandwidth and the NIC buffer (which stores the packets, different from the cache). The violation definition for *NVIDIA HW TC* therefore is the same as that of *NVIDIA SR-IOV*.

The first three rows of Table 3 show the isolation effect provided by SR-IOV, HW TC, and the combination of them. Unfortunately, we find both SR-IOV and HW TC fail to provide enough isolation on RNIC’s microarchitecture resources. For example, by exhausting RNIC’s cache through either control verbs or data verbs, Husky can successfully affect the colocated victim’s applications, even when both SR-IOV and HW TC are enabled. The key reason is that both SR-IOV and HW TC only isolate the architectural resources (e.g., link bandwidth) and do not restrict the cache usage of a single tenant. Husky therefore is able to use an attacker workload that exhausts RNIC cache, such as MTT/MPT cache. Other applications would suffer from severe cache miss and hence the performance drop. In addition, we find that although SR-IOV is mainly aimed at virtualization, it has indeed enforced some isolation, especially for RNIC PUs. The RC RNR error

handling can cause RNIC PUs to pause and even hang the colocated applications if there is no performance isolation mechanism enabled. With SR-IOV, the RC RNR error does not affect tenants running on other VFs. However, the similar RNR exception handling process for UD and UC still violates the isolation of SR-IOV. Due to the RNIC’s black box nature, we do not know the root cause of such a difference. Our best guess is that some part of the RNIC’s PUs (e.g., that handles RC RNR) is isolated by different VFs, while other parts are not well isolated. These hardware-based solutions also cannot isolate PCIe bandwidth well. We observe that an attacker can consume substantial PCIe bandwidth and reduce the victim’s usable bandwidth.

We then evaluate the software-based solution, Justitia. Justitia is not designed for the public cloud and requires the tenant to cooperate (e.g., using modified RDMA libraries). Husky can certainly break its isolation by bypassing the modified libraries, but this would defeat the purpose of testing Justitia. We therefore require all of Husky’s traffics (both the victim and the attacker) to go through Justitia’s modified drivers and be paced by Justitia. In addition, Justitia only supports limited types of data verbs on the latest drivers (i.e., mlx5), so we restrict the applications to only use the opcodes that Justitia supports. Justitia aims at providing each tenant a fair share of the NIC resource. We only set up two tenants, so we simply define the violation of Justitia as the victim’s bandwidth is less than $(1 - \alpha) \min(B_a, 50)$, similar to the definition for SR-IOV. We also test the combination of Justitia and HW TC.

As shown in Table 3, Justitia does provide some PU isolation but to a limited extent. For example, Justitia takes the RNIC’s request rate (i.e., execution throughput) into its isolation consideration. It therefore uses a pacer to control the request rate for each tenant and successfully prevent a single tenant from posting a large number of requests to exhaust the PUs. However, its isolation is violated when the attacker keeps posting requests that trigger error handling on the RNIC. The reason is that these errors are detected and handled by RNIC, which is out of Justitia’s control. In addition, Justitia does not take cache and PCIe into consideration. The attacker tenant therefore can still exhaust the RNIC cache and PCIe bandwidth and cause other tenants to suffer from excessive cache misses or low usable PCIe bandwidth.

It is worthwhile to note that these solutions already provide more or less tolerable isolation for architectural resources, e.g., NIC bandwidth. Husky includes a set of workloads that only contend for NIC bandwidth, and we do not see such violation on those workloads when enabling these solutions. However, ignoring microarchitecture resources makes these solutions insufficient for real public cloud deployment.

5.2 Impact for Real Applications

Next, we conduct experiments on a larger testbed to study how microarchitecture resource exhaustion impacts real application workloads when using state-of-the-art performance

isolation solutions. We use the allreduce workload [54] on an RDMA-based MPI implementation [55] and eRPC-based Masstree (a key-value store) [27, 40] as two real victim applications. Our testbed consists of four physical servers. Each server is equipped with one 100 Gbps NVIDIA ConnectX-5 RNIC. The other settings are the same as §5.1. The victim applications run their VMs on all the four servers. The attacker tenant controls two VMs, each on a different server. We set up the testbed this way to emulate a real multi-tenant environment because an attacker may not have VMs colocated with all the victim’s VMs. However, our results demonstrate that violation of performance isolation in a subset of the victim’s VMs is already enough to substantially reduce the overall end-to-end performance of the real distributed applications.

For protection mechanisms, we enable either SR-IOV + HW TC or Justitia + HW TC to provide isolation for the collective communication application. For eRPC-based Masstree, we only enable SR-IOV + HW TC. This is because Justitia only supports high-performance RDMA WRITE on the latest NVIDIA drivers, but eRPC-based Masstree leverages UD SEND/RECV for its communication.

We use four types of attackers from the Husky test suite to demonstrate our results: (1) **BW attack** is the baseline. We use the standard Perftest [56] `ib_write_bw` to set up a bandwidth-hungry application. It uses 16 RC QPs and each QP keeps 128 outstanding 1 MB WRITE requests to saturate the link bandwidth (consuming ~ 50 Gbps when rate limiter is enabled). BW attack does not target any microarchitecture resources. (2) **PCIe attack** exhausts PCIe TX bandwidth. It runs 36 RC QPs on 6 cores and keeps 128 outstanding 257 B WRITE requests. It also consumes almost 50 Gbps link bandwidth (less than 20 Mrps) but causes more than 73 Gbps PCIe TX bandwidth consumption. This leaves only about 50 Gbps usable PCIe TX bandwidth (i.e., less than 50 Gbps usable network bandwidth) for the victim. (3) **Cache attack** exhausts RNIC cache. It runs 1536 RC QPs on 6 cores, uses 12288 MRs and each QP keeps only a single 256 B outstanding request. This attacker causes severe cache miss and only uses less than 7 Gbps link bandwidth (i.e., 3 Mrps). (4) **PU attack** pauses RNIC PUs. It runs 1 UC QP on a single core and keeps 128 outstanding SEND/RECV requests. Its receiver side does not post any receive requests, so the RNIC has to handle many receive not ready exceptions. It consumes less than 0.5 Gbps and less than 0.5 Mrps.

We begin with testing the RDMA-based allreduce workload. Allreduce is a collective communication operation widely used in distributed deep learning training. It aggregates a vector across all workers and propagates the result back to all workers. We set up 2 workers on each host (8 in total) to run allreduce. The allreduce buffer size is set to 1 MB. We run allreduce continuously and record the execution rate (allreduce operations per second). The raw rate without any isolation mechanism and interference is shown as the leftmost bars in the figure. The bar of no attack indicates the effect of

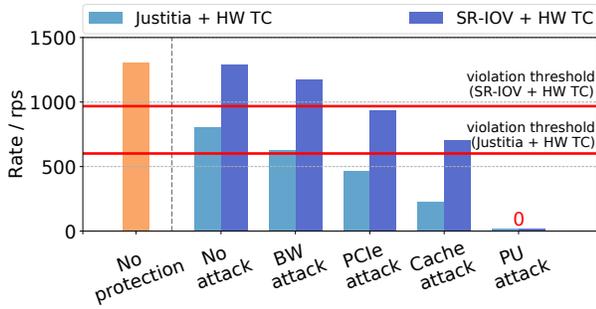

Figure 8: Allreduce results under exhaustion of different resources.

enabling these isolation solutions. When Justitia is enabled, the allreduce rate drops by 38.5%. One possible reason is that Justitia uses a shim layer (the pacer) to exert sender admission control, which introduces extra performance overheads compared to the hardware-based solutions. Since the allreduce workload only uses less than half of the NIC bandwidth (23 Gbps), its performance under attack should be at least $(1 - \alpha)P_a$, where α is 25% and P_a is its performance without any attack. We can then compute a violation threshold in allreduce rate for each isolation solution based on the bandwidth the victim should consume.

The result for allreduce is shown in Figure 8. The horizontal red lines show the violation threshold. Bars under the red line indicate isolation violation. P_a for the application with Justitia + HW TC is 38.5% lower than that with SR-IOV + HW TC. This means the violation threshold is also 38.5% lower for Justitia + HW TC. We first observe that the BW attack only causes a negligible performance drop for SR-IOV + HW TC setting. And Justitia + HW TC also achieves the bandwidth isolation goal within the tolerance. We then observe that all the PCIe, Cache, and PU attacks successfully violate the isolation provided by either Justitia + HW TC or SR-IOV + HW TC. For example, the PCIe attack can cause the performance of the allreduce application to drop 27.3% for SR-IOV + HW TC and 42.1% for Justitia + HW TC. The impact of the Cache attack is more significant. Allreduce workload’s performance drops more than half (71.3%) for Justitia + HW TC and almost half for SR-IOV + HW TC. We observe that the PU attack is the most powerful. It can directly stall the allreduce application by exhausting the RNIC PUs.

We use the same set of attackers to test the eRPC-based Masstree. We use the default setting of eRPC-based Masstree (e.g., key size and the number of threads). We set up the key-value server in one physical server and three clients each in a different physical server. We colocate one attacker VM with the key-value server and another attacker VM with one of the clients. We collect the execution rate (in terms of the number of GET requests per second) and the latency from all the clients. The Masstree server only uses 14 Mrps and less than 20 Gbps, so we define the isolation violation as the same as the violation of allreduce. Figure 9 and Figure 10 show the GET rates and the latency results. The SR-IOV + HW TC

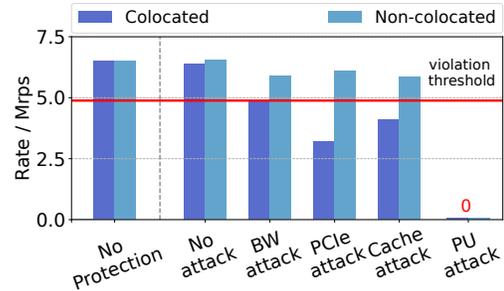

Figure 9: Mastree’s GET rate under exhaustion of different resources. colocated means that the client and the attacker are on the same host. Non-colocated means that they are on different hosts.

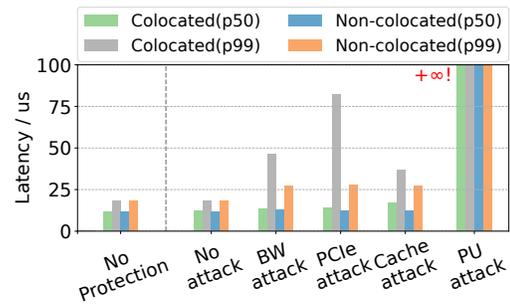

Figure 10: Mastree’s latency under exhaustion of different resources.

more or less achieves the BW isolation goal within tolerance. We find that all microarchitecture resource exhaustion attacks successfully violate the isolation for the client that is colocated with an attacker VM. Similar to the allreduce workload, the PU attacker stalls the entire key-value store system. Worse still, it even pauses the clients that are not colocated with an attacker VM. This is because we stall the key-value server.

Another observation is that the performance of eRPC-based Masstree is impaired by the cache exhaustion attack but to a very limited extent. One possible reason is that the eRPC leverages UD transport. A UD QP does not need as much connection metadata as an RC QP does and therefore is less sensitive to the RNIC internal cache miss. In addition, we find that the Masstree is more sensitive to PCIe exhaustion. This is probably due to its small request size. According to our key finding #4, requests of a relatively small size cause more extra PCIe TX bandwidth consumption.

We have several high-level takeaways from the real application results.

Takeaway #1: targeting microarchitecture resources makes violating performance isolation easy. If we treat the RNIC as a black box, it is quite difficult to break performance isolation. The BW attack targets the bandwidth resource, and we observe that all the existing solutions provide good protection. However, once we know a few more details about how an RNIC works (e.g., the potential microarchitecture resources), breaking isolation becomes simple. Our attack is very efficient. For example, Cache Attack only needs 7 Gbps and 3 Mrps. PU Attack stalls victims with even less bandwidth

and request rate. Note that these attacks are only targeting publicly disclosed microarchitecture components.

Takeaway #2: applications' sensitivity for resource contention is different. Applications' end-to-end performance drops can be quite different even for the same attack. The allreduce application is more sensitive to the cache exhaustion while the Masstree is more vulnerable to the PCIe exhaustion.

Takeaway #3: distributed applications need performance isolation on every single server. For both applications, the attacker only has two VMs, but why does the application-level performance drop substantially even if the application is running across four machines? Many modern distributed systems' performance is usually bottlenecked by a few slowest workers in the system. For example, in allreduce, each iteration requires synchronization of all workers. Thus, our attack on one or two workers can slow down the entire allreduce procedure.

5.3 Analysis for Existing Solutions

Our evaluation shows that all existing approaches fail to provide RDMA performance isolation. We now analyze the fundamental restrictions of these solutions and some potential improvements we may achieve.

SR-IOV and separate HW TC. These hardware based solutions already provide some hardware resource isolation (e.g., the hardware queue and the on-NIC packet buffer). Theoretically, RNIC vendors should be able to incorporate more hardware isolation features to these solutions. For example, to statically separate NIC PU or partition NIC cache for different VFs can help to build a better isolation mechanism for SR-IOV. However, these hardware modifications are non-trivial and can hardly be applied to existing hardware. RNIC vendors usually release these new features together with their new hardware products. Cloud providers thus cannot use these features in existing hardware.

Justitia. Justitia provides modified userspace libraries and uses sender admission control to enforce fair sharing of both bandwidth and execution rates for all tenants. Justitia does not work for a multi-tenant cloud because its policies are not enforceable: a malicious application can easily circumvent the modified user libraries. Putting the security aspect aside, it is worthwhile to ask whether a pure software solution like Justitia could in theory support RDMA performance isolation. We do not have a direct answer to this question, and we believe it is an interesting future research direction. We reckon that this can be quite difficult for the following reasons. First, it is challenging to track and control how much cache a tenant has occupied without hardware support. Second, it is challenging to establish a quantitative resource consumption model for verbs. Finally, error handling is deeply integrated into RDMA NIC hardware, and is opaque to software.

6 Guidelines

Our results show that, unfortunately, no existing RNIC performance isolation solution is sufficient. We analyze the fail-

ure of existing isolation solutions based on our key findings, and we present several design guidelines for potential future RDMA performance isolation work. These guidelines may also be helpful for RDMA application developers to write better RDMA applications under multi-tenant environments.

Hardware support for isolation is needed. Software approaches like Justitia [71] have a common problem. They only monitor architecture-level metrics, e.g., latency, bandwidth, and request rate. They cannot detect contention in microarchitecture resources, e.g., caches, let alone manage and fair share those resources. We believe future performance isolation solutions will have to leverage hardware support, similar to how modern hypervisors can use Intel Resource Director Technology (RDT) to monitor and manage access to the last-level cache and memory. NVIDIA RNICs expose several useful hardware counters, but they are still insufficient. For example, we can only observe cache misses, but we cannot manage the cache access or split the cache for different tenants.

A layer of indirection is needed. RDMA means kernel bypass for data verbs. This enables low latency and reduced CPU overheads. So where should performance isolation be enforced? We believe that future performance isolation solutions will require a layer of indirection either in NIC or in software. Having the enforcement point in the userland RDMA library (as Justitia) does not work, because it lacks security. Instead, a software indirection can have a microkernel-like design, with a set of cores running the isolation logic in a separate protection domain [43]. RDMA performance isolation should be enforced in such a central controller that takes over both control verbs and data verbs.

Programmer, compiler, and library support for RDMA applications. After a future performance isolation solution is invented, applications may need modification as well. If the future performance isolation solution requires strict partitioning of microarchitecture resources, this means each application has limited microarchitecture resources to use and can lead to substantially reduced performance. The amount of microarchitecture resource an application uses may also vary (depending on how many other tenants are on the same server or other configurations). Building high-performance RDMA applications will require additional effort for the programmer, compiler, and application library to efficiently use these limited resources. For CPU cache, these efforts occurred in the research community two decades ago [35, 36, 42].

7 Discussion

The impact of broken RDMA performance isolation. Our evaluation shows that a malicious tenant can cause other tenants' to suffer from drastic performance drop or even get stuck. In addition, a broken performance isolation exposes vulnerability for malicious users to conduct side-channel attacks. Since the tenant can affect others' performance on the same host, it can set up side channels that leak access pat-

terns of victim nodes or deliver information by affecting the host's performance in a pattern [65]. RDMA performance isolation therefore is a critical feature for a secured RDMA public cloud.

What RDMA performance isolation solution should cloud providers use today? One good news is that we are not aware of any cloud provider that currently using commodity RNICs to provide RDMA-capable VMs with partitioned host resources. To rent an RDMA-capable VM, customers have to rent the entire physical machine. This means currently we do not need an RNIC performance isolation solution at all, because the RNIC only runs a single tenant's traffic. To move forward to multi-tenant usage of an RNIC, we believe performance isolation is still a major blocker, and multi-tenancy should not be enabled until a mature performance isolation solution is ready, one that can at least pass our test suite.

Generalizability to other kernel bypass host networking architectures. Our test suite design is based on the *verbs* interface, which is RDMA-specific. However, we believe our methodology should be generalizable to find violations of performance isolation in other kernel bypass architectures, e.g., DPDK [13], IRMA [64], as these implementations commonly require RDMA-like mechanisms in the DMA portion of the design. The industry trend today is to offload functions to hardware accelerators. For example, RDMA is offloading congestion control and reliable message delivery into the hardware. Microarchitecture resources in hardware are critical to delivering these offloaded functions. Paying attention to these microarchitecture resources for performance isolation is going to be increasingly important.

8 Related Work

Microarchitecture resources in RNICs. The existence of RNIC microarchitecture resources is well-known in the networking community, and many studies focus on how to design RDMA applications to circumvent certain RNIC performance anomalies due to these resources. For example, HERD [28], FaSST [30], and eRPC [27] avoid using RDMA reliable connection to mitigate the QP context cache miss for better scalability. ScaleRPC [5] and Flock [50] multiplex reliable connections in a time-sharing manner to mitigate the scalability problem. Kalia et al. [29] studies the RNIC's PCIe behaviors and provides guidelines for writing efficient RDMA programs. Unfortunately, these works only focus on optimizing applications to fully utilize the limited resources in RNICs. However, public cloud providers cannot control the third-party tenants' applications. Collie [33] conducts a systematic search on RDMA performance anomalies, and the anomalies are mostly due to oversubscribed microarchitecture resources. However, since Collie only focuses on first-party traffic, it just builds a search space based on normal operations. It therefore only considers normal data verbs and fails to uncover findings related to other types of behaviors. For example, the key find-

ings #1, #2, and #3 in §3 are fundamentally not covered by Collie's search space because Collie does not take control verbs, error handling, and expensive atomic verbs into consideration. In all, prior works focus more from the perspective of application developers. Our work is on a complementary aspect by looking from the public cloud provider's perspective: how these microarchitecture resources affect performance isolation. This requires us to be microarchitecture resource aware and take a look at all types of RDMA behaviors, including control verbs and error handling, because we need to deal with misbehaving and even malicious tenants.

Other NIC performance isolation solutions. PicNIC [34] provides isolation for both packet processing and bandwidth on NIC. This allows latency-bound workloads not to be affected by bandwidth-bound workloads. FairNIC [15] isolates resources in SoC-based SmartNICs. Compared with them, our work focuses on the RDMA-related resources on NICs.

Performance isolation in other contexts. Performance isolation problems are not limited to NICs. Other server hardware components also have this issue, and they already have corresponding solutions. There exist several partitioning techniques for CPU caches [11, 20] and memory bandwidth [22]. Network bandwidth in the network fabric is also a crucial resource to isolate [1, 3, 4, 6, 16, 24, 25, 37, 58–60, 62, 68] as well as the switch processing pipelines [67].

9 Conclusion

RDMA is a promising networking technology to enable low latency and high CPU efficiency in datacenter networks. To enable RDMA in a multi-tenant environment, performance isolation is an important property, and RDMA NICs (RNICs) bring new challenges due to the existence of microarchitecture resources (e.g., RNIC cache, processing units). We present an RNIC operation model on how these resources are used by different RDMA operations. Using this model, we create Husky, the first test suite to evaluate RNIC performance isolation solutions. Our results show that none of the existing RNIC performance isolation solutions provides sufficient isolation against workloads that try to exhaust these microarchitecture resources. Our findings are acknowledged and reproduced by one of the largest RDMA NIC vendors. We believe that building a usable RNIC performance isolation solution will be a long battle.

Acknowledgement

We thank Chelsio, and Intel for their technical support. We especially thank NVIDIA, who gives us timely and insightful feedback, including the root causes of our findings and the corresponding solutions. We thank our shepherd Brent Stephens and other anonymous reviewers for their insightful feedback. Our work is partially supported by gifts from Adobe, Amazon, Meta, and IBM.

A Network v.s. PCIe

To transmit a payload through Ethernet-based IP-routed RDMA network (i.e., RoCEv2), the network protocol introduces the following overhead.

1. **Ethernet overhead.** Each Ethernet frame includes 14-byte Ethernet (exclude VLAN) header and 4-bytes CRC as L2 overhead. In addition, each Ethernet frame has L1 overhead - each frame is preceded by a 7-byte preamble and 1-byte start-of-frame delimiter. The frame is also followed by an inter-frame gap. The gap should be at least 12-byte. The total Ethernet overhead per frame therefore is 38-byte [23].
2. **IP overhead.** IP overhead comes from the IP header, with a least size 20-byte.
3. **UDP overhead.** UDP overhead comes from the 8-byte UDP header.
4. **Infiniband overhead.** The Infiniband protocol implements headers inside the UDP payload. A simple WRITE message through reliable connection (RC) needs 12-byte Base Transport Header (BTH), 16-byte RDMA Extended Transport Header (RETH), and 4-byte invariant CRC. Hence, the Infiniband protocol overhead is at least 32-byte [2].

To transmit the payload from the host DRAM to the RNIC, the RNIC PCIe behaviors include the following overhead.

1. **Ring the doorbell.** To post a work request, users need to ring the RNIC's doorbell through memory-mapped IO (MMIO). Each MMIO has a fixed aligned size 64-byte.
2. **Work Queue Element.** The RNIC needs to fetch a work queue element (WQE) from host DRAM to the NIC. A WQE for RC/UC is 36-byte, and 68-byte for UD.
3. **TLP overhead.** Each PCIe transaction has PCIe Transaction Layer Packet (TLP) header, and the header size varies for different PCIe implementation. We assume its least size as 20-byte according to [29, 69].

We next shows the computation of the 29-byte payload example in §3. The 29-byte payload is obviously less than the MTU, and can be sent using a single network packet. Therefore, the network bytes consumed by this payload is:

$$\begin{aligned}
 \text{Bytes(network)} &= \text{Bytes(payload)} + \text{Bytes(Ethernet)} \\
 &\quad + \text{Bytes(IP)} + \text{Bytes(UDP)} + \text{Bytes(IB)} \\
 &= 29 + 38 + 20 + 8 + 32 \\
 &= 127(\text{bytes})
 \end{aligned}$$

For PCIe consumption, the 29-byte payload is larger than the maximal inline size (28-byte). So it cannot be delivered

in the same PCIe transaction as the WQE. It therefore needs three PCIe transactions: (1) Doorbell, (2) WQE, and (3) payload, and consume the following bytes:

$$\begin{aligned}\text{Bytes(PCIe)} &= \text{Bytes(payload)} + \text{Bytes(payload TLP)} \\ &+ \text{Bytes(WQE)} + \text{Bytes(WQE TLP)} \\ &+ \text{Bytes(Doorbell)} + \text{Bytes(DB TLP)} \\ &= 29 + 20 + 36 + 20 + 64 + 20 \\ &= 189(\text{bytes})\end{aligned}$$

Therefore, the PCIe consumption for such payload when saturating the link capacity (100 Gbps) is:

$$\begin{aligned}\text{Bandwidth(PCIe)} &= \text{Bandwidth(network)} * \frac{\text{Bytes(PCIe)}}{\text{Bytes(network)}} \\ &= 100 * \frac{189}{127} = 148.8(\text{Gbps})\end{aligned}$$

B Response from NIC Vendors

We report our findings and results to the NIC vendors, including NVIDIA, Intel, and Chelsio. NVIDIA, one of the largest RDMA NIC vendors, has spent substantial effort on acknowledging and reproducing our experiments. They have successfully reproduced all of our findings in their own environment. In addition, NVIDIA provides us with detailed analysis and feedback. We would like to share them here.

Key finding #1: control verbs can cause excessive cache misses and a drastic performance reduction. NVIDIA provides a more accurate analysis of this finding: the deregistration control verbs can cause drastic performance reduction mainly because of the NIC internal QoS scheduling policy. The deregistration control verbs have higher priority than other types of operations and will be scheduled first. Consequently, these deregistration verbs trigger excessive cache misses and cause the performance to drop drastically. NVIDIA has already figured out a solution to address this issue. The high-level idea is to tune the NIC internal QoS policy so that deregistration does not have such a high priority. They are planning for a firmware upgrade to fix this issue.

Key finding #2: performance interference between different data verbs depends on the complexity of verbs. NVIDIA is familiar with this phenomenon and will roll out new firmware upgrades to address this issue.

Key finding #3: error handling can stall RNIC processing units and hang all the applications. NVIDIA provides a more accurate explanation of this phenomenon: for unreliable transport types (UC and UD), there is not the same specific RNR exception handling procedure as RC. Instead, they have other processing logic that involves firmware that handles

out-of-order packets. This is the root cause of the performance interference when attacking using unreliable transport types. NVIDIA also provides a potential solution to mitigate such interference. NVIDIA Connect-X series NICs support monitoring per-VM consumption of the NIC resources. The cloud operators therefore can enforce VM capabilities policy based on the visibility of NIC resources consumption. Furthermore, NVIDIA is planning to introduce an additional layer of protection in the coming NIC firmware/hardware release to completely eliminate the attack vector for RC.

Key finding #4: PCIe bandwidth will only become the bottleneck when the request size is in a specific range. Though PCIe bandwidth contention is not a unique interference brought by RDMA, NVIDIA still acknowledged and confirmed our observation on the PCIe consumption for RDMA NIC.

We thank NVIDIA for their kind and great support. We believe the above understanding will benefit cloud operators and RDMA application developers. In addition, our collaboration with NVIDIA also demonstrates how Husky can help to improve existing RDMA solutions and build robust RDMA performance isolation in the future.

Empowering Azure Storage with RDMA

Microsoft

Abstract

Given the wide adoption of disaggregated storage in public clouds, networking is the key to enabling high performance and high reliability in a cloud storage service. In Azure, we choose Remote Direct Memory Access (RDMA) as our transport and aim to enable it for both storage frontend traffic (between compute virtual machines and storage clusters) and backend traffic (within a storage cluster) to fully realize its benefits. As compute and storage clusters may be located in different datacenters within an Azure region, we need to support RDMA at regional scale.

This work presents our experience in deploying intra-region RDMA to support storage workloads in Azure. The high complexity and heterogeneity of our infrastructure bring a series of new challenges, such as the problem of interoperability between different types of RDMA network interface cards. We have made several changes to our network infrastructure to address these challenges. Today, around 70% of traffic in Azure is RDMA and intra-region RDMA is supported in all Azure public regions. RDMA helps us achieve significant disk I/O performance improvements and CPU core savings.

1 Introduction

High performance and highly reliable storage is one of the most fundamental services in public clouds. In recent years, we have witnessed significant improvements in storage media and technologies [73] and customers also desire similar performance in the cloud. Given the wide adoption of disaggregated storage in the cloud [35, 46], the network interconnecting compute and storage clusters becomes a key performance bottleneck for cloud storage. Despite the sufficient bandwidth capacity provided by Clos-based network fabrics [25, 48], the legacy TCP/IP stack suffers from high processing delay,

low single-core throughput, and high CPU consumption, thus making it ill-suited for this scenario.

Given these limitations, Remote Direct Memory Access (RDMA) offers a promising solution. By offloading the network stack to the network interface card (NIC) hardware, RDMA achieves ultra-low processing latency and high throughput with near zero CPU overhead. In addition to performance improvements, RDMA also reduces the number of CPU cores reserved on each server for network stack processing. These saved CPU cores can then be sold as customer virtual machines (VMs) or used for application processing.

To fully utilize the benefits of RDMA, we aim to enable it for *both* storage frontend traffic (between compute VMs and storage clusters) and backend traffic (within a storage cluster). This is different from previous work [46] that targets RDMA only for the storage backend. In Azure, due to capacity issues, corresponding compute and storage clusters may be located in different datacenters within a region. This imposes a requirement that our storage workloads rely on support for RDMA at regional scale.

In this paper, we summarize our experience in deploying intra-region RDMA to support Azure storage workloads.

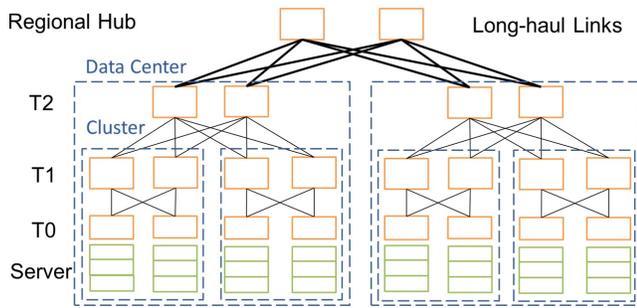

Figure 2: The network architecture of an Azure region.

Compared to previous RDMA deployments [46, 50], intra-region RDMA deployment introduces many new challenges due to high complexity and heterogeneity within Azure regions. As Azure infrastructure keeps evolving incrementally, different clusters may be deployed with different RDMA NICs. While all the NICs support DCQCN [112], their implementations are very different. This results in many undesirable behaviors when different NICs communicate with each other. Similarly, heterogeneous switch software and hardware from multiple vendors significantly increase our operational effort. In addition, long-haul cables interconnecting datacenters cause large propagation delays and large round-trip time (RTT) variations within a region. This brings new challenges to congestion control.

We have made several changes to our network infrastructure, from application layer protocols to link layer flow control, to safely enable intra-region RDMA for Azure storage traffic. We developed new RDMA-based storage protocols with many optimizations and failover support, and seamlessly integrated them into the legacy storage stack (§4). We built RDMA Estats to monitor the status of the host network stack (§5). We leveraged SONiC to enforce a unified software stack across different switch platforms (§6). We updated firmware of NICs to unify their DCQCN behaviors and used the combination of Priority-based Flow Control (PFC) and DCQCN to achieve high throughput, low latency and near zero packet losses (§7).

In 2018, we started to enable RDMA for storage backend traffic. In 2019, we started to enable RDMA to serve customer frontend traffic. Figure 1 gives traffic statistics of all Azure public regions between January 18 and February 16, 2023. As of February 2023, around 70% of traffic in Azure was RDMA and intra-region RDMA was supported in all Azure public regions. RDMA helps us achieve significant disk I/O performance improvements and CPU core savings.

2 Background

In this section, we first present background on Azure’s network and storage architecture. Then, we introduce the moti-

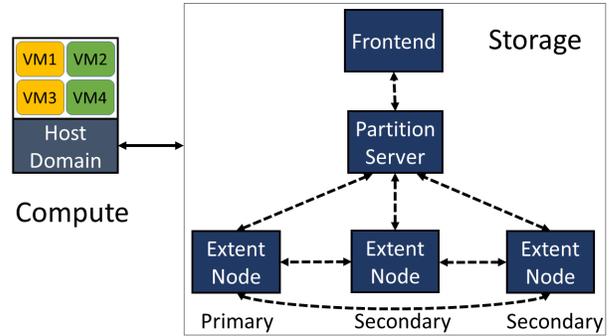

Figure 3: High-level architecture of Azure storage.

vation for and challenges to enabling intra-region RDMA.

2.1 Network Architecture of an Azure Region

In cloud computing, a region [2, 5, 8] is a group of datacenters deployed within a latency-defined perimeter. Figure 2 shows the simplified topology of an Azure region. The servers within a region are connected through an Ethernet-based Clos network with four tiers of switches¹: tier 0 (T0), tier 1 (T1), tier 2 (T2) and regional hub (RH). We use external BGP (eBGP) for routing and equal-cost multi-path (ECMP) for load balancing. We deploy the following four types of units.

- Rack: a T0 switch and the servers connected to it.
- Cluster: a set of racks connected to the same set of T1 switches.
- Datacenter: a set of clusters connected to the same set of T2 switches.
- Region: datacenters connected to the same set of RH switches. In contrast with short links (several to hundreds of meters) in datacenters [50], T2 and RH switches are connected by *long-haul* links whose lengths can be as long as tens of kilometers.

There are two things to notice about this architecture. First, due to long-haul links between T2 and RH, the base round-trip time (RTT) varies from a few microseconds within a datacenter to as large as 2 milliseconds within a region. Second, we use two types of switches: pizza box switches for T0 and T1, and chassis switches for T2 and RH. The pizza box switch, which has been widely studied in the research community, typically has a single switch ASIC with shallow packet buffers [31]. In contrast, chassis switches are built using multiple switch ASICs with deep packet buffers based on the Virtual Output Queue (VoQ) architecture [3, 6].

2.2 High Level Architecture of Azure Storage

In Azure, we disaggregate compute and storage resources for cost savings and auto-scaling. There are two main types of

¹In this paper, we use switch to denote the layer 3 switch which can perform IP routing. We use the terms switch and router interchangeably.

clusters in Azure: compute and storage. VMs are created in compute clusters but the actual storage of Virtual Hard Disks (VHDs) resides in storage clusters.

Figure 3 shows the high-level architecture of Azure storage [35]. Azure storage has three layers: the frontend layer, the partition layer, and the stream layer. The stream layer is an append-only distributed file system. It stores bits on the disk and replicates them for durability, but it does not understand higher level storage abstractions, e.g., Blobs, Tables and VHDs. The partition layer understands different storage abstractions, manages partitions of all the data objects in a storage cluster, and stores object data on top of the stream layer. The daemon processes of the partition layer and the stream layer are called the Partition Server (PS) and the Extent Node (EN), respectively. PS and EN are co-located on each storage server. The frontend (FE) layer consists of a set of servers that authenticate and forward incoming requests to corresponding PSs. In some cases, FE servers can also directly access the stream layer for efficiency.

When a VM wants to write to its disks, the disk driver running in the host domain of the compute server issues I/O requests to the corresponding storage cluster. The FE or PS parses and validates the request, and generates requests to corresponding ENs in the stream layer to write the data. At the stream layer, a file is essentially an ordered list of large storage chunks called "*extents*". To write a file, data is appended to the end of an active *extent*, which is replicated three times in the storage cluster for durability. Only after receiving successful responses from all the ENs, the FE or PS sends the final response back to the disk driver. In contrast, disk reads are different. The FE or PS reads data from any EN replica and sends the response back to the disk driver.

In addition to user-facing workloads, there are also many background workloads in the storage clusters, e.g., garbage collection and erasure coding [57]. We classify our storage traffic into two categories: frontend (between compute and storage servers, e.g., VHD write and read requests) and backend (between storage servers, e.g., replication and disk reconstruction). Our storage traffic has incast-like characteristics. The most typical example is data reconstruction, which is implemented in the stream layer [57]. The stream layer erasure codes a sealed extent to several fragments, and then sends encoded fragments to different servers to store. When the user wants to read a fragment which is unavailable due to a failure, the stream layer will read the other fragments from multiple storage servers to reconstruct the target fragment.

2.3 Motivation for Intra-Region RDMA

Storage technology has improved significantly in recent years. For example, Non-Volatile Memory Express (NVMe) Solid-State Drives (SSDs) can provide tens of Gbps of throughput with request latencies in the hundreds of microseconds [105]. Many customers demand similar performance in the cloud.

High performance cloud storage solutions [1, 4] impose stringent performance requirements to the underlying network due to the disaggregated and distributed storage architecture (§2.2). While datacenter networks generally provide sufficient bandwidth capacity, the legacy TCP/IP stack in the OS kernel becomes a performance bottleneck due to its high processing latency and low single-core throughput. What is worse, the performance of the legacy TCP/IP stack also depends on OS scheduling. To provide predictable storage performance, we must reserve enough CPU cores on both compute and storage nodes for the TCP/IP stack to process peak storage workloads. Burning CPU cores takes away the processing power that could otherwise be sold as customer VMs, thus increasing the overall cost of providing cloud services.

Given these limitations, RDMA offers a promising solution. By offloading the network stack to the NIC hardware, RDMA achieves predictable low processing latency (a few microseconds) and high throughput (line rate for a single flow) with near zero CPU overhead. In addition to its performance benefits, RDMA also reduces the number of CPU cores reserved on each server for network stack processing. These saved CPU cores can then be sold as customer VMs or used for storage request processing.

To fully achieve the benefits of RDMA, we must enable RDMA for both storage frontend traffic and backend traffic. Enabling RDMA for backend traffic is relatively easy because almost all the backend traffic stays within a storage cluster. In contrast, frontend traffic crosses different clusters within a region. Even though we try to co-locate corresponding compute and storage clusters to minimize latency, sometimes they may still end up located in different datacenters within a region due to capacity issues. This imposes the requirement that our storage workloads rely on support for RDMA at regional scale.

2.4 Challenges

We faced many challenges when enabling intra-region RDMA because our design was limited by many practical constraints.

Practical considerations: We aimed to enable intra-region RDMA over the legacy infrastructure. While we had some flexibility to reconfigure and upgrade software stacks, e.g., the NIC driver, the switch OS, and the storage stack, it was *operationally infeasible* to replace the underlying hardware, e.g., the NICs and switches. Hence, we adopted RDMA over commodity Ethernet v2 (RoCEv2) [29] to keep compatibility with our IP-routed networks (§2.1). Before starting this project, we had deployed a significant number of our first generation RDMA NICs, which implement go-back-N retransmission in the NIC firmware with limited processing capacity. Our measurements showed that it took hundreds of microseconds to recover a lost packet, which was even worse than the TCP/IP software stack. Given such a large performance degradation, we made the decision to adopt Priority-based Flow Control

(PFC) [60] to eliminate packet losses due to congestion.

Challenges: Before this project, we had deployed RDMA in some clusters to support Bing services [50], and we learnt several lessons from this deployment. Compared to intra-cluster RDMA deployments [46, 50], intra-region RDMA deployments introduce many new challenges due to the high complexity and heterogeneity of the infrastructure.

- **Heterogeneous NICs:** Cloud infrastructure keeps evolving incrementally, often one cluster or one rack at a time with the latest generation of server hardware [91]. Different clusters within a region may have different NICs. We have deployed three generations of commodity RDMA NICs from a popular NIC vendor: Gen1, Gen2 and Gen3. Each NIC generation has a different implementation of DCQCN. This results in many undesired interactions when different NIC generations communicate with each other.
- **Heterogeneous switches:** Similar to server infrastructure, we keep deploying new switches to reduce costs and increase the bandwidth capacity. We have deployed many switch ASICs and multiple switch OSEs from different vendors. However, this has increased our operational effort significantly because many aspects are vendor specific, for example, buffer architectures, sizes, allocation mechanisms, monitoring and configuration, etc.
- **Heterogeneous latency:** As shown in §2.1, there are large RTT variations from several microseconds to 2 milliseconds within a region, due to long-haul links between T2 and RH. Hence, RTT fairness re-emerges as a key challenge. In addition, the large propagation delay of long-haul links also imposes large pressure on PFC headroom [12].

Like other services in public clouds, availability, diagnosis, and serviceability are key aspects for our RDMA storage system. To achieve high availability, we always prepare for unexpected *zero-day* problems despite large investments in testing. Our system must detect performance anomalies and perform automatic failover if necessary. To understand and debug faults, we must build fine-grained telemetry systems to deliver crystal clear visibility into every component in the end-to-end path. Our system also must be serviceable: storage workloads should survive NIC driver updates and switch software updates.

3 Overview

We have made several changes to our network infrastructure, from application layer protocols to link layer flow control, to safely empower Azure storage with RDMA. We developed two RDMA-based protocols: sU-RDMA (§4.1) and sK-RDMA (§4.2), which we have seamlessly integrated into our legacy storage stack to support backend communication and frontend communication, respectively. Between the storage protocols and the NIC, we deployed a monitoring system RDMA Estats (§5), giving us visibility into the host network

stack by providing an accurate breakdown of cost for each RDMA operation.

In the network, we use the combination of PFC and DCQCN [112] to achieve high throughput, low latency, and near zero losses due to congestion. DCQCN and PFC were the state-of-the-art commercial solutions when we started the project. To optimize the customer experience, we use two priorities to isolate storage frontend traffic and backend traffic. To mitigate the switch heterogeneity problem, we developed and deployed SONiC [15] to provide a unified software stack across different switch platforms (§6). To mitigate the interoperability problem of heterogeneous NICs, we updated the firmware of NICs to unify their DCQCN behaviors (§7). We carefully tuned DCQCN and switch buffer parameters to optimize performance across different scenarios.

3.1 PFC Storm Mitigation Using Watchdogs

We use PFC to prevent congestion packet losses. However, malfunctioning NICs and switches can continually send PFC pause frames in the absence of congestion [50], thus *completely* blocking the peer device for a long time. Moreover, these endless PFC pause frames can eventually propagate into the whole network, thus causing collateral damage to innocent devices. Such *endless* PFC pause frames are called a PFC storm. In contrast, normal congestion-triggered PFC pause frames only *slow down* the data transmission of the peer device through *intermittent* pauses and resumes.

To detect and mitigate PFC storms, we designed and deployed a PFC watchdog [11, 50] on every switch and bump-in-the-wire FPGA card [42] between T0 switches and servers. When the PFC watchdog detects that a queue has been in the paused state for an abnormally long duration, e.g., hundreds of milliseconds, it disables PFC and drops all the packets on this queue, thereby preventing PFC storms from propagating into the whole network.

3.2 Security

We use RDMA to empower first-party storage traffic in a trusted environment, including storage servers, the host domain of compute servers, switches and links. Therefore we are secure against issues described in [69, 94, 104, 109].

4 Storage Protocols over RDMA

In this section, we introduce two storage protocols built on top of RDMA Reliable Connections (RC): sU-RDMA and sK-RDMA. Both protocols aim to optimize performance while keeping good compatibility with legacy software stacks.

4.1 sU-RDMA

sU-RDMA [87] is used for storage backend (storage to storage) communication. Figure 4 shows the architecture of our

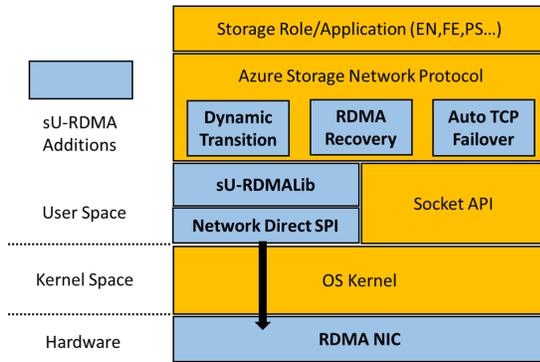

Figure 4: Azure storage backend network stack.

storage backend network stack with the sU-RDMA modules highlighted. The Azure Storage Network Protocol is an RPC protocol directly used by applications to send request and response objects. It leverages socket APIs to implement connection management, sending and receiving messages.

To simplify RDMA integration with storage stack, we built sU-RDMALib, a user space library that exposes socket-like byte-stream APIs to upper layers. To map socket-like APIs to RDMA operations, sU-RDMALib needs to handle the following challenges:

- When the RDMA application cannot directly write into an existing memory regions (MR), it must either register the application buffer as a new MR or copy its data into an existing MR. Both options can introduce large latency penalties and we should minimize these overhead.
- If we use RDMA `Send` and `Receive`, the receiver must pre-post enough `Receive` requests.
- The RDMA sender and receiver must be in agreement on the size of data being transferred.

To reduce memory registrations, which are especially expensive for small messages [44], sU-RDMALib maintains a common buffer pool of pre-registered memory shared across multiple connections. sU-RDMALib also provides APIs to allow applications to request and release registered buffers. To avoid Memory Translation Table (MTT) cache misses on the NIC [50], sU-RDMALib allocates large memory slabs from the kernel and registers memory over these slabs. This buffer pool can also autoscale based on runtime usage. To avoid overwhelming the receiver, sU-RDMALib implements a receiver-driven credit-based flow control where credits represent the resources (e.g., available buffers and posted `Receive` requests) allocated by the receiver. The receiver sends credit update messages back to the sender regularly. When we started designing sU-RDMALib, we did consider using RDMA `Send` and `Receive` with a fixed buffer size S for each `Send/Receive` request to transfer data. However, this design causes a dilemma. If we use a large S , we may waste much memory space because a `Send` request fully uses the receive buffer of the

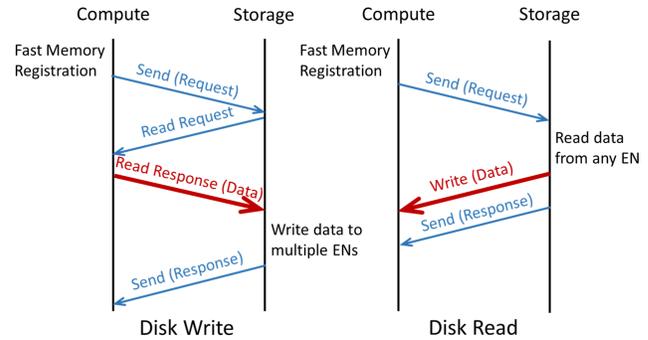

Figure 5: sK-RDMA's data flow. We use blue arrows and red arrows to represent control messages and data messages, respectively. Arrow width represents data size.

Receive request, regardless of its actual message size. In contrast, a small S causes large data fragmentation overhead. Hence, sU-RDMALib uses three transfer modes based on the message size [87].

- Small messages: Data is transferred using RDMA `Send` and `Receive`.
- Medium messages: The sender posts a RDMA `Write` request to transfer data, and a `Send` request with "Write Done" to notify the receiver.
- Large messages: The sender first posts a RDMA `Send` request carrying the description of the local data buffer to the receiver. Then the receiver posts a `Read` request to *pull* the data. Finally, the receiver posts a `Send` request with "Read Done" to notify the sender.

On top of sU-RDMALib, we built modules to enable dynamic transitions between TCP and RDMA, which is critical for failover and recovery. The transition process is gradual. We periodically close a small portion of all connections and establish new connections using the desired transport.

Unlike TCP, RDMA uses rate based congestion control [112] without tracking the number of in-flight packets (the window size). Hence, RDMA tends to inject excessive in-flight packets, thus triggering PFC. To mitigate this, we implemented a static flow control mechanism in the Azure Storage Network Protocol by dividing a message into fixed-sized chunks and only allowing a single in-flight chunk for each connection. Chunking can significantly improve performance under high-degree incast with negligible CPU overhead.

4.2 sK-RDMA

sK-RDMA is used for storage frontend (compute to storage) communication. In contrast with sU-RDMA which runs RDMA in user space, sK-RDMA runs RDMA in kernel space. This enables the disk driver, which runs in kernel space in the host domain of compute servers, to directly use sK-RDMA to

issue network I/O requests. sK-RDMA leverages and extends Server Message Block (SMB) Direct [14] which provides socket-like kernel-mode RDMA interfaces. Similar to sU-RDMA, sK-RDMA also provides credit-based flow control and dynamic transition between RDMA and TCP.

Figure 5 shows sK-RDMA’s data flow for reading and writing disks. The compute server first posts a Fast Memory Registration (FMR) request to register data buffers. Then it posts an RDMA `Send` request to transfer a request message to the storage server. The request carries a disk I/O command, and a description of FMR registered buffers available for RDMA access. According to the InfiniBand (IB) specification, the NIC should wait for the completion of the FMR request before processing any subsequently posted requests. Hence, the request message is actually pushed onto the wire after the memory registration. The data transfer is initiated by the storage server using RDMA `Read` or `Write`. After the data transfer, the storage server sends a response message to the compute server using RDMA `Send With Invalidate`.

To detect data corruptions, which can happen *silently* due to various software and hardware bugs along the path, both sK-RDMA and sU-RDMA implement a Cyclical Redundancy Check (CRC) on all application data. In sK-RDMA, the compute server calculates the CRC of the data for disk writes. These calculated CRCs are included in the request messages, and used by the storage server to validate the data. For disk reads, the storage server performs the CRC calculations and includes them in the response messages, and the compute server uses them to validate the data.

5 RDMA Estats

To understand and debug faults, we need fine-grained telemetry tools to capture behaviors of every component in the end-to-end path. Despite many existing tools [51, 97, 114] to diagnose switch and link faults, none of these tools gives us good visibility into the RDMA network stack at end hosts.

Inspired by diagnostic tools for TCP [79], we developed RDMA Extended Statistics (Estats) to diagnose performance problems in both the network and the host. If an RDMA application is performing poorly, RDMA Estats enables us to tell if the bottleneck is in the sender, the receiver, or the network.

To this end, RDMA Estats provides a fine-grained breakdown of latency for each RDMA operation, in addition to collecting regular counters such as bytes sent/received and number of NACKs. The requester NIC records timestamps at one or more measurement points as the work queue element (WQE) traverses the transmission pipeline. When a response (ACK or read response) is received, the NIC records additional timestamps at measurement points along the receive pipeline (Figure 6). The following measurement points are required in any RDMA Estats implementation in Azure

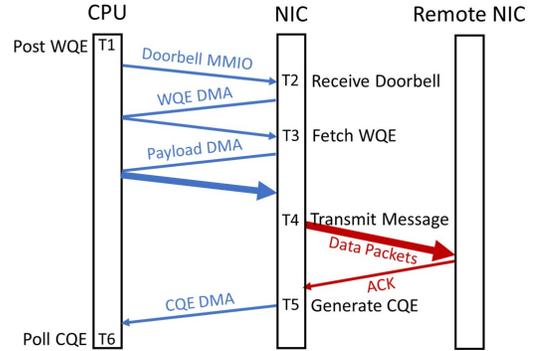

Figure 6: RDMA Estats measurement points. There are four NIC timestamps and two host timestamps. We use blue arrows and red arrows to represent PCIe transactions and network transfers, respectively. Arrow width represents data size.

T_1 : WQE posting: Host processor timestamp when the WQE is posted to the submission queue.

T_5 : CQE generation: NIC timestamp when the completion queue element (CQE) is generated in the NIC.

T_6 : CQE polling: Host timestamp when the CQE is polled by software.

In Azure, the NIC driver reports various latencies derived from the above timestamps. For example, $T_6 - T_1$ is the operation latency seen by the RDMA consumer, while $T_5 - T_1$ is the latency seen by the NIC. A user-mode agent groups the latency samples by connection, operation type, and (success/failure) status to create latency histograms for each group. By default, a histogram covers a one-minute interval. Each histogram’s quantiles and summary statistics are fed into Azure’s telemetry pipeline. As our diagnostics evolved, we added to our user-mode agent the ability to collect and upload NIC and QP state dumps during high latency events. Finally, we extended the scope of event-triggered data collection by the user-mode agent to include NIC statistics and state dumps in case of events not specific to RDMA (e.g., servicing operations that impact connectivity).

The collection of latency samples adds overhead to the WQE posting and completion processing code paths. This overhead is dominated by keeping the NIC and host time stamps synchronized. To reduce the overhead, we developed a clock synchronization procedure that attempts to minimize the frequency of reading the NIC clock registers, while maintaining low deviations.

RDMA Estats can significantly reduce the time to debug and mitigate storage performance incidents by quickly ruling out (or in) network latency. In §8.3, we share our experience in diagnosing the FMR hidden fence bug using RDMA Estats.

6 Switch Management

6.1 Overcoming Heterogeneity with SONiC

Our RDMA deployment heavily relies on the support of switches. However, heterogeneous switch ASICs and OSEs from multiple vendors have brought significant challenges to network management. For example, commercial switch OSEs are designed to satisfy diverse requirements of all the customers, thus leading to complex software stacks and slow feature evolution [39]. In addition, different switch ASICs provide different buffer architectures and mechanisms, thus increasing the effort to qualify and test them for Azure’s RDMA deployment.

Our solutions to the above challenges were two-fold. On one hand, we worked closely with our vendors to define concrete feature requirements and test plans, and to understand their low-level implementation details. On the other hand, in collaboration with many partners, we developed and deployed an in-house cross-platform switch OS called Software for Open Networking in the Cloud (SONiC) [15]. Based on a Switch Abstraction Interface (SAI) [20], SONiC manages heterogeneous switches from multiple vendors with a simplified and unified software stack. It breaks apart monolithic switch software into multiple containerized components. Containerization provides clean isolation, improves development agility, and enables choices on a per-component basis. Network operators can customize SONiC with only the features they require, thereby creating a "lean stack".

6.2 Buffer Model and Configuration Practices of SONiC on Pizza Box Switches

SONiC provides all the features required by RDMA deployments, such as ECN marking, PFC, a PFC watchdog (§3.1) and a shared buffer model. In the interest of space, we briefly introduce the buffer model and configuration practices of SONiC on pizza box switches, which are used at T0 and T1 (§2.1). We provide a buffer configuration example in §A.

We typically allocate three buffer pools on a pizza box switch: (1) the `ingress_pool` for ingress admission control of all packets, (2) the `egress_lossy_pool` for egress admission control of lossy packets, and (3) the `egress_lossless_pool` for egress admission control of lossless packets. Note that these buffer pools and queues are not backed by separate dedicated buffers, but instead are essentially counters applied to a single physical shared buffer and used for admission control purposes. Each counter is updated only by the packets mapped to it, and the same packet can be mapped to multiple queues and pools simultaneously. For example, a lossless (lossy) packet of priority p from source port s to destination port d updates ingress queue (s, p) , egress queue (d, p) , `ingress_pool` and `egress_lossless_pool` (`egress_lossy_pool`). A packet is accepted only if it passes both ingress and egress admission controls. Counters incre-

ment by the size of the admitted packet, and decrement by the size of the departing packet. We use both dynamic thresholds [40] and static thresholds to limit the queue lengths.

We apply ingress admission control only to lossless traffic, and we apply egress admission control only to lossy traffic. If the switch buffer size is B , then the `ingress_pool` size must be smaller than B , reserving enough space for PFC headroom buffer (§7.1). When an ingress lossless queue hits the dynamic threshold, the queue enters the “paused” state, and the switch sends PFC pause frames to the upstream device. Future arriving packets on this ingress lossless queue use the PFC headroom buffer rather than `ingress_pool`. In contrast, for ingress lossy queues we configure a static threshold which equals to the switch buffer size B . Since ingress lossy queue lengths cannot hit the switch buffer size, lossy packets can *bypass* ingress admission control.

At egress, lossy and lossless packets are mapped to the `egress_lossy_pool` and `egress_lossless_pool`, respectively. We configure both the size of the `egress_lossless_pool` and the static thresholds for egress lossless queues to B so that lossless packets bypass egress admission control. In contrast, the size of the `egress_lossy_pool` must be no larger than the size of the `ingress_pool` because lossy packets should not use any of the PFC headroom buffer at ingress. Egress lossy queues are configured to use dynamic thresholds [40] to drop packets.

6.3 Testing RDMA Features with SONiC

We use nightly tests to track the quality of SONiC switches. In this section, we briefly introduce our methods for testing RDMA features with SONiC switches.

Software-based Tests: We leveraged the Packet Testing Framework (PTF) [10] to develop test cases for SONiC in general. PTF is mostly used for testing packet forwarding behaviors, with which testing RDMA features require additional effort.

Our testing approach is inspired by breakpoints in software debugging. To set a “breakpoint” for the switch, we first block the transmission of a switch port using SAI APIs. We then generate a series of packets destined for the blocked port and capture one or several snapshots of the switch states (e.g., buffer watermark), analogous to dumping the values of variables in software debugging. Next, we release the port and dump the received packets. We determine if the test passes by analyzing both the captured switch snapshots and the received packets. We use this approach to test buffer management mechanisms, buffer related counters, and packet schedulers.

Hardware-based Tests: While the above approach gives us good visibility into switch states and packet micro-behaviors, it cannot meet the stringent performance requirements of some tests. For example, to test PFC watchdog [50], we need to generate continuous PFC pause frames at high speed and accurately control their intervals due to the small pause duration

enforced by each PFC frame.

To conduct such performance-sensitive tests, we need to control traffic generation at μ s or even ns timescales and have high-resolution measurement of data plane behaviors. This motivated us to build a hardware-based test system by leveraging hardware programmable traffic generators [9]. Our hardware-based system focuses on testing features like PFC, PFC watchdog, RED/ECN marking.

As of February 2023, we built 32 software test cases and 50 hardware test cases for RDMA features. The documentation and implementation of our test cases are available at [18].

7 Congestion Control

We use the combination of PFC and DCQCN to mitigate congestion. In this section, we discuss how we scale both techniques at regional scale.

7.1 Scaling PFC over Long Links

Once an ingress queue pauses the upstream device, it requires a dedicated headroom buffer to absorb in-flight packets before the PFC pause frame takes effect on the upstream device [50, 112]. The ideal PFC headroom value depends on many factors, e.g., link capacity and propagation delay [12]. The total demand on the headroom buffer for a switch is also in proportion to the number of lossless priorities².

To extend RDMA from cluster scale [46, 50] to regional scale, we must deal with long links between T2 and RH (tens of kilometers), and between T1 and T2 (hundreds of meters), which demand much larger PFC headroom than that of intra-cluster links. At first glance, it may seem that a T1 switch in our production environment can reserve half of the total buffer for PFC headroom and other usages. At T2 and RH, given the high port density (100s) of chassis switches and long-haul links, we need to reserve several GB of PFC headroom buffer.

To scale PFC over long links, we leverage the fact that pathological cases, e.g., all the ports are congested simultaneously, and ingress lossless queues of a port pause peers sequentially, are likely to be rare. Our solution is two-fold. First, on chassis switches at T2 and RH, we use deep packet buffers of off-chip DRAM³ to store RDMA packets. Our analysis shows that our chassis switches in production can provide abundant DRAM buffers for PFC headroom. Second, instead of reserving PFC headroom per queue, we allocate a PFC headroom pool shared by all the ingress lossless queues on the switch. Each ingress lossless queue has a static threshold to limit its maximum usage in the headroom pool. We oversubscribe the headroom pool size with a reasonable ratio,

²For an ingress port, the worst case is that its lossless queues *sequentially* pause the peer queues, and none of its packets can be drained from the buffer.

³Unlike on-chip SRAM, the bandwidth of off-chip DRAM is slightly smaller than the forwarding capacity of the switch ASIC. When all the ports send and receive traffic at line rate, DRAM will suffer from packet drops.

thus leaving more shared buffer space to absorb bursts. Our production experience shows that the oversubscribed PFC headroom pool can effectively eliminate congestion losses and improve burst tolerance.

7.2 DCQCN Interoperability Challenges

We use DCQCN [112] to control the sending rate of each queue pair (QP). DCQCN consists of three entities: the sender or reaction point (RP), the switch or congestion point (CP), and the receiver or notification point (NP). The CP performs ECN marking at the egress queue based on the RED algorithm [43]. The NP sends Congestion Notification Packets (CNPs) when it receives ECN-marked packets. The RP reduces its sending rate when it receives CNPs. Otherwise, it leverages a byte counter and a timer to increase the rate.

We deployed three generations of commodity NICs from a popular NIC vendor: Gen1, Gen2 and Gen3, for different types of clusters. While all of them support DCQCN, their implementation details differ significantly. This causes an interoperability problem when different generations of NICs communicate with each other.

DCQCN implementation differences: On Gen1, most of the DCQCN functionality, such as the NP and RP state machines, is implemented in firmware. Given the limited processing capacity of the firmware, Gen1 minimizes CNP generation through coalescing at the NP side. As described in [112], the NP generates at most one CNP in a time window for a flow, if any arriving packets within this window are ECN marked. Correspondingly, the RP reduces the sending rate upon receiving a CNP. In addition, Gen1 also has limited cache resources. Cache misses can significantly impact RDMA's performance [50, 63]. To mitigate cache misses, we increase the granularity of rate limiting on Gen1 from a single packet to a burst of packets. Burst transmissions can effectively reduce the number of active QPs in a fixed interval, thus lowering pressure on the very limited cache resources of Gen1 NICs.

In contrast, Gen2 and Gen3 have hardware-based DCQCN implementations and adopt a RP-based CNP coalescing mechanism, which is the exact opposite of the NP-based CNP coalescing used by Gen1. In Gen2 and Gen3, the NP sends a CNP for every arriving ECN-marked packet. However, the RP only cuts the sending rate for a flow at most once in a time window if it receives any CNPs within that window. It is worthwhile to note that RP-based and NP-based CNP coalescing mechanisms essentially provide the same congestion notification granularity. The rate limiting is on a per-packet granularity on Gen2 and Gen3.

Interoperability challenges: Storage frontend traffic, which crosses different clusters, may lead to communication between different generations of NICs. In this scenario, the DCQCN implementation differences cause undesirable behaviors. First, when a Gen2/Gen3 node sends traffic to a Gen1 node, its per-packet rate limiting tends to trigger many cache misses

on the Gen1 node, thus slowing down the receiver pipeline. Second, when a Gen1 node sends traffic to a Gen2/Gen3 node through a congested path, the Gen2/Gen3 NP tends to send excessive CNPs to the Gen1 RP, thus causing excessive rate reductions and throughput losses.

Our solution: Given the limited processing capacity and resources of Gen1, we cannot make it behave like Gen2 and Gen3. Instead, we try to make Gen2 and Gen3 behave like Gen1 as much as possible. Our solution is two-fold. First, we move the CNP coalescing on Gen2 and Gen3 from the RP side to the NP side. On the Gen2/Gen3 NP side, we add a per-QP CNP rate limiter and set the minimal interval between two consecutive CNPs to the value of CNP coalescing timer of the Gen1 NP. On the Gen2/Gen3 RP side, we minimize the time window for rate reduction so that the RP almost always reduces the rate upon receiving a CNP. Second, we enable per-burst rate limiting on Gen2 and Gen3.

7.3 Tuning DCQCN

There were certain practical limitations when we tuned DCQCN in Azure. First, our NICs only support global DCQCN parameter settings. Second, to optimize customer experience, we classify RDMA flows into two switch queues based on their application semantics, rather than RTTs. Hence, instead of using different DCQCN parameters for inter-datacenter and intra-datacenter traffic, we use global DCQCN parameter settings (on the NICs and switches) that work well given the large RTT variations within a region.

We took a three-step approach to tune DCQCN parameters. First, we leveraged the fluid model [113] to understand theoretical properties of DCQCN. Second, we ran experiments with synthetic traffic in our lab testbed to evaluate solutions to the interoperability problem and deliver reasonable parameter settings. Third, we finalized the parameter settings in test clusters, which use the same setup as production clusters carrying customer traffic. We ran stress tests with real storage applications and tuned DCQCN parameters based on the application performance.

To illustrate our findings, we use K_{min} , K_{max} , and P_{max} to denote the minimum threshold, the maximum threshold, and the maximum marking probability of RED/ECN [43], respectively. We make the following three key observations (more experiment results appear in §B):

- DCQCN does not suffer from RTT unfairness as it is a rate-based protocol and its rate adjustment is independent of RTT.
- To provide high throughput for DCQCN flows with large RTTs, we use *sparse* ECN marking with large $K_{max} - K_{min}$ and small P_{max} .
- DCQCN and switch buffers should be jointly tuned [112]. For example, before increasing K_{min} , we ensure that ingress thresholds for lossless traffic are large enough. Otherwise,

PFC may be triggered before ECN marking.

8 Experience

In 2018, we started to enable RDMA to serve customer back-end traffic. In 2019, we started to enable RDMA to serve customer frontend traffic, with storage and compute clusters co-located in the same datacenter. In 2020, we enabled intra-region RDMA in the first Azure region. As of February 2023, around 70% of traffic in Azure public regions was RDMA (Figure 1) and intra-region RDMA was supported in all Azure public regions.

8.1 Deployment and Servicing

We took a three-step approach to gradually enable RDMA in production environments. First, we leveraged the lab testbed to develop and test each individual component. Second, we conducted end-to-end stress tests in test clusters with the same software and hardware setups as those of production counterparts. In addition to normal workloads, we also injected common errors, e.g., random packet drops, to evaluate the robustness of the system. Third, we cautiously increased the deployment scale of RDMA in production environments to carry more customer traffic. During our deployment, NIC driver/firmware and switch OS updates were common. Thus it was crucial to minimize the impact of such updates to customer traffic.

Servicing switches: Compared to switches in T1 or tiers above, T0 switches, especially in compute clusters, were more challenging to service as they could be a single point of failure (SPOF) for customer VMs. In this scenario, we leveraged fast reboot [17] and warm reboot [19] to reduce the data plane disruption time from a few minutes to less than a second.

Servicing NICs: In some cases, servicing the NIC driver or firmware required unloading the NIC driver. The driver could safely unload only after all the NIC resources had been released. To this end, we needed to signal consumers, e.g., disk driver, to close RDMA connections and shift traffic to TCP. Once RDMA and other NIC features with similar concerns had been disabled, we could reload the driver.

8.2 Performance

Storage backend: Currently almost all the storage backend traffic in Azure is RDMA. It is no longer feasible to run large-scale A/B tests with customer traffic because the CPU cores saved by RDMA have been used for other purposes, not to mention customer experience degradation. Hence we demonstrate results of an A/B test conducted in a test cluster in 2018. In this test, we ran storage workloads with high transactions per second (TPS) and switched transport between RDMA and TCP. Figure 7 plots normalized CPU utilization of storage

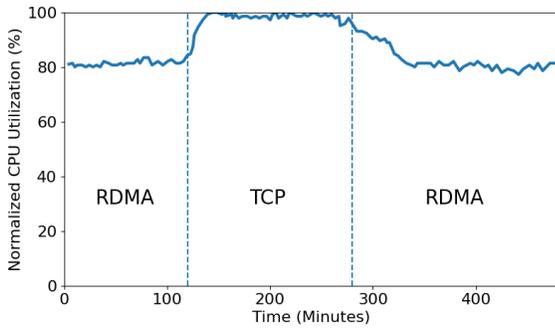

Figure 7: Average CPU usage of storage servers of a storage tenant. We normalize results to the maximum CPU usage. We switched traffic between RDMA and TCP twice.

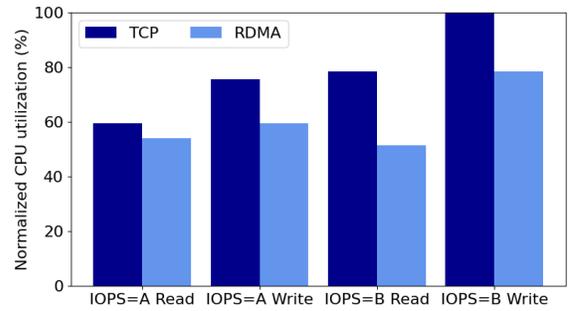

Figure 9: Average CPU usage of the host domain. We normalize results to the maximum value.

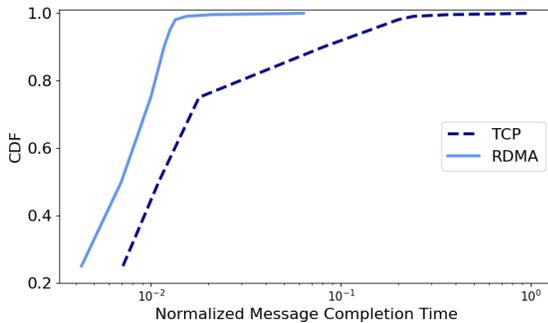

Figure 8: Message completion times of storage backend traffic measured in a test cluster. We normalize results to the maximum message completion time.

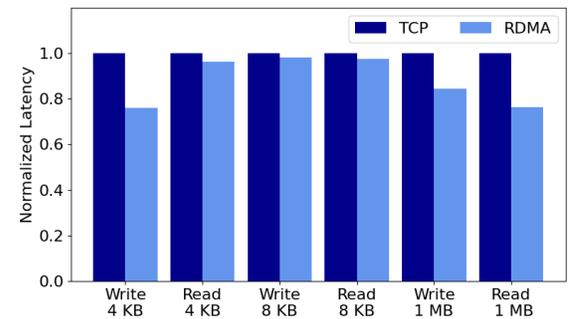

Figure 10: Average access latencies of a type of SSDs across all Azure public regions between February 22, 2022, and February 22, 2023. We normalize RDMA results to corresponding TCP results.

servers during two transport switches. It is worthwhile to note that CPU utilization here includes all the types of processing overhead, e.g., storage application, Azure Storage Network Protocol, and TCP/IP stack. Figure 8 gives message completion times measured in Azure Storage Network Protocol layer (Figure 4), which excludes the overhead of application processing. Compared to TCP, RDMA achieved obvious CPU saving and significantly accelerated network data transfer.

Storage frontend: Since we cannot perform large-scale A/B tests with customer traffic, we present results of an A/B test conducted in a test cluster in 2018. In this test, we used DiskSpd to generate read and write workloads at A IOPS and B IOPS ($A < B$). The I/O size was 8 KB. Figure 9 gives average CPU utilization of the host domain during the test period. Compared to TCP, RDMA could reduce the CPU utilization by up to 34.5%.

To understand the performance improvement introduced by RDMA, we leverage an always-on storage monitoring service. This service allocates some VMs in each region, uses them to periodically generate disk read and write workloads, and collects end-to-end performance results. The monitoring service

covers different I/O sizes, types of disks, and transports for storage frontend traffic.

Figure 10 shows the overall average access latencies of a type of SSDs across all Azure public regions collected by the monitoring service for a year. Note that the RDMA and TCP in this figure only refer to the transport of frontend traffic generated by test VMs. We normalize RDMA results to corresponding TCP results. Compared to TCP, RDMA yielded better access latencies with every I/O size. In particular, 1 MB I/O requests benefited the most from RDMA with 23.8% and 15.6% latency reductions for read and write, respectively. This is due to the fact that large I/O requests are more sensitive to throughput than smaller I/O requests, and RDMA improves throughput drastically since it can run at line rate using a single connection without slow starts.

Congestion control: We ran stress tests in a test cluster to drive the DCQCN parameter setting that could achieve reasonable performance even under peak workloads. Figure 11 gives results of the 99th percentile message completion time, the key metric we used to guide our tuning. At the beginning, we disabled DCQCN and only tuned switch buffer param-

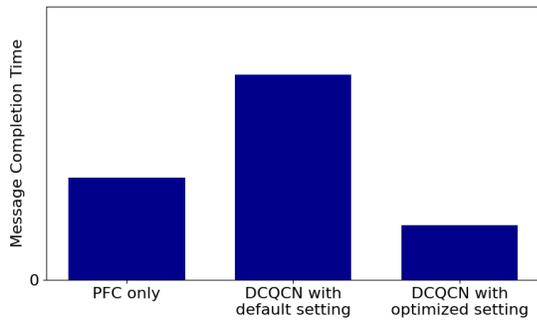

Figure 11: The 99th percentile message completion times of different schemes measured in a test cluster.

ters, e.g., the dynamic threshold of ingress lossless queues, to explore the best performance achieved by PFC only. After reaching the best performance of PFC only, we enabled DCQCN using the default parameter setting, which was derived on the lab testbed using synthetic traffic. While DCQCN reduced the number of PFC pause frames, it degraded the tail message completion time as the default setting reduced the sending rate too aggressively. Given this, we adjusted ECN marking parameters to improve DCQCN’s throughput. With optimized setting, DCQCN performs better than using PFC alone. Our key takeaway from this tuning experience was that DCQCN and switch buffer should be jointly tuned to optimize the application performance, rather than PFC pause duration.

8.3 Problems Discovered and Fixed

During tests and deployments, we discovered and fixed a series of problems in NICs, switches and our RDMA applications.

FMR hidden fence: In sK-RDMA (§4.2), every I/O request from compute servers requires a FMR request followed by a Send request to the storage server, which contains the description of FMR registered memory and storage commands. Therefore, the send queue consists of many FMR/Send pairs.

When we deployed sK-RDMA in compute and storage clusters located in different datacenters, we found that the frontend traffic showed extremely low throughput, even though we kept many outstanding FMR/Send pairs in the send queue. To debug this problem, we used RDMA Estats to collect $T_5 - T_1$ latency for every Send request (§5). We found a strong correlation between $T_5 - T_1$ and inter-datacenter RTT, and noticed that there was only a single outstanding Send request per RTT. After we shared these findings with the NIC vendor, they identified the root cause: to simplify the implementation, NICs processed the FMR request only after the completions of previously posted requests. In sK-RDMA, the FMR request created a *hidden fence* between two Send requests, thus only allowing a single Send request in the air, which could not fill the large

network pipe between datacenters. We have worked with the NIC vendor to fix this problem in the new NIC driver.

PFC and MACsec: After we enabled PFC on long-haul links between T2 and RH, many long-haul links reported high packet corruption rates, thus triggering alerts. It turned out that the MACSec standard [21] did not specify whether PFC frames should be encrypted. As a result, different vendors had no agreement on whether PFC frames sent should be encrypted and what to do with arriving encrypted PFC frames. For example, switch A may send unencrypted PFC frames to switch B, while switch B was expecting encrypted PFC frames. As a result, switch B would treat those PFC frames as corrupted packets and report errors. We have worked with switch vendors to standardize how MACsec enabled switch ports treat PFC frames.

Congestion leaking: The problem was found in the testbed. When we enabled interoperability features (§7.2) on Gen2 NICs, we found that their throughput would be degraded. To dig into this problem, we used the water filling algorithm to calculate theoretical per-QP throughput results and compared them with actual throughput results measured from the testbed. We had two interesting observations when comparing the results. First, flows sent by a Gen2 NIC always had near identical sending rates regardless of their congestion degrees. Second, actual sending rates were very close to the theoretical sending rate of the slowest flow sent from the NIC. It seemed that all the flows from a Gen2 NIC were throttled by the slowest flow. We reported these observations to the NIC vendor, and they identified a head-of-line blocking in the NIC firmware. We have fixed this problem on all the NICs with interoperability features.

Slow receiver due to loopback RDMA: This problem was found in a test cluster. During stress tests, we found that a large number of servers sent PFC pause frames to T0 switches. However, unlike slow receivers found before, PFC watchdog was not triggered on any T0 switches. It seemed that those servers only gracefully slowed down the traffic coming from T0 switches, rather than completely blocking T0 switches for a long duration. In addition, where slow receivers were common at Azure’s scale, it was very unlikely that a significant portion of servers in a cluster became “mad” simultaneously.

Based on the above observations, we suspected that these slow receivers were caused by our applications. We found that each server actually ran multiple RDMA application instances. All the inter-instance traffic ran on RDMA, regardless of their locations. Therefore, loopback traffic and external traffic co-existed on every NIC, thus creating a 2:1 congestion on PCIe lanes of the NIC. Since the NIC could not mark ECN, it could only throttle loopback traffic and external traffic through PCIe back pressure and PFC pause frames. To validate the above analysis, we disabled RDMA for loopback traffic on some servers, then these servers stopped sending PFC frames. We notice that recent work [61, 70] also found this problem.

9 Lessons and Open Problems

In this section, we summarize the lessons learned from our experience and discuss open problems for future exploration.

Failovers are very expensive for RDMA. While we have implemented failover solutions in both sU-RDMA and sK-RDMA as the last resort, we find that failovers are particularly expensive for RDMA, and should be avoided as much as possible. Cloud providers adopt RDMA to save CPU cores and then use freed CPU cores for other purposes. To move traffic away from RDMA, we need to allocate *extra* CPU cores to carry these traffic. This increases CPU utilization, and even runs out of CPU cores at high loads. Hence, it is risky to perform large-scale RDMA failovers, which we treat as serious incidents in Azure. Given the risk, only after all the tests have passed, we gradually increase the RDMA deployment scale. During the rollout, we continuously monitor network performance and immediately stop the rollout once anomalies are detected. After unavoidable failovers, we should aggressively switch back to RDMA when possible.

Host network and physical network should be converged.

In 8.3, we present a new type of slow receivers, which is essentially due to congestion inside the host. Recent work [24] also presents evidence and characterization of host congestion in production clusters. We believe this problem is just a tip of the iceberg, while many problematic behaviors between host network and physical network remain unexposed. In conventional wisdom, host network and physical network are separated entities and NIC is their border. If we look into the host, it is essentially a network connecting heterogeneous nodes (e.g., CPU, GPU, DPU) with proprietary high speed links (e.g., PCIe link and NVLink) and switches (e.g., PCIe switch and NVSwitch). Inter-host traffic can be treated as north-south traffic for the host. With the increase of the datacenter link capacity and wide adoptions of hardware offloading and device direct access technologies (e.g., GPUDirect RDMA), inter-host traffic tends to consume larger and more various resources inside the host, thus resulting in more complex interactions with intra-host traffic.

We believe that host network and physical network should be converged in the future. And we envision this converged network will be an important step towards the dis-aggregated cloud. We look forward to operating this converged network in similar ways as we manage physical network today.

Switch buffer is increasingly important and needs more innovations. The conventional wisdom [26] suggests that low latency datacenter congestion control [26, 71, 82, 112] can alleviate the need of large switch buffers as they can preserve short queues. However, we find a strong correlation between switch buffers and RDMA performance problems in production. Clusters with smaller switch buffers tend to have more performance problems. And many performance problems can be mitigated by just tuning switch buffer parameters without

touching DCQCN. This is why we always tune switch buffers before touching DCQCN (§8.2). The importance of switch buffer lies in the prevalence of bursty traffic and short-lived congestion events in datacenters [108]. Conventional congestion control solutions are ill-suited for such scenarios given their reactive nature. Instead, switch buffer plays as the first resort to absorb bursts and provide fast responses.

With the increase in datacenter link speed, we believe that switch buffer is increasingly important, thus deserving more efforts and innovations. First, the buffer size per port per Gbps on pizza box switches keeps decreasing in recent years [31]. Some switch ASICs even split the packet memory into multiple partitions, thus reducing effective buffer resource. We encourage more efforts to put into the development ASICs with deeper packet buffers and more unified architectures. Second, today's commodity switch ASICs only provide buffer management mechanisms [40] designed decades ago, thus limiting the scope of solutions to handle congestion. Following the trend of programmable data plane [32], we envision that future switch ASICs would provide more programmability on buffer models and interfaces, thus enabling the implementation of more effective buffer management solutions [22].

Cloud needs unified behavior models and interfaces for network devices.

The diversity in software and hardware brings significant challenges to network operation at cloud scale. Different NICs from the same vendor can even have different behaviors that cause interoperability problems, not to mention devices from different vendors. In spite of all the efforts we put into the unified switch software (§6) and NIC congestion control (§7.2), we still experienced problems due to diversity, e.g., unexpected interactions between PFC and MACsec (§8.3). We envision that more unified models and interfaces will emerge to simplify operations and accelerate innovations in the cloud. Some key areas include chassis switches, smart network appliances, and RDMA NICs. We notice that there have been some efforts on standardizing congestion control for different data paths [85] and APIs for heterogeneous smart appliances [16].

Testing new network devices is crucial and challenging.

From the day one of this project, we have been making large investments in building various testing tools and running rigorous tests in both testbeds and test clusters. Despite the significant number of problems discovered during tests, we still found some problems during deployments (§8.3), mostly due to micro-behaviors and corner cases that were overlooked. Some burning questions are given as follows:

- How to precisely capture micro-behaviors of RDMA NIC implementations in various scenarios?
- Despite many endeavors to measure switches' micro-behaviors (§6.3), we still rely on domain knowledge to design test cases. How to systematically test the correctness and performance of a switch?

These questions motivate us to rethink challenges and re-

quirements of testing emerging network devices with more and more features. First, many features lack clear specifications, which is a prerequisite for systematic testing. Many seemingly simple features are actually entangled with complex interactions between software and hardware. We believe that unified behavior models and interfaces discussed above can help with this. Second, the test system should be able to interact with network devices at high speed, and precisely capture micro-behaviors. We believe programmable hardware can help on this [33, 37]. We note that there have been some recent progresses on testing RDMA NICs [69, 70] and programmable switches [37, 110].

10 Related Work

This paper focuses on RDMA for cloud storage. The literature of RDMA and storage systems is vast. Here we only discuss some closely related ideas.

Deployment experience of RDMA and storage networks:

Before this project, we had deployed RDMA to support some Bing workloads and encountered many problems, such as PFC storms, PFC deadlocks, and slow receivers [50]. We learnt several lessons from this deployment. Gao et al. [46] summarized the experience of deploying intra-cluster RDMA to support storage backend traffic in Alibaba. Miao et al. [80] presented two generations of storage network stacks to carry Alibaba's storage frontend traffic: LUNA and SOLAR. LUNA is a high performance user-space TCP stack while SOLAR is a storage-oriented UDP stack implemented in proprietary DPU. Scalable Reliable Datagram (SRD) [96] is a cloud-optimized transport protocol implemented in AWS custom Nitro networking card, and used by HPC, ML, and storage applications [7]. In contrast, we use commodity hardware to enable intra-region RDMA to support both storage frontend and backend traffic.

Congestion control in datacenters: There is a large body of work on datacenter congestion control, including ECN-based [26, 27, 99, 112], delay-based [71, 72, 76, 82], INT-based [23, 75, 101], credit-based [34, 38, 45, 52, 55, 84, 86, 88] and packet scheduling [28, 30, 36, 49, 54]. Our work focuses on regional networks which have large RTT variations. We notice that some efforts [95, 107] target at similar scenarios.

Improve RDMA in datacenters: In addition to congestion control, there are many efforts to improve RDMA's reliability, security and performance in datacenters, such as deadlock mitigation [56, 92, 103], support of multi-path [77], resilience over lossy networks [78, 83, 102], security mechanisms [94, 98, 104], virtualization [53, 67, 89, 100], testing [69, 70], and performance isolation in multi-tenant environments [109]. Our work focuses on first party traffic in the trusted environment. Given the limited retransmission performance of our NICs, we enable RDMA over lossless networks (§2.4).

Accelerate storage systems using RDMA and other tech-

niques: Many proposals [41, 62–66, 74, 93, 106, 111] leverage RDMA to accelerate storage systems or networked systems in general. Similar to some solutions [13, 47, 74, 90], our RDMA protocols (§4) provide socket-like interfaces to keep compatibility with legacy storage stack. In addition to RDMA, some recent proposals improve storage systems using new kernel designs [58, 59, 73] and SmartNIC [68, 81].

11 Conclusions and Future Work

In this paper, we summarize our experience in deploying intra-region RDMA to support storage workloads in Azure. The high complexity and heterogeneity of our infrastructure brings a series of new challenges. We have made several changes to our network infrastructure to address these challenges. Today, around 70% of traffic in Azure is RDMA and intra-region RDMA is supported in all Azure public regions. RDMA helps us achieve significant disk I/O performance improvements and CPU core savings.

In the future, we plan to further improve our storage systems through innovations on system architecture, hardware acceleration, and congestion control. We also plan to bring RDMA to more scenarios.

Acknowledgements

We thank our shepherd Marco Canini and the anonymous reviewers for their valuable feedback that significantly improved the final paper. Yuanwei Lu, Liang Yang and Danushka Menikkumbura also provided important feedback. Yibo Zhu made contributions to DCQCN and PFC deadlock avoidance at the early stage of this project. Ranysha Ware contributed to DCQCN tuning. Zhuolong Yu helped us measure RDMA's retransmission performance. This project represents the work of many engineers, product managers, researchers, data scientists, and leaders across Microsoft over many years, more than we can list here. We thank them all. Finally, we thank our partners: Arista Networks, Broadcom, Cisco, Dell, Keysight and NVIDIA for their technical contributions and support.

Listing 1: SONiC Buffer Configuration Example

Listing 1 gives a buffer configuration example of a SONiC pizza box switch with 24 MB packet buffer. `ingress_pool` has 18 MB (`size`) shared buffer for all the ingress queues, and 6 MB (`xoff`) PFC headroom buffer exclusively for ingress lossless queues in the paused state. `egress_lossy_pool` and `egress_lossless_pool` have 14 MB and 24 MB shared buffer, respectively. It is worthwhile to notice that the sum of pool sizes can be larger than the physical buffer limit, as they are only virtual counters for admission control purposes.

Lossless packets are mapped to both ingress lossless queues (`ingress_lossless_profile`) and egress lossless queues (`egress_lossless_profile`). We use Dynamic Threshold (DT) algorithm [40] to manage the buffer occupancy of the ingress lossless queue in the 18 MB shared buffer space of `ingress_pool`. DT algorithm is controlled by a parameter called α , which is $1/8$ ($2^{\text{dynamic_th}}$) in Listing 1. Once the ingress lossless queue hits the dynamic threshold ($\alpha \times$ remaining buffer), it will enter the paused state (send PFC pause frames) and start to use PFC headroom. All the ingress lossless queues in the paused state share a 6 MB PFC headroom pool (`xoff` of `ingress_pool`). Each ingress lossless queue can use up to 96928 bytes buffer (`xoff` of `ingress_lossless_profile`) in the PFC headroom pool. We bypass the egress admission control for lossless traffic by setting the static threshold of the egress lossless queue (`static_th` of `egress_lossless_profile`) to 24 MB, which equals to the switch buffer size.

In contrast, we only want to apply egress admission

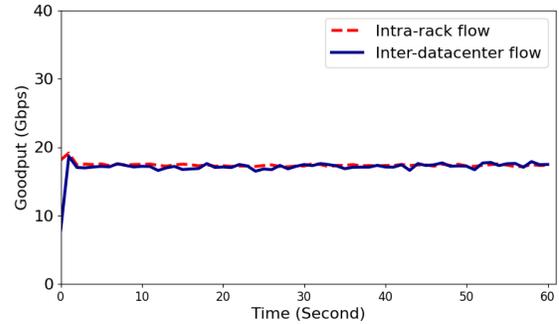

Figure 12: Goodput of two flows with different RTTs.

control for lossy traffic. To bypass ingress admission control for lossy traffic, we configure a sky-high static threshold 24 MB (`static_th` of `ingress_lossy_profile`) for each ingress lossy queue. Since lossy traffic can only use 18 MB shared buffer space of `ingress_pool`, the size of `egress_lossy_pool` should be no larger than 18 MB (`size` of `ingress_pool`). In Listing 1, the size of `egress_lossy_pool` is 14 MB. This guarantees that ingress lossless queues can exclusively use 4 MB shared buffer (`size` of `ingress_pool` - `size` of `egress_lossy_pool`) in `ingress_pool` before entering the paused state. We use DT algorithm to manage the egress lossy queue length and set α to $1/2$ ($2^{\text{dynamic_th}}$). Once the egress lossy queue hits the dynamic threshold, its arriving packets will be dropped.

B DCQCN experiment results

We conduct an experiment in our lab testbed to demonstrate the RTT fairness of DCQCN. Our lab testbed uses a four-tier Clos topology like Figure 2. We use 80 km cables to interconnect T2 switches to a RH switch to emulate a region.

In this experiment, we use two hosts *A* and *B* as senders and a host *C* as the receiver. Each host is equipped with a Gen1 40 Gbps NIC. Host *A* and *C* are located within the same rack with $\sim 2 \mu\text{s}$ base RTT. In contrast, *B* is in another datacenter. The base RTT across the RH switch is ~ 1.77 ms. On each sender, we use `ndperf` to create a QP with the receiver and keep posting 64 KB Write messages. Each QP can keep up to 160 in-flight Write messages, resulting in around 10 MB in-flight data, which is enough to saturate the large inter-datacenter pipe ($40 \text{ Gbps} \times 1.77 \text{ ms} = 8.85 \text{ MB}$). We set RED/ECN marking parameters K_{min} , K_{max} and P_{max} to 1 MB, 2 MB and 5%, respectively.

As shown in Figure 12, two DCQCN flows achieve similar goodput regardless of their RTTs. A flow can achieve around 17 Gbps goodput, which is close to half of the line rate. We also keep polling queue watermark counters at the congested switch and find queue watermarks oscillate around 1.36 MB, which is smaller than K_{max} . This experiment demonstrates that DCQCN does not suffer from RTT unfairness.

Transparent GPU Sharing in Container Clouds for Deep Learning Workloads

Bingyang Wu* Zili Zhang* Zhihao Bai† Xuanzhe Liu* Xin Jin*

*Peking University †Johns Hopkins University

Abstract

Containers are widely used for resource management in datacenters. A common practice to support deep learning (DL) training in container clouds is to statically bind GPUs to containers in entirety. Due to the diverse resource demands of DL jobs in production, a significant number of GPUs are underutilized. As a result, GPU clusters have low GPU utilization, which leads to a long job completion time because of queueing.

We present TGS (Transparent GPU Sharing), a system that provides transparent GPU sharing to DL training in container clouds. In stark contrast to recent application-layer solutions for GPU sharing, TGS operates at the OS layer beneath containers. Transparency allows users to use any software to develop models and run jobs in their containers. TGS leverages adaptive rate control and transparent unified memory to simultaneously achieve high GPU utilization and performance isolation. It ensures that production jobs are not greatly affected by opportunistic jobs on shared GPUs. We have built TGS and integrated it with Docker and Kubernetes. Experiments show that (i) TGS has little impact on the throughput of production jobs; (ii) TGS provides similar throughput for opportunistic jobs as the state-of-the-art application-layer solution AntMan, and improves their throughput by up to $15\times$ compared to the existing OS-layer solution MPS.

1 Introduction

Containers [1–3] are widely used for resource management in datacenters. Containers provide lightweight virtualization, and can significantly reduce the complexity and cost of deployments and managements in datacenters.

Deep learning (DL) is an important workload in datacenters. With recent advancements in deep neural networks (DNNs) [4] and the burst of big data space, DL models have been increasingly integrated into applications and online services. Large enterprises build multi-tenant GPU clusters that are shared by many teams to develop and train DL models.

A common practice to support DL training in container clouds is to statically bind complete GPUs to containers. When a GPU is allocated to a container, the container has exclusive access to the GPU, which provides performance isolation for production jobs. But it means that other containers

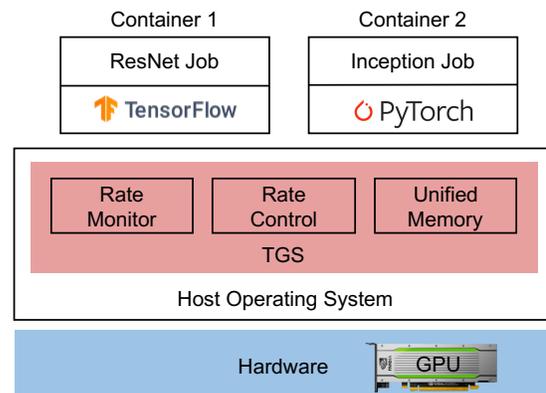

Figure 1: TGS architecture.

on the same machine cannot use the GPU when the GPU is under-utilized or is even completely idle.

The major limitation of this approach is *low resource utilization*. A recent study on a production GPU cluster by Microsoft shows that the mean GPU utilization is only 52% [5]. Another measurement on a production GPU cluster at Alibaba shows even lower GPU utilization—the median GPU utilization is no more than 10% [6]. However, due to exclusive GPU allocation, incoming jobs have to wait in the queue to be scheduled even when many GPUs are not fully utilized. This causes a long job completion time for subsequent jobs.

This is a known problem in production GPU clusters [5, 6]. The problem can be addressed by GPU sharing to increase GPU utilization. In production environments [6–8], DNN training jobs are typically classified into two classes: *production* jobs, which must run without much great performance degradation caused by other jobs, and *opportunistic* jobs, which utilize spare resources. It is natural to share GPUs between the two classes of jobs to improve GPU utilization. Yet, it is critical for production environments to ensure that the impact of GPU sharing on production jobs is minimized.

GPU sharing solutions can be realized at either the application layer or the OS layer. AntMan [6] is a state-of-the-art application-layer solution. While AntMan can provide high GPU utilization and performance isolation, it modifies DL frameworks non-trivially and restricts users to use particular versions of given frameworks. NVIDIA Multiple Process

Sharing (MPS) [9] is an OS-layer solution. MPS requires application knowledge to set resource limits for performance isolation and does not support GPU sharing under GPU memory oversubscription. It merges several processes into a single CUDA context, leading to fate sharing between jobs.

We present TGS, a system that provides transparent GPU sharing to DL training in container clouds. Unlike application-layer solutions, TGS works at the OS layer and realizes the benefits of application-layer solutions at the OS layer without the limitations of existing OS-layer solutions. Transparency allows users to choose any version of any DL framework (either TensorFlow, PyTorch or a custom framework) to develop models and run jobs in containers.

The core of TGS is a lightweight indirection layer between containers and GPUs. It intercepts the system calls from containers to GPUs and regulates the GPU resource usage for concurrent jobs. TGS enables GPU sharing between the production job and the opportunistic job, but largely isolates the production job from contention.

There are two primary technical challenges in realizing an OS-layer GPU sharing solution with performance isolation. The first challenge is to share GPU compute resources between containers adaptively without application knowledge. Inaccurately setting resource limits for each container would either degrade job performance or leave resources unused. MPS and MIG require application knowledge to manually set resource limits. TGS applies an adaptive rate control approach to address this challenge without application knowledge. It monitors the performance of production jobs at runtime, and adaptively updates the resource allocation to opportunistic jobs. The control loop automatically converges to the point that opportunistic jobs utilize as many resources as possible without much affecting production jobs.

The second challenge is to enable transparent GPU memory oversubscription. GPUs have their own memory to keep the application state. MPS fails when the total GPU memory required by containers exceeds the GPU memory size. AntMan uses a custom memory management component in DL frameworks to manage memory swapping between GPU memory and host memory at the application layer. We design a transparent unified memory mechanism based on CUDA unified memory to enable unified memory at the OS layer, obviating the need to explicitly modify applications. This mechanism manages memory swapping underneath when the GPU memory is oversubscribed. TGS leverages placement preferences to ensure that GPU memory is prioritized for production jobs to protect their performance.

In summary, we make the following contributions.

- We propose TGS, a system that provides transparent GPU sharing for DL training in container clouds.
- We design adaptive rate control and transparent unified memory mechanisms to simultaneously achieve high GPU utilization and performance isolation.

- We implement TGS and integrate it with Docker and Kubernetes. Experiments show that (i) TGS has little impact on the throughput of production jobs; (ii) TGS provides similar throughput for opportunistic jobs as state-of-the-art application-layer solution AntMan and improves their throughput by up to $15\times$ compared to existing OS-layer solution MPS.

2 Background and Motivation

In this section, we first introduce containers, deep learning training, and the current practice to support deep learning training in container clouds. Then, we show the limitations of existing solutions to motivate TGS.

2.1 Container Clouds

Containers [1–3] (e.g., Docker) are used widely to manage resources and deploy workloads in datacenters, and provide *portability* and *isolation*. A container is a standalone software package including everything needed to run an application. A containerized application can run across various environments without any modifications. Such portability enables developers to use the tools and application stacks of their choice to develop and run their applications, without worrying about deployment environments. Applications in different containers are isolated by using independent namespaces.

Containers are lightweight, compared with virtual machines. Virtual machines use a guest OS, but containers use the host OS kernel. Thus, applications can achieve bare metal performance when running in containers. Cloud operators use a container orchestration platform [10, 11] to provision, manage and update containers on many machines in a datacenter.

2.2 DL Training Workloads

DL training uses a dataset to train a DNN model. A training job contains many iterations. Each iteration uses a batch of samples from the dataset to train the DNN model. An iteration includes a forward pass and a backward pass. The forward pass uses the DNN model to compute the labels of the samples in the batch. A loss is computed based on the output labels and the actual labels using a loss function. The backward pass propagates the loss from the last layer to the first layer of the DNN model and computes the gradients for each weight. The DNN model is updated based on the gradients using an optimizer. DL training is compute-intensive, so GPUs are typically used. However, widely-adopted exclusive GPU allocation leads to low GPU utilization in production, as reported by Microsoft [5] and Alibaba [6].

2.3 Limitations of Existing Solutions

A natural way to increase GPU utilization is GPU sharing. If a single container cannot utilize all the GPU resources, a GPU can be shared by multiple containers to increase GPU utilization. However, containers on a shared GPU will compete for compute and memory resources of the GPU, and the interference can slow down the jobs.

	AntMan [6]	Salus [12]	PipeSwitch [13]	MPS [9]	MIG [14]	TGS
Transparency				✓	✓	✓
High GPU utilization	✓	✓				✓
Performance isolation	✓	✓	✓	✓	✓	✓
Fault isolation	✓		✓		✓	✓

Table 1: Comparison between TGS and existing GPU sharing solutions.

GPU sharing can be done either at the application layer or the OS layer. The primary drawback of application-layer solutions [6, 12, 13] is that they are not *transparent* to users, i.e., they require significant modifications to DL frameworks. Users are restricted to use the set of supported versions of given frameworks and have to wait for the integration if a newer version of a particular DL framework comes. This approach loses the advantage of allowing users to use any tools to develop and run applications in containers.

NVIDIA MPS [9] is an OS-layer solution for GPU sharing. It requires application knowledge to properly set the resource limit for each process to ensure performance isolation. More importantly, MPS requires the total GPU memory of the processes to fit within the GPU memory capacity and relies on applications to handle memory swapping between GPU memory and host memory. Another limitation of MPS is that it does not provide *fault isolation*. MPS merges the CUDA contexts of multiple processes into a single CUDA context to share the GPU. When a process fails, it leaves the MPS server and other processes in an undefined state and may result in process hangs, corruptions, or failures.

NVIDIA Multi-Instance GPU (MIG) [14, 15] is another OS-layer solution. MIG requires GPU hardware support and is currently only available on three high-end GPUs, i.e., NVIDIA A100, NVIDIA A30, and NVIDIA H100. MIG cannot *arbitrarily* partition a GPU based on application needs; it only supports GPU partitioning for a given set of configurations. For example, an NVIDIA A100 GPU can be partitioned into *GPU instances* with separate compute and memory resources for different DL training jobs, but MIG only provides seven fixed configurations for each GPU instance and each GPU instance cannot use more than 4/7 of the GPU compute resources or half of the GPU memory resources. Furthermore, it cannot *dynamically* change GPU resources owned by GPU instances if there are running jobs on the GPU even if the GPU usage of a container changes. Reconfiguration of MIG can only happen when the GPU is idle. MIG does not support memory oversubscription.

3 TGS Overview

TGS is a GPU sharing system for deep learning training in container clouds that is designed to meet the following goals. Table 1 compares TGS with existing GPU sharing solutions regarding these four goals.

- **Transparency.** The system should be transparent to applications so that users can use any software to develop and train DNN models in containers.
- **High GPU utilization.** The system should achieve high GPU utilization for both compute and memory resources.
- **Performance isolation.** The system should provide performance isolation for DL jobs. Production jobs should not be significantly affected by opportunistic jobs.
- **Fault isolation.** Application faults should be isolated by containers. The fault of an application in one container should not crash applications in other containers.

Architecture. Figure 1 shows that TGS is an OS-layer approach: it sits between containers and GPUs. Containers and applications are unaware of TGS. Users can use any custom framework to develop and train DNN models. A GPU is exposed as a regular GPU to the containers. The processes in the containers issue GPU kernels, i.e. functions executed on the GPU, to the GPU as they do with a dedicated GPU. TGS uses a lightweight indirection layer to share the GPU between workloads of several containers. The indirection layer intercepts the GPU kernels from containers and regulates these GPU kernels to control the resource usage of each container.

Key ideas. TGS leverages an adaptive rate control mechanism and a transparent unified memory mechanism to tackle two challenges in providing transparent GPU sharing at OS layer. The first challenge is to adaptively share GPU compute resources between containers without application knowledge. To address this challenge, the rate monitor of TGS monitors the performance of each container, and provides the number of *CUDA blocks* (a basic scheduling and execution unit on the GPU) as a real-time signal for the control loop. Based on the signal, the rate control of TGS adaptively controls the rate of sending GPU kernels to the GPU for each container. The control loop automatically converges to the point that opportunistic jobs utilize as many remaining resources as possible to achieve high GPU utilization without greatly affecting the performance of production jobs.

The second challenge is to enable transparent GPU memory oversubscription. AntMan [6] modifies DL frameworks to swap GPU memory when GPU memory is oversubscribed. OS-layer solution MPS does not support GPU memory oversubscription, and relies on applications to handle memory swapping. These approaches are not transparent. To address this challenge, TGS exploits CUDA unified memory [16] which unifies GPU memory and host memory in a single

memory space. TGS intercepts and redirects GPU memory allocation calls from containers to the CUDA unified memory space. When the GPU memory is oversubscribed, TGS can automatically evict some data of opportunistic jobs to the host memory, and change the mapping of the corresponding virtual addresses to the new data locations in the host memory. The entire process is transparent to applications. To ensure performance isolation, TGS uses memory placement preferences to prioritize allocating GPU memory for production jobs over opportunistic jobs.

The design of TGS has two other benefits. First, the architecture is *lightweight*. TGS has low overhead and conforms with the principle of containers. Second, TGS provides the same *fault isolation* property as regular containers. The containers in TGS use separate GPU contexts, as opposed to MPS which merges the CUDA contexts of the containers into one. Therefore, an application fault in one container does not affect or terminate other containers.

4 TGS Design

In this section, we present the design of TGS. We first describe the adaptive rate control mechanism to share GPU compute resources. Then we describe the unified memory mechanism to share GPU memory resources.

4.1 Sharing GPU Compute Resources

Application code is encapsulated into functions to be executed on a GPU, which are known as GPU kernels. GPU kernels are highly optimized based on the particular architecture and execution model of the GPU. A small DNN training job may not use all the compute resources of a GPU. In this case, the GPU has low utilization if it is exclusively allocated to the container of the job. TGS improves GPU utilization by GPU sharing. In TGS, a GPU can be exposed to and shared by multiple containers to increase GPU utilization.

TGS ensures the performance of production jobs is not greatly affected by opportunistic jobs. Opportunistic jobs use no more than the resources left by production jobs. To achieve this, we need to solve two problems. First, we need to estimate how many resources are left by production jobs. Second, we need to control opportunistic jobs to use no more than the remaining resources.

Strawman solution: priority scheduling. A strawman solution is priority scheduling. It intercepts the GPU kernels from containers and puts them into a production queue and an opportunistic queue based on the priority of the job. The kernels in the opportunistic queue are only scheduled to the GPU when the production queue is empty. In this solution, whether there are remaining resources is estimated by checking whether the production queue is empty, and controlling the resource usage of opportunistic jobs is achieved by prioritizing the scheduling of the kernels in the production queue. This is a canonical solution to performance isolation and high utilization, and has been widely used in computer systems.

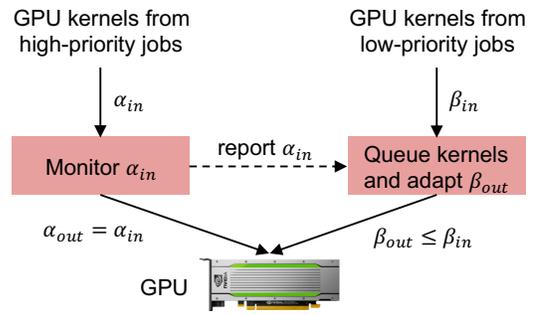

Figure 2: Adaptive rate control.

However, this solution is not suitable for GPU sharing. An empty production queue for GPU jobs does not mean production jobs are not using the GPU. A GPU kernel is an optimized GPU function that runs for some time. The GPU kernels scheduled in the past may still be running on the GPU, while the production queue is empty. Similarly, an empty queue also cannot tell how many resources are left on the GPU. Therefore, if the kernels in the opportunistic queue are sent to the GPU and the production jobs are using most of the GPU resources, then the GPU kernels from both jobs would contend with each other, which incurs large overhead for production jobs. Keeping track of GPU kernels running on the GPU is also not feasible, because the state of the GPU is not fully visible.

It may be possible to implement a priority scheduler into the GPU device driver, so that the scheduler can have full visibility of the resource usage and can perform fine-grained control. This solution is not general. It is tightly tied to the low-level GPU specifics and requires deep integration with each type of GPU based on their architecture and execution model. Some GPUs are blackboxes and do not expose such control to the OS.

Our solution: adaptive rate control. TGS uses an adaptive rate control approach (Figure 2). The main idea is to carefully control the dequeuing rate of the kernels in the opportunistic queue based on the kernel arrival rate, so that opportunistic jobs can use up the remaining compute resources without greatly affecting the production job. This is a general OS-layer approach: it is decoupled from low-level GPU specifics and does not require access to GPU internal control.

This approach requires a feedback signal to tell the control loop whether the dequeuing rate of the opportunistic queue can be increased to use more resources or should be decreased to avoid degrading production jobs. Ideally, we want to use the application performance, i.e., the training throughput for DL training workloads, as the feedback signal, because this is the metric we ultimately care about. However, we cannot directly obtain the training throughput, because this requires application knowledge, and we aim to design an OS-layer solution that is transparent to applications.

One choice of the signal is GPU utilization, i.e., increase the rate if the GPU utilization is below 100%. While this choice

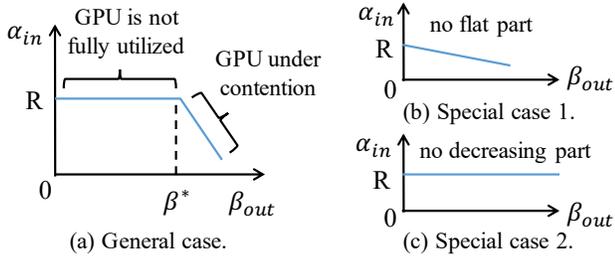

Figure 3: Relationship between the rates of production and opportunistic jobs.

seems natural, it has two drawbacks. First, the definition of GPU utilization is hardware-specific and is often vague [17]. Today’s GPUs contain different types of compute units on a single chip, e.g., Tensor cores and CUDA cores for different data types on NVIDIA GPUs. GPU utilization reported by GPU drivers (if supported) often lacks a precise definition. Even if it does (e.g., the percentage of stream processors that are used), it is unclear what a single utilization value actually means for a GPU with several types of compute units. Second, GPU utilization is only loosely coupled with the application performance. Even when the reported GPU utilization is below 100%, it does not mean we can increase the dequeuing rate of the opportunistic queue without slowing down production jobs. For example, a production job and an opportunistic job may compete for the same type of compute units that are already used up by the production job alone, though there are other types of compute units that are idle; two jobs may also compete for other resources than the one captured by GPU utilization.

In TGS, we use the kernel arrival rate of production jobs (i.e., the rate that TGS receives kernels from the containers) as the feedback signal. A DL training job constructs a compute graph based on the DNN model for its training process. It uses the compute graph to generate and send kernels to the GPU to perform training. The compute graph captures the dependencies between the kernels. The kernel arrival rate directly corresponds to the training throughput. If the training is slowed down, the kernels are finished slower, the dependencies are satisfied slower, and the kernel arrival rate drops. Therefore, TGS uses a rate monitoring module to monitor the kernel arrival rate of production jobs, and uses it as the feedback signal to control the kernel dequeuing rate of opportunistic jobs. Note that any contention between production jobs and opportunistic jobs can be captured by this kernel arrival rate, including GPU cache contention, CPU contention and network contention. Some of them are beyond what a GPU hardware design can control, and TGS uses rate control as a knob to control all of them. Since there can be a small variance in the kernel arrival rate, TGS uses a moving average to smooth the estimation of the kernel arrival rate. For the kernels from production jobs, TGS only performs a simple counting operation to estimate the kernel arrival rate. It does

not queue the kernels and directly passes them to the GPU, to minimize the impact on the performance of production jobs.

Rate adaptation algorithm. The rate adaptation algorithm controls the kernel dequeuing rate of the opportunistic queue, so that the kernel arrival rate of production jobs is not greatly affected and the kernel dequeuing rate of opportunistic jobs is maximized. Formally, let α_{in} and α_{out} be the rates that the kernels of production jobs arrive at and departure from TGS respectively, and β_{in} and β_{out} be those of the opportunistic jobs. TGS only monitors, but does not limit the rate of production jobs. So $\alpha_{in} = \alpha_{out}$. Let the kernel arrival rate of production jobs when the GPU is not shared be R . The rate control algorithm is to maximize β_{out} so that $\alpha_{in} = R$. In the formulation, β_{out} is the variable controlled by the algorithm and α_{in} is dependent on β_{out} . Let f be the function that captures the relationship between α_{in} and β_{out} , i.e., $\alpha_{in} = f(\beta_{out})$. Then the algorithm has to solve the following optimization problem.

$$\max \beta_{out} \quad (1)$$

$$s.t. \quad \alpha_{in} = f(\beta_{out}) \geq R \quad (2)$$

$$\beta_{out} \geq 0 \quad (3)$$

The exact shape of $f(\beta_{out})$ is unknown, but we know its rough shape by the nature of the problem. Specifically, $f(\beta_{out})$ is flat and is equal to R when β_{out} is small, and is monotonically decreasing when β_{out} is large, as illustrated in Figure 3(a). The intuition is that when β_{out} is small, the GPU is not fully utilized and executing the kernels of opportunistic jobs does not affect the performance of production jobs, resulting in a flat line; after the tipping point β^* , opportunistic jobs start to compete with production jobs for GPU resources, causing the performance of production jobs to drop. Note that the monotonically decreasing part is not necessarily linear; Figure 3(a) illustrates the general trend that α_{in} decreases when β_{out} increases. The goal of the algorithm is to find the tipping point β^* from which $f(\beta_{out})$ starts to decrease.

Figure 3(a) is the general case. There are two special cases. Figure 3(b) is the special case where the GPU is already fully utilized by production jobs, so that even executing a small number of kernels for opportunistic jobs would degrade the performance of production jobs. In this case, the line does not have a flat part. Figure 3(c) is the special case where the demand of opportunistic jobs is very small, so that even when the dequeuing rate is not limited, the performance of production jobs is not affected. In this case, the line does not have a monotonically decreasing part.

To approximate the optimal β_{out} , we use the canonical additive increase multiplicative decrease (AIMD) method to control the rate β_{out} , as shown in Algorithm 1. Specifically, TGS first measures the rate R of a production job on a GPU before it adds an opportunistic job to the GPU for sharing (line 1 – 3). After the opportunistic job is added, TGS additionally increases β_{out} , if α_{in} is greater than or equal to R (line 24 –

25), or multiplicatively decreases β_{out} , if α_{in} is below R (line 29 – 30). AIMD ensures that β_{out} can approximately converge to the tipping point β^* . To accelerate convergence, a slow start phase is adopted (line 17 – 22). Experiments in §6 shows that the convergence is fast. When the production job changes its resource usage pattern, TGS detects that the variance of R is beyond a threshold. In this case, the rate control module suspends the opportunistic job and measures new R (line 26 – 28). When R becomes stable, the rate control module uses AIMD to adjust β_{out} to the tipping point. We have the following theorem to ensure the convergence of the adaptive rate control algorithm at most cases.

Theorem 1 *Assuming DL jobs are stable during the profiling phase and the convergence phase, the adaptive rate control algorithm converges in $O(B \log B)$ function calls, where B is the throughput limit of jobs in the GPU.*

The proof of the theorem is in Appendix A. The proof is based on the stability of the deep learning training workload. For readers familiar with congestion control in computer networking, our problem resembles the bandwidth allocation problem when multiple flows compete for the bandwidth resources of a shared link. In bandwidth allocation, each flow uses a congestion control algorithm to control its own rate, and after the system converges, each flow gets a fair share of the link bandwidth. Our problem is subtly different from bandwidth allocation in that we do not limit the rate of production jobs, and only control the rate of opportunistic jobs to ensure that the performance of production jobs is not greatly affected by resource sharing.

4.2 Sharing GPU Memory Resources

GPUs have GPU memory that is separated from the host memory. The memory size in modern GPUs ranges from a few GB to tens of GB. GPU memory stores the state and data needed by applications to perform their computation on the GPU. The compute units in the GPU can access the GPU memory much faster than the host memory. The GPU device driver exposes the GPU memory to users with an API, which is similar to the memory management API for the host memory. Users use the API to allocate and manage GPU memory for their GPU programs, e.g., `cudaMalloc` for GPU memory allocation on NVIDIA GPUs. Similar to GPU compute resources, the GPU memory can be shared by multiple containers when a single container cannot utilize all the GPU memory resources.

Strawman solution: pass-through allocation. A strawman solution is to directly pass the GPU memory allocation calls from containers to the GPU. In this way, the GPU memory is fully utilized as long as there is enough demand from containers. The major limitation of this solution is that it has large overhead for production jobs. In this solution, when production jobs do not use all the GPU memory, opportunistic jobs can obtain the remaining memory. Later, if the production job wants to allocate more GPU memory, they would not be able

Algorithm 1 Adaptive Rate Control Algorithm

```

1: procedure INIT
2:    $R = \text{measure\_high\_prio\_job\_rate}()$ 
3:    $\beta_{out} = 0$ 
4:    $state = SLOW\_START$ 
5:
6: procedure UPDATE_HIGH_RATE
7:    $R_{avg} = \text{avg}(\text{high\_rate\_window})$ 
8:    $dR = |R - R_{avg}|/R$ 
9:   if  $dR < R\_threshold$  then
10:     $R = \max(R, R_{avg})$ 
11:  else
12:     $R = \text{measure\_high\_prio\_job\_rate}()$ 
13:
14: procedure UPDATE_LOW_RATE_LIMIT
15:    $d\alpha = |R - \alpha_{in}|/R$ 
16:   switch  $state$  do
17:     case  $SLOW\_START$  :
18:       if  $d\alpha < \text{threshold}_{slow\_start}$  then
19:          $\beta_{out} * = \delta_{SS}$ 
20:       else
21:          $\beta_{out} / = \delta_{SS}$ 
22:          $state = CA$ 
23:     case  $CA$  :
24:       if  $d\alpha < \text{threshold}_1$  then
25:          $\beta_{out} + = \delta_{AI}$ 
26:       else if  $d\alpha > \text{threshold}_2$  then
27:          $\beta_{out} = 0$ 
28:          $state = SLOW\_START$ 
29:       else
30:          $\beta_{out} * = \delta_{MD}$ 

```

to do so because the remaining memory has been allocated to opportunistic jobs. Without sufficient GPU memory, production jobs may run at a lower speed, or even fail, which violates fault isolation.

Another limitation of this solution is that it does not consider the characteristics of DL frameworks. When starting a job, some DL frameworks (e.g., TensorFlow) claim all the available GPU memory even if the training job does not request that much memory. These DL frameworks typically have a memory pool that caches all the allocated memory, and give the memory to the training job on demand. They do not free and return the allocated memory back to the GPU when some memory is not used. This is an optimization in these DL frameworks to avoid the overhead of frequently calling GPU memory to allocate and release during a job.

This optimization introduces challenges to sharing the GPU memory. Application-layer solutions like AntMan [6] can directly modify DL frameworks to obtain the memory usage of training jobs and disable unnecessary memory caching to return unused GPU memory back to the GPU. However, to design a transparent OS-layer solution, modifications on DL frameworks or applications are not allowed.

Our solution: unified GPU and host memory. Modern GPUs provide a feature called *unified memory* which unifies GPU memory and host memory in a single address space. Unified memory is traditionally used by applications to simplify GPU memory management. TGS applies CUDA unified

memory [16] in a novel way: it uses CUDA unified memory allocation as an *indirection* of GPU memory allocation, in order to achieve transparency and performance isolation for GPU memory sharing. Specifically, TGS exposes CUDA unified memory as pseudo GPU memory to containers. When a container issues a GPU memory allocation call, whether the call is for regular GPU memory or CUDA unified memory, TGS intercepts this call and allocates the memory requested by the call in the CUDA unified memory space. When production jobs do not use up the GPU memory, opportunistic jobs can obtain the remaining GPU memory.

Pseudo GPU memory refers to that the allocated memory appears to be normal GPU memory to containers and applications, while it can actually come from either GPU memory or host memory depending on availability. Note that we do not change the virtual memory system. Pseudo memory is still virtual memory, and applications use virtual memory addresses to access allocated pseudo memory. A GPU/host virtual memory address is translated to a GPU/host physical memory address by the GPU/host memory management unit.

The transparent unified memory in TGS is different from the original CUDA unified memory in two aspects, which are (i) performance isolation and (ii) transparent oversubscription of GPU memory. To provide performance isolation, TGS uses placement preferences in CUDA unified memory to prioritize the allocation of GPU memory to production jobs. When the GPU memory is not full, the memory allocation requests from any job get the GPU memory. When the GPU memory is full, TGS tries to place the blocks of production jobs in the GPU memory, and evict the blocks of opportunistic jobs to the host if necessary. This is transparent to the containers, as the containers still use the same virtual memory addresses to access their allocated memory space. The virtual memory addresses are translated to physical memory addresses at different locations. This mechanism also does not introduce additional out-of-memory (OOM) faults, because in the view of DL training jobs, the GPU memory capacity is the same as the size of the original GPU memory.

The transparent unified memory in TGS also addresses the issue of overclaiming the GPU memory in existing DL frameworks, without modifications to DL frameworks. When the DL framework claims all the available GPU memory, TGS allocates the requested amount of memory from the CUDA unified memory space. The actually used memory would trigger GPU page faults and be swapped to the GPU memory when it is used for the first time, and then would reside in the GPU memory. Consequently, only the portion actively used by the training job is in the GPU memory; the remaining portion is in the host memory. This allows opportunistic jobs to efficiently share the GPU memory.

5 Implementation

We have implemented a system prototype for TGS with ~3000 lines of code in C++ and Python, and integrated it

with Docker and Kubernetes. A coordinator process takes charge of resource management and leverages the indirection layer of TGS to enable GPU sharing between containers. Specifically, the adaptive rate control and the transparent unified memory provided by TGS are used for GPU sharing. The code of TGS is open-source and is publicly available at <https://github.com/pkusys/TGS>.

Adaptive rate control. TGS intercepts CUDA driver API calls related to CUDA kernel launch from containers for rate monitoring and rate control. Because CUDA kernel launch may be evoked by multiple threads in the container, TGS uses a global counter to record the number of CUDA blocks launched in a given time period. A CUDA block is a group of threads that must execute in the same SM (Streaming Multiprocessor) and different CUDA blocks can run independently in parallel. As the number of a CUDA block that a kernel contains is specified in the CUDA driver API call, the number of pending CUDA blocks can be treated as a real-time signal to estimate the performance of production jobs. For a production container, a standalone thread serves as the rate monitor, which reads this counter of the TGS periodically and sends the value to the rate-control component of the opportunistic container on the same GPU. For an opportunistic container, a rate control thread is created when the CUDA driver starts to work. The rate control thread adjusts the rate limit of the opportunistic container according to the received statistics. To keep the kernel launch rate of the opportunistic container at a desirable value, all CUDA kernel launch API calls are redirected to the rate control component first. The rate control component accesses statistics generated by the rate monitor to examine whether the rate limit is satisfied and defers the kernel launch if the rate of the opportunistic container exceeds the rate limit.

Unified memory management. To implement transparent memory sharing, TGS intercepts CUDA driver API calls related to GPU memory allocation, such as `cuMemAlloc`, and replaces these calls with unified memory allocation calls using `cuMemAllocManaged`. We use `cuMemAdvise` to prioritize the allocation of GPU memory for production containers. Specifically, we use `cuMemAdvise` to set the preferred location of memory allocation as the current GPU to avoid eviction for production containers. When the production container finishes, the indirection layer in the opportunistic container would use CUDA driver API `cuMemPrefetchAsync` to prefetch memory located in the host memory transparently.

6 Evaluation

Setup. Most experiments are conducted on a server machine configured with an Intel Xeon Silver 4210R CPU, two NVIDIA A100 40 GB PCIe GPUs and 126 GB host memory. AntMan [6] only open-sourced one particular version based on TensorFlow 1.15.4 and the version is not compatible

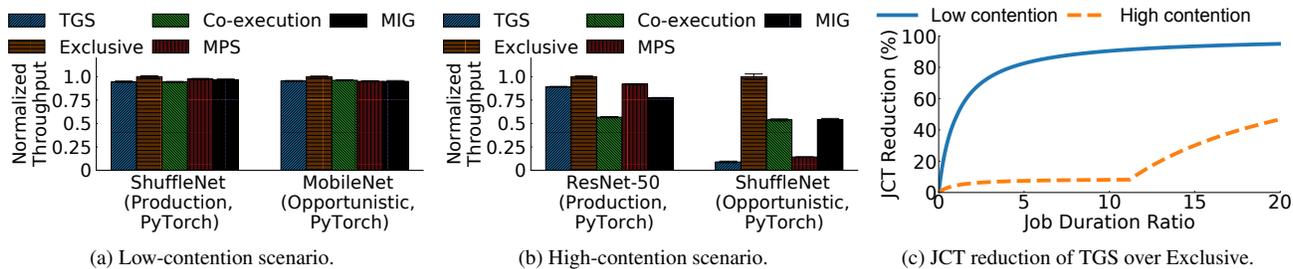

Figure 4: Throughput of production and opportunistic jobs for different model pairs when GPU memory is sufficient.

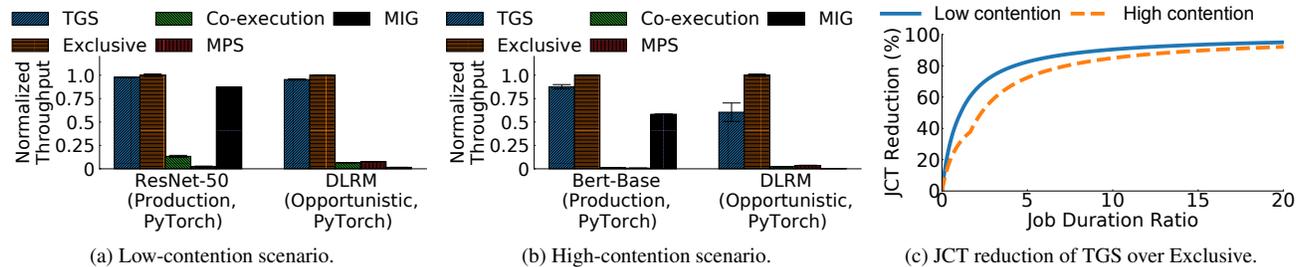

Figure 5: Throughput of production and opportunistic jobs for different model pairs under GPU memory oversubscription.

with A100. Therefore, all experiments involved in TensorFlow are conducted on an AWS p3.2xlarge instance which is configured with eight Intel Xeon Scalable (Skylake) vCPUs, one NVIDIA V100 16 GB Tensor Core GPU and 61 GB host memory. The software environment includes NVIDIA driver 460.91.03, CUDA 11.2, Docker 20.10.5, PyTorch 1.9.0, TensorFlow 1.15.4, torchvision 0.10.0 and scipy 1.6.3.

Workloads. We use various models for evaluation. The models include ShuffleNet, MobileNet, GCN (Graph Convolutional Network), ResNet-50, BERT-Base, DLRM (Deep Learning Recommendation Model) and ESPnet2. These models are representative and widely-used, and are standard benchmarks for evaluating DL systems. They vary in terms of GPU resource usage, which allows us to evaluate TGS under different levels of GPU resource contention.

Comparison. To demonstrate the benefits of TGS, we compare the following mechanisms in the experiments. Each job runs in a separate container. We use throughput (iterations per second) as the main metric to evaluate the performance of different mechanisms, because it is a direct metric of a job’s speed. We run at least 100 seconds for each case to measure the variance of the throughput, which typically includes 2000 iterations of a DL training job. Because a DL training job performs the same computation for each iteration (only the input data is different), the variance is low. We also use job completion time (JCT), but it depends both on the throughput and the number of iterations. The latter is configured by the user and varies from job to job.

- **TGS.** This is the proposed system.
- **Exclusive.** The production and opportunistic jobs are given exclusive access to a GPU when they run.

- **Co-execution.** The production job and the opportunistic job are executed concurrently without TGS.
- **NVIDIA MPS.** The production job and the opportunistic job run concurrently with NVIDIA MPS. We manually find the appropriate resource limit to set for each job in MPS to ensure that the performance of the production job is not affected by the opportunistic job.
- **NVIDIA MIG.** We manually set the best configuration to partition GPUs into different GPU instances so that the performance degradation of the production job brought by the opportunistic job is minimal.

Due to the compatibility issue of AntMan [6], we compare it with TGS in §6.7.

6.1 Adaptive Rate Control

TGS uses an adaptive rate control approach to allocate GPU compute resources between containers in order to simultaneously achieve high GPU utilization and performance isolation. In this experiment, we show that TGS packs an opportunistic job with a production job on a GPU to increase GPU utilization when the production job cannot use up all the GPU resources, and that the overhead of the production job is 5% to 10.8%. We use two different pairs of DNN models for the production job and the opportunistic job to evaluate TGS under different scenarios of resource contention. In this experiment, the total required GPU memory of the two jobs does not exceed the GPU memory capacity. This allows us to focus on evaluating the effectiveness of adaptive rate control. In the experiment, the two jobs arrive at the same time, and we measure the throughput for each job. To clearly show the difference between the five mechanisms, we normalize the throughput of each mechanism to that of Exclusive.

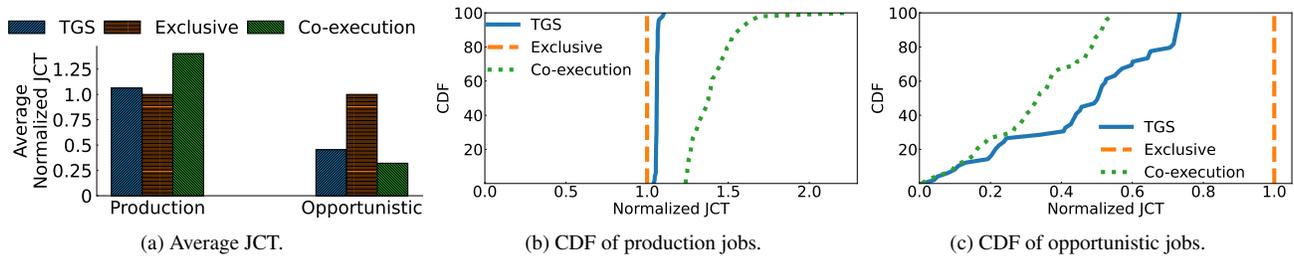

Figure 6: Performance comparison under a mixed workload job stream.

Figure 4a compares the performance of the five mechanisms when the production job trains ShuffleNet with batch size 4 and the opportunistic job trains MobileNet with batch size 4. These two models are small, so this case has low resource contention, and the throughput of the production job and the opportunistic job is almost the same for the five mechanisms. The overhead of TGS is 5%.

Figure 4b shows the results when the production job trains ResNet-50 with batch size 24 and the opportunistic job trains ShuffleNet with batch size 64. Both models are more computation-intensive than the models in Figure 4a. Thus, this case has a higher resource contention. TGS and MPS provide higher performance of the production job compared to Co-execution, because TGS and MPS control the resource allocation. Co-execution does not provide performance isolation, so the contention with the opportunistic job causes the throughput of the production job to reduce to 57% of that under Exclusive. The opportunistic job gets more resources than it should get by contending with the production job under co-execution. Thus the throughput of the opportunistic job under co-execution is high. TGS incurs 10.8% overhead for the production job although the resource contention is high. The performance provided by MPS is also comparable with TGS, although MPS sacrifices fault isolation. MIG only provides limited configurations for each GPU instance. On an NVIDIA A100 GPU, each GPU instance can only use at most one half of the total GPU memory and 4/7 of total SMs for GPU computation when a GPU is partitioned into two instances. In the high contention scenario, when the production job needs more GPU SMs than 4/7 for computation, the performance of the production job suffers, and is reduced to 77% of that under Exclusive. The opportunistic job gets more resources than it should, so its throughput is quite high.

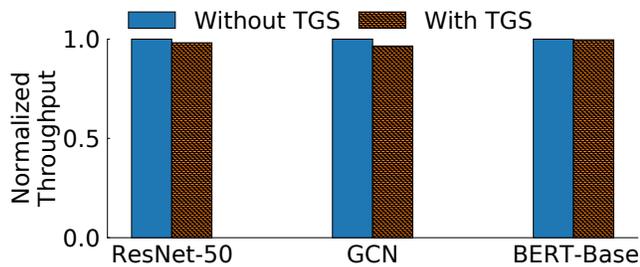

While TGS protects production jobs from high contention caused by the opportunistic job, some sharing overhead is inevitable. In terms of throughput, Exclusive slightly outperforms TGS, because Exclusive runs DL models exclusively on the GPU. However, in this case, opportunistic jobs have to wait until the completion of the production job before execution. This leads to longer JCT for opportunistic jobs. Figure 4c shows that as the ratio of the job duration of the production job to that of the opportunistic job becomes larger, TGS can significantly reduce the queuing delay and thus speed up the

opportunistic job over Exclusive. When the ratio is 20, TGS can reduce the JCT of the opportunistic job by 95% than Exclusive at the low-contention scenario and by 47% at the high-contention scenario.

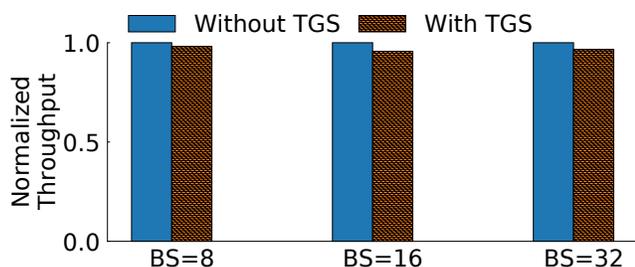

6.2 Unified Memory Management

In this experiment, we show that TGS provides high GPU utilization and performance isolation for GPU sharing even when the GPU memory is oversubscribed. We use two different pairs of DNN models to evaluate TGS under different scenarios. To oversubscribe the GPU memory, we use DLRM as the model of the opportunistic job for both pairs. DLRM is a large recommendation model with high GPU memory consumption. Similar to previous experiments, two jobs arrive at the same time, and we measure the throughput of each job. To clearly show the differences between the five mechanisms, we normalize the throughput of each mechanism to that of Exclusive for each job. Because MPS and Co-execution do not support GPU memory oversubscription, we modify the DL frameworks to use unified memory to evaluate them.

Figure 5a compares the performance of the five mechanisms when the production job trains ResNet-50 with batch size 16 and the opportunistic job trains DLRM with batch size 2048. The overhead of TGS is 2.3% compared to Exclusive. Co-execution has lower throughput due to resource contention. While MPS can set resource limits for SM usage, it cannot prioritize GPU memory allocation, and the two jobs contend for GPU memory resources when the GPU memory is oversubscribed. This causes significant memory swapping between GPU memory and host memory for both jobs, which degrades the performance of the production job under GPU memory oversubscription. MIG can partition the GPU memory resources, but it cannot provide sufficient GPU SMs with the production job due to the configuration constraints. Therefore, the performance of the production job under MIG is lower than that of Exclusive and TGS. In terms of the opportunistic job, Co-execution and MPS have lower throughput due to GPU memory contention. TGS improves the throughput by $7.8\times$ over MPS for the opportunistic job by prioritizing memory allocation. MIG cannot partition GPU memory flexibly. The GPU instance of the opportunistic job can only use one half of the GPU memory to maintain performance of the production job. Therefore, the throughput of the opportunistic

(a) Different DNN models.

(b) Different batch sizes.

Figure 7: System overhead of TGS.

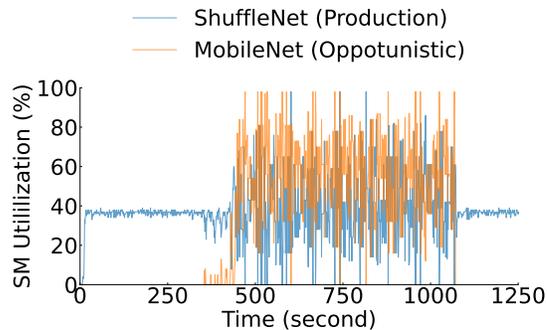

job under MIG is even lower than that of Co-execution and MPS.

Figure 5b shows the results when the production job trains BERT-Base with batch size 4 and the opportunistic job trains DLRM with batch size 256. BERT-Base is more computation-intensive than ResNet-50, and thus there is heavier contention. TGS maintains the performance as Exclusive with 12.3% overhead for the production job. Due to heavier contention, Co-execution and MPS perform worse for the production job. Due to more GPU compute resource demand, MIG performs also worse. TGS improves the throughput by $36\times$ over Co-execution, $72\times$ over MPS, and $1.5\times$ over MIG for the production job. TGS also performs the best for the opportunistic job compared to MIG, MPS and Co-execution. They are slower due to resource contention and simply use unified memory without leveraging priority information. For the opportunistic job, TGS improves the throughput by $24\times$, $15\times$ and $259\times$, compared to co-execution, MPS, and MIG, respectively.

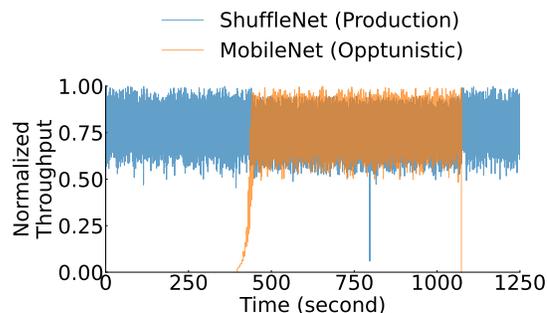

Exclusive provides all GPU resources to the production job, even though GPU resources are not fully utilized. As a result, the opportunistic job has a long queuing time—it has to wait for the production job to finish before it can be executed. As shown in figure 5c, when the ratio of the job duration of the production job to that of the opportunistic job reaches 20, TGS reduces the JCT of the opportunistic job by 95% over Exclusive at the low-contention scenario and by 92% at the high-contention scenario.

6.3 Mixed Workload Job Stream

In this experiment, we compare TGS with Exclusive and Co-execution when sharing a GPU between a mixed workload job stream. The DNN models used in the trace are consistent with previous experiments, including ResNet-50, MobileNet,

(a) GPU utilization.

(b) Training throughput.

Figure 8: Convergence under dynamic job arrival.

ShuffleNet, GCN, BERT-Base, and DLRM. The running time of the jobs are from a production DL training job trace of Microsoft [5]. The job stream contains 100 jobs, where half are production jobs and the other half are opportunistic jobs. We use fast-forwarding [18] to speed up the experiment. NVIDIA MIG and NVIDIA MPS cannot dynamically change GPU resources allocated to a DL training job, so we do not compare them in this experiment.

Figure 6a shows the average JCT when executing the trace. For fair comparison, we normalize the JCT of each mechanism to that of Exclusive for each job. As shown in figure 6b, because Co-execution cannot protect production jobs from contention caused by GPU sharing, the average normalized JCT of production jobs under Co-execution is 135% of that under Exclusive, while TGS only incurs 6% overhead. Compared to Exclusive, Figure 6c shows that TGS can significantly reduce the JCT of opportunistic jobs. This is because TGS can reduce the queuing time of opportunistic jobs, as they can use remaining GPU resources not used by production jobs, instead of waiting for production jobs to complete. TGS reduces the average normalized JCT of opportunistic jobs to 48% of that under Exclusive.

6.4 System Overhead

TGS monitors the rate of production jobs, and relies on the monitoring to decide whether a GPU can be shared and how many resources can be allocated to opportunistic jobs. When a GPU is shared, experiments in previous sections have demonstrated that opportunistic jobs do not greatly affect production

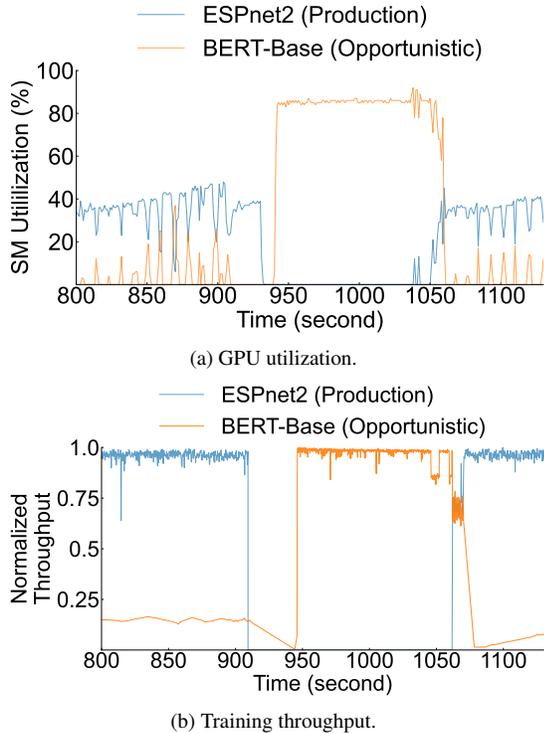

Figure 9: Convergence under dynamic resource usage.

jobs. In this experiment, we explore the system overhead of the rate monitoring component in TGS. We measure the throughput of a job with and without TGS for different configurations, and normalize the throughput to that without TGS.

Figure 7a shows the throughput under different DNN models. The throughput is almost the same with and without TGS for ResNet-50, GCN and BERT-Base. Figure 7b shows the throughput under different batch sizes. We use ResNet-50 as the DNN model. Similarly, the JCT is almost the same with and without TGS for batch size 8, 16 and 32. The results demonstrate that the rate monitoring component of TGS incurs 0.3% to 5% overhead for production jobs.

6.5 Convergence

We evaluate the convergence of TGS in different scenarios. The first scenario evaluates the convergence under *dynamic job arrivals*, i.e., a job arrives in the middle to share the GPU with an existing job. In this scenario, the production job training ShuffleNet with batch size 4 is running in the beginning. The opportunistic job training MobileNet with batch size 4 is started after 350 seconds and runs for 240 seconds before it finishes. Figure 8a and Figure 8b show the time series of the GPU utilization and normalized throughput, respectively. As shown in Figure 8a, there are still idle GPU resources when the production job runs, so the total GPU utilization increases when the two jobs run concurrently and share the GPU. Figure 8b shows that the throughput of the opportunistic job increases when it is launched at 350 seconds. At the

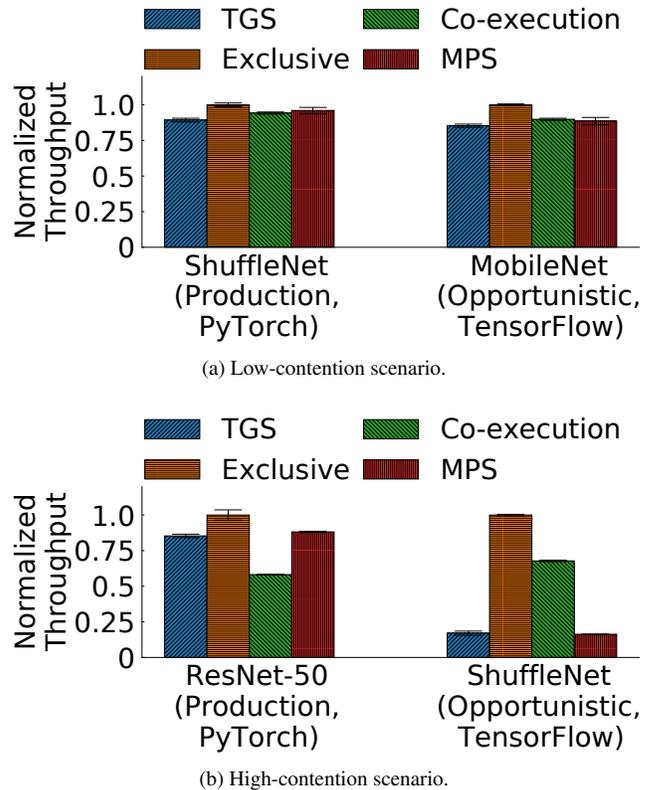

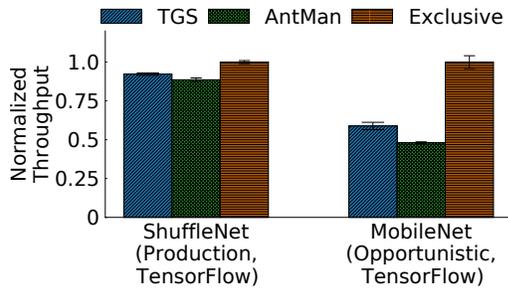

Figure 10: GPU sharing between different DL frameworks.

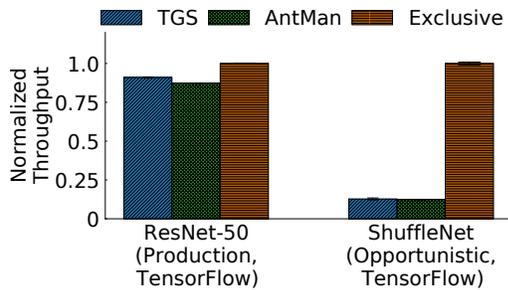

same time, GPU sharing does not affect the throughput of the production job.

The second scenario evaluates the convergence under *dynamic resource usage*, i.e., a job dynamically switches between high and low GPU utilization, and the other job utilizes the unused GPU resources. In this scenario, the production job trains ESPnet2 with batch size 1 and the opportunistic job trains BERT-Base with batch size 16. ESPnet2 has several phases, so it changes GPU utilization periodically. Figure 9a and Figure 9b show the time series of the GPU utilization and normalized throughput during a transition, respectively. When ESPnet2 needs more GPU resources, the production job keeps its maximum throughput. Between 910 and 940 seconds, ESPnet2 does not train, but runs validation in the GPU. Thus ESPnet2 still utilizes GPU but the throughput is zero. After 940 seconds, ESPnet2 runs into a phase that primarily uses CPU, and Figure 9a shows that the GPU utilization of ESPnet2 decreases to 0. TGS detects the change and dynamically allocates more GPU resources to the opportunistic job. After 1060 seconds, the production job starts using GPU again and reclaims all GPU resources. TGS ensures that the production job is not greatly affected by the opportunistic job.

In summary, these experiments demonstrate that TGS can converge in different scenarios. On the contrary, MIG cannot change GPU resource allocation to each GPU instance whenever there is a job running on the GPU, and MPS cannot change GPU resources allocated to a job after the job begins.

(a) Low-contention scenario.

(b) High-contention scenario.

Figure 11: Comparison between TGS and AntMan.

6.6 Supporting Different DL Frameworks

The experiments in previous sections are based on PyTorch, because TensorFlow-like frameworks claim all GPU memory by default when DL models start and the baselines cannot be directly used for GPU sharing for these frameworks. Specifically, Co-execution does not support GPU memory oversubscription or GPU memory allocation on demand. When one job claims all GPU memory, another job cannot use any GPU memory and would be aborted under Co-execution. MPS also suffers from this behavior. To compare TGS with them, we modify DL frameworks to use CUDA unified memory and enable dynamic GPU memory allocation.

Figure 10a compares the performance of the four mechanisms when the production job trains ShuffleNet with batch size 4 on PyTorch and the opportunistic job trains MobileNet with batch size 4 on TensorFlow. The result is similar to that of Figure 4a.

Figure 10b compares the performance of the four mechanisms in the high contention scenario. The production job trains ResNet-50 with batch size 16 and the opportunistic job trains ShuffleNet with batch size 32. Similar to figure 4b, TGS reduces the throughput of the production job by 14% compared to Exclusive, while Co-execution reduces the throughput by 41%. MPS achieves comparable performance, but it has to be manually tuned and breaks fault isolation.

6.7 Comparison with AntMan

In this experiment, we compare TGS with AntMan [6], which is a state-of-the-art application-layer solution for GPU sharing. AntMan is closely coupled with DL frameworks and uses an application-layer metric, iteration time, to control the oppor-

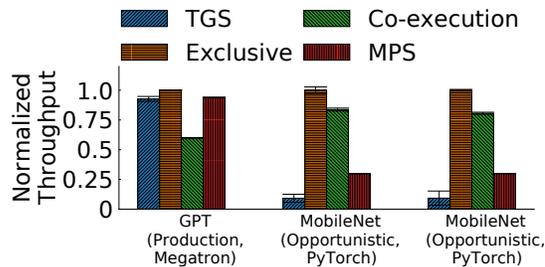

Figure 12: GPU sharing with the large model.

tunistic job. The open-sourced GitHub repository of AntMan is not fully functional. It does not include the logic to dynamically allocate resources to jobs. We contacted the authors of AntMan and followed their instructions to add necessary code in order to run AntMan. Figure 11a and 11b show the comparison under low-contention (ShuffleNet with batch size 4 and MobileNet with batch size 4) and high-contention scenarios (ResNet-50 with batch size 8 and ShuffleNet with batch size 4), respectively. Although AntMan uses application-layer knowledge and controls the jobs at the application layer, TGS still achieves similar performance to AntMan. The throughput of the production job under TGS is 104.1% to 104.3% than that under AntMan, while the throughput of the opportunistic job using TGS is 103% to 122% than that of AntMan. Compared to AntMan, TGS provides the same benefit of GPU sharing and is transparent to DL frameworks.

6.8 GPU Sharing for Large Model Training

In §6.2, we have shown that even if a large model (e.g., DLRM) with large batch size (e.g., 2048) and large memory consumption (e.g., 38 GB) runs on a GPU, TGS can still mostly maintain the performance of the production job, while providing the remaining GPU resources to the opportunistic job. In this experiment, we show that although it is not a common scenario, TGS can provide GPU sharing capability when training a bigger model (e.g., GPT). We train a GPT with batch size 32 using two NVIDIA A100 GPUs as the production job, while running two single-GPU opportunistic jobs training MobileNet with batch size 4. Figure 12 shows that TGS still can achieve comparable performance compared to MPS, while MPS breaks fault isolation and Co-execution breaks performance isolation. NVIDIA MIG does not support multi-GPU jobs when a GPU is partitioned into several GPU instances, so it is not evaluated in this case.

7 Discussion

Distributed training. Many solutions have been proposed to achieve high GPU utilization for distributed training jobs [19–23]. With these solutions, it is unlikely that a distributed training job would leave substantial GPU resources unused; otherwise, the job should reduce its GPUs. Therefore, there is little need for TGS. It is most suitable for sharing GPUs between single-GPU jobs, which is also how GPU sharing is used in previous solutions [6, 12, 13]. Yet, TGS

can be applied to increase GPU utilization for unoptimized distributed jobs, by controlling the GPU resource usage of an opportunistic job on each GPU as for single-GPU jobs.

GPU cluster scheduling. Many solutions [7, 18, 24–28] have been proposed to minimize job completion time and provide fairness for a GPU cluster. GPU cluster scheduling is orthogonal and complementary to TGS. TGS provides the mechanism for transparent GPU sharing, which can be used by cluster schedulers when they schedule and place jobs. We note that some schedulers [18, 28] pack multiple jobs on a GPU, which are at the application level and require modifications to DL frameworks. Also, they do not support GPU memory oversubscription. These schedulers can benefit from TGS.

Space sharing and time sharing. The concepts of GPU compute sharing and memory sharing are orthogonal to space sharing and time sharing. Sharing GPU compute resources can be done either in space sharing or in time sharing. The adaptive rate control mechanism and transparent unified memory mechanism of TGS can be used either in space sharing or in time sharing. GPU space sharing needs hardware support and is not well supported. Current space sharing solutions reduce performance isolation (e.g. MIG) or fault isolation (e.g. MPS). Therefore, TGS currently uses time sharing.

8 Related Work

Deep learning systems. Many DL frameworks have been proposed for developing and running DNN models [29–36]. Some works optimize communication to improve distributed training performance [19–23]. Some works use memory swapping to handle the GPU memory problem for training large DNN models [16, 37–39]. They focus on improving the performance of a single training job, while TGS provides a solution for improving the GPU utilization of running many jobs in a cluster. Some works [40, 41] propose algorithms for inter-job GPU memory management, but they are not transparent to applications and require modifications to DL frameworks. GPUswap [42] proposes a transparent GPU memory swapping system, but it needs to modify GPU drivers. However, most current commercial GPU drivers, such as NVIDIA GPU drivers, are not open-source. Open-source GPU drivers are not as high performance as the commercial ones, so they are not widely used for DL training workloads. MIG-Serving [43] tries to find better configurations to use MIG for GPU sharing. However, MIG itself has limitations as described above. We compare MIG with the best configuration and TGS in the evaluation section, and show the benefits of TGS. There are many solutions for optimizing DL inference workloads [44, 45]. We focus on GPU clusters for training workloads in this paper. Several scheduling algorithms have been designed to schedule DL training jobs in a GPU cluster [7, 18, 24–28]. These works are orthogonal to TGS.

Containers. Containers provide lightweight virtualization for applications. Due to the benefits of portability, isola-

tion and performance, containers are widely used in datacenters. Major public cloud services, such as AWS, Microsoft Azure and Google Cloud, offer containers as a service [46–48]. Many container runtimes (e.g., Docker) and orchestration systems (e.g., Kubernetes) are developed and deployed [1–3, 10, 11, 49, 50]. Some work is proposed to provide high-performance networking with isolation [51–56]. These solutions are orthogonal to TGS, which focuses on improving GPU utilization.

GPU sharing. Several solutions have been proposed for GPU sharing. Early solutions [57–65] explored OS-layer techniques like driver call interception and application-layer techniques like introducing new programming APIs, for sharing GPU between applications. They focus on jobs with a few kernels, and are not specifically designed for DL training that typically has hundreds of kernels. With the emergence of DL applications, recent solutions [6, 12, 13] have been designed for GPU sharing of DL training. AntMan [6] is the state-of-the-art application-layer solution for GPU sharing. Salus [12] uses centralized GPU memory management and kernel scheduling for GPU sharing. It requires all the applications to fit in the GPU memory. PipeSwitch [13] provides fast context switching for DNN jobs, but only one job can run at each time. They all modify DL frameworks. MPS [9] is an OS-layer solution, but it requires application knowledge to correctly set resource limits, does not support GPU memory oversubscription and does not provide fault isolation. Planaria [66] is an accelerator designed for the multi-tenant scenario. In comparison, TGS is a software solution that can be used for sharing a variety of hardware.

9 Conclusion

We have presented TGS, a system that transparently shares GPUs for DL workloads to improve GPU utilization in container clouds. TGS is distinguished from state-of-the-art application-layer solutions in that it enables users to use any DL framework and library to develop and train DNN models in containers. Shared GPUs are exposed to containers as regular GPU devices, and TGS transparently runs multiple containers on a GPU when a single container cannot utilize all GPU resources. TGS achieves both high utilization and decent performance isolation.

A Convergence of Adaptive Rate Control Algorithm

We assume each GPU has an unknown constant throughput limit B . The TGS's goal is to maximize throughput of the opportunistic job without affecting the production job very much. We assume throughput of the production job is relatively stable. Therefore, the adaptive rate control algorithm can accurately measure the throughput of the production job, i.e. α_{in} . When throughput of the production job is unstable beyond a manual tuned threshold, TGS re-estimates α_{in} . In this context, we define that a *cycle* is a phase starting after TGS detects contention and ending when TGS detects contention again. A *step* is defined as an invocation of the rate control component to adjust rate limit of the opportunistic job, such as an additive increase or a multiplicative decrease. Hence, a *cycle* consists of one multiplicative decrease *step* and multiple continuous additive increase *steps*. Let the initial value of β_{out} be β_0 ($\beta_0 \leq B$). The simplified convergence of the rate adaptive control algorithm is shown as follow:

Opportunistic Job	production Job
β_0	$\min(R, B - \beta_0)$
$\beta_1 = \beta_0 + \delta_{AI}$	$\min(R, B - \beta_1)$
$\beta_2 = \beta_0 + \delta_{AI} + \delta_{AI}$	$\min(R, B - \beta_2)$
\vdots	\vdots
$\beta_k = \beta_0 + \underbrace{\delta_{AI} + \dots + \delta_{AI}}_k$	$\min(R, B - \beta_k)$
Detect Contention:	$R + \beta_0 + k\delta_{AI} \geq B$
Action:	Multiplicative Decrease
$\beta_{k+1} = \frac{\beta_0 + k\delta_{AI}}{\delta_{MD}}$	$\min(R, B - \beta_{k+1})$
$\beta_{k+2} = \frac{\beta_0}{\delta_{MD}} + \frac{k\delta_{AI}}{\delta_{MD}} + \delta_{AI}$	$\min(R, B - \beta_{k+2})$
$\beta_{k+3} = \frac{\beta_0}{\delta_{MD}} + \frac{k\delta_{AI}}{\delta_{MD}} + \delta_{AI} + \delta_{AI}$	$\min(R, B - \beta_{k+3})$
\vdots	\vdots
$\beta_{k+l+1} = \frac{\beta_0}{\delta_{MD}} + \frac{k\delta_{AI}}{\delta_{MD}} + \underbrace{\delta_{AI} + \dots + \delta_{AI}}_l$	$\min(R, B - \beta_{k+l+1})$
Detect Contention:	$R + \frac{\beta_0}{\delta_{MD}} + \frac{k\delta_{AI}}{\delta_{MD}} + l\delta_{AI} \geq B$
Action:	Multiplicative Decrease
$\beta_{k+l+2} = \frac{\beta_0}{\delta_{MD}^2} + \frac{k\delta_{AI}}{\delta_{MD}^2} + \frac{l\delta_{AI}}{\delta_{MD}}$	$\min(R, B - \beta_{k+l+2})$
\vdots	\vdots
$\beta^* = \frac{\beta_0}{\delta_{MD}^{\log \beta_0}} + \frac{k\delta_{AI}}{\delta_{MD}^{\log \beta_0}} + \frac{l\delta_{AI}}{\delta_{MD}^{\frac{\log \beta_0}{2}}} + \dots + m$	$\min(R, B - \beta^*)$

We assume the unit of bandwidth is indivisible. As shown above, the adaptive rate control algorithm converge in $O(\log \beta_0)$ *cycles*, because the unknown term β_0 decreases to zero in $O(1 + \log \beta_0)$ *cycles*, i.e. $O(B \log B)$ *steps*. Therefore, the complexity of the adaptive rate control algorithm is $O(B \log B)$.

ARK: GPU-driven Code Execution for Distributed Deep Learning

Abstract

Modern state-of-the-art deep learning (DL) applications tend to scale out to a large number of parallel GPUs. Unfortunately, we observe that the collective communication overhead across GPUs is often the key limiting factor of performance for distributed DL. It under-utilizes the networking bandwidth by frequent transfers of small data chunks, which also incurs a substantial I/O overhead on GPU that interferes with computation on GPU. The root cause lies in the inefficiency of CPU-based communication event handling as well as the inability to control the GPU’s internal DMA engine with GPU threads.

To address the problem, we propose a *GPU-driven* code execution system that leverages a GPU-controlled hardware DMA engine for I/O offloading. Our custom DMA engine pipelines multiple DMA requests to support efficient small data transfer while it eliminates the I/O overhead on GPU cores. Unlike existing GPU DMA engines initiated only by CPU, we let GPU threads directly control DMA operations, which leads to a highly efficient system where GPUs drive their own execution flow and handle communication events autonomously without CPU intervention. Our prototype DMA engine achieves a line-rate from a message size as small as 8KB (3.9x better throughput) with only 4.3 μ s of communication latency (9.1x faster) while it incurs little interference with computation on GPU, achieving 1.8x higher all-reduce throughput in a real training workload.

1 Introduction

Modern machine learning (ML) applications tend to harness an increasingly larger number of accelerators (especially GPUs in this work) [19, 26]. State-of-the-art deep learning (DL) algorithms often need to scale out to thousands of GPUs for higher throughput and accuracy [26]. Unfortunately, this poses a substantial communication overhead to the entire system, which harms GPU utilization by delaying or interfering with numeric computation.

The communication overhead mainly arises in two different aspects. First, collective communication (e.g., all-reduce, split-and-gather, all-to-all, etc.), which is widely adopted in most of popular DL algorithms, often splits the data for transfer into multiple small chunks for pipelining or for sending to multiple different destinations. The chunk size tends to get smaller as we scale out, which is detrimental to efficient utilization of networking bandwidth. Second, popular communication libraries for GPUs such as NCCL [32] and RCCL [5] often incur a severe I/O overhead on GPU. This is because they commonly leverage memory-mapped I/O (MMIO) for data copies between GPUs, which consumes a substantial amount of GPU resources (i.e., core cycles and L2 cache/DRAM bandwidth). We observe that concurrent execution of collective communication and numeric computation on GPU heavily interferes with each other – in our training experiment with BERT-Large [10], the throughput of parallel computation drops by 45% while it achieves only 53.6% of the peak communication throughput (see details in Section 2.3).

Unfortunately, it is challenging for existing systems to address both issues (i.e., large transfer delay for small chunks and I/O overhead on GPU) at the same time. One may avoid the I/O overhead by offloading the I/O to a hardware DMA engine instead of employing MMIO with GPU threads. However, the current DMA engine on commodity GPU is initiated only by CPU threads, which often enrolls CPU’s control on the critical path of communication. This incurs the CPU-GPU synchronization overhead that bloats up the communication latency, especially detrimental to the throughput of small data chunk transfer. In fact, one can observe hundreds of μ s of communication latency in a popular DL framework as it leverages the DMA engine. Similarly, if one does not employ the DMA engine for communication of data chunks, the communication would suffer from high I/O overhead on GPU.

This paper proposes the *GPU-driven* system named *ARK*, a communication-motivated DL system design. The key idea of the GPU-driven system lies in autonomous execution control of GPU code without any control by external devices. This regime tightly connects computational power of every GPU

[†] Now at Horizon Robotics.

core across machines by allowing GPU threads to communicate directly with remote GPUs without any external control signals, which ends up achieving low-latency communication. At the same time, to avoid the I/O overhead on GPU, we design a GPU-controlled DMA engine. Specifically, our custom DMA engine is directly initiated by GPU threads, which avoids the heavy MMIO without CPU intervention.

Our evaluation shows that our DMA engine prototype is especially beneficial for small messages, achieving a high communication throughput (3.87x over `cudaMemcpy` with 8KB messages) at low latency (9.1x faster over CPU intervention). Furthermore, it does not interfere with computation on GPU, which delivers both computation and communication throughput gains over using MMIO-based libraries [5, 32] (1.8x faster all-reduce in BERT-Large [10] training, see Section 5.3).

To realize the GPU-driven system, we also present an efficient scheduler of autonomous execution on GPU. Our key observation is that online dynamic scheduling is unnecessary as DL workloads are typically deterministic at runtime. Instead, we present the *virtual Cooperative Thread Array* (vCTA) framework that abstracts *offline* GPU scheduling. Offline scheduling allows eliminating the runtime scheduling overhead at the back-end, while reusing the existing front-end interface and GPU kernel implementations.

ARK supports efficient and flexible parallel execution models for data-, tensor-, and pipeline-parallelisms. Our evaluation demonstrates that ARK delivers substantial performance gains both in training and inference, achieving 2.5x and 3.6x throughput improvement, respectively.

2 Background & Motivation

This section explains existing inter-GPU communication technologies and their limitations.

2.1 Small Data Transfer in Distributed DL

Collective communication consists of several communication primitives that concurrently exchange the data across multiple GPUs, which is widely adopted to implement various parallelism methods in distributed DL. Popular use cases include *all-reduce* for data-parallelism, *split-and-gather* for tensor-parallelism [22, 40], and *all-to-all* for expert-parallelism [11]. As the number of employed GPUs gets larger, the size of unit data transfer in collective communication becomes smaller as it splits the local data into multiple pieces to be delivered to different GPUs. This small transfer size makes the overall performance of collective communication highly dependent on the control plane overhead before and after each data transfer. Unfortunately, we observe that the control plane overhead either with *CPU-controlled* or even *GPU-controlled* communication is pretty substantial (See Section 2.2 and Section 2.3). Also, existing workarounds (e.g., *tensor fusion* [39]) that batch a large amount of data to avoid small transfers would not completely address the problem as they trade off computational throughput by intentionally delaying data transfer.

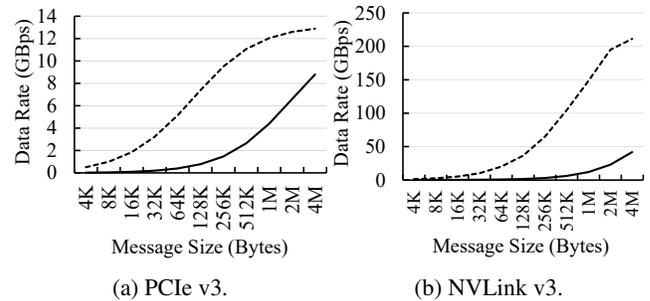

Figure 1: Data dependency between GPUs decreases the inter-GPU data rate due to event handling delays. Solid lines refer to actual data rate (for sending one message at a time) in TensorFlow’s CPU-controlled communication crossing a PCIe v3 or a NVLink v3 switch while dashed lines indicate the ideal data rate without event handling delays.

2.2 External Execution Control Overhead

Existing GPU program execution heavily relies on an external processor (i.e., CPU) to submit GPU commands for kernel execution or data transfer. Unfortunately, this model often incurs a large overhead due to the delay for command delivery from the host side to GPU hardware queue (i.e., *stream*). One can use the conventional GPU event interface (i.e., `cudaEvent`) to hide the delay, but it would also suffer from substantial delay for event handling. When adopted to inter-GPU communication, which we call *CPU-controlled* communication (in contrast to *GPU-controlled* communication by NCCL [32]), we observe that event handling becomes the primary cause for large communication delay beyond the data transfer itself.

We consider a common communication scenario where two GPUs have a data dependency – one GPU receives computation results of another GPU to feed them as input to its own computation. In every data transfer, event handling is needed to check the dependency between the copy and the GPU commands around the copy operation, which reduces the actual data rate between GPUs. Figure 1 compares the ideal inter-GPU data rate (`cudaMemcpy` throughput) with the actual data rate in TensorFlow’s CPU-controlled communication, which is still used along with NCCL especially for model-parallelism implementations. We see that the event handling overhead with `cudaMemcpy` drastically lowers the data rate both in the PCIe and NVLink interfaces. We explain two implementations when GPU A sends data to GPU B.

2.2.1 Runtime Intervention for the Control

CPU can serve as an intermediary to deliver an event between two communicating GPUs. In fact, if GPUs are located in different NUMA nodes or on different machines, the runtime intervention by CPU is required for communication. Also, some frameworks like TensorFlow implement a generic interface that always uses CPU for GPU event handling regardless of the placement. Figure 2 illustrates the event handling overhead due to CPU intervention when GPU A sends its data to

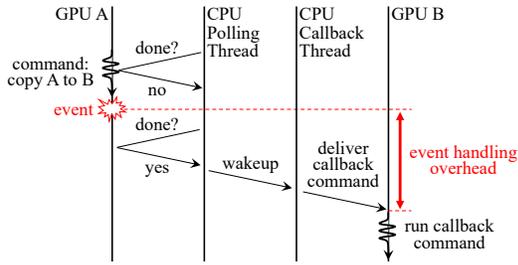

Figure 2: CPU intervention in inter-GPU event handling.

GPU B that plans to run the next command with the data.

We notice three places for the overhead. First, it is inefficient for a CPU thread to poll GPU events because the event interface disallows the CPU thread to monitor multiple events at the same time. While it takes only $\sim 3\mu\text{s}$ for a dedicated busy-waiting CPU thread to be notified of a triggered GPU event,² this approach does not scale when an application has to run many parallel tasks, which will run many polling threads. Instead, the event polling loop of TensorFlow uses only one CPU thread, which incurs a $\sim 58.3\mu\text{s}$ of polling gap on average (see Table 1). Second, it takes time to wake up the CPU thread that invokes the callback function of the triggered event. In TensorFlow, it takes $\sim 58.7\mu\text{s}$ for the callback thread to acquire the mutex lock from when it is released by the polling thread. This delay could be reduced to as low as $5\mu\text{s}$ if both threads are running on the same CPU core, but co-locating the threads or even merging them into a single one would increase the event polling interval as well as the overall processing time. Lastly, it is inefficient for the callback thread to deliver the computation command to GPU B. Delivering the event signal to GPU B would take only $2\sim 3\mu\text{s}$ if implemented efficiently,³ but we need to deliver the callback command binary as well. We can avoid the extra delay if we deliver the GPU command in advance and trigger it later on the CPU side, but this is not supported by commodity GPU.

2.2.2 Asynchronous Control

If the GPUs are under the same NUMA node, CPU can reserve a GPU event to be triggered asynchronously so that GPUs can directly communicate with each other when the event occurs. In this case, one can deliver the callback command to GPU B before the actual event and use the conventional GPU event interface (i.e. `cudaEvent` or a higher-level wrapper such as `CUDA Graphs` [27]) to trigger the callback command on GPU B with GPU A's event. Ideally, this should take as short as sending a single bit from GPU A to GPU B. However, we find that triggering a GPU event ($\sim 4\mu\text{s}$) and waking up a dependent GPU command ($10\sim 20\mu\text{s}$) are disappointingly slow – it ends up taking as much as sending the command

²Please refer to the experiment setup in Section 5.

³This is roughly estimated based on that it takes $\sim 2\mu\text{s}$ for a GPU thread to read a 4-byte data on the host DRAM and it takes $\sim 3\mu\text{s}$ for a busy-waiting CPU to read a GPU event.

Overhead Detail	Delay (μs)
Initiation	
Trigger send ready event on the GPU	3.8
Sync comp. stream and comm. stream	11.6
Completion Check	
Event polling gap	58.3
Delay of pthread mutex lock	58.7
GPU kernel launch overhead	19.2
Total	151.6

Table 1: Breakdown of the constant overhead of inter-GPU data transfer using TensorFlow in Figure 1.

binary to the GPU at runtime. We suspect that this is due to inefficient hardware implementation on GPU for event handling. In TensorFlow, this overhead contributes to the delay for initiating a transfer that depends on GPU computation as shown in Table 1.

2.3 I/O Overhead of GPU-side Control

Since CPU intervention incurs a large overhead, how about managing the communication with GPU itself? NCCL [32]⁴ leverages `GPUDirect` [31] to enable this approach, which exposes the GPU memory space for peer-to-peer access so that GPU threads can read/write data to/from another GPU.⁵ As GPU threads can directly invoke data copy, they can handle communication events efficiently without the involvement of CPU. Since commodity GPU hardware disallows GPU threads to initiate its own DMA engine, GPU-controlled communication leverages MMIO, which will implicitly conduct DMA when GPU threads write data on the mapping. Figure 3 compares CPU-controlled and GPU-controlled communication. The former one (Figure 3a) takes the following steps: ① CPU is notified when the data is ready, ② CPU initiates the DMA engine, and ③ DMA copies the data. On the other hand, GPU-controlled communication with MMIO (Figure 3b) follows ① CPU creates a memory map (`mmap`) of the destination GPU's address space prior to runtime execution, ② the data is ready at runtime, and ③ GPU threads copy the data into the `mmap`, which implicitly conducts DMA copy.

Unfortunately, data copying by GPU threads often heavily interferes with parallel kernel computation, especially due to L2 cache pollution and warp scheduler operations. Specifically, a data-copy GPU thread needs to load the data onto its register file for data transfer, but this pollutes the L2 cache as one cannot bypass the L2 cache when reading from DRAM on commodity GPU [34]. It leads to severe performance degradation over initiating DMA directly, as the latter copies the data on DRAM directly to the I/O bus (PCIe or NVLink). Additionally, the copying threads frequently issue 'load/store'

⁴Equally applied to RCCL [5] on AMD GPU as well. For convenience, we borrow the terms from CUDA or NVIDIA GPUs, which can be easily converted into corresponding terms in OpenCL or AMD GPUs.

⁵CPU-controlled communication also leverages `GPUDirect` for efficient `cudaMemcpy` between peer GPUs without crossing the root complex, but its execution path is different from that of GPU-controlled communication.

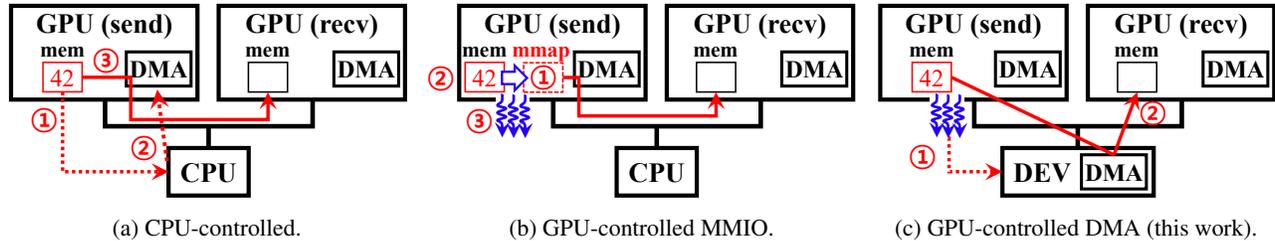

Figure 3: Comparison between CPU-controlled and GPU-controlled communication – the latter has two different approaches, which leverage (b) MMIO (like NCCL) or (c) directly initiated DMA (this work). DEV refers to any kinds of devices that can implement our DMA engine.

instructions that drive warp schedulers busy, which makes other threads for parallel computation yield their clock cycles. Although the affected computation threads are limited to those that co-run warp schedulers with data-copy threads, they delay the entire kernel by falling behind the other threads.

To analyze the impact of the contention, we measure the slowdown of two different GPU kernels that heavily access only a specific type of GPU resources each: L2 cache (1.96 TBps read) and warp schedulers (2.02 IPC),⁶ respectively (all numbers measured on a V100 GPU), while running concurrently with NCCL (v2.11.4) 64 MB all-gather⁷ kernels using 8x V100 GPUs. We leverage NVIDIA Visual Profiler (NVVP) and Nsight Compute to verify that (1) the L2 cache kernel shows near-zero DRAM access and L1 data cache hit rate and (2) the warp schedulers kernel shows near-zero L2 cache/DRAM throughput. We have also verified the concurrency of computation and all-gather kernels and no other CPU/GPU activities during the experiment. In this experiment, the slowdowns due to L2 cache and warp schedulers contention are up to 2.4x and 2.0x, respectively, where it slows down either the computation or the concurrent NCCL communication (when one side is degraded less, the other side tends to be impacted more). This result shows that heavy contention could arise depending on the GPU resource usage of concurrent computation kernels.

We run a microbenchmark to evaluate the contention of NCCL all-reduce during data-parallel training of a BERT-Large [10] model. This model performs 32 MB of all-reduce at a time, which issues 4 MB data transfer in parallel with eight GPU workers. On a server with 8x V100 GPUs (connected with a single PCIe switch (16x PCIe v3)), the parallel computation throughput drops by 45.0% while all-reduce achieves only 5.0 GBps on average, degraded to 53.6% of the peak throughput without the interference. On a server with 8x A100 GPUs (connected with an NVSwitch (NVLink v3)), the slowdown of all-reduce is even worse – the parallel computation throughput drops by 14.3% while the NCCL all-reduce achieves only 30.9% of the peak throughput (49.0 GBps).

⁶Heavy usage of warp schedulers means frequent instruction fetches, i.e. large instructions per cycle (IPC). > 99.2% of instructions are FFMA.

⁷We use all-gather as it only performs communication without any extra computation such as reduction in all-reduce.

3 ARK Framework Design

In this section, we present the design of ARK, our approach with the *GPU-driven* code execution that avoids the communication overhead on GPU without CPU intervention.

3.1 GPU-controlled DMA Engine

We claim that a GPU-controlled DMA engine (Figure 3c) can eliminate the communication overhead, which in turn serves as the basis of our GPU-driven system. The GPU-controlled DMA engine enables a GPU thread to directly initiate DMA operations when the data is ready (①), which will immediately push the data into the I/O bus without wasting GPU cycles (②). We leverage existing GPUDirect techniques to expose the GPU’s physical address space to our DMA engine.

While GPU-controlled DMA would deliver low-latency communication without the MMIO overhead, it is non-trivial to realize this feature. In fact, an ideal implementation would be to modify the existing DMA engine on GPU to support GPU-controlled DMA, but it is infeasible as we cannot update the GPU hardware. Instead, we consider employing an external device as illustrated in Figure 3c at the cost of extra communication latency from GPU threads.

Despite of performance benefits, adopting new hardware for GPU-controlled DMA engine might be costly in many existing systems. To provide an interim solution, we pursue a general DMA engine design that can be implemented as either software or hardware on any hardware platforms (e.g., CPU, GPU, SmartNIC, FPGA, etc.) or I/O bus types (PCIe, NVLink [33], or Infinity Fabric Link (xGMI) [3]). Regardless of the platform, all implementations need to share the same runtime interface for GPU kernels. Also, the DMA interface should support low latency and flexibility while meeting the different requirements of software and hardware engines.

In this paper, we present both a software implementation and a hardware prototype of GPU-controlled DMA engine. Our software engine works over any existing systems without additional hardware as it leverages host CPU cores – busy-waiting CPU threads read DMA requests from GPU and initiate DMA accordingly. This design is aligned with the principle of GPU-driven system as GPU threads directly initiate the data transfer, while CPU threads only mechanically initiate

data copies without any GPU event handling or GPU resource consumption. Our hardware engine prototype is implemented on FPGA, which we present to show the potential benefit of hardware deployment over the software engine. We explain the details of DMA engine implementations in Section 4.1.

3.2 Loop Kernel & Virtual CTA

GPU-controlled DMA engines would be easily adopted by existing systems, e.g., NCCL can replace its MMIO with initiating our DMA engines. However, existing systems would not fully exploit the benefit of GPU-controlled communication as the communication APIs are launched by CPU – the CPU intervention barrier still remains between computation and communication.

To remove this barrier, we propose a GPU-driven code execution system that runs an entire DL application in a single kernel, called a *loop kernel*. Our key observation is that online dynamic scheduling is unnecessary as DL workloads are typically deterministic at runtime. Instead of dynamically launching GPU kernels with CPU at runtime, our GPU-driven system automatically merges all kernels into a loop kernel (one for each GPU) at compile time and launches it only once at application start. Then, the loop kernel runs continuously during the entire lifetime of the application. A loop kernel is generated by our code generator that reads an operational graph of a DL application and automatically assembles corresponding code snippets of GPU operators to build loop kernel code. We call this code generation as *offline scheduling* as all GPU operators are statically distributed across GPU cores, or *Streaming Multiprocessors* (SMs), by the code. Offline scheduling lets GPUs efficiently control the application, which would minimize the event handling overhead for inter-GPU communication. We discuss several technical details of the loop kernel in Section 4.2.

Figure 4 shows that the loop kernel design deviates from the conventional framework for declaring, scheduling, and executing GPU tasks. In both CPU- and GPU-driven systems, a GPU operator is commonly defined as a set of multiple unit operators that each computes a part of the entire output in the SIMD manner. Meanwhile, both systems declare the operator differently in the GPU code. The CPU-driven system declares each unit operator as a Cooperative Thread Array (CTA)⁸ and the entire operator as a separate kernel, which requires launching multiple kernels for multiple operators. In contrast, our GPU-driven system disallows multiple kernels as it executes all operators in the single loop kernel. Instead, it exploits intermediate declaration of unit operators that are scheduled as part of the CTAs of the loop kernel, which we call *virtual CTAs* (vCTAs).

vCTA provides the key abstraction for offline scheduling in ARK, which enables *software-defined* SM scheduling. A vCTA declares the code for a unit operator that is affinitized

⁸CTA is conceptually and functionally the same as a thread block in CUDA or a workgroup in OpenCL.

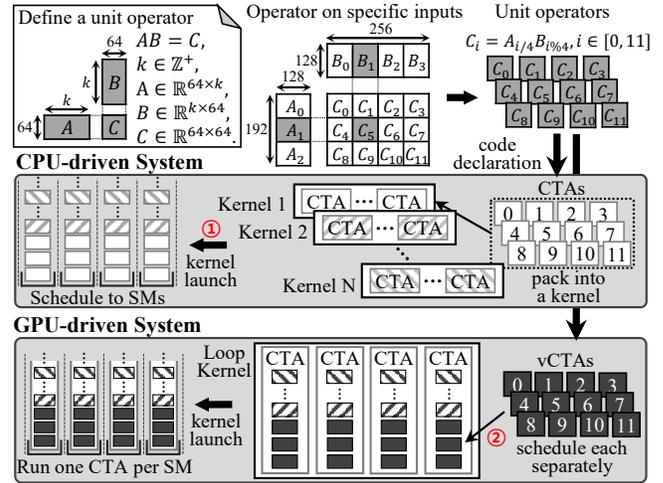

Figure 4: Comparing the procedures for declaring, scheduling, and executing GPU computation tasks between CPU- and GPU-driven systems. For instance, the figure shows a matrix multiplication operator with a 192x256 output, which is split into 12 unit operators that calculate 64x64 outputs each.

to a specific SM inside the loop kernel. While a CPU-driven system relies on the non-programmable hardware scheduler that distributes the CTAs across SMs at kernel launch (① in Figure 4), a GPU-driven system implements a custom logic that distributes vCTAs across CTAs (② in Figure 4). By launching one CTA per SM that assigns each CTA to use the entire resources of an SM, ARK can control the SM-affinity of vCTAs in a programmable manner. This enables fine-grained GPU scheduling, which is useful for the GPU-driven system to implement various computational optimization techniques such as *operator fusion* [17, 24, 35].

Migration of existing code to ARK is straightforward as ARK can reuse existing GPU kernel implementations with minimal modification: replacing the CTA ID (blockIdx in CUDA), thread ID (threadIdx in CUDA), SM-local memory address (shared memory in CUDA), and synchronization functions (e.g., __syncthreads() in CUDA) into corresponding constants or functions provided by the ARK framework. This modification guarantees the correctness of the framework which we have extensively verified.

As shown in Figure 4, offline scheduling writes a code snippet of each vCTA inside the if-branch of the loop kernel that only a particular CTA (or SM) enters. Since each CTA statically executes specific vCTAs that are planned offline, the GPU actually runs a static while() loop rather than being controlled dynamically – internal busy-polling loops inside vCTAs handle runtime events. For example, in Figure 5b, each of CTA 0 (ctaId is 0) and CTA 1 (ctaId is 1) are assigned three vCTAs from the operator op_0 and two vCTAs from the operator op_1. Each CTA uses 256 threads, and vCTAs from op_0 are executed sequentially by thread 0~127, while tasks from op_1 are executed by thread 128~255 (which im-

Figure 5: Example of auto-generated code by the ARK scheduler. Note that the code is simplified for readability.

plies that each vCTA is implemented to use 128 co-working threads). Each vCTA is declared by passing a certain vCTA ID to a GPU function that defines an operator like in Figure 5a. The kernel code library of ARK provides the implementation of common operators (Add or Matmul in the figure) that take the addresses of data chunks and a vCTA ID as runtime arguments.⁹ The framework assigns proper offsets to the global GPU buffer (BUF) for each data chunk, and the vCTA ID locates a specific part of the chunk that the vCTA deals with.

3.3 Offline Scheduler

Figure 6 shows the scheduling workflow in ARK. Overall, it reads the DAG of a DL model and generates the corresponding loop kernel code. The ARK scheduler is composed of a high-level scheduler and a profiling module. The high-level scheduler implements operator fusion with profiling results fed by the module. In the initial phase, it builds an *OpGraph* that spots all operators and their dependencies in the model, and generates the code to profile all types of vCTAs that are needed. Then, the high-level scheduler generates its first scheduling decision with the profiling results. The decision may consist of multiple different candidates that need to be profiled to choose the fastest one, then it iterates the overall process to compare against multiple other candidates, which may require additional profiling. The scheduler finally returns the loop kernel when only a single candidate remains.

Reducing compilations in the profiler. Since the code generator conducts deterministic scheduling with static vCTA-SM affinity, it can accurately estimate the performance (i.e. latency and core resource usage) of every scheduling decision by only profiling the performance of vCTAs, which reduces

⁹Other arguments such as input data sizes can be fixed during compilation by passing as template arguments, which we omit here.

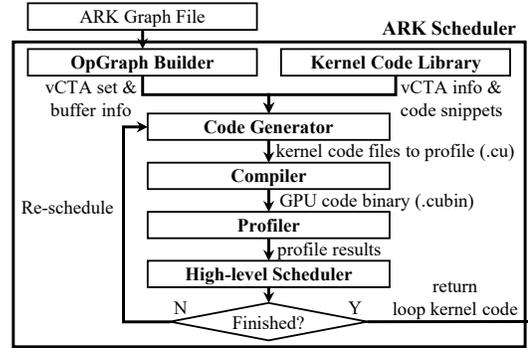

Figure 6: The ARK scheduler workflow.

the compilation for evaluating scheduling strategies. Say there are n parallel operators and each operator has m different implementations of the unit operator (or vCTAs),¹⁰ then up to $O(m^n)$ different kernels should be compiled to find the best fusion decision. Since this number could be unreasonably large, existing works have developed heuristics to focus on only promising candidates [17].

At first glance, this appears to require only $O(nm)$ kernels for vCTA evaluations, but it is more complicated as vCTAs often complete faster when they are run concurrently on the same SM than when executed serially, which we say they have *joint efficiency*. Joint efficiency arises largely due to two causes: (1) because the L1 cache hit ratio improves as they access the common memory space running on the same SM, (2) because the execution of one vCTA hides the memory access of another (and vice versa) that improves simultaneous utilization of ALUs and LSUs. The first case is often found in the vCTAs from the same operator, while the second case is prevalent in most vCTAs, i.e., almost all vCTAs have the joint efficiency with each other.

Considering the joint efficiency, in general, we need to measure the latency when different types of vCTAs co-run on the same SM, which requires one kernel compilation for each. Say up to k vCTAs can run simultaneously in one SM, then the complexity of the number of compilations is $\sum_{i=1}^k \binom{n}{i} m^i = O(n^k m^k)$. In practice, this is much smaller than $O(m^n)$ because k is typically a small constant ≤ 4 due to the limitation of SM resources (# of maximum threads, bytes of shared memory, and # of registers).

SM load balancing in the code generator. The code generator automatically maximizes the SM utilization of the loop kernel by distributing parallel vCTAs across SMs to balance their workload. Unfortunately, finding the optimal load balancing is an NP-hard problem due to the joint efficiency. A brute-force searching would take unreasonably long due to the large number of vCTAs to schedule simultaneously.

To tackle this issue, we implement a heuristic load balanc-

¹⁰It is common to implement multiple different unit operators for the same operator, e.g. cuBLAS [30] implements at least 8 different-sized unit matrix multiplications and choose one depending on the input sizes.

ing on SM by leveraging an existing *graph partitioning* algorithm. Graph partitioning is a popular load balancing problem that splits a graph into a given number of subgraphs by cutting several edges, while achieving two goals: (1) balancing the total node weights of subgraphs and (2) minimizing the total weights of cut edges. We represent the SM load balancing problem into a graph partitioning problem. Specifically, we first group independent vCTAs that need to be distributed across SMs. Each group is represented as a graph where each node represents a vCCTA and each edge indicates that the connecting nodes (i.e. vCTAs) have joint efficiency. The node weight is the latency of running the vCCTA on an SM, and the edge weight measures joint efficiency, which is calculated as the fraction of latency reduction when we run both vCTAs simultaneously in the same SM compared with when we run both sequentially.

However, it takes too long to run the partitioning because it makes too many edges – since almost all vCTAs have joint efficiency with each other, the graph becomes nearly a mesh connection. To accelerate the algorithm, we adopt *hypergraph* representation [2] instead of an ordinary graph, which represents an equal-weighted mesh connection of multiple nodes as a single edge called *hyperedge*. Fortunately, this representation substantially reduces the time for code generation especially when we use a large batch size (which creates a lot of vCTAs), from tens of hours to only several seconds.

3.4 Limitations

The vCCTA-based scheduling takes a whitebox approach that assumes all operators to be open-sourced, thus ARK cannot schedule close-sourced binaries such as cuDNN [28] (similar to Rammer [24]). Also, the offline scheduler of ARK only supports static computational graphs, which is less flexible comparing to e.g. PyTorch’s dynamic graph [13]. However, such a limitation is commonly found in many popular frameworks including TensorRT [35] and ONNX Runtime [25].

4 Implementation

This section describes technical details of ARK.

4.1 DMA Engine Implementations

We first present our DMA engine interface, and then introduce our software and hardware DMA engines.

4.1.1 Interface

The key consideration of our interface design is ensuring high communication performance while keeping the interface consistent across software and hardware platforms. One key issue lies in the design of a DMA request message from GPU, which we call a *send request* (SR), as it has significant impact on the performance and the implementation complexity. In terms of hardware, receiving a large SR whose size exceeds the data bus width (64 bits in modern 64-bit processors) will take multiple cycles, which would require SR buffer

management, reassembly of segmented SRs, and handling dropped SRs (caused by SR buffer overflow). Implementing them on hardware would significantly complicate the logic and increase the spatial cost. As implementing them on hardware would significantly complicate the logic and increase the spatial cost, we share an 8-byte SR design for both software and hardware engines. While it is challenging to hold the metadata of a general memory copy (two addresses and a copy length) within 8 bytes, we address this by adopting a small number of send/recv buffers, which reduces the address space by replacing general 8-byte addresses with a few bits of buffer indices. This is feasible thanks to the static nature of collective communication where the communicating entities are fixed – it enables offline pre-scheduling of data transfers so that receivers know which data arrives at which buffer without any additional metadata received at runtime. Meanwhile, the DMA requests on different buffers are pipelined for low latency and high throughput.

In terms of software, keeping an SR buffer would be more efficient as it would otherwise require extra control to prevent overwriting a previous SR. That is, unlike a hardware implementation where a fully received SR can immediately trigger the internal DMA pipeline at every cycle, a software thread could overwrite an unread SR unless the sender (GPU) coordinates with the receiver (the DMA stack) prior to sending a new SR. Unfortunately, such coordination would incur an extra delay as the GPU needs to read a remote flag on the DMA stack before sending an SR. We address this issue by maintaining a specialized ring buffer for SR, where the GPU checks only a local replica of the buffer head before sending an SR, and the replica is asynchronously updated by the DMA stack. This removes the coordination delay from the critical path of communication while providing a consistent SR interface for both software and hardware engines.

4.1.2 Software Engine

Our software engine harnesses CPU as the data plane while GPU serves as the control plane. We implement a CPU thread that busy-waits for SRs and invokes `cudaMemcpy` or RDMA writes accordingly, i.e., it leverages the existing hardware DMA engine on the sender GPU. Note that this is different from CPU-controlled communication as we use CPU only for data plane operations while the control plane (event handling) is managed by GPU threads. For high throughput, the busy-waiting loop drains all SRs in the ring buffer and invoke copy once for sending on a continuous memory space. Also, instead of slow `cudaEvent`, we use MMIO for the CPU-GPU communication that delivers SR, SC (Send Completion), and RC (Receive Completion) signals, which takes only 2~3 μ s.

Alternatively, the software engine can perform MMIO with CPU threads instead of initiating the hardware DMA engine, which can reduce the `cudaMemcpy` overhead (i.e., sending a copy request from CPU to the DMA engine on GPU). However, this approach fails to achieve the line rate in most host

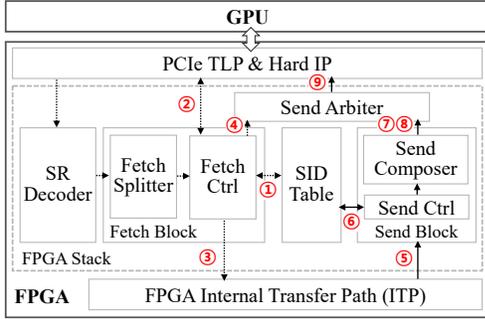

Figure 7: Implementation of the hardware DMA engine.

CPU architectures due to their poor throughput of crossing the PCIe root complex [41, 44]. This issue might be resolved in the future CPU architectures or by leveraging ARM cores on SmartNICs [4], which is left as our future work.

4.1.3 Hardware Engine

We implement a custom hardware with FPGA for DMA operations, which delivers two benefits over our software engine prototype. First, our hardware engine avoids the extra communication delay incurred by the overhead of `cudaMemcpy` as it performs DMA directly. Second, unlike existing hardware DMA engines on GPU, our custom hardware implements pipelining of multiple parallel DMA operations. This helps achieve a high data rate even for sending small data chunks. Table 2 shows resource usage of our implementation on an Intel Arria 10 FPGA.

Note that our FPGA prototype is limited to support the communication between only two GPUs and it does not support NVLink as there is no programmable hardware (or an off-the-shelf device) that can connect to NVLink. Instead, we consider it as a proof-of-concept that demonstrates the ideal benefit rather than a practical device that can be deployed on a large scale. A more practical implementation would be realized by future advances in CPU, GPU, or SmartNICs.

Figure 7 shows the hardware structure of inter-GPU communication stack on the FPGA. Unlike the existing GPU DMA engine, our DMA stack is designed to pipeline multiple DMA requests with different SIDs to be handled simultaneously. This is implemented by splitting a long-length request into multiple short-length sub-requests, which prevents head-of-line blocking and improves the PCIe throughput when GPU sends multiple different data at the same time. We explain how each request is processed by the sender- and the receiver-side stacks, respectively.

Sender side. When the sender stack receives an SR, the Fetch Block reads the decoded SR and retrieves the requested SID, which is translated into the physical source GPU address by looking up the SID Table (①). Using the address, the Fetch Ctrl fetches one sub-request at a time and it may fetch multiple times if the copy length is long. Each sub-request reads the corresponding source data from the GPU and stores it in a

Module Name	ALMs		BRAM Blocks	
	#	Capacity	#	Capacity
FPGA Stack	14253	3.34%	188	6.93%
PCIe	1364	0.32%	13	0.48%

Table 2: Resource usage of a single DMA stack.

FIFO buffer of the Fetch Ctrl (②). When the source data is fully read from the GPU, the stored data and the sub-request are forwarded to the receiver stack through FPGA Internal Transfer Path (ITP). (③). After processing all sub-requests out of an SR, the Fetch Ctrl gives an SC flag to the Send Arbiter, which will be written on the GPU-side SC flag. (④). **Receiver side.** The receiver stack receives the sub-request from the sender stack and stores the data into a FIFO buffer of the Send Ctrl (⑤). At the same time, the SID information in the sub-request is translated into the physical destination GPU address (⑥). The Send Ctrl sends the data to the destination address, and when it is done, the Send Composer sends an RC flag to the Send Arbiter, which will be written on the GPU-side RC flag (⑦, ⑧).

Resource usage and limitations. We implement the DMA stack on Intel Arria 10 FPGA [16]. Table 2 shows that each stack is implemented at a low cost, using only 14253 ALMs and 188 M20K BRAMs. Note that our current implementation supports communication between only two GPUs by directly connecting the FPGA ITP interfaces of their corresponding FPGA stacks. Our design considers leveraging DUA [41] to support routing between multiple stacks (either intra- or inter-machine), but we leave it as future work.

4.2 Loop Kernel Implementation

This section explains several details of optimizing the loop kernel performance in ARK.

Per-thread register optimization. GPU kernels often fine-tune the number of concurrent threads per SM by evaluating the trade-off between running more threads (gain more parallelism) vs. running fewer threads with more registers per each (gain more computational throughput per thread). So, the loop kernel also needs to tune it. The ARK scheduler generates multiple versions of the loop kernel with a different number of per-thread registers and picks the best-performing one. Actually, in NVIDIA GPUs, only 32, 64, 128, and 256 are available candidates due to hardware limitation.

Dependency on GPU Architecture. Section 3.2 explains that ARK launches one CTA per SM, but it may launch two or more CTAs per SM depending on the GPU architecture. This is because one CTA may be limited to utilize the entire resources of an SM in some architecture. In such cases, we need to launch two CTAs per SM to use the entire SM resources. The ARK scheduler automatically analyzes the resource requirement of the loop kernel and determines the number of CTAs per SM accordingly.

Program size. We reduce the program size of a loop kernel by coalescing multiple identical unit operators, e.g., if

a model consists of many convolution operators, only several unique implementations of convolution will be actually defined, which are shared across all operators. Thus, the program size depends only weakly on the number of operators in the model. Instead, it is subject to the aggregate size of operator implementations, which is very limited – e.g., cuBLAS provides only ~ 10 instances of a matrix-multiplication implementation on a single GPU architecture, while a loop kernel can accommodate over 5000 instances. This should cover an arbitrary DL program as the size of the matrix-multiplication implementation is one of the largest among the popular operators in DL.

5 Evaluation

We evaluate ARK by comparing it with existing DL frameworks largely in three different aspects. First, the fast inter-GPU communication of ARK contributes to higher end-to-end throughput and lower latency of DL applications. Second, the benefits on communication are obtained without losing the computational throughput of GPU. Third, ARK has flexibility to support various parallelism strategies including data-, tensor-, and pipeline-parallelism.

5.1 Experiment Setup

Software Engine. For experiments that use the software DMA engine, unless specified differently, we use two Intel Xeon Gold 6240R CPUs (48 cores each, 2.40 GHz) and eight NVIDIA V100 GPUs. We have two NUMA nodes in the machine but only a single NUMA node hosts all GPUs, i.e. node 0 connects two PCIe v3 switches to its PCIe root complex and each switch is directly connected to 4 GPUs. For multi-node experiments, we use four Azure NDv4 SKUs [7] with 32x NVIDIA A100 GPUs in aggregate (8 per node), where each GPU has dedicated 200 Gbps NVIDIA Mellanox HDR InfiniBand connection.

Hardware Engine. For experiments that use the hardware DMA engine, we use an Intel Xeon Gold 5118 CPU (24 cores, 2.30 GHz), two NVIDIA V100 GPUs, and an Intel Arria 10 FPGA. Both GPUs and the FPGA are behind the same PCIe v3 switch. We use the hardware engine only for experiments in Section 5.2 and Section 5.5.

5.2 DMA Engine Performance

Figure 8 compares the performance of communication between two GPUs with our DMA engines (G-Drv-S and G-Drv-H) over a CPU-controlled communication baseline (C-Drv). C-Drv is our own minimal implementation of a typical CPU-driven system, but unlike TensorFlow, C-Drv leverages asynchronous control using `cudaEvent` when the event is used only by GPUs, which further reduces CPU-GPU synchronizations to accelerate inter-GPU communication.

We measure the throughput by sending many parallel messages at the same time and reporting the maximum throughput

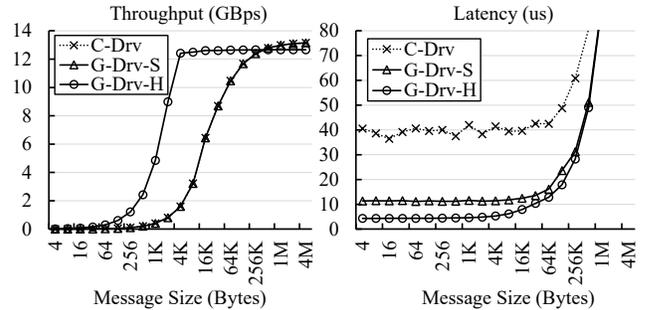

Figure 8: Performance comparison between the CPU-controlled communication (C-Drv) and the GPU-controlled DMA engines (G-Drv-S (software) and G-Drv-H (hardware)) over PCIe v3.

achieved with varying message sizes. For latency measurements, we implement a ping-pong application and report one-way latency – unlike throughput measurements, this includes communication event handling delays. This experiment assumes a favorable scenario for the CPU-controlled baseline where we can adopt the asynchronous control (explained in Section 2.2.2). In this scenario, a one-way trip requires triggering only two GPU events and two stream synchronizations.

In the left graph of Figure 8, our software engine (G-Drv-S) shows the same throughput as that of C-Drv, since both use `cudaMemcpy` for the data-plane. In contrast, our hardware engine (G-Drv-H) shows huge throughput improvement, saturating the bandwidth with only 8 KB messages while G-Drv-S needs 4 MB messages for saturation. This is because the hardware DMA engine pipelines processing multiple DMA requests while `cudaMemcpy` cannot. This improvement would be especially beneficial when GPU sends multiple messages to different destinations at the same time, e.g., all-to-all communication for expert-parallelism, which is popular for scaling out state-of-the-art Transformer-based models [11].

We note that the maximum achieved throughput of G-Drv-H is 3.68% lower than G-Drv-S. This is because an external DMA stack needs to send both read and write requests to sender and receiver GPUs, respectively, while the native DMA engine on the sender GPU needs to send only write requests. However, as the gap is small, it would not affect the end-to-end application performance much.

The right graph of Figure 8 shows that the one-way latency of C-Drv is at least $\sim 39.3\mu\text{s}$ on average. In contrast, G-Drv-S and G-Drv-H achieve 3.5x and 9.1x better latency, respectively. This is because our DMA engines handle the communication events directly in GPU threads while C-Drv relies on the `cudaEvent` interface that suffers from large overhead to trigger the events and synchronize streams. This improvement would be especially beneficial when GPUs perform split-and-gather of intermediate results to distribute the workload, as in tensor-parallelism [22, 26]. One thing to note about our DMA engine is that the benefit is obtained with little GPU cycle consumption. We evaluate this in the following section.

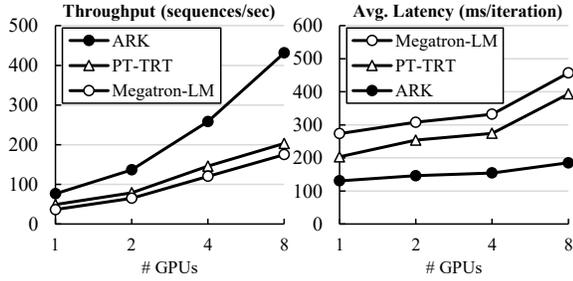

Figure 9: BERT-Large data-parallel training throughput and average latency per iteration with varying numbers of GPUs (sequence length 384, batch size 10, mixed-precision).

5.3 Avoiding Communication Interference

To compare the interference between computation and communication of using NCCL against using our DMA engine, we evaluate data-parallel training throughput of ARK by training representative NLP models.

Baselines. PT-TRT accelerates PyTorch [12] by adopting TensorRT [35], which does not scale out to multiple machines. Megatron-LM [26] is a PyTorch-based framework that supports large-scale training of NLP models but we use only for single-node experiments here. SuperBench [42] provides formal DL benchmarks for system performance evaluation also based on PyTorch, which we use for multi-node experiments. All baselines leverage NCCL [32] for communication.

Single Node. Single-node experiments train BERT-Large [10] model using up to 8x V100 GPUs as shown in Figure 9. The figure shows that ARK outperforms Megatron-LM and PT-TRT respectively by **2.46x** and **2.12x** with 8 GPUs. We find two reasons for the speedup.

First, NCCL adversely affects the computational throughput during back-propagation while ARK does not as it leverages DMA instead of employing GPU threads for data copy. Specifically, 64.5% of the end-to-end gap between ARK and PT-TRT with 8 GPUs is obtained as NCCL operations slow down due to the interference of MMIO with back-propagation computation, showing only 5.0 GBps of all-reduce throughput. We find that NCCL kernels result in 45.0% slowdown of the overall back-propagation computation, an increase from 107.63 ms to 156.02 ms. On the other hand, our DMA engine suffers near-zero interference by initiating DMA directly instead of using MMIO, achieving 9.10 GBps of all-reduce throughput (**1.82x** faster).

Second, ARK performs more efficient computation on GPU. For example, for about 37.8% of the computation time of PT-TRT, it executes 1.2 thousands of memory-intensive kernels per iteration, such as element-wise arithmetic or intra-GPU data movement. Running these operators as separate kernels would be inefficient because it would incur unnecessary kernel launches and intra-GPU synchronizations. ARK largely reduces such overhead as it schedules all operators in a single loop kernel, similar as operator fusion [17, 24, 35].

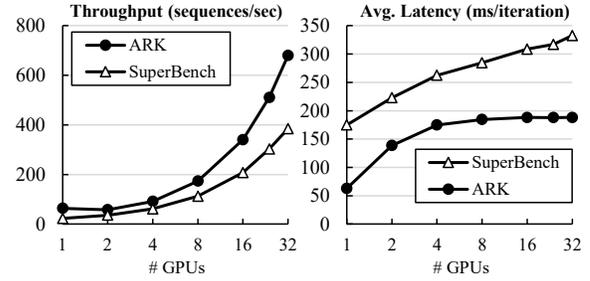

Figure 10: GPT-2 data-parallel training throughput and average latency per iteration with varying numbers of GPUs (sequence length 384, batch size 4, mixed-precision).

Multiple Nodes. Multi-node experiments train the GPT-2 [36] model using up to 32x A100 GPUs as shown in Figure 10. All results use only InfiniBand for communication (no NVLink) and use the ring reduction algorithm. The figure shows that ARK outperforms SuperBench by **1.77x** with 32 GPUs. Furthermore, while per-iteration latency of SuperBench is consistently increasing, the increment in ARK is only marginal. This shows the efficiency of our communication stack over NCCL, which minimizes the interference between communication and computation. We also find a big computational benefit of ARK even without communication (when using a single GPU), which is further explained in the following section.

5.4 Offline Scheduling Evaluation

This section shows that the offline scheduler of ARK can generate comparable or even better GPU kernels comparing with existing DL optimization techniques. Rather than claiming state-of-the-art performance in DL optimization, we intend to show that the communication gain of our GPU-driven system does not come up with any computational performance drop.

We compare the inference performance of popular DL models over different frameworks using a single GPU. The DL models include image classification (ResNet-50 [14] and GoogLeNet [43]), object detection (SSD [23]), and NLP (BERT-Large [10]) models. TensorFlow (TF) is the primary comparison target of ARK because it supports flexible parallelism for DL applications like ARK. We also compare with TensorFlow-XLA (TF-XLA) [1] that implements automatic operator fusion in the TF back-end, but it is not always beneficial to the performance because the fused kernel might perform worse than using vendor-provided kernels (e.g. cuDNN) without fusion. Rammer [24] and TensorRT implement optimized operator fusion that often outperforms TF or TF-XLA, but they support only limited parallelism. For example, TensorRT supports only intra-node data-parallelism by adopting it to accelerate other frameworks like TF and PyTorch, as TensorRT itself does not support distributed execution. Nimble [20] presents careful asynchronous control (or ahead-of-time scheduling) of GPU kernels to reduce runtime

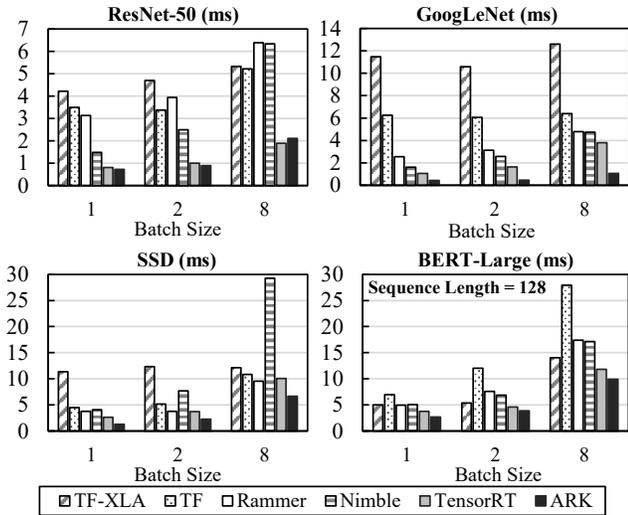

Figure 11: Inference latency comparison of popular DL models over different DL frameworks using a single GPU. All experiments use mixed-precision computation.

overhead of kernel launch and GPU events. As explained in Section 2.2.2, however, asynchronous control is limited to tackle the communication overhead. Nimble also works only on a single GPU at the moment.

Figure 11 shows that ARK achieves faster single-GPU inference against existing frameworks in most cases. For instance, ARK shows $1.11x \sim 3.56x$ lower latency than TensorRT, except the case of ResNet-50 with batch size 8 that is $\sim 9.90\%$ worse than TensorRT. This is because our matrix multiplication kernel is slower than the cuDNN [28] kernel used in TensorRT in this case (note that we implement convolution via matrix multiplication). ARK currently does not implement vCTAs specialized for large matrix multiplications (one side of the unit operator’s output is larger than 256 elements), so it is often slower than existing kernels when the model consists of large matrix multiplications.

We note that the gain of ARK is especially large when the model consists of many parallel operators like GoogLeNet or SSD. This is because our high-level scheduler maximizes overall SM utilization by choosing the best vCTA (or unit operator) for each parallel operators. Specifically, when a lightweight operator runs alone in the GPU, we schedule it to use fine-grained vCTAs so that it utilizes more concurrent SMs. In contrast, when the GPU is overloaded due to other co-running operators, we need to use coarse-grained vCTAs to utilize SMs more efficiently. This is because coarse-grained vCTAs work on more input data at the same time and thus have more opportunities to better utilize the parallelism in an SM. As explained in Section 3.3, the optimization to find the best-performing vCTAs is easy in the ARK framework because it accurately estimates the performance with different vCTAs without running all candidates. We note that other frameworks do not provide a similar optimization like this.

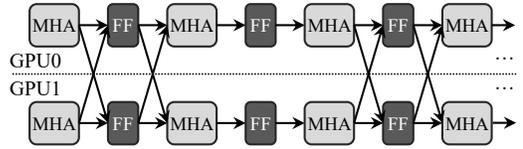

Figure 12: MoE model-parallel execution for Transformer architecture using 2 GPUs, composed of MHA (multi-headed attention) and FF (feed-forward) modules.

Architecture	Message Size (KB)	Time Gap (us)
BERT-Large [10]	256	60.9
GPT-3 XL [8]	512	187.4
T5 3B [37]	256	166.9
M4 [6]	256	60.9

Table 3: The message size and the smallest time gap between transactions for MoE inference. The input sequence length is 128. Time gaps are measured using the ARK framework.

5.5 Tensor-parallel Inference

This section presents the latency improvement with the tensor-parallel approach called mixture-of-experts (MoE) that efficiently scales up the Transformer [45] architecture, which is commonly used in many popular NLP models [6, 8, 11, 37]. This method is suggested to scale NLP models to one trillion of model parameters [11, 22], but since we do not have enough GPUs to run the entire model, we evaluate the tensor-parallel inference of the model using two GPUs. In real practice, this is replicated to other GPUs to apply pipeline-parallelism (for training or inference) and data-parallelism (only for training) as well at the same time.

Figure 12 illustrates the MoE execution. The message size and the smallest time gap in-between the exchanges depend on the model hyperparameters, and some examples are shown in Table 3. Even though we present only 2-GPU experiments here, the result would be similar to a larger-scale one because MoE is designed to send each message only up to a small constant number (e.g. two in GShard [22]) of selected GPUs, not to all other GPUs.

We evaluate ARK using the hardware engine with three different comparison baselines – TF, TF-XLA, and C-Drv. Note that TensorRT-accelerated TensorFlow (TF-TRT) does not support model-parallelism, so it is not evaluated here.

Results in Figure 13 shows that ARK outperforms TF and TF-XLA by $1.66x \sim 3.48x$ and $1.25x \sim 2.31x$, respectively. In terms of only the communication latency, ARK reduces it by $3.68x \sim 5.65x$ and $1.77x \sim 3.31x$, respectively. Overall, C-Drv achieves better communication latencies over TF or TF-XLA, but its computation is less efficient because it reuses GPU kernel implementations in ARK but it does not benefit from ARK scheduler optimization. We also find that the GPU-driven communication of ARK delivers a substantial speedup over the CPU-driven communication of C-Drv, as shown in Section 5.2. We note that ARK computation is slower than

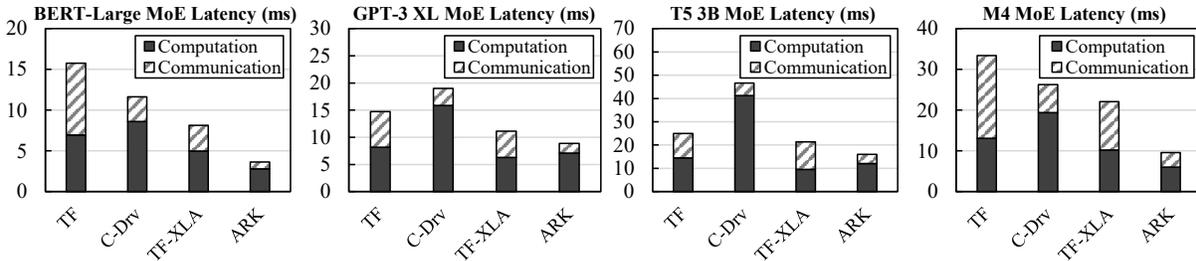

Figure 13: MoE inference latencies with different NLP model architectures (batch size 1, mixed-precision).

TF-XLA in GPT-3 XL and T5 3B. This is because our matrix multiplication kernel performs worse than TF-XLA in these cases, as explained in Section 5.4.

5.6 Pipeline-parallel Training

In this section, we train the GPT-3 [8] 6.7B model, which is the largest variation of GPT-3 that can fit the memory of eight V100 GPUs via pipeline-parallel training. The model consists of 32 sequential layers and each GPU trains 4 layers in the sequential order – GPU 0 reads the input data and runs the forward-pass of layer 0~3, and the 16 MB output is passed to GPU 1, and so on. When GPU 7 completes the forward-pass, it moves on to the backward-pass of layer 31~28, and the 16 MB of back-propagating gradient is passed to GPU 6, and so on. We use the mixed-precision computation and set the number of pipeline stages to 5, the batch size of each stage to 1, and the sequence length to 2048. ARK uses the emulated DMA stack in this evaluation.

In this experiment, the training throughputs of TF, TF-XLA, Megatron-LM, and ARK are 0.35, 0.47, 1.69, and 2.38 sequences per second, respectively, i.e. ARK outperforms TF, TF-XLA, and Megatron-LM by 6.80x, 5.06x, and 1.40x, respectively. In this case, most of the improvement of ARK comes from the computational efficiency on GPU, as pipeline-parallel training typically overlaps most of the communication delay with the computation time. This evaluation shows that ARK delivers the gain of operator fusion while supporting flexible parallelism for DL.

6 Future Work & Related Work

We expect that hardware advances in near future would enable more efficient implementations. For example, implementing our software DMA engine on SmartNIC would avoid the throughput issue of the PCIe root complex [44] via direct PCIe connection with GPUs (e.g., NVIDIA H100 CNX [9] combines GPU with SmartNIC), which enables efficient MMIO on SmartNIC. NVIDIA has announced their hardware accelerators for inter-GPU communication on SmartNICs (e.g., all-to-all engine on NVIDIA BlueField-3 [29]), which implies that a similar implementation with our hardware engine might be realized in the future. Additionally, host CPU architectures in the future may fix the root complex issue, which will enable our software DMA engine to replace `cudaMemcpy` with

CPU-side MMIO, or even more efficiently, DMA engines on CPU (e.g., Intel I/OAT [15] or AMD PTDMA [21]).

ACE [38] proposes offloading the entire collective communication logic to a hardware accelerator that resides on intra-machine fabric, which cannot be extended to an external network (Ethernet, InfiniBand, etc). Our work differs from ACE as it is generally applicable to any (R)DMA networking and we can reuse most of existing software logic in popular collective communication libraries.

GPUnet [18] presents a network socket API set for GPU threads and leverages CPU intervention to let GPU threads to trigger DMA. This is inefficient as they add a substantial intervention overhead especially for small messages because they do not pipeline processing multiple DMA requests. Its throughput could be suboptimal as it implements a general socket interface on GPU while ARK reduces the overhead by leveraging offline scheduling to remove the metadata to be managed during runtime.

Nimble [20] accelerates DL execution by minimizing runtime scheduling overhead of kernels, but it works only on a single GPU. The proposed methods also cannot help reduce communication event handling overhead as it still relies on the CPU-side control using `cudaEvent` and multi-stream interfaces. ARK tackles this by letting GPU threads fully control all computation and communication tasks.

7 Conclusion

This paper envisions a GPU-driven code execution system that enables autonomous control of GPU throughout the entire lifetime of DL applications. We present the GPU-controlled DMA engine at the heart of the GPU-driven system that enables GPUs to communicate with each other without any external control. To avoid interference between computation and communication, we design our DMA engine and offline GPU scheduling to consume little GPU resources for communication, so that its high communication performance is delivered without sacrificing computational throughput of GPU. While our software engine already shows benefits over commodity hardware, we also present a proof-of-concept of a hardware engine that shows even higher performance, which indicates that our system performance would be further improved with future advances in commodity hardware such as CPU, GPU, or SmartNIC.

Abstract

Graph neural networks (GNNs) have extended the success of deep neural networks (DNNs) to non-Euclidean graph data, achieving ground-breaking performance on various tasks such as node classification and graph property prediction. Nonetheless, existing systems are inefficient to train large graphs with billions of nodes and edges with GPUs. The main bottlenecks are the process of preparing data for GPUs – subgraph sampling and feature retrieving. This paper proposes BGL, a distributed GNN training system designed to address the bottlenecks with a few key ideas. First, we propose a dynamic cache engine to minimize feature retrieving traffic. By co-designing caching policy and the order of sampling, we find a sweet spot of low overhead and a high cache hit ratio. Second, we improve the graph partition algorithm to reduce cross-partition communication during subgraph sampling. Finally, careful resource isolation reduces contention between different data preprocessing stages. Extensive experiments on various GNN models and large graph datasets show that BGL significantly outperforms existing GNN training systems by 1.9x on average.

1 Introduction

Graphs, such as social networks [23, 36], molecular networks [19], knowledge graphs [21], and academic networks [47], provide a natural way to model a set of objects and their relationships. Recently, there is increasing interest in extending deep learning methods for graph data. Graph Neural Networks (GNNs) [22, 36, 46] have been proposed and shown to outperform traditional graph learning methods [50, 57, 59] in various applications such as node classification [36], link prediction [56] and graph property prediction [51].

Real-world graphs can be massive. For example, the user-to-item graph on Pinterest contains over 2 billion entities and 17 billion edges with 18 TB data size [53]. As a major online service provider, we also observe over 100 TB size of

graph data, which consists of 2 billion nodes and 2 trillion edges. Such large sizes make it impossible to load the entire graph into GPU memory (at tens of GB) or CPU memory (at hundreds of GB), hence turning down proposals that adopt full graph training on GPUs [55]. Recent works [23, 28, 53] have resorted to mini-batch sampling-based GNN training, aggregating neighborhood information on sampled subgraphs.

Distributed systems [2, 17, 48] for this training typically include *distributed graph store servers* to store partitioned large-scale graphs and *worker machines* where each worker has one GPU for model training. Each training iteration contains three stages: (1) *sampling subgraphs* stored in distributed graph store servers, (2) *feature retrieving* for the subgraphs from graph store servers to workers, and (3) forward and backward *computation* of the GNN model.

The first two stages, which we refer to as *data I/O and preprocessing*, are often the performance bottlenecks in such sampling-based GNN training. After analyzing popular GNN training frameworks (e.g., DGL [48], PyG [17], and Euler [2]), we made two key observations. (1) High data traffic for retrieving training samples: when the sampled subgraph is stored across multiple graph store servers, there can be frequent cross-partition communication for sampling; retrieving corresponding features from the storage to worker machines also incurs large network transmission workload. (2) Modern GPUs can perform the computation of state-of-the-art GNN models [22, 36, 46] quite fast, leading to high demand for data input. To mitigate these problems, Euler adopts parallel feature retrieval; DGL and PyG prefetch the sampling results. Unfortunately, none of them fully resolves the I/O bottleneck. For example, we observe only around 10% GPU utilization in a typical DGL training job on a large graph (§2 and §5), which means around 90% of GPU cycles are wasted.

In this paper, we propose BGL, a GPU-efficient GNN training system for large graph learning, to accelerate training and achieve high GPU utilization (near 100%). Focusing on eliminating data I/O and preprocessing bottlenecks, we identify three key challenges in the existing frameworks, namely: (1) very heavy network traffic for retrieving features, (2) large

^{*}Tianfeng Liu and Yangrui Chen contributed equally to this work as first authors.

cross-partition communication overhead during sampling, and (3) resource contention between different training stages. We address those challenges, respectively.

The biggest bottleneck of distributed GNN training systems often lies in retrieving large features (§2.3). PaGraph [38], a state-of-the-art cache design for GNN training, uses a static cache (no replacement during training) and explicitly avoids dynamic caching policy (replacing some cached features at runtime) because of high overhead. However, we find that static cache has low hit ratios when the graphs are so large that only a small fraction of nodes can be cached. Hence, we co-design a dynamic cache policy and the sampling order of nodes. We show that a FIFO policy has acceptable overhead and high hit ratios combined with our *proximity-aware ordering*. The key idea is to leverage *temporal locality* – in nearby mini-batches, we always attempt to visit the neighboring training nodes in the graph. This approach largely increases the cache hit ratio of FIFO policy. We will further explain the details of how we ensure the consistency of our multi-GPU cache engine and GNN convergence in §3.2.

After optimizing feature retrieval, the cross-partition communication for subgraph sampling could become the major performance bottleneck. Existing algorithms either do not scale to large graphs or ignore *multi-hop neighbor* connectivity inside each partition. It leads to heavy cross-partition communication because, in GNN training, the sampling algorithm usually requests *multi-hop neighbors* from a given node. Hence, we design a graph partition algorithm tailored for the typical GNN sampling algorithms. Our algorithm (in §3.3.2) strives to maintain multi-hop connectivity in each partition, while maintaining load balance partitions and scaling to giant graphs.

Finally, data preprocessing in GNN training takes multiple stages and is much more complex than that in traditional DNN training. Execution of some stages may compete for CPU and bandwidth resources, throttling the performance. Existing frameworks largely ignore it and let the preprocessing stages freely compete with each other. Unfortunately, some stages do not scale well with more resources. They may acquire more resources than they need, leading to blocking other stages. Hence, we optimize the resource allocation of data preprocessing by profiling-based resource isolation. Our key idea is to formulate the resource allocation problem as an optimization problem, use profiling to find out the resource demands of each stage, and isolate resources for each stage.

We implement BGL, including the above design points, and replace the data I/O and preprocessing part of DGL with it. The design of BGL is generic – e.g., BGL can also be used with Euler’s computation backend. However, our evaluation focuses on using BGL with the DGL GPU backend because it is more mature and performant. We conduct extensive experiments using multiple representative GNN models with various graph datasets, including the largest publicly available dataset and an internal billion-node dataset. We demonstrate

that BGL outperforms existing frameworks, and the geometric mean of speedups over PaGraph, PyG, DGL, and Euler is 1.91x, 3.02x, 7.04x, and 20.68x, respectively. With the same GPU backend as DGL, BGL can push the V100 GPU utilization to 99% even when graphs are stored remotely and distributedly, higher than existing frameworks. It also scales well with the size of graphs and the number of GPUs.

2 Background and Motivation

2.1 Sampling-based GNN Training

We start by explaining sampling-based GNN training.

Graph. The most popular GNN tasks¹ are to train on graphs with node features, $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{F})$, where \mathcal{V} and \mathcal{E} denote the node set and edge set of the graph, and \mathcal{F} denotes the set of feature vectors assigned to each node. For example, in the graph Ogbn-papers [47], each node (*i.e.*, paper) has a 128-dimensional feature vector representing the embeddings of the paper title and abstract. We assume graph structures and node features are *immutable* in this paper.

Graph neural networks (GNNs). Graph neural networks are neural networks learned from graphs. The basic idea is collectively aggregating information following the graph structure and performing various feature transformations. For instance, the Graph Convolution Network (GCN) [36] generalizes the convolution operation to graphs. For each node, GCN aggregates the features of its neighbors using a weighted average function and feeds the result into a neural network. For another example, GraphSAGE [23] is a graph learning model that uses neighbor sampling to learn different aggregation functions on different numbers of hops.

Real-world graphs, such as e-commerce and social networks [13, 53, 55], are often large. The Pinterest graph [53] consists of 2B nodes and 17B edges, and requires at least 18 TB memory during training. Even performing simple operations for all nodes would require significant computation power, not to mention the notoriously computation-intensive neural networks. Similar to other DNN training tasks, it is appealing to use GPUs to accelerate GNN training.

Sampling-based GNN training. There are two camps of training algorithms adopted in existing GNN systems: *full-batch training* and *mini-batch training*. Full-batch training loads the entire graph into GPUs for training [36], like NeuGraph [40] and ROC [31]. Unfortunately, for very large graphs like Pinterest’s, such an approach would face the limitation of GPU memory capacity.

Thus, we focus on the other approach, *mini-batch training*, or often called *sampling-based GNN training*. In each iteration, this approach samples a subgraph from the large original graph to construct a mini-batch as the input to neural networks. Mini-batch training is more popular and adopted by literature [11, 23, 54] and popular GNN training frameworks like DGL [48], PyG [18] and Euler [2].

¹We focus on node classification tasks in this work.

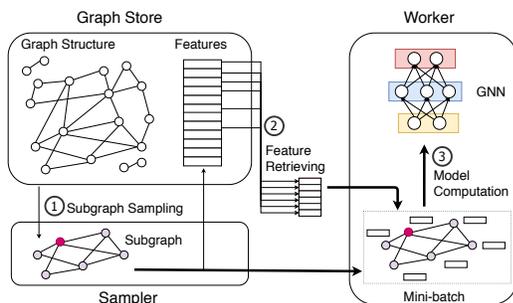

Figure 1: Sampling-based GNN training process.

The process of sampling-based GNN training is shown in Figure 1. The fixed graph data (including the graph structure and node features) are partitioned and stored in a distributed *graph store*. Multiple workers run on *worker machines*, with each worker equipped with one GPU. Each training iteration consists of three stages: ① **Subgraph sampling**: *Samplers* sample a subgraph from the original graph and send it to workers. ② **Feature retrieving**: After *workers* receive the subgraph, the features of its nodes are further retrieved from the graph store server and placed in GPU memory. ③ **Model computation**: Like typical DNN training, workers on GPU forward-propagate the prepared mini-batch through the GNN model, calculate the loss function, and then compute gradients in backward propagation. Then model parameters are updated using optimizers (e.g., SGD [61], Adam [35]).

In the rest of this paper, we refer to the first two stages as *Data I/O and Preprocessing*.

2.2 Data I/O and Preprocessing Bottlenecks

Unfortunately, existing GNN training frameworks suffer from data I/O and preprocessing bottlenecks, especially when running model computation on GPUs. Here, we test two representative frameworks, DGL [48] and Euler [2]. We train GraphSAGE [23] model with one GPU worker. Using the partition algorithms of DGL and Euler, we split the Ogbn-papers graph [47] into four partitions and store them on four servers as a distributed graph store. More configuration details and the other framework results are in §5.

Figure 2 shows the training time of one mini-batch and the time breakdown of each stage. 87% and 82% of the training time were spent in data I/O and preprocessing by Euler and DGL, respectively. Long data preprocessing time leads to not only poor training performance but also low GPU utilization. The maximum GPU utilization of DGL and Euler is 15% and 5%, respectively, as shown in Figure 3.

In GNN training, such a bottleneck is much more severe than in DNN training like computer vision (CV) or natural language processing (NLP) for two main reasons.

First, due to the neighbor explosion problem [12, 54], the size of mini-batch data required by each training iteration is very large. For example, if we sample a three-hop subgraph from Ogbn-products with batch size 1,000 and fan out {15,10,5}, each mini-batch consists of 5MB subgraph struc-

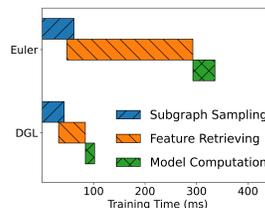

Figure 2: Training time per mini-batch of DGL and Euler.

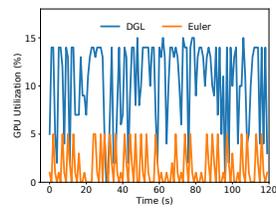

Figure 3: GPU utilization of DGL and Euler.

ture (roughly 400,000 nodes) and 195 MB node features. Assuming that we use a common training GPU server like AWS p3dn.24xlarge [4] (8x NVIDIA V100 GPUs and 100Gbps NIC) as the worker, and that we could saturate the 100Gbps NIC pulling such data, we can only pull 60 mini-batches of data in every second.

Second, the model sizes and required FLOPS of GNN are much smaller than classic DNN models like BERT [15] or ResNet [25]. V100 needs only 100MB and 20ms to compute a mini-batch of popular GNN models like GraphSAGE. P3dn.24xlarge can compute 400 mini-batches per second.

There is clearly a huge gap between the data I/O and preprocessing speed, and GPU computation speed. Consequently, though frameworks like DGL and Euler adopt pipelining, the data I/O and preprocessing bottlenecks can only be hidden by a small fraction and dominate the end-to-end training speed.

Some recent work [20, 29, 38] also observed this problem and made promising progress. Unfortunately, it still falls short in performance (§5) and cannot handle giant graphs well. Next, we will elaborate on the main challenges existing GNN training frameworks face.

2.3 Challenges in Removing the Bottlenecks

We identify three main challenges. Two are on large communication traffic for feature retrieving and subgraph sampling (as shown in Figure 1 and 2). The other is about resource contention when running all the stages together.

Challenge 1: Ineffective caching for node feature retrieving. As shown in Figure 2, due to the large volume of data being pulled to workers, node feature retrieval renders the biggest bottleneck. A natural idea to minimize such communication traffic is to leverage the power-law degree distribution [16] of real-life graphs. For example, PaGraph [38] adopted a static (no replacement at runtime) cache that stores the predicted hottest node features locally. Upon cache hit, the traffic of feature retrieving can be saved. Unfortunately, on giants graphs like Pinterest graph [53], such a static cache may only be able to store a small fraction of nodes due to memory constraints. We find, when only 10% of nodes can be cached, the static cache only yields <40% cache hit ratios.

Why not use dynamic (replacing some caches at runtime) cache policies? It is challenging because it would incur large searching and updating overhead, pointed out in [38]. Overheads become even larger when the cache is large (tens of GB) and stored on GPU. Our best-effort implementation

Table 1: Qualitative comparison of graph partition algorithms.

Partition Algorithms	Scalability to Giant Graphs	Balanced Training Nodes	Multi-hop Connectivity
Random [2, 30]	✓	✓	✗
METIS [32] & ParMETIS [33]	✗	✓	✓
GMiner [10]	✓	✗	✗
PaGraph [38]	✗	✓	✓

echos [42, 44] – we also find that popular policies like LRU and LFU lead to a near 80-millisecond overhead for updating.

Nevertheless, we will show in §3.2 that it is still possible to achieve a good trade-off between cache hit ratios and dynamic cache overhead by exploiting the characteristics of GNN training and carefully designing the cache engine.

Challenge 2: Need for a graph partition algorithm that is scalable and friendly to subgraph sampling. Beyond node feature retrieving, communication overhead of subgraph sampling renders another major bottleneck.

The partition algorithms affect the sampling overheads in two ways. First, they determine cross-partition communication overhead. GNN sampling algorithms construct a subgraph by sampling from a training node’s *multi-hop* neighbors. If the neighbors are hosted on the same graph store server, the *sampler* colocated with graph store servers can finish sampling locally. Otherwise, it must request data from other servers, incurring a high communication overhead. Like random partitioning² [2, 30], naive algorithms are agnostic to the graph structure. Most state-of-the-art (SOTA) partition algorithms on graph processing and graph mining, like GMiner [10] and CuSP [26], only consider one-hop connectivity instead of multi-hop connectivity, which is suboptimal.

Second, partition algorithms determine the load balance across graph store servers and sampler processes. In a training epoch, one must iterate all *training nodes* and sample subgraphs based on them. For good load balance, one should balance the training nodes across partitions. However, SOTA graph partition algorithms only consider balancing all the nodes, of which only 10% [27, 47] are training nodes. Because they focus on maintaining neighborhood connectivity, they may produce less balanced partitions than the pure random algorithm, especially imbalanced for the training nodes.

Since we aim for GNN training on giant graphs, the partition algorithm must be scalable to giant graphs as well. Like the METIS [32, 33] used by DGL, some partition algorithms rely on maximal matching to coarsen the graph, which is not friendly to giant graphs due to high memory complexity [24]. Some other algorithms, such as PaGraph [38], have high time complexity and are not friendly to giant graphs.

Ideally, we need a partition algorithm that works on giant

²Also including Lux [30], which is a random partition algorithm that frequently re-partitions the graph for load balancing.

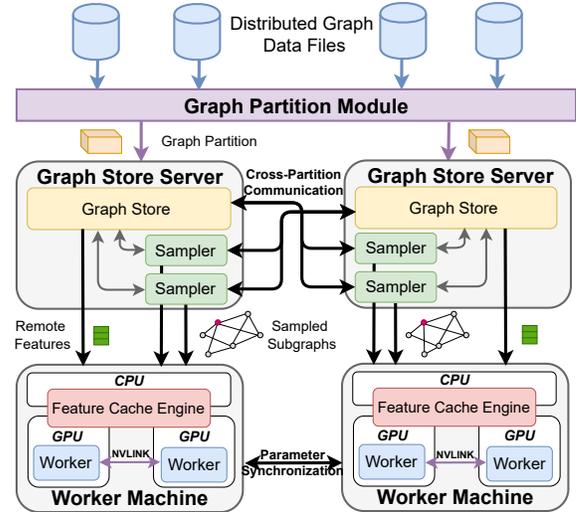

Figure 4: The architecture of BGL.

graphs and simultaneously minimizes the cross-partition communication and load imbalance during sampling. As shown in Table 1, none of the existing partition algorithms satisfies our needs, which motivates our algorithm (§3.3).

Challenge 3: Different data preprocessing stages contend for resources. When running all stages together, we further identify a unique problem of GNN training – the preprocessing is much more complex than traditional DNN training. The subgraph sampling, subgraph structure serialization and de-serialization, node feature retrieving, and cache engine all consume CPU and memory/PCIe/network bandwidth resources. We observe that if all the processes freely compete for resources, the resource contention may lead to poor performance. Some operations may try to acquire more resources than what they need and hence block other operations, while they do not scale well with more resources.

Existing GNN training frameworks largely ignore this problem. DGL, PyG, and Euler either blindly let all processes freely compete or leave the scheduling to underlying frameworks like TensorFlow and PyTorch. The low-level frameworks are agnostic to the specifics in GNN training, and thus are also naive and suboptimal. Our answer to this challenge is a carefully designed resource isolation scheme (§3.4).

3 Design

We design BGL to address the challenges presented in §2.3.

3.1 Architecture and Workflow

The overall architecture of BGL is shown in Figure 4. A training job has the following stages.

Pre-training preparation: graph partition. The *graph partition module* loads the graph data stored in the distributed storage system (e.g., HDFS), and shards the whole graph into several partitions. Graph partitioning is a *one-time cost*, and the results can be saved in storage and used by other GNN training tasks later. Then, each partition is loaded into a graph store server’s memory, ready for subgraph sampling.

To address Challenge 2 in §2.3, BGL’s graph partition module first uses multi-source BFS to merge nodes into several blocks for reducing the graph size. Optimal graph partitioning is NP-hard [7]. Hence, we propose a partition heuristic considering both multi-hop connectivity of blocks and training workload balancing to maximize the partition locality, thus minimizing the cross-partition sampling time.

Subgraph sampling at each training step. Samplers run on the CPUs of graph store servers. They select several training nodes and sample their multi-hop neighbors by iteratively sampling next-hop neighbors several times. If all the next-hop neighbors are stored in the current graph store server, samplers can get the list locally; otherwise, they need to send network requests to other graph store servers.

Training GNN using the sampled subgraphs. Each worker in BGL runs on 1 GPU. It receives sampled subgraphs from samplers and retrieves features of subgraph nodes from graph store servers, with a local *feature cache engine* to improve the retrieving efficiency.

To address Challenge 1 in §2.3, BGL’s feature cache engine adopts an algorithm-system co-design. We leverage the temporal locality — in nearby mini-batches, we always attempt to train nodes with close distance in the graph. Combined with a FIFO policy, BGL achieves high cache hit ratios and low cache overheads. Increasing the temporal locality of training nodes may influence the convergence of GNN models. We show BGL can preserve the SOTA training accuracy by carefully introducing randomness in ordering training nodes. On the system side, we exploit high-bandwidth GPU-to-GPU communication with NVLinks, and design a multi-GPU cache supporting dynamic caching strategies.

Finally, BGL uses a fine-grained pipeline, allowing parallel and asynchronous execution of each stage. To address Challenge 3 in §2.3, BGL adopts resource isolation when assigning resources to each pipeline stage. Specifically, BGL formulates an optimization problem and assigns isolated resources accordingly to minimize the execution time of each pipeline stage under resource constraints (§3.4).

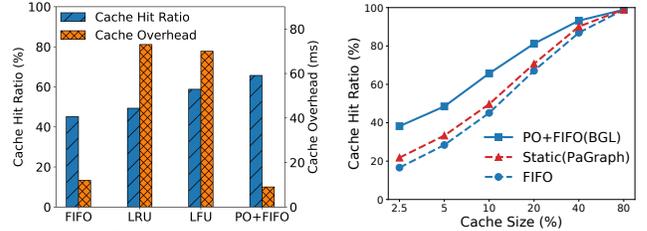

3.2 Feature Cache Engine

Feature retrieving contributes to the majority of communication overheads. We propose a feature cache engine, which uses system-algorithm co-design to minimize this overhead.

3.2.1 Dynamic Cache Policy

The first question is, which dynamic caching policy should we choose? PaGraph [38] indicates that dynamic policies have too high overheads. Based on our best-effort implementation³, we compare popular caching policies, including LRU, LFU and FIFO in Figure 5a. Since cache queries arrive in batches, we define the cache hit ratio as the percentage of hit nodes in total number of nodes in a batch. The cache overhead is

³We implement LFU and LRU with $O(1)$ time complexity and use a contiguous ID array as a HashMap to speed up key searching.

(a) Trade-off between hit ratios and (b) Cache hit ratios with different cache sizes.

Figure 5: We test the cache hit ratios and overhead on Ognb-papers with different cache sizes. PO is short for proximity-aware ordering, which is proposed in §3.2.2.

the *amortized* time, including cache lookup on all nodes *and* cache update upon cache misses. Hence, a higher cache hit ratio, representing less frequent cache updates for dynamic caching, can help reduce the amortized overhead.

LRU [42] and LFU [44] indeed have intolerable cache overhead. FIFO’s overhead (<20ms per batch) meets the throughput requirement for GNN training – as mentioned in §2, an iteration of typical GNN model computation on GPU is around 20ms. In an asynchronous pipeline with cache as a part of data prefetching, FIFO cache will not become the bottleneck.

However, FIFO’s cache hit ratio is unimpressive – it is even lower than static policy’s (Figure 5b). The reason is that FIFO does not leverage the distribution of node features. Regardless of how hot the node feature is, it is evicted as frequently as other colder node features.

3.2.2 Proximity-Aware Ordering

To address the above problem, we propose *proximity-aware ordering* – in nearby mini-batches, we always attempt to visit the neighboring training nodes in the graph. Figure 5b shows that FIFO combined with proximity-aware ordering can achieve the highest cache hit ratio among all candidate cache policies while maintaining low cache overhead.

We observe that each node may appear more than once among different training batches (e.g., node ⑨ in Figure 6a appears three times in sampled subgraphs). This gives us an opportunity for data reuse by caching node features in nearby mini-batches (a.k.a., *temporal locality*). With random training nodes sampling, the chances of a node in nearby training batches are low. In order to increase the probability, we propose to select training nodes in a BFS order. BFS preserves the graph connectivity in terms of number of hops. Hence, nearby training nodes in graphs are more likely to be selected in consecutive batches. As a result, this ordering increases the probability that each node appears in consecutive batches and improves the cache hit ratio.

For example, in Figure 6a, starting from a BFS root node ⑰, we can generate a BFS sequence of training nodes. Random ordering (Figure 6b) results in no cache hits in the first three batches. On the contrary, with proximity-aware ordering (Figure 6c), the second batch and the third batch contain nodes that exist in the previous batches (*i.e.*, {⑰, ⑨, ③})

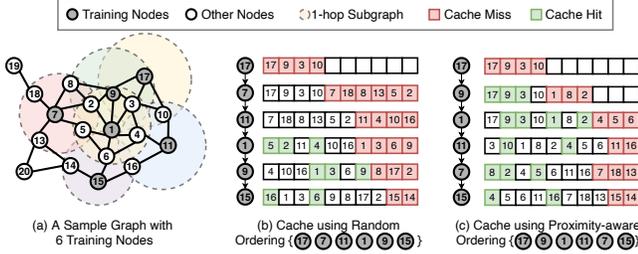

Figure 6: Compared to random ordering, using proximity-aware ordering improves hit ratios of FIFO cache.

in the second batch and $\{9, 3, 1, 2\}$ in the third batch). Consequently, FIFO cache hits are improved from 8 to 14.

However, there is a trade-off between improving the temporal locality and ensuring model convergence. Traversal-based ordering improves the temporal locality but violates the i.i.d. requirement of SGD, leading to different label distributions of batches and slowing model convergence. On the other hand, random ordering, such as random shuffling, achieves state-of-the-art model accuracy by selecting random training nodes, with the cost of poor temporal locality.

Our proximity-aware ordering needs to balance the above trade-off. The key idea is that SGD is robust enough, and slightly relaxing the i.i.d. requirement does not influence the convergence rate. Theorem 3.15 in [41] shows that if there is *little difference* between the output distribution of one ordering algorithm A and the uniform distribution, A will not cause accuracy degradation. Hence, in BGL, samplers still select training nodes based on BFS traversal, while we carefully introduce randomness to reduce the difference.

We introduce the following randomness. First, we use several different BFS sequences, instead of only one, and each of them is generated by selecting random BFS roots. To form a training batch, we select training nodes from different sequences in a round-robin manner. Second, we circularly shift each BFS sequence by a random position. Since giant graphs have lots of small connected components [37], they are more likely to be traversed at last and appended at the end of each BFS sequence in our implementation. This deterministic behavior harms the model accuracy. Shifting by a random position minimizes its impact to the model, and circular shifting preserves the order of consecutive nodes in BFS sequences.

How many BFS sequences should we select? We find, as long as the model convergence is guaranteed, we should use the minimum number of sequences to maximize the temporal locality. Meng et al. [41] define the difference ϵ , named *shuffling error*, as the total variation distance between the two distributions, and proves that, if $\epsilon \leq \sqrt{bM}/n$, the convergence is not influenced, where b is the batch size, M is the number of workers and n is the size of training data.

Based on the above theorem, we determine the number of sequences as follows. We use the label distribution to calculate the shuffling error. The label distribution of proximity-aware ordering is estimated as the probability of each label appearing in each mini-batch. Before training, BGL firstly generates

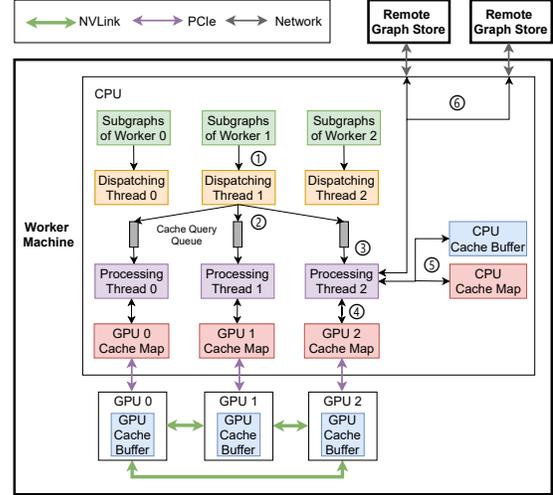

Figure 7: Structure and workflow of feature cache engine.

hundreds of BFS sequences. After that, it gradually increases the number of BFS sequences from one until the shuffling error is smaller than the requirement of convergence (\sqrt{bM}/n). During training, BGL constructs each training batch by introducing randomness and reusing generated sequences. This procedure incurs negligible overheads ($<1\%$ training time).

3.2.3 Maximizing Cache Size

Based on the observation that GNN models are typically small (§2.3) and large GPU and CPU memory are unused, in BGL, we jointly use the memory of multiple GPUs (if the training job uses multiple GPUs) and CPU memory to build a two-level cache, which can enlarge the cache size and increase the cache hit ratio. The detailed structure and cache workflow of our feature cache engine is shown in Figure 7.

Multi-GPU Cache. We create one *cache map* and one *cache buffer* for each GPU. Cache map is a HashMap with node IDs as keys and the pointers to buffer slots in cache buffer as values. Cache buffer contains buffer slots, storing node features. Each GPU cache map manages its own cache buffer.

To avoid wasting precious GPU memory, we ensure no duplicated entries among all GPU cache buffers by assigning different and disjoint node IDs to each GPU cache map (mod by the number of workers). A GPU can fetch node features from another GPU via P2P GPU memory copy using NVLinks. As mentioned in §2.2, transferring 60 mini-batches can saturate the 100Gbps NIC and PCIe 3.0 x16 bandwidth. Hence, using NVLinks not only provides high bandwidth and low latency for inter-GPU communication, but it also alleviates heavy communication in the network and PCIe links.

Since CPU memory is much larger than GPU memory, BGL also adds a CPU cache on top of the multi-GPU cache to further increase the cache size and reduce the communication traffic to graph store servers. The CPU cache uses the same cache policy as the GPU cache, so we omit the details.

Cache Workflow that Guarantees Consistency. As shown in Figure 7, the workflow of the cache engine goes as follows.

After receiving sampled subgraphs (①), dispatching threads split the subgraph nodes by `mod` operation into multiple *cache queries*⁴ and send them to *cache query queues* (②). Each processing thread is assigned to one GPU cache buffer and processes all cache queries on this buffer (③). It first looks up the subgraph nodes in the GPU cache map and then gathers cached features of those nodes from GPU cache buffers (④). In case of GPU cache misses, it looks up the CPU cache map for uncached nodes, gathers cached feature tensors from CPU cache buffer, and sends them to the GPU (⑤). The remainders are requested from graph store servers and sent to GPUs once received (⑥). Finally, the cache map and the cache buffer are updated according to our FIFO caching policy.

Though node features are immutable (§2), cache buffers are still mutable. The cache buffer and the cache map may be *inconsistent* when some buffer slots are read and written by different GPU workers simultaneously (which occurs when different nodes are assigned to the same buffer slot). To ensure the consistency between the cache buffer and the cache map, a naive solution is to use locks for each buffer slot. But, this locking means synchronization in CUDA APIs for GPUs, leading to large overhead. Our solution is to queue all the operations towards a given GPU cache, including queries and updates. Only one processing thread polls the queue and then reads or writes the corresponding GPU cache buffer. This reduces the overhead by 8x compared with using locks while avoiding racing.

3.3 Graph Partition Module

3.3.1 Partition Workflow

Graph partitioning largely impacts the cross-partition communication when sampling subgraphs. As described in §2.3, a good partition algorithm should have the following properties: (1) scalability to billion-node graphs, ensuring (2) multi-hop connectivity, and (3) training load balance.

Our algorithm exploits two types of processes: *block generators* and a *block assigner*. Block generators generate blocks, each of which is a connected subgraph and treated as one node in the coarsened graph. The block assigner collects blocks of the coarsened graph from block generators and assigns each block to one partition. We outline the three major steps of our partition algorithm in Figure 8.

(1) Multi-level Coarsening: Each block generator loads disjoint graph data from HDFS and generates blocks on the loaded graph.

Different from merging procedures used in other partition algorithms (*e.g.*, maximal matching in METIS), we use multi-source BFS to generate blocks, which can preserve multi-hop connectivity in the original graph. The block generator randomly chooses a few nodes as the BFS source nodes. Each source node is assigned a unique block ID and broadcasts the

⁴A cache query contains all nodes which are assigned to one GPU cache buffer by `mod` operation in a sampled subgraph.

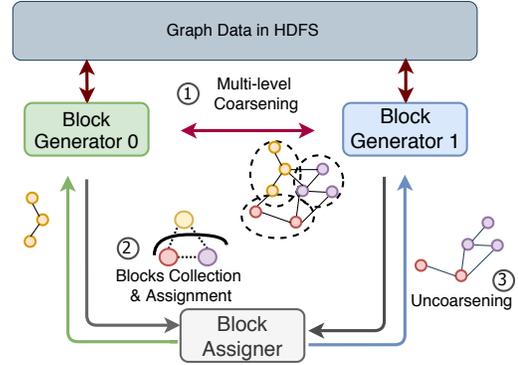

Figure 8: The partition workflow. Node colors denote different blocks in the coarsened graph (step ②), or the nodes belonging to different blocks (steps ① and ③).

block ID to its neighbors. Once the block size (*i.e.*, the number of nodes with the same block ID) exceeds a threshold (*e.g.*, 100K), or there are no unvisited neighbors in BFS, a block is generated. When all nodes are visited, the block generating procedure stops. At the same time, block generators maintain a mapping from the node ID to block ID, and synchronize it among them for uncoarsening.

However, we find billion-node graphs have numerous connected components [37]. After one round of coarsening, the coarsened graph still contains a large quantity of nodes, which results in large partition complexity. Hence, we further deploy a multi-level coarsening strategy. First, for small blocks connecting to large blocks⁵, we merge them to their large block neighbors. Second, other small blocks without large block neighbors are randomly merged. By considering neighborhood relationship, this approach not only speeds up the partition process but also preserve the multi-hop connectivity.

(2) Block Collection & Assignment: The block assigner collects the blocks of the multi-level coarsened graph from block generators. It applies a greedy assignment heuristic for each block, targeting both multi-hop locality and training node balancing. The block assigner then broadcasts the block partitions to the generators. We leave the details of the assignment heuristics in §3.3.2.

(3) Uncoarsening: Upon receiving the block assignment results from the block assigner, the block generators start mapping back the blocks to the nodes in the original graph, *i.e.*, uncoarsening. The partition results are then saved to the HDFS file (step ③ of Figure 8).

As a result, our partition algorithm has low time complexity and is friendly to giant graphs. Let \mathcal{E}_1 be the set of edges in the coarsened block graph after BFS. \mathcal{E}_2 denotes the set of edges in the graph for assignment after multi-level block merging, and j denotes the number of hops to maintain connectivity. We reduce the time complexity of the assignment to $O(|\mathcal{E}_2|^j)$, much lower than SOTA $O(|\mathcal{E}|^j)$ [38], where $|\mathcal{E}_2| \ll |\mathcal{E}|$. The total partitioning complexity is $O(|\mathcal{E}| + |\mathcal{E}_1| + |\mathcal{E}_2|^j)$.

⁵Empirically, we set blocks with top 10% sizes as large blocks.

3.3.2 Assignment Heuristic

Since optimal graph partitioning is NP-hard [7], we propose a new heuristic for assigning blocks to partitions by considering the special requirements of GNN training.

Our heuristic is to derive the block assignments by solving the following maximization problem:

$$\max_{i \in [k]} \left\{ \left(\sum_j |P(i) \cap \Gamma^j(B)| \right) \cdot \left(1 - \frac{|T(i)|}{C_T} \right) \cdot \left(1 - \frac{|P(i)|}{C} \right) \right\}$$

where k is the number of partitions; each partition is referred by its index $P(i)$. Based on this heuristic, each block B is assigned to the partition with the maximum value.

The first term in the heuristic is the *multi-hop block neighbor* term, $\sum_j |P(i) \cap \Gamma^j(B)|$, which counts the intersection between the set of j -hop neighbor blocks of B , $\Gamma^j(B)$, and the current partition $P(i)$. Using this term, we tend to assign the current block to a partition with the maximum number of neighbors and preserve the multi-hop connectivity. Second, we introduce the *training node penalty* term, $(1 - |T(i)|/C_T)$, where $T(i)$ denotes the set of training nodes that have been assigned to the i th partition, and $C_T = |T|/k$ denotes the training node capacity constraint on each partition. By maximizing this term, each partition is enforced with the same number of training nodes. Third, we introduce the *node penalty* term, $(1 - |P(i)|/C)$, where $C = |\mathcal{V}|/k$ is the capacity constraint on each partition. This term is commonly used in existing partition algorithms to balance the number of nodes among the partitions. Finally, we multiply the three terms to maximize them simultaneously.

3.4 Resource Isolation For Contending Stages

To improve resource utilization and training speed, we divide GNN training into 8 asynchronous pipeline stages (see Figure 9) with careful consideration of data dependency and resource allocation. This is more complex than traditional DNN training. Some of the stages contend for CPU, Network, and PCIe bandwidth resources: (i) Processing sampling requests and constructing subgraphs compete for CPUs on graph store servers. (ii) Subgraph processing (e.g., converting graph format) and executing cache workflow compete for CPUs in the worker machine. (iii) Moving subgraphs and copying features to GPUs compete for PCIe bandwidth.

However, we find that if all the processes freely compete for resources, the resource contention may lead to poor performance. A key reason is that some operators may acquire more resources than what they actually need and block other stages, with which they do not scale well.

For example, we observe that for the executing cache workflow stage (Stage 4 in Figure 9), when the number of CPU cores exceeds a threshold (e.g., 40), the performance converges or even degrades with more CPU cores (e.g., more than 64). This is because of the memory bandwidth limit, synchronization and scheduling overhead in the multi-threading library like OpenMP [8].

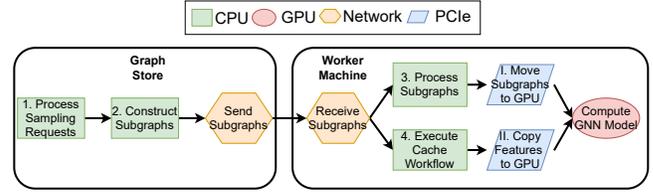

Figure 9: GNN training pipeline in BGL.

To solve the above problem, we propose a *profiling-based resource allocation* to assign isolated resources to different pipeline stages. We first profile the execution time of each stage and then adjust resource allocation to balance the execution time of each stage. We formulate the following optimization problem to compute the best resource allocation in a given GNN training task:

$$\begin{aligned} \min \max & \left\{ \frac{T_1}{c_1}, \frac{T_2}{c_2}, T_{net}, \frac{T_3}{c_3}, \frac{D_I}{b_I}, f(c_4), \frac{D_{II}}{b_{II}}, T_{gpu} \right\} \\ \text{s.t.} & \quad c_1 + c_2 \leq C_{gs}, \quad c_3 + c_4 \leq C_{wm}, \quad b_I + b_{II} \leq B_{pcie} \end{aligned}$$

The objective is to minimize the maximal completion time of all pipeline stages. The constraints are resource capacity constraints for CPU on graph store servers, CPU on worker machines, and PCIe bandwidth. The main decision variables are c_i ($i \in \{1, 2, 3, 4\}$), the number of CPUs required for the i th stage; and b_i ($i \in \{I, II\}$), PCIe bandwidth of the i th stage. All the other quantities are profiled by our system, including the time of the i th stage T_i , the data size of processed subgraphs D_I , and the average data size of missed features D_{II} when the cache is stable. C_{gs} and C_{wm} denote the number of CPU cores on graph store servers and worker machines, respectively, and B_{pcie} is the PCIe bandwidth of the worker machines. We assume linear acceleration of CPU execution, except on processing caching operation (Stage 4 in Figure 9). We introduce a fitting function $f(c_4) = a/c_4 + d$ to output the completion time of caching stage with a certain number of CPU cores c_4 , where a and d are approximated by pre-running.

We use brute-force search to find the optimal resource allocation. To reduce the search space, we add integer assumptions on bandwidth variables b_I and b_{II} . The time complexity is $O(C_{gs}^2 + C_{wm}^2 + B_{pcie}^2)$ in the worst case. On average, our method spends less than 20ms on searching for the best resource allocation strategy for GNN training pipeline.

4 Implementation

We implement BGL with over 4,400 lines of C++ code and 3,300 lines of Python code. We reused the graph store module and GPU backend of the open-sourced Deep Graph Library (DGL v0.5 [1, 48]), and utilized the graph processing module of GMiner [10] for partitioning. Our design can be applied to other GNN frameworks with little change. We are collaborating with the DGL team to upstream our implementation.

Requirement. BGL exploits NVLinks/NVSwitches for high-bandwidth low-latency cross-GPU communication for multi-GPU cache. Our measurement shows that without NVLinks, the feature cache engine retrieves cached features from other

Table 2: Datasets used in evaluation.

	Ogbn-products	Ogbn-papers	User-Item
Nodes	2.44M	111M	1.2B
Edges	123M	1.61B	13.7B

Validation Set	393K	125K	10M
Test Set	2.21M	214K	10M

GPUs via PCIe with much lower bandwidth, which could decrease throughput of BGL by 50%.

Feature Cache Engine. Cache workflow in feature cache engine contains several GPU operations, such as copying tensor from CPU memory to GPU memory and launching kernels to copy tensor from/to other GPUs. To make cache processing asynchronous, we enqueue all cache GPU operations into a *dedicated* CUDA stream, and pre-allocate dedicated CPU memory as buffers and pin these memory. Our cache engine uses CUDA Unified Virtual Addressing and enables fast GPU P2P communication on each cache processing thread. The cache processing thread enqueues a lightweight CUDA callback function into the CUDA stream, which counts the number of finished cache queries and notifies workers.

To further expedite FIFO performance, BGL uses multiple OpenMP threads to execute FIFO concurrently. We maintain an atomic `tail` shared by all threads to record the next column index of the GPU cache buffer for insertion or eviction. When inserting a new node, each thread finds the next position by atomically increasing `tail`, and the real position is $(tail+1)\%buffer_size$. If this position has an old node, it evicts the old node from the GPU cache map. Since we assume node features are immutable during training, old node features are implicitly evicted by inserting new node features.

Inter-Process Communication. We use separate processes for sampling, feature retrieving, and GNN computation stages. To minimize the IPC overhead, we use shared memory to avoid unnecessary memory copy among different processes. Specifically, we use Linux Shared Memory and CUDA IPC to avoid unnecessary CPU and GPU memory copy, respectively.

5 Evaluation

5.1 Methodology

Testbed. We evaluate BGL on a heterogeneous cluster with 4 GPU servers and 32 CPU servers. The GPU server has 8 Tesla V100-SMX2-32GB GPUs (connected by NVLink v2), 96 vCPU cores, and 356GB memory. Each CPU server has 96 vCPU cores and 480GB memory. All servers are interconnected with 100Gbps Mellanox CX-5 NICs. The graph datasets are stored in HDFS.

Datasets. As shown in Table 2, we train GNNs on three datasets with different sizes, including two public graph

datasets: Ogbn-products [27] and Ogbn-papers [47], as well as a proprietary web-scale graph dataset: User-Item.

GNN Models. We evaluate BGL with three representative GNN models: GCN (Graph Convolution Network) [36], GAT (Graph Attention Network) [46] and GraphSAGE [23]. We use the same model hyper-parameters as OGB leaderboards [3], e.g., 3 layers and 128 hidden neurons per layer.

Mini-batch Sampling Algorithms. In our experiments, we use Neighbor Sampling [23], which is shown to achieve comparable model performance with full-batch graph training.⁶ Except for the experiment in §5.7, we set the mini-batch size to 1000, *i.e.*, each mini-batch contains 1000 sampled subgraphs and each subgraph contains one training node and its three-hop neighbors with fanout {15,10,5}.

Baselines. We use four open-sourced and widely-used GNN training frameworks as baselines for comparison⁷.

- Euler [2]: Euler (v1.0) is a distributed graph learning system built atop TensorFlow [5]. We use TensorFlow’s GPU backend for acceleration.
- DGL [1]: DGL is a deep learning library for graphs, compatible with multiple deep learning frameworks. We use the DGL v0.5 release (DistDGL [58]).
- PyG [17]: PyG (v1.6.0) extends PyTorch for deep learning on graphs. It contains a mini-batch loader for multi-GPU support in a single machine.
- PaGraph [38]: PaGraph is a sampling-based GNN framework with a static cache strategy on GPU, which supports multi-GPU in a single server.

Specifically, PyG co-locates graph store servers and workers and allows graph sampling on the same machine only, making it unable to process large graph datasets (*i.e.*, Ogbn-papers and User-Item) due to memory limit. Hence, we only compare BGL with PyG on Ogbn-products dataset. When training on User-Item dataset with DGL and PaGraph, we separate the graph store servers from the workers since our GPU servers do not have enough memory to load the graph partitions. To evaluate the performance boundary, we use 4, 8 and 32 CPU-based graph store servers for all frameworks on Ogbn-products, Ogbn-papers and User-Item respectively.

Graph Partitioning. DGL uses METIS partitioning for small graphs (*i.e.*, Ogbn-products), and Random partitioning for large graphs that cannot be fitted into a single machine (*i.e.*, Ogbn-papers and User-Item). Euler uses random partitioning for all graphs, and BGL uses the proposed algorithm in §3.3, where we set $j = 2$, *i.e.*, searching two-hop neighbors.

5.2 Overall Performance

Figure 10, 11 and 12 show the training speed of baselines and BGL in *log* scale when training the three GNN models

⁶BGL can also be applied to other vertex-centric GNN sampling algorithms, e.g., layer-wise sampling [11] and random walk sampling [53]. We omit the evaluation of other sampling algorithms since it is beyond our scope.

⁷We omit P^3 [20] because it is not open-sourced.

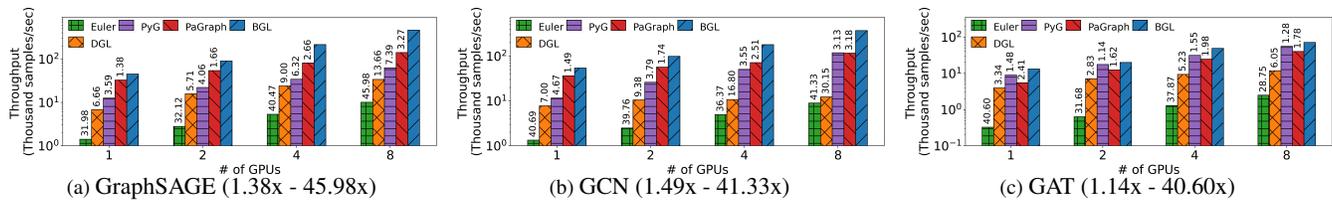

Figure 10: Throughput of 3 GNN models on Ogbn-products in log scale. Numbers above bars are speedups of BGL over other systems.

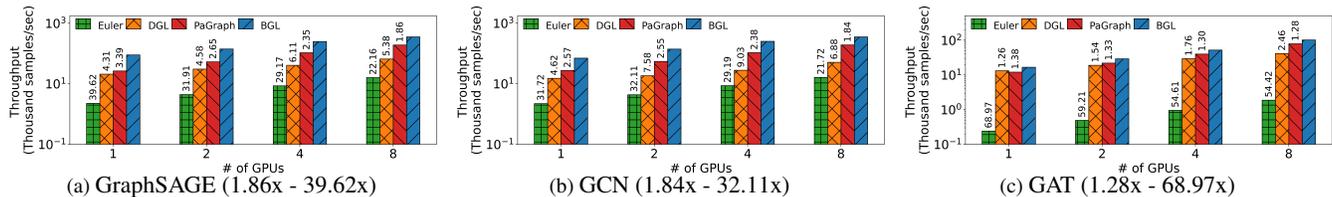

Figure 11: Training throughput of 3 GNN models on Ogbn-papers in log scale. Numbers above bars are speedups of BGL over other systems.

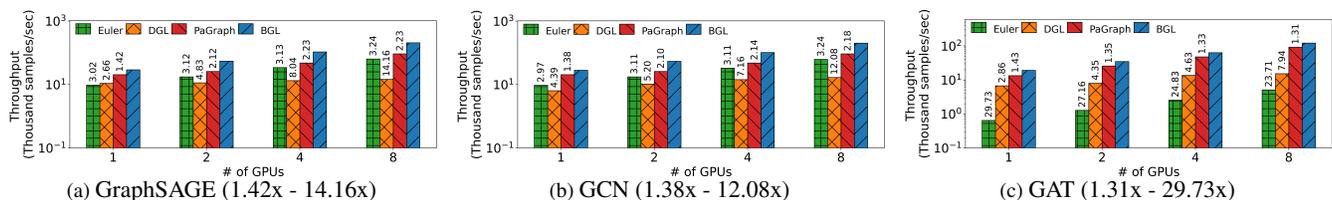

Figure 12: Training throughput of 3 GNN models on User-Item in log scale. Numbers above bars are speedups of BGL over other systems.

on three graph datasets, with the number of workers ranging from 1 to 8, where each worker has one GPU. We use *samples/sec* as the metric to measure the training speed. A sample is a sampled subgraph of one training node.

Different Frameworks. BGL achieves 1.14x - 69x speedups over four baselines in all settings. BGL has 69x (the most) speedup over Euler. This is because Euler’s random sharding in graph partition has very low data locality, resulting in frequent cross-partition communication in sampling. DGL does not cache features on GPU, introducing significant feature retrieving time. Thus, BGL outperforms DGL by up to 30x. PaGraph performs the best among baselines. It places graph structure data on each GPU with static caching on node features, leading to much faster data preprocessing. Even in this case, BGL still has up to 3.27x speedup, thanks to dynamic feature caching and resource isolation for contending pipeline stages. BGL outperforms all other systems, and the geometric mean of speedups over PaGraph, PyG, DGL and Euler is 1.91x, 3.02x, 7.04x and 20.68x, respectively.

Different GNN models. The training performance varies significantly across different GNN models. We see that BGL achieves significantly higher performance improvement with GraphSAGE and GCN models, by up to 30x as compared to DGL and PyG. With the computation-intensive GAT model, however, the training speed of PyG and DGL is closer to that of BGL. Hence the gain for BGL ranges from 14% to 8x. It is because the GAT model is computation-bound due to incorporating the attention mechanism into the propagation step, while its communication is less intensive than the other two GNN models; the higher ratio of computation over other stages results in a smaller improvement space for BGL. We

see that Euler performs the worst in GAT, since it does not optimize the GPU kernels for irregular graph structures.

Scalability. BGL also outperforms other frameworks in terms of scalability. Without caching features on GPU, the throughput of baseline frameworks is bounded by PCIe bandwidth. For example, DGL has only 3x speedups when increasing the number of GPUs from 1 to 8. BGL reduces the transmitted data through PCIe bandwidth with efficient GPU cache, resulting in linear scalability in throughput. Multi-GPU systems often suffer poor scalability due to synchronization overhead or resource contention. However, our design and implementation of multi-GPU memory sharing scales well with the increased number of GPUs. With extra bandwidth brought by NVLink, accessing cache entries on other GPUs introduces negligible overhead. On the contrary, the increased cache capacity improved the cache hit ratio (Figure 5b) and reduced overall feature retrieving time (Figure 13).

We observe the relatively lower improvement with the User-Item dataset. On the billion-node graph dataset, the subgraph sampling and feature retrieving becomes more time consuming, due to the inconsistent sampling performance of DGL graph store server and sparse graph structure. Hence, BGL cannot produce the similar level of overlapping with the unchanging model computation time.

GPU Utilization. We compare the GPU utilization achieved by BGL and DGL with the same GPU backend. We run GraphSAGE and GAT models on Ogbn-products dataset with 8 GPU. BGL achieves 99% GPU utilization with the computation-intensive GAT model, while DGL’s utilization is only 38%. For GraphSAGE model with shallow neural layers, BGL improves the GPU utilization from 10% to 65%.

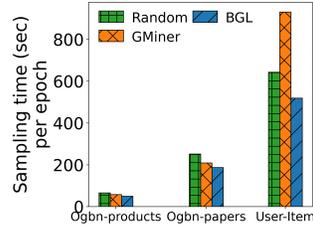

Figure 14: Graph sampling time per epoch during training.

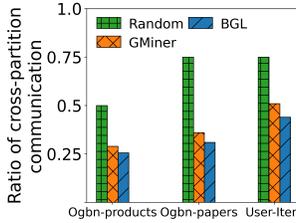

Figure 15: BGL reduces ratio of cross-partition communication.

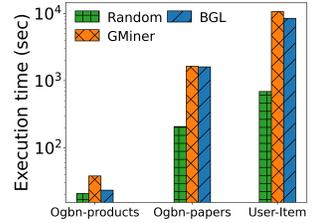

Figure 16: One-time partitioning execution time before training.

5.3 Impact of Feature Cache Engine

In §3.2, we have shown the cache hit ratio with different cache policies and cache sizes. The trend of them is similar on other datasets. Here, we present the amortized feature retrieving time with the feature cache engine.

We compare the feature retrieving time of one mini-batch using different GPUs on Ogbn-papers. We implement PaGraph static caching policy in BGL, which caches the features of high-degree nodes. Euler and DGL do not have cache, so the feature retrieving time is the elapsed time of transmitting features from graph store servers to GPU memory. As shown in Figure 13, due to high cache hit ratios and low cache overhead, the feature retrieving time of BGL is the shortest among all systems. Compared to other systems on 1 GPU worker, BGL reduces the feature retrieving time by 98%, 88% and 57% for Euler, DGL and PaGraph, respectively.

5.4 Impact of Graph Partition

We compare the graph partition algorithm in BGL with Random and GMiner partitioning, since only these two partition algorithms can scale to Ogbn-papers and User-Item. We evaluate the sampling time per epoch and the one-time partition time (counted from loading the graph data to saving the partition results to files) under different partition algorithms. Ogbn-products, Ogbn-papers and User-Item are divided into 2, 4 and 4 partitions, respectively.

Figure 14 shows the graph sampling time (per epoch) under different partition algorithms. BGL achieves the best performance across different graph datasets, reducing the sampling time by at least 20% over Random partition algorithm. Compared to GMiner, BGL manages to drop the sampling time by 14% and 10% for Ogbn-products and Ogbn-papers, respectively, thanks to its training node balancing and multi-hop connectivity of partitioning.

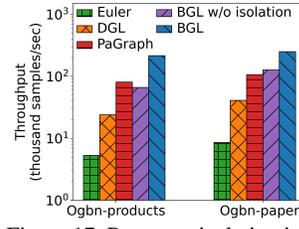

Figure 17: Resource isolation improves training throughput.

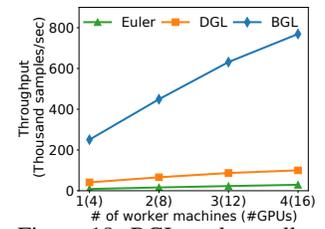

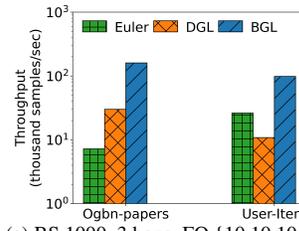

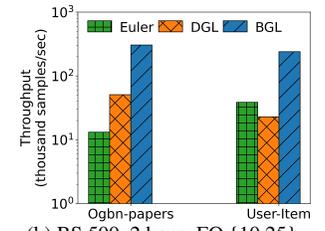

Figure 18: BGL scales well to multiple worker machines.

(a) BS 1000, 3 hops, FO {10,10,10}.

(b) BS 500, 2 hops, FO {10,25}.

Figure 19: Training throughput of GraphSAGE using different hyper parameters on 4 GPUs. BS and FO stand for ‘batch size’ and ‘fanout’.

The reduction in sampling time mainly comes from the reduced cross-partition (inter-server) communication during distributed neighbor sampling. As shown in Figure 15, by including multi-hop locality when partitioning, BGL reduces the ratio of cross-partition communication by 25%, 44%, and 33% for Ogbn-products, Ogbn-papers and User-Item, respectively. The cross-communication traffic is only determined by the number of partitions, but not the number of graph store servers or worker machines.

Partitioning a large-scale graph is time consuming. Hence, BGL introduces multi-level coarsening to mitigate the extra complexity brought by computing multi-hop locality. Figure 16 shows BGL’s partition algorithm runs as fast as the well-optimized original GMiner, and is even better than GMiner on graph User-Item with 20% reduction of time.

5.5 Impact of Resource Isolation

To evaluate the effectiveness of our resource isolation mechanism, we compare BGL with Euler, DGL, PaGraph, and BGL without resource isolation when training GraphSAGE with 4 GPUs on datasets Ogbn-products and Ogbn-papers. ‘BGL w/o isolation’ is a naive resource allocation method that shares all pipeline stages resources. It increases resource utilization but incurs larger contention and parallel overhead.

As shown in Figure 17 (in log scale), BGL achieves the highest throughput. Both BGL and ‘BGL w/o isolation’ outperform Euler and DGL. Due to the overhead of resource contention, the performance of ‘BGL w/o isolation’ on Ogbn-products is even lower than that of PaGraph. BGL uses resource isolation method, which mitigates the resource contention among different pipeline stages and incurs a lower parallel overhead of OpenMP. As a result, BGL speeds up the throughput by up to 2.7x, compared to the naive resource allocation strategy without isolation and PaGraph.

5.6 Scalability to Multiple Worker Machines

To show the scalability of multiple worker machines, we vary the number of worker machines from 1 to 4, and each has 4 GPUs. We train GraphSAGE model on graph Ognb-papers with Euler, DGL and BGL. The number of graph store servers remains the same as in §5.2.

As shown in Figure 18, BGL improves throughput from 250K to 769K (76% of linear scalability) when the number of worker machine increases from 1 to 4. Due to no feature cache on GPU and bottleneck in PCIe and network bandwidth, throughput of Euler and DGL cannot scale well when increasing the number of worker machines. Since our GPU servers only use NVLink v2, the cache engine cannot share GPU memory across machines, and BGL’s throughput increases slightly slower than linear scaling.

5.7 Impact of Hyper Parameters

To verify the robustness of BGL, we evaluate training speedup under different hyperparameters (batch size, number of layers and fanouts). As shown in Figure 19, we use another two widely-used training settings in OGB leaderboards [3]. We train GraphSAGE on graph Ognb-papers and User-Item with 4 GPUs. BGL outperforms DGL and Euler as well. The geometric mean of speedup of BGL for Euler and DGL is 10.44x and 7.50x, respectively. The computation of 2-layer GraphSAGE is faster than that with 3 layers. Hence, throughput of three systems in Figure 19b is higher than in Figure 19a.

5.8 Model Accuracy

To verify the correctness of BGL, we evaluate the test accuracy on GAT and GraphSAGE with Ognb-products, Ognb-papers and User-Item. Each task is trained with 100 epochs for convergence. DGL uses RO while BGL uses PO. As shown in Figure 20, BGL converges to almost the same accuracy as the original DGL but the convergence of BGL is much faster.

6 Related Work

Graph Partition Algorithms. Graph partitioning is widely adopted when processing large graphs. NeuGraph [40] leverages the Kernighan-Lin [34] algorithm to partition graphs into chunks with different sparsity levels. Cluster-GCN [12] constructs the training batches based on the METIS [32] algorithm, together with a stochastic multi-clustering framework to improve model convergence. When dealing with large graphs in distributed GNN training, partition algorithms, such as Random [2, 30, 39], Round-Robin, and Linear Deterministic Greedy [6], are often used [2, 48, 55, 60]. They incur low partitioning overhead while not ensuring partition locality.

GNN Training Frameworks. In recent years, new specialized frameworks have been proposed upon existing deep learning frameworks to provide convenient and efficient graph operation primitives for GNN training [2, 17, 40, 48, 60]. Other than DGL [48], Euler [2] and PyG [17], NeuGraph [40] translates graph-aware computation on dataflow and recasts graph

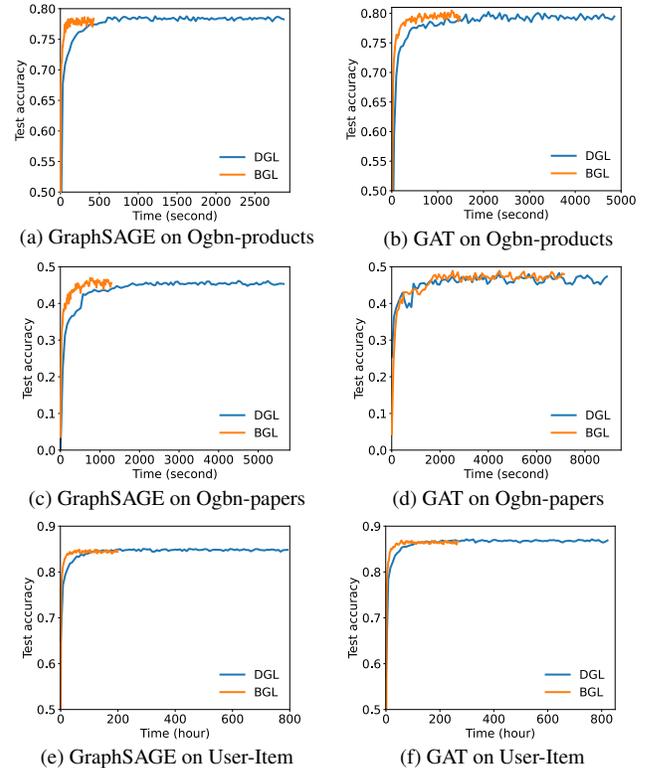

Figure 20: BGL achieves the same accuracy as DGL, using 1 GPU.

optimizations to support parallel computation for GNN training. However, it can only train small graphs on multi-GPUs in a single machine. AliGraph [60] is a GNN system that consists of distributed graph storage, optimized sampling operators and runtime to support both existing GNNs and in-house developed ones for different scenarios. AGL [55] is a scalable and integrated GNN system implemented on MapReduce [14] that guarantees good system properties. However, neither AliGraph nor AGL exploits GPU acceleration.

GNN Training Acceleration. Various systems have been devoted to improving GNN training performance.

Some works [9, 31, 40, 45, 49] target full-batch training. GNNAdvisor [49] explores the GNN input properties and proposes a 2D workload management and specialized memory customization for system optimizations. DGCL [9] proposes a communication planning algorithm to optimize GNN communication among multiple GPUs with METIS partition. Both projects assume graphs are stored in a single machine.

Some works [20, 38, 60] target mini-batch training. PaGraph [38] adopts static GPU caching for high-degree nodes. GNNLab [52] proposes a pre-sampling-based static caching policy. They assume that a graph can be loaded in a single machine, making them infeasible for billion-node graphs.

P^3 [20] reduces retrieving feature traffic by combining model parallelism and data parallelism. However, hybrid parallelism in P^3 incurs extra synchronization overhead. Its performance suffers when hidden dimensions exceed 128 (a com-

mon practice in modern GNNs). Further, P^3 overlooked the subgraph sampling stage, where random hashing partitioning leads to extensive cross-partition communication.

Some works try to improve graph sampling performance on GPUs, such as NextDoor [29] and C-SAW [43]. However, their performance is limited by small GPU memory. Hence, they are not suitable for giant graphs.

7 Conclusion

We present BGL, a GPU-efficient GNN training system for large graph learning that focuses on removing the data I/O and preprocessing bottleneck to achieve high GPU utilization and accelerate training. To minimize feature retrieving traffic, we propose a dynamic feature cache engine with proximity-aware ordering, and find a sweet spot of low overhead and high cache hit ratio. BGL employs a novel graph partition algorithm tailored for sampling algorithms to minimize cross-partition communication during sampling. We further optimize the resource allocation of data preprocessing using profiling-based resource isolation. Our extensive experiments demonstrate that BGL significantly outperforms existing GNN training systems by 1.91x on average. We will open-source it in the future and hope to continue evolving it with the community.

Zeus: Understanding and Optimizing GPU Energy Consumption of DNN Training

Jie You* Jae-Won Chung* Mosharaf Chowdhury
University of Michigan

Abstract

Training deep neural networks (DNNs) is becoming increasingly more resource- and energy-intensive every year. Unfortunately, existing works primarily focus on optimizing DNN training for faster completion, often without considering the impact on energy efficiency.

In this paper, we observe that common practices to improve training performance can often lead to inefficient energy usage. More importantly, we demonstrate that there is a tradeoff between energy consumption and performance optimization. To this end, we propose Zeus, an optimization framework to navigate this tradeoff by automatically finding optimal job- and GPU-level configurations for recurring DNN training jobs. Zeus uses an online exploration-exploitation approach in conjunction with just-in-time energy profiling, averting the need for expensive offline measurements, while adapting to data drifts over time. Our evaluation shows that Zeus can improve the energy efficiency of DNN training by 15.3%–75.8% for diverse workloads.

1 Introduction

Deep neural networks (DNNs) have received ubiquitous adoption in recent years across many data-driven application domains such as computer vision [20, 38, 65], natural language processing [21, 57], personalized recommendation [32, 39], and speech recognition [33]. To effectively support such growth, DNN models are predominantly trained in clusters of highly parallel and increasingly more powerful GPUs [15, 70].

However, growing demand for computation ultimately translates to greater energy demand. For instance, training the GPT-3 model [13] consumes 1,287 megawatt-hour (MWh) [75], which is equivalent to 120 years of electricity consumption for an average U.S. household [1]. This trend continues to grow: Meta reports an increasing electricity demand for AI, despite a 28.5% operational power footprint reduction [96]. Yet, existing literature on DNN training mostly ignores energy efficiency [83].

We observe that *common performance optimization practices for DNN training can lead to inefficient energy usage*. For example, many recent works prescribe large *batch sizes* for higher training throughput [29, 84]. However, we show that maximizing raw throughput may come at the cost of lower

energy efficiency. Similarly, modern GPUs allow the configuration of a *power limit* that caps its maximum power draw, but existing solutions often ignore it. Our analysis of four generations of NVIDIA GPUs shows that none of them are entirely power proportional, and drawing maximum power gives diminishing return. Indeed, carefully choosing the right batch size and GPU power limit can reduce energy consumption by 23.8%–74.7% for diverse workloads (§2.2).

Unfortunately, reducing energy consumption is not entirely free – we discover that there is a tradeoff between energy consumption and training time for a given target accuracy (§2.3). Our characterization of the energy-time Pareto frontier highlights two notable phenomena. First, for a given training job, all Pareto-optimal configurations provide varying amounts of energy reductions in comparison to blindly using the maximum batch size and GPU power limit. Second, the amount of reduction in energy consumption often has a non-linear relationship with the increase of training time. This raises a simple question: *how do we automatically identify and navigate the tradeoff between energy consumption and training time for DNN training?*

In this paper, we present Zeus to address this question. Zeus is a plug-in optimization framework that automatically configures the batch size and GPU power limit to minimize the overall energy consumption and training time for DNN training jobs (§3). Unlike some recent works that only consider GPU-specific configurations [11, 87], Zeus simultaneously considers job- and GPU-related configurations. Moreover, it does not require per-job offline profiling or prediction model training [90, 101], both of which can be prohibitive in large clusters with heterogeneous hardware and time-varying workloads [94]. Instead, Zeus takes an online exploration-exploitation approach tailored to the characteristics of DNN training workflows. That is, as new data flow into the pipeline, models need to be periodically re-trained [37], manifesting itself as *recurring jobs* in production clusters [37, 94]. Leveraging this fact, Zeus automatically explores various configurations, measures corresponding gains or losses, and continuously adjusts its actions based on its measurements (§4).

Designing such a solution is challenging due to two sources of uncertainty in DNN training. First, due to the randomness introduced from DNN parameter initialization and data loading, the energy consumed until a DNN reaches its target accuracy varies even when training is run with the exact same configuration [19, 82]. Thus, evaluating a configura-

*Equal contribution.

tion only once does not provide sufficient information about its *expected* energy consumption. Second, since both DNN models and GPUs have diverse architectures and unique energy characteristics [93], offline profiling results do not easily generalize to other DNNs and GPUs. Aggravating these challenges is the large size of the possible configuration space, with each configuration taking hours or even days to evaluate.

Zeus can efficiently determine the optimal set of knobs in the configuration space by *decoupling* the optimization of batch size and power limit without losing optimality. Specifically, it captures the stochastic nature of DNN training by formulating the batch size optimization problem as a Multi-Armed Bandit (MAB) and runs online optimization under random observations using the Thompson Sampling policy [88]. Additionally, Zeus’s just-in-time (JIT) energy profiler finds the optimal power limit while training is running, making Zeus a completely online optimization framework.

We have implemented Zeus and integrated it with PyTorch [74] (§5). Evaluation on a diverse workload consisting of speech recognition, image classification, NLP, and recommendation tasks shows that Zeus reduces energy consumption by 15.3%–75.8% and training time by 60.6% w.r.t. simply selecting the maximum batch size and maximum GPU power limit. Zeus converges to optimal configuration among available ones quickly and can adapt to data drift effectively. Zeus’s benefits expand to multi-GPU settings as well (§6).

In summary, we make the following contributions:

- To the best of our knowledge, we are the first to characterize the energy consumption vs. performance tradeoff for DNN training in terms of job- and GPU-specific configuration parameters.
- We present an online optimization framework that can learn from and adapt to workload dynamics over time.
- We implement and evaluate the optimizer in Zeus that integrates with existing DNN training workflows with little code change and negligible overhead, while enabling large benefits.

Zeus is open-source and available on GitHub.²

2 Motivation

In this section, we present an overview of energy consumption characteristics of DNN training on GPUs, opportunities for reducing energy consumption, and conclude with characterizing the tradeoff between reducing energy consumption and improving training performance.

2.1 DNN Training

Modern DNNs are trained by going over a large dataset multiple times, where each pass over the dataset is termed an *epoch* [28]. One epoch of training consists of thousands of *iterations* of gradient descent over equally sized mini-

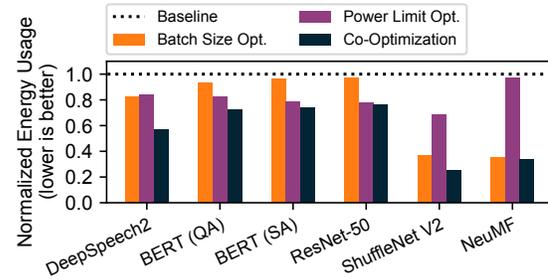

Figure 1: Energy usage normalized against baseline for DNN training, measured on NVIDIA V100 GPU. Baseline uses maximum power limit and the default batch size presented in the original model publication when available or the maximum batch size which can consistently reach the target metric.

batches, with the *batch size* affecting model accuracy,³ training throughput, and energy consumption. The performance of DNN training is often measured in terms of time-to-accuracy (TTA) for a given target accuracy [19], and increasing training throughput (or precisely goodput [77]) leads to lower TTA.

Modern DNNs are predominantly trained on increasingly more powerful GPUs, consuming more energy in the process [4, 75, 96]. Recent benchmarks show that GPUs are responsible for around 70% of the total energy consumption during DNN training [22, 41].

In production GPU clusters, as new data flow into the machine learning pipeline, DNNs need to be periodically re-trained at intervals as short as every hour [37]. This need manifests itself as *recurring jobs* in the GPU cluster [37, 94].

2.2 Opportunities for Improving Energy Efficiency

We highlight two job and hardware configurations that can cause sizable energy inefficiency in DNN training: (1) batch size and (2) power limit of the GPU.

Impact of batch size on energy efficiency. The size of each mini-batch during DNN training (batch size) determines how many samples are processed in one iteration. The higher it is, the faster we can go over the entire input dataset.

We observe across diverse DNN training workloads that common choices of batch size can lead to more energy consumption for the same target accuracy. Specifically, we performed a sweep over a large range of valid batch sizes (from 8 to the maximum batch size that fits in GPU memory) for six deep learning workloads including computer vision (CV), natural language processing (NLP), recommendation, and speech recognition on an NVIDIA V100 GPU (Figure 1).⁴ Section 6.1 provides details on workloads and methodology. We find that the energy-optimal batch size (Batch Size Opt. in Figure 1) can lead to 3.4%–65.0% lower energy consumption than the default choice for the same target accuracy.

³In this paper, we specifically consider the *validation accuracy* of the model, which captures how well the model generalizes to unseen data.

⁴We measure GPU power consumption using NVML [2].

The two gray dotted lines indicate two boundaries characterized by average power consumption. The green line indicates the Pareto frontier over all configurations. (b) Zoom-in view on the Pareto frontier in (a), with batch size and power limit annotated on each data point.

Impact of GPU power limit on energy efficiency. Setting a GPU’s power limit will have the device internally trigger dynamic voltage and frequency scaling (DVFS) such that its power draw does not exceed the power limit [69]. If not set manually, the power limit is at the maximum by default. We performed a sweep over a wide range of GPU power limits⁵ for the aforementioned setup. We found that the optimal energy consumption (Power Limit Opt. in Figure 1) may happen at a lower power limit than the maximum and can reduce energy consumption by 3.0%–31.5%.

Joint optimization. As Figure 1 shows, we can achieve even more energy savings (23.8%–74.7% reduction) if we jointly optimize both configurations. Note that we observed similar opportunities for reducing energy consumption for other generations of GPUs as well (Figure 15 in Appendix A).

2.3 Energy-Performance Tradeoffs

Opportunities for reducing DNN training energy consumption comes with a cost. When optimized for energy efficiency, DNN training performance (time-to-accuracy, or TTA) may be impacted. In the following, we characterize this tradeoff.

We define the energy consumption of DNN training until it reaches its target accuracy as its *energy-to-accuracy* (ETA):

$$\text{ETA}(b, p) = \text{TTA}(b, p) \times \text{AvgPower}(b, p), \quad (1)$$

where p denotes the GPU power limit, b the batch size, and $\text{AvgPower}(b, p)$ the average power consumption during training with configuration (b, p) . Similar to TTA, ETA captures the end-to-end goal of DNN training.

Note that $\text{AvgPower}(b, p)$ is not the same as the GPU power limit. When changes in configuration (b, p) lead to

⁵From the minimum to the maximum power limit allowed by NVIDIA System Management Interface [3]; from 100W to 250W for NVIDIA V100.

an increase in TTA, ETA does not always follow because $\text{AvgPower}(b, p)$ can decrease more. This motivates us to investigate the *tradeoff* between ETA and TTA.

Tradeoff between ETA and TTA. We characterize and elaborate on this tradeoff using DeepSpeech2 trained on LibriSpeech as an example (Figure 2). It shows a scatter plot of (TTA, ETA) for the batch size and power limit sweep experiments in Section 2.2. We observe similar results for other workloads as well (Figure 16 in Appendix B).

Let us start with Figure 2a, where each data point denotes the (TTA, ETA) of training the model for a certain configuration. While sweeping the configurations, we focus on the boundary of all feasible (TTA, ETA) pairs. We find them to be bounded by two straight lines characterizing the average GPU power consumption. When the GPU is under heavy load, the (TTA, ETA) data points appear closer to 210W. On the other hand, when the GPU is under lighter load, its average power consumption tends closer to 90W, which is close to the GPU’s idle power consumption of 70W. More importantly, we find a curve along which all (TTA, ETA) pairs achieves Pareto optimality [16], for which we cannot improve ETA without sacrificing TTA, and vice versa.

Now let us take a closer look at the Pareto frontier in Figure 2b, with the configurations used during training annotated along each data point. We highlight two takeaways:

1. These results show that baseline configurations can lead to suboptimal energy efficiency (§2). Moreover, it shows that blindly going for high batch size and power limit configurations can lead to suboptimal TTA as well.
2. There exists a tradeoff between ETA and TTA, with different optimums for each. The configuration optimizing the ETA ($b=32, p=100\text{W}$) is different from that optimizing TTA ($b=48, p=250\text{W}$).

3 Zeus Overview

Zeus is an optimization framework that navigates the ETA-TTA tradeoff by automatically configuring the batch size and GPU power limit of recurring DNN training jobs. It enables developers to optimize energy and/or performance metrics using a single knob.

3.1 Optimization Metric

Defining a good cost metric for users to express their preference in this tradeoff is critical in designing Zeus. We propose a simple cost metric:

$$C(b, p; \eta) = \eta \cdot \text{ETA}(b, p) + (1 - \eta) \cdot \text{MAXPOWER} \cdot \text{TTA}(b, p) \quad (2)$$

Here η is the parameter specified by the user to express the relative importance of energy efficiency and training performance (throughput). When $\eta = 0$, we are only optimizing for time consumption, whereas when $\eta = 1$, we are only optimizing for energy consumption. MAXPOWER is the maximum power limit supported by the GPU, a constant introduced to unify the units of measure in the cost metric.

3.2 Challenges in Picking the Optimal Configuration

Combining Equations 1 and 2, we have:

$$C = (\eta \cdot \text{AvgPower}(b, p) + (1 - \eta) \cdot \text{MAXPOWER}) \cdot \text{TTA}(b, p). \quad (3)$$

Picking the optimal configuration(s) to minimize the energy-time cost C for DNN training is challenging because the search space $[b \times p]$ is large and obtaining the cost of each configuration is difficult. This is because it is hard to determine the value of both $\text{AvgPower}(b, p)$ and $\text{TTA}(b, p)$ efficiently, as explained below.

- **Complex power consumption model:** The total energy consumption of a GPU is affected in a non-linear fashion by both the characteristics of the workload such as the number of instructions and memory accesses, as well as the GPU hardware configurations such as the frequency and voltage of the cores and memory on board [6, 46]. Existing efforts estimate GPU energy consumption based on instruction- or kernel-level information [43, 64], which are architecture-specific and workload-dependent.
- **Stochastic nature of DNN training:** Modeling and predicting the duration for training a specific model to target accuracy (TTA) is known to be difficult [31]. Moreover, the randomness introduced during model initialization and data loading leads to variations of TTA, even when the same job is run on the same GPU with the same configuration – TTA variations can be as large as 14% [19].

Fortunately, DNN training jobs often recur in production clusters [37, 94]. This provides opportunities for empirical estimation through repeated measurements across recurrences of the same training job.

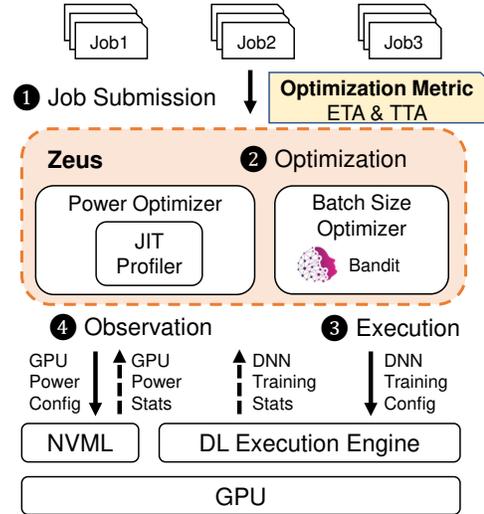

Figure 3: Zeus Workflow.

3.3 Architectural Overview

At a high-level, Zeus takes an online exploration-exploitation approach to minimize the aggregate cost of recurrent DNN training jobs. Zeus addresses the aforementioned challenges with two key components:

1. A just-in-time (JIT) online profiler, which efficiently profiles the energy characteristics of the training job online.
2. Multi-Armed Bandit (MAB) with Thompson sampling, which allows us to embrace the stochastic nature of DL training and optimize under uncertainty while also adapting to changing workloads such as data drift.

The combination of the JIT profiler and MAB makes Zeus a fully online solution, allowing it to immediately begin optimizing for incoming jobs.

Workflow of Zeus. Figure 3 shows an overview of the high-level workflow of Zeus. In a production environment, users submit ① recurrent DNN training jobs (a tuple of data, model, optimizer, and the target validation metric) to Zeus, along with a set of feasible batch sizes \mathcal{B} and power limits \mathcal{P} to explore. Zeus then predicts ② the optimal batch size and power limit configuration based on past execution history, and launches ③ the training job with that configuration. During and after the training process, ④ statistics about DNN training (e.g., validation metric) and GPU power consumption are collected and fed back to the Zeus optimizer. The Zeus optimizer learns from the feedback and adjusts its internal states. The training job will be terminated upon either reaching target metric or exceeding a stopping threshold determined by Zeus. The whole process is an automated feedback loop that minimizes the key objective of energy-time cost.

Building Zeus requires both algorithm design and systems support. Next we describe the core optimization algorithm details (§4) and Zeus implementation highlights (§5).

4 Zeus Algorithm Design

In this section, we delve into the details of how Zeus selects the best batch size and GPU power limit to optimize the overall cost of recurrent DNN training tasks. We first present the optimization problem formulation and how we decouple the optimizations of batch size and power limit (§4.1). Next, we show how to optimize power limit (§4.2) and batch size (§4.3) under the decoupled framework. We conclude by discussing how we address common challenging scenarios (§4.4).

4.1 Problem Formulation

The objective of Zeus is to minimize the cost of a recurring job by automatically exploring the feasible set of batch sizes \mathcal{B} and power limits \mathcal{P} . In essence, we neither want to incur too much cost searching for the optimal configuration, nor do we want to miss it. Minimizing the *cumulative* cost of the job over recurrences captures the implicit tradeoff between exploration and exploitation. Put formally in terms of the cost function defined by Equation 2, our objective becomes

$$\begin{aligned} \min_{b,p} \quad & \sum_{t=1}^T C(b_t, p_t; \eta) \\ \text{s.t.} \quad & b_t \in \mathcal{B}, p_t \in \mathcal{P}, \forall t \in [1, T], \end{aligned} \quad (4)$$

where b_t and p_t respectively denote the batch size and power limit chosen at the t th recurrence of the job, and b and p are vectors of length T .

This is a challenging problem without modification, mainly because the size of the search space can be in the order of hundreds, and each value of $C(b, p; \eta)$ inside the search space can only be obtained by running DNN training until it reaches the target metric. However, further expanding the cost function (Equation 3) allows us to *decouple* the exploration of batch size and power limit, making the problem more tractable:

$$\begin{aligned} C(b, p; \eta) &= (\eta \cdot \text{AvgPower}(b, p) + (1 - \eta) \cdot \text{MAXPOWER}) \cdot \text{TTA}(b, p) \\ &= \text{Epochs}(b) \cdot \frac{\eta \cdot \text{AvgPower}(b, p) + (1 - \eta) \cdot \text{MAXPOWER}}{\text{Throughput}(b, p)}. \end{aligned} \quad (5)$$

where $\text{Epochs}(b)$ denotes the number of epochs needed to reach the target, and $\text{Throughput}(b, p)$ epochs per second.

We find two key insights that allow the decoupling of batch size b and power limit p :

1. Given b , $\text{AvgPower}(b, p)$ and $\text{Throughput}(b, p)$ can be profiled quickly during training for all possible choices of p . This is due to the iterative nature of DNN training, yielding stable power and throughput estimations even with a small number of iterations.
2. $\text{Epochs}(b)$ is not affected by the choice of p as changing the power limit does not change what is computed.

This implies that the optimal power limit, given any batch size, can be determined independently based on online profiling. Moreover, since any choice of batch size is automatically

accompanied by the optimal power limit, our search space is reduced to the set of batch sizes \mathcal{B} .

Formally put, we have decoupled the problem in Equation 4 into an equivalent two-level optimization problem

$$\min_{b \in \mathcal{B}^T} \sum_{t=1}^T \text{Epochs}(b_t) \cdot \text{EpochCost}(b_t; \eta) \quad (6)$$

where

$$\begin{aligned} & \text{EpochCost}(b_t; \eta) \\ &= \min_{p_t \in \mathcal{P}} \frac{\eta \cdot \text{AvgPower}(b_t, p_t) + (1 - \eta) \cdot \text{MAXPOWER}}{\text{Throughput}(b_t, p_t)}. \end{aligned} \quad (7)$$

When a job arrives, Zeus will first decide which batch size to use based on Equation 6 (§4.3). Then, based on the batch size, Zeus will pick the optimal power limit based on Equation 7 (§4.2).

4.2 Optimizing the Power Limit

We start with how Zeus determines the optimal power limit based on Equation 7, given a choice of the batch size. As highlighted earlier, we leverage the iterative nature of DNN training and the recurrent nature of jobs in production DNN training workflows.

When a job with batch size decision b is submitted, our just-in-time (JIT) profiler is triggered and checks if this batch size had been profiled before. For an unseen batch size b , it profiles $\text{AvgPower}(b, p)$ and $\text{Throughput}(b, p)$ for all possible power limits p during the first epoch of the job by partitioning the epoch into slices at iteration boundaries and dynamically changing the GPU power limit for each slice. The profile information is fed back to Zeus, and the optimal power limit of the batch size is determined by solving Equation 7. The rest of the epochs are executed with the optimal power limit. Our *online* JIT profiling approach consumes strictly less time and energy compared to offline profiling before running the job, because the profiling process itself contributes to training without affecting its accuracy. We show that JIT profiling incurs negligible overhead in Section 6.5.

4.3 Optimizing the Batch Size

Now we focus on how Zeus determines the batch size b_t for each job recurrence t that optimizes Equation 6. As seen in Section 4.2, $\text{EpochCost}(b_t; \eta)$ is a cheap and deterministic function that identifies the optimal power limit for any batch size b_t and returns the optimal cost of one epoch. Thus, we may limit our exploration to choosing the optimal batch size because whichever batch size we choose, the optimal power limit will accompany it.

Due to the unpredictable and stochastic nature of DNN training, picking out the optimal batch size without adequate exploration is difficult. Hence, a good solution must (1) incorporate such nature of DNN training into its exploration process, and (2) intelligently tradeoff the cost of exploring for

Input: Batch sizes \mathcal{B}

Belief posterior parameters $\hat{\mu}_b$ and $\hat{\sigma}_b^2$

Output: Batch size to run b^*

Function Predict ($\mathcal{B}, \hat{\mu}_b, \hat{\sigma}_b^2$):

```
1  foreach batch size  $b \in \mathcal{B}$  do
   |   /* Sample from the belief distribution */
2  |   Sample  $\hat{\theta}_b \sim \mathcal{N}(\hat{\mu}_b, \hat{\sigma}_b^2)$ 
3  end
   |   /* Select the arm with smallest mean cost sample */
4  |    $b^* \leftarrow \operatorname{argmin}_b \hat{\theta}_b$ 
```

Algorithm 1: Gaussian Thompson Sampling: Choosing the next batch size to run (Predict)

potentially better batch sizes and the gain of exploiting batch sizes that are already known to be good.

Grid search is suboptimal. We argue that exhaustively going through all batch sizes and selecting the one with the smallest cost is still suboptimal due to the stochastic nature of DNN training. That is, because the cost of a DNN training job can differ even when executed with the exact same configurations, it must be modeled as a *cost distribution* with unknown mean and variance. Although performing several trials for each batch size may yield a better estimation of the mean cost, such a strategy leads to *high exploration cost* because it does not quickly rule out obviously suboptimal batch sizes.

Multi-Armed Bandit formulation. Zeus aims to explore the cost of different batch sizes and converge to the optimal batch size, while not incurring too much exploration cost.

Zeus formulates the problem as a Multi-Armed Bandit (MAB) with T trials and B arms, where each trial corresponds to a recurrence of the job and each arm to a batch size in \mathcal{B} . MAB is a good fit to our problem scenario in that it captures the stochasticity of DNN training by modeling the cost of each batch size as a random variable. Specifically, we choose the Gaussian distribution [81] due to its representational flexibility. The objective of the MAB formulation is to minimize the *cumulative cost regret* defined as

$$\sum_{t=1}^T \operatorname{Regret}(b_t; \eta) \quad (8)$$

where the regret of choosing b_t is defined as

$$\begin{aligned} \operatorname{Regret}(b_t; \eta) &= \operatorname{Epochs}(b_t) \cdot \operatorname{EpochCost}(b_t; \eta) - \min_{b,p} \operatorname{Cost}(b, p; \eta). \end{aligned} \quad (9)$$

Minimizing cumulative cost regret aligns with our objective in Equation 6.

Thompson Sampling. We adopt the Thompson Sampling [81] policy for the MAB formulation to tradeoff exploration and exploitation, not only because it is known to

Input: Batch size b and observed cost C

Previous cost observations C_b for b

Belief prior parameters $\hat{\mu}_0$ and $\hat{\sigma}_0^2$

Output: Belief posterior parameters $\hat{\mu}_b$ and $\hat{\sigma}_b^2$

Function Observe ($b, C, C_b, \hat{\mu}_0, \hat{\sigma}_0^2$):

```
1  /* Add the most recent cost observation to history */
   |    $C_b \leftarrow C_b \cup \{C\}$ 
   |   /* Compute the variance of the cost */
2  |    $\tilde{\sigma}^2 \leftarrow \operatorname{Var}(C_b)$ 
   |   /* Compute the belief distribution's posterior variance */
3  |    $\hat{\sigma}_b^2 \leftarrow \left( \frac{1}{\hat{\sigma}_0^2} + \frac{|C_b|}{\tilde{\sigma}^2} \right)^{-1}$ 
   |   /* Compute the belief distribution's posterior mean */
4  |    $\hat{\mu}_b \leftarrow \hat{\sigma}_b^2 \left( \frac{\hat{\mu}_0}{\hat{\sigma}_0^2} + \frac{\operatorname{Sum}(C_b)}{\tilde{\sigma}^2} \right)$ 
```

Algorithm 2: Gaussian Thompson Sampling: Updating the belief distribution (Observe)

perform well in practice [17, 81] and had successful adoption recently [58, 67], but also because its modeling assumptions fit our problem scenario well.

At a high level, Thompson Sampling is an online procedure that refines its *belief* about the *mean cost* of each arm (batch size) based on experience. At each recurrence, the belief is used to pick the arm with the lowest estimated mean cost (Algorithm 1), and the belief is updated based on the actual cost observed (Algorithm 2).

Specifically, the cost distribution is modeled as a Gaussian distribution with unknown mean θ_b . Then, the belief about θ_b is modeled with its conjugate prior distribution, which is also a Gaussian distribution [24]. That is, $\theta_b \sim \mathcal{N}(\hat{\mu}_b, \hat{\sigma}_b^2)$. Here it is important to note that $1/\hat{\sigma}_b^2$ can be thought as of how confident the policy is in its belief about that arm, with the confidence increasing as it accumulates more observations of the cost of choosing that arm. Then, Thompson Sampling automatically balances exploration and exploitation by choosing the arm with the smallest mean cost sample $\hat{\theta}_b \sim \mathcal{N}(\hat{\mu}_b, \hat{\sigma}_b^2)$ (Algorithm 1). With low confidence (high variance), $\hat{\theta}_b$ will be dispersed across a wider range of costs, having higher chances of getting chosen even if some of its initial observations showed high cost. In contrast, when the arms observed a lot of cost samples and the confidence is high (low variance), $\hat{\theta}_b$ is likely to be centered around the mean observed cost, allowing the exploitation of arms that are known to be good. After the actual cost of an arm is observed, the belief parameters of that arm are updated using the Bayes Rule [81] (Algorithm 2).

The belief prior parameters $\hat{\mu}_0$ and $\hat{\sigma}_0^2$ reflect prior belief about the mean cost of using the batch size for training and the confidence of such belief. Hence, the choice of prior parameters serve as a way to initialize the arms such that they reflect prior knowledge about the cost of each arm. If such

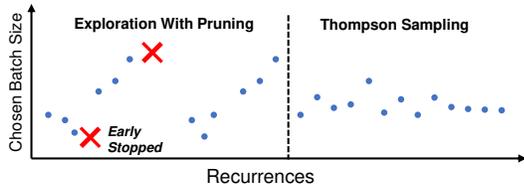

Figure 4: An example of batch sizes chosen by Zeus for a recurring job. Each point is a recurrence. During pruning, Zeus explores each batch size 2 times in order to observe the cost variance (Line 2 in Algorithm 2).

information is not available, which is our default assumption, it is also possible to initialize the arms with a flat prior that assumes no prior knowledge – in our case, this is a Gaussian distribution with zero mean and infinite variance.

In contrast to grid search, our formulation using MAB and Thompson Sampling meets the two requirements mentioned earlier. That is, MAB inherently incorporates the stochastic nature of DNN training in that it models cost as a random variable. Moreover, Thompson Sampling can quickly rule out batch sizes that are obviously suboptimal because the probability of a smaller mean cost being sampled from an arm that observed noticeably large cost is low.

4.4 Extensions for Challenging Scenarios

Handling unknown cost variance. Unlike conventional Gaussian Thompson Sampling applications, we may not assume that the variances of the cost of each arm are known. That is, the cost variance (i.e., how much the cost will fluctuate even when training is run with the same batch size) is not known before any observation. Moreover, the cost variance depends not only on the batch size, but also on the DNN’s robustness to the randomness in parameter initialization and data loading, making it difficult to quantify at the time the MAB is constructed. Hence, our approach is to *learn* the cost variance as we observe cost samples (Line 2 in Algorithm 2).

Handling stragglers during exploration. There may be cases where an exploratory job does not reach the target metric within a reasonable amount of cost, especially during the earlier exploration stage. To handle this, we employ *early stopping* and *pruning*. The intuition is that if a batch size does not reach the target metric even after incurring an exceedingly large cost, it is highly unlikely to be the optimal one.

For early stopping, we define a cost threshold $\beta \cdot \min_t C_t$, meaning that when the cost of the current job is to exceed β times the minimum cost observed so far, we stop the job and retry with another batch size. Here β is a parameter to account for the stochastic nature of DL training. By default, we choose $\beta = 2$, with which we should be able to tolerate variations of TTA between different runs of the same configuration, which is usually less than the 14% [19].

For pruning, as illustrated in Figure 4, we begin with the default batch size provided by the user and first try smaller batch sizes until we meet the minimum batch size or a batch

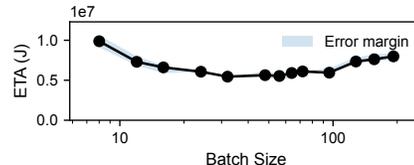

Figure 5: ETA of each batch size for DeepSpeech2 trained on LibriSpeech. Plots for rest of the workloads are in the Appendix C.

Input: Set of batch sizes \mathcal{B}
 Default batch size b_0
 Belief prior parameters $\hat{\mu}_0$ and $\hat{\sigma}_0^2$

```

/* Exploration With Pruning */
1 Recurrence  $t \leftarrow 0$ 
2 repeat 2 times
3   Explore  $b_0$ 
4   Explore  $b < b_0$  until convergence failure
5   Explore  $b > b_0$  until convergence failure
6    $\mathcal{B} \leftarrow \{b : b \text{ converged}\}$ 
7    $b_0 \leftarrow b$  with smallest cost observed
8    $t \leftarrow t + |\mathcal{B}|$ 
9 end
/* Thompson Sampling */
10 while  $t \leq T$  do
11    $b^* \leftarrow \text{Predict}(\mathcal{B}, \hat{\mu}_b, \hat{\sigma}_b^2 \forall b \in \mathcal{B})$ 
12   Run job with batch size  $b^*$  and add cost to  $C_b$ 
13   /* Update our belief of the mean cost */
14    $\hat{\mu}_b, \hat{\sigma}_b^2 \leftarrow \text{Observe}(b, C_b, \hat{\mu}_0, \hat{\sigma}_0^2)$ 
15    $t \leftarrow t + 1$ 
16 end

```

Algorithm 3: Gaussian Thompson Sampling Batch Size Optimizer.

size that fails to reach the target metric before the early stopping threshold. The same process is repeated for batch sizes larger than the default batch size. Then, only the batch sizes that reached the target metric are kept in the batch size set we explore. After performing an initial round of pruning, the default batch size is updated to be the one with the smallest cost observed, and we perform pruning once more starting from the new default batch size.

The intuition behind our batch size pruning approach is the convexity we observe in the BS-ETA curve around the optimal batch size (See Figure 5). Moreover, pruning allows Zeus to quickly rule out batch sizes that are noticeably suboptimal (typically too large, leading to more training epochs and loss of accuracy [27, 49], or too small, yielding gradients that are too noisy [80]), thus cutting down the cost of exploration.

The overall process is depicted in Algorithm 3.

Handling concurrent job submissions. Classic multi-armed bandit scenarios assume that the MAB immediately observes the cost of pulling an arm. However, in a DNN

training cluster, recurring jobs may overlap in their execution when a later job starts before the completion of an earlier job. In this case, the MAB does not get to observe the cost of the earlier job at the time it has to decide the batch size for the later job. For deterministic policies like [8, 56], this leads to duplication exploration of the same batch size back-to-back, reducing the efficiency of exploration.

However, Thompson Sampling naturally mitigates this problem without modification because deciding the next batch size to explore (Predict) is a random function. That is, because Thompson Sampling *samples* the estimated mean cost from each arm’s belief distribution and returns the arm with the lowest sampled value, concurrent jobs can run different batch sizes even if there was no information gained between the invocations of Predict. This is especially the case during the early stage of Thompson Sampling when the arms’ belief distributions have large variances (low confidence), losing little exploration efficiency.

During the short initial pruning phase, we run concurrent job submissions with the best-known batch size at that time. As the best batch size constantly updates throughout the exploration stage, this strategy fairly distributes the additional exploration opportunities from concurrent job submissions to batch sizes that are known to converge. We evaluate Zeus’s efficacy on handling concurrent job submissions in Section 6.3.

Handling data drift. In production training clusters, the data on which the model is trained shifts, which is one of the reasons why re-training is triggered [61, 63]. The implication of drift in the perspective of the MAB is that the cost distribution of each arm is non-stationary.

Thompson Sampling allows a simple modification that allows us to handle non-stationary cost distributions. Since older cost observations become less and less relevant, we only operate on a window of N most recent cost observations [10], and the belief distributions will not take old observations into account. Unlike exponential decay, windowing also allows the cost variance of the most recent observations to be estimated directly. When old history entries are evicted, computing the new parameters of the arm is also cheap thanks to the conjugate prior property. This way, Zeus transparently adapts to data drifts in an *online* manner, as we show in Section 6.4.

5 Zeus Implementation

Zeus is implemented as a Python library that can be imported into DNN training scripts. The `ZeusDataLoader` class integrates with PyTorch [74]. The class profiles power and throughput online by slicing epochs in iteration boundaries and invoking the NVML [2] library for power limit configuration and profiling. We have observed that five seconds of profiling for each power limit is enough to yield stable results. With the information, the optimal power limit can be automatically determined and applied. Moreover, `ZeusDataLoader` monitors the cost incurred by training and early stops the job if needed. Listing 1 shows an example training loop integrated

```

1  from zeus import ZeusDataLoader
2
3  train_loader = ZeusDataLoader(
4      train_set, batch_size, max_epochs, target_metric)
5  eval_loader = ZeusDataLoader(eval_set, batch_size)
6
7  for epoch in train_loader.epochs(): # may early stop
8      for batch in train_loader:
9          # Learn from batch
10         for batch in eval_loader:
11             # Evaluate on batch
12         train_loader.report_metric(validation_metric)

```

Listing 1: Zeus Integration Example

with Zeus.

Observer Mode. `ZeusDataLoader` supports *Observer Mode*, where it profiles the power consumption and throughput of each power limit and determines the optimal one, but keeps the power limit at the maximum. By doing so, without affecting time or energy consumption, `ZeusDataLoader` reports how much time and energy the job *would have* consumed if the power limit were the optimal one, allowing the user to get an idea of the impact of using Zeus. We believe that such a feature can encourage Zeus’s adoption by informing users of its potential savings.

6 Evaluation

We evaluate Zeus’s effectiveness in terms of navigating the energy-time tradeoff. Our key findings are as follows:

1. Zeus reduces energy consumption by 15.3%–75.8%. It achieves this by trading off small performance for jobs that are already throughput-optimal; otherwise, it reduces training time by up to 60.1% too (§6.2).
2. Zeus quickly converges to optimal configurations (§6.2).
3. Zeus can handle workloads with data drift (§6.4) and overall incurs low overhead (§6.5).
4. Zeus scales to multi-GPU settings (§6.6) and provides consistent savings across four generations of GPUs (§6.7).

6.1 Experimental Setup

Testbed Setup. We evaluate Zeus with four generations of NVIDIA GPUs as specified in Table 2.

Workloads. Table 1 summarizes our workloads. The default batch size (b_0) is chosen from the original model publication when available; otherwise, it is set to be the maximum batch size which consistently achieves the target accuracy.

In terms of learning rate, models trained with the Adadelta [99] optimizer do not require an initial learning rate. For optimizers that do require an initial learning rate, we made our best effort in choosing a batch size and learning rate pair that achieves reasonable accuracies by experimenting with values from the original publication of the model and those discovered by popular DL frameworks [95].

After collecting the initial batch size and learning rate pairs,

Task	Dataset	Model	Optimizer	b_0	Target Metric
Speech Recognition	LibriSpeech [73]	DeepSpeech2 [33]	AdamW [62]	192	WER = 40.0%
Question Answering	SQuAD [79]	BERT (QA) [21]	AdamW [62]	32	F1 = 84.0
Sentiment Analysis	Sentiment140 [26]	BERT (SA) [21]	AdamW [62]	128	Acc. = 84%
Image Classification	ImageNet [20]	ResNet-50 [38]	Adadelata [99]	256	Acc. = 65%
Image Classification	CIFAR-100 [53]	ShuffleNet-v2 [65]	Adadelata [99]	1024	Acc. = 60%
Recommendation	MovieLens-1M [34]	NeuMF [39]	Adam [51]	1024	NDCG = 0.41

Table 1: Models and datasets used in our evaluation. The provided target metrics is the target for each training job. Here b_0 denotes the default batch size presented in the original work when feasible, otherwise we choose the maximum batch size which can consistently reach the target. The BERT(QA) and BERT(SA) means fine-tuning BERT on the tasks of question answering and sentiment analysis, respectively.

Table 2: Hardware used in the evaluation.

when we scale the batch size, we applied Square Root Scaling [42] for adaptive optimizers such as Adam [51] following recent theoretical results [30].

Baselines. We compare against the following baselines:

1. *Default* ($b = b_0$, $p = \text{MAXPOWER}$). This is often the default configuration used by practitioners, where the GPU power limit is set to, or rather *not changed from*, the maximum. This is the most conservative baseline with no exploration.
2. *Grid Search with Pruning*. This one tries out one configuration of (b, p) for each recurrence of the job and selects the best one. We optimize naïve grid search by having it prune out batch sizes that failed to reach the target metric.

Metric. Our primary metrics are ETA (energy consumption) and TTA (training time). Ideally, we want to reduce both; but due to their tradeoff, sometimes it may not be possible to simultaneously do both.

Defaults. All experiments are done on NVIDIA V100 GPUs, unless otherwise mentioned. By default, we highlight $\eta = 0.5$ to strike a balance between ETA and TTA. Later, we sweep η from 0 to 1 (§6.7). The early-stopping threshold β is set to 2, and we also sweep β from 1.5 to 5 (§6.7).

Methodology. Due to resource constraints and environmental concerns, we cannot afford to repeatedly train all of our workloads with various configurations end-to-end hundreds of times sequentially. However, similar to how Zeus *decouples* the exploration of batch size and power limit, we may apply the same decoupling in our experimentation. That is, we instead take a trace-driven approach, where we collect two

kinds of trace data:

1. *Training trace*. We train all possible combinations of models and batch sizes until convergence and record the number of epochs the model took to reach its target accuracy. We repeat this with four different random seeds for every combination to capture the stochasticity in DNN training.
2. *Power trace*. We use our JIT profiler to collect the throughput and average power consumption of all possible combinations of model, batch size, and power limit.

We then replay these traces when we need to train a model and reconstruct its TTA and ETA values in order to evaluate the decisions made by Zeus and baselines. Moreover, since we have access to all the possible choices and their outcomes, we also know the optimal choice. Therefore, with the traces, we can evaluate the regret achieved by Zeus and baselines.

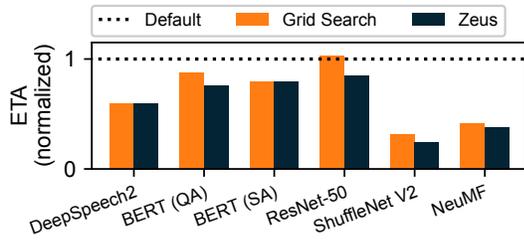

Note that Zeus does not directly learn from these traces (which would be offline-profiling), but instead only learns from the *replay* of these traces in an online fashion.

While the aforementioned trace-driven method is used widely throughout our evaluation, we run Zeus end-to-end for the evaluation of handling data drift (§6.4) because it is more expensive to construct the trace for the drifting dataset.

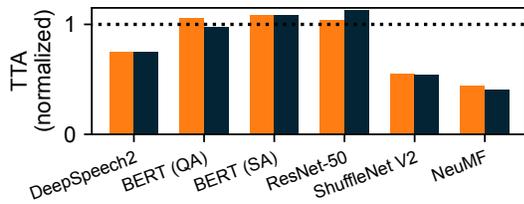

6.2 Zeus Performance

In this section, we evaluate the performance of Zeus in terms of energy consumption and training time as well as the convergence characteristics of our Multi-Armed Bandit algorithm. Each experiment is run across multiple recurrences of DNN training jobs. We select the recurrence number to be $2 \cdot |\mathcal{B}| \cdot |\mathcal{P}|$, so that the Grid Search baseline finishes exploration and also has plenty of chances to exploit its choice.

Improvements in ETA. Figure 6a shows the energy consumption (ETA) of the last five recurrences of Zeus and Grid Search w.r.t. the Default baseline, aiming to compare the final point each approach converged to. Zeus reduces energy consumption (ETA) by up to 15.3%–75.8% w.r.t. the baseline. This is also comparable to the reduction we found by exhaustively searching through all the configurations in Section 2 as well as by using Grid Search.

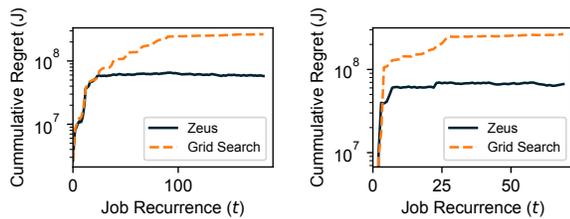

(a) Energy Consumption

(b) Training Time

Figure 6: Zeus reduces energy consumption for all workloads. (a) energy consumption, (b) training time of each workload, normalized by the Default baseline. Results are computed with the last five recurrences, capturing the knobs each method converged to.

(a) DeepSpeech2

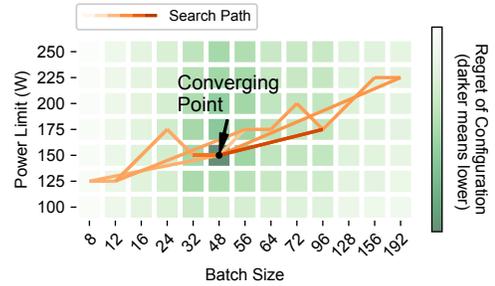

(b) ResNet-50

Figure 7: Cumulative regret of Zeus vs. Grid Search for (a) DeepSpeech2 and (b) ResNet-50.

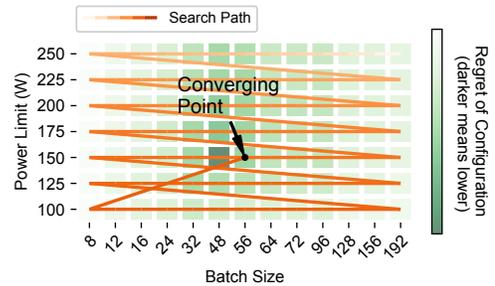

Tradeoff with TTA. Figure 6b shows the time consumption (TTA) of the last five recurrences of Zeus and Grid Search w.r.t. the Default baseline. Even though Zeus reduces training time by up to 60.1%, for some workloads TTA is increased by 12.8% (Figure 6b). This is due to the tradeoff between ETA and TTA, which is the central focus of this paper. This is especially true for workloads with a b_0 tuned for minimizing training time, where there is little room for TTA improvement.

Cumulative regret. While Zeus and Grid Search perform close to each other, Zeus uses significantly smaller amount of resources to converge. As a bandit-based solution, the effectiveness of our algorithm can be quantified via regret, the difference between the decision selected and the optimal choice (Equation 9 in Section 4.3).

Figure 7 shows the cumulative regret of Zeus and Grid Search for DeepSpeech2 and ResNet-50. The optimal configuration is identified separately by an exhaustive parameter sweep. We observe that in both workloads, Zeus is able

(a) Zeus

(b) Grid Search

Figure 8: Search paths of (a) Zeus and (b) Grid Search for DeepSpeech2. The heatmap in the background shows the regret of each (Batch Size, Power Limit) configuration. Darker background denotes lower regret and therefore better configuration. The colored line with shifting color shows the search path, with darker color being later recurrences.

to achieve better regret from the first job recurrence. Zeus reaches the plateau in the cumulative regret earlier than Grid Search, which means it converges to the optimal solution earlier. We observe similar results for other workload as well (Appendix D). In the worst case, Grid Search results in $72\times$ more cumulative regret than Zeus until convergence.

Convergence to a Pareto-optimal configuration. Despite having no information about the application beforehand, Zeus learns the energy characteristics of it online in a few iterations. Figure 8 shows the search path of Zeus and Grid Search during training DeepSpeech2. Due to the decoupling in the optimization of power limit and batch size, Zeus explores the configuration space more efficiently and converges to the optimal configuration much faster. We observe similar results for other workloads (see Appendix E). Moreover, in Figure 8b we observe that Grid Search may not even converge to optimal configuration. This is due to the stochastic nature of DNN training, with even the same batch size yielding different energy and time consumptions. Hence, Grid Search may choose a suboptimal configuration when a suboptimal configuration luckily yields good energy and time consumptions.

6.3 Trace-Driven Simulation Using the Alibaba Trace

Here we evaluate how Zeus can save energy and time consumption for DNN training in large clusters. We run trace-

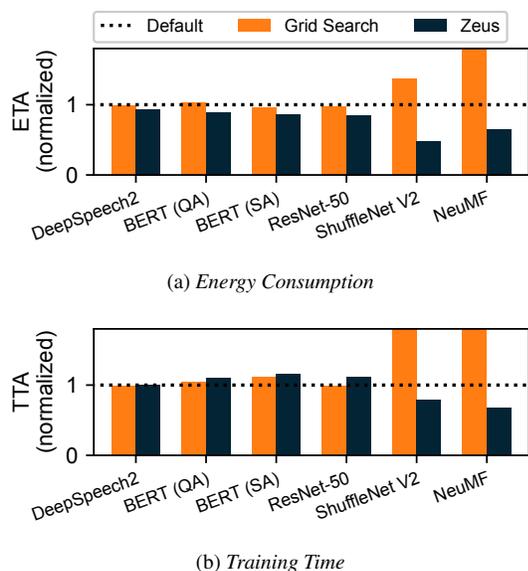

Figure 9: Zeus reduces energy consumption for all jobs in the Alibaba cluster trace [94], compared to Grid Search and Default. (a) Energy consumption with Zeus comparing against baselines, (b) Training time of each type of workload. Both are normalized by the Default baseline.

driven simulation using the Alibaba GPU cluster trace [94] which contains over 1.2 million jobs spanning a period of two months. The Alibaba GPU cluster trace is suitable for our evaluation for two reasons. First, the trace identifies groups of recurring jobs, and each job is annotated with its group ID. Second, jobs within the same group show overlap in their execution, allowing us to evaluate Zeus’s capability of handling concurrent job submissions with Thompson Sampling.

In order to assign job groups to the workload (Table 1) that best resembles its runtime, we remove jobs that did not successfully terminate and run K-Means clustering [36] on the mean job runtime of each group to form six clusters. Then, we match the six clusters with our six workloads in the order of their mean runtime. When running simulation, in order to capture the intra-cluster runtime variation of each job, we scale the job runtime with the ratio of the job’s original runtime to its cluster’s mean runtime. We compare Zeus with Default and Grid Search and plot the results in Figure 9.

Figure 9a shows the cumulative energy consumption of training using all three approaches. Zeus outperforms both baselines for workloads of all types and sizes. Note that there are scenarios where the Grid Search performs worse than Default, due to it wasting too much energy and time during the exploration stage. Thanks to Zeus’s *early stopping* and quick online power optimization, its energy and time cost during the exploration stage is significantly reduced. Across all the models, Zeus reduces training energy usage by 7%–52%. Figure 9b shows the training time using Zeus to be increased by at most 16%, and in many cases even decreased by up to 33%. Finally, similar to earlier experiments, Zeus

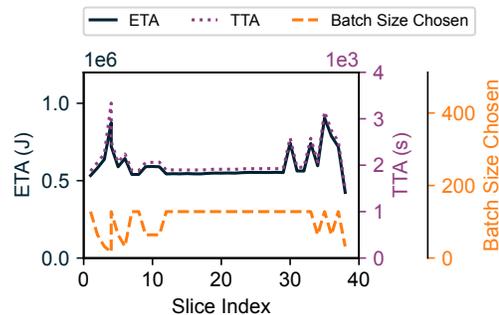

Figure 10: Energy and time consumption of training BERT with Zeus on Capriccio and the batch size chosen for each slice.

had significantly lower cumulative regret than Grid Search.

6.4 Handling Data Drift

While there are previous works that attempt to identify and address data drift in general ML settings [63], existing datasets are classification tasks based on small feature vectors [12, 35], completely synthetic [25, 44], or private [66].

Therefore, we create and open-source a new sentiment analysis dataset called *Capriccio* that is suitable for evaluating DNN models. Capriccio consists of 1.6 million tweets over three months from the Sentiment140 [26] dataset, labeled with sentiment scores and the timestamp of the tweet. We emulate data drift by capturing a sliding window of 500,000 tweets (roughly the amount of tweets in one month) at a time and moving the window forward by each day, generating 38 slices. We skip empty dates to avoid having identical slices.

We train BERT [21] on Capriccio with Zeus configured with a window size of 10, roughly corresponding to a time frame of two weeks on Twitter. We plot the selected batch size for each recurrence (slice) and its corresponding ETA and TTA of training in Figure 10. It can be seen that spikes in ETA and TTA (signaling that the current batch size may no longer be optimal) trigger the exploration of a batch size that is different from the one previously converged to.

6.5 Overhead of JIT Profiling

Measurements with the Deepspeech2 model using the default batch size b_0 show that JIT profiling results in a 0.01% increase in energy consumption and a 0.03% increase in time consumption. Such a tiny overhead is possible because the time needed to profile all power limits is very small (less than one minute) while one epoch of training spans hours (which is typical for DL workloads). Measurements on ShuffleNet-v2, which has much shorter epoch duration, show that JIT profiling results in a 0.6% increase in terms of time consumption and a 2.8% reduction in energy consumption.

6.6 Scaling to Multi-GPU

While the primary focus of this paper is on single-GPU settings, in this section, we show that Zeus can be extended to single-node multi-GPU training settings by profiling the power consumption of all GPUs that participate in training.

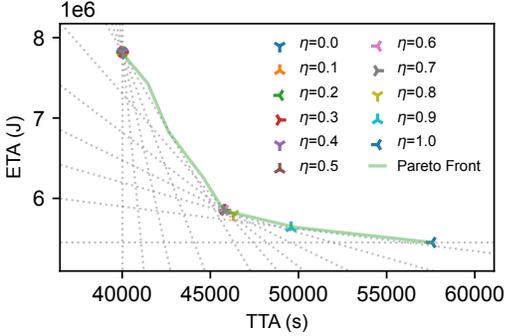

Figure 11: Pareto Front of DeepSpeech2 and how η navigates it.

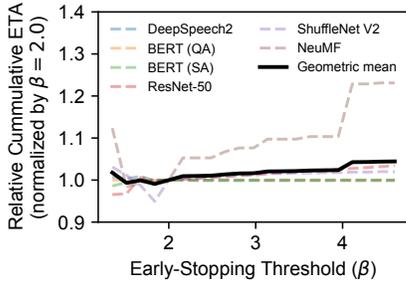

Figure 12: Relative cumulative energy consumption of Zeus across all jobs, w.r.t. the early-stopping threshold β .

Extensions to distributed multi-GPU setups that involve network communication is a potential future work.

Extending to multi-GPU allows us to compare our energy and time consumption with Pollux [77], a state-of-the-art distributed cluster scheduler that dynamically tunes the batch size during DNN training in order to maximize *goodput*. Training DeepSpeech2 on LibriSpeech on four NVIDIA A40 GPUs, Zeus consumes 12% more time but 21% less energy, comparing favorably. We especially note that while Pollux does not take energy into account, Zeus allows the user to select a different energy-time tradeoff point (e.g., speed up training but consume more energy) by selecting an appropriate η .

6.7 Sensitivity Analysis and Ablation Studies

Impact of η . To characterize the impact of η as defined in Equation 2, we perform a sweep of $0 \leq \eta \leq 1$ when training DeepSpeech2 and plot the resulting optimal (TTA, ETA) in Figure 11. We also plot the corresponding Pareto Front for reference. We observe that the resulting (TTA, ETA) data points fall closely to the Pareto Front. Moreover, we plot the lines along which the C in Equation 2 is a constant, shown as the dotted lines. As expected, these lines form an envelope around the Pareto Front. Additional sensitivity analysis for η can be found in Appendix F.

Impact of early-stopping threshold β . To study impact of the early-stopping threshold β , we sweep β from 1.5 to 5 and measure the cumulative ETA across all jobs. We calculate the difference in ETA relative to our default choice of $\beta = 2.0$, and plot the result of all jobs as well as a geometric mean across all jobs in Figure 12. The result shows that the default

Figure 13: Performance breakdown of Zeus.

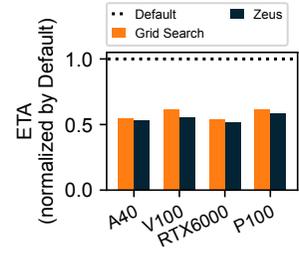

Figure 14: Normalized ETA w.r.t. GPU models.

$\beta = 2.0$ chosen by Zeus achieves the lowest geometric mean across all jobs. The intuition behind this is that when β is too low, Zeus prematurely stops exploratory runs, reducing the effectiveness of exploration. In contrast, when β is too high, it dilutes the benefit of early stopping which leads to inflated exploration cost.

Impact of individual components. In order to show the gains from each component, we show the degradation of removing one component from Zeus: no early stopping (setting β to infinity), no pruning (keeping a batch size that didn't reach the target accuracy), and no JIT profiling (profiling each power limit in different recurrences). Figure 13 shows the slowdown relative to Zeus after disabling these components. We observe that the Zeus benefits mostly from early stopping.

Impact of GPU models. Figure 14 shows the geometric mean of ETA normalized against Default across all jobs. Zeus achieves consistent ETA reductions across four generations of NVIDIA GPUs. See Appendix G for all results.

7 Discussion

Choice of configuration knobs. In this paper, we pick the batch size and GPU power limit as the configuration knobs for Zeus to optimize. We choose these two to strike a balance in the tradeoff between the granularity of control and the size of the search space. For instance, one can set the frequency and voltage for individual components on the GPU for more fine-grained control and potentially higher energy efficiency, but this would result in prolonged exploration in the bigger search space. In contrast, we choose the GPU power limit, which effectively controls both frequency and voltage via DVFS and reduces the search space.

On the DL job configuration side, we pick the batch size as the knob for a similar reason. Changing the batch size has a broader impact on energy consumption of end-to-end DNN training, because it affects both the training time and the average power consumption during training. In comparison, other candidate configuration knobs such as learning rate fall short because they only affect the training time.

Hyperparameter optimization. Hyperparameter optimization is an important workload, where many DL training jobs (trials) are submitted with specific hyperparameters chosen from a user-defined search space [9, 59, 60, 98]. If the users

submit these trials with a specific batch size, they can specify the feasible batch size set \mathcal{B} to only contain that single batch size. In this case, Zeus can still reduce energy consumption by searching for the optimal GPU power limit.

Supporting distributed training. Zeus currently only supports single-node training, but it can easily be extended to support distributed scenarios. Since the same type of GPU will have the same time and power consumption characteristics, we can apply the same power limit configuration across all GPUs to avoid stragglers. The definition of cost can be extended to sum over the time and energy consumption of all GPUs participating in training, and all other components in our solution can remain identical.

Supporting heterogeneous GPUs. Our solution assumes that the training job runs on the same type of GPU across all of its recurrences. However, in practice, this may not always be possible due to varying resource contention or availability.

It is straightforward to add support for heterogeneous GPUs under our formulation. That is, cost values observed from one GPU can be *translated* to values that represent the characteristics of another GPU. As shown in Equation 6, energy-time cost can be written as the product of Epochs(b) and EpochCost($b; \eta$). Here, the former term is independent with the choice of the GPU. Moreover, the latter term can be quickly profiled on any GPU because it consists of only AvgPower(b, p) and Throughput(b, p). Thus, we can obtain cost values that represent the new GPU by quickly profiling EpochCost($b; \eta$) for each batch size on the new GPU and multiplying it with Epochs(b) observed from the previous GPU. These translated cost observations can then be used to learn a new MAB that specializes on the new GPU.

8 Related Work

DNN training. A large body of recent studies focus on creating fast kernels for tensor operations [18, 45, 92, 100], efficiently placing data and/or computation [55, 72, 78, 97], and optimizing communication [76, 91]. However, most of them optimize for TTA and are oblivious of their energy impact. These works can be applied together with Zeus, potentially accelerating training while making it energy efficient.

Another recent effort in reducing TTA (without considering energy) in multi-GPU DNN training settings is Pollux [77]. Pollux dynamically changes the batch size *during* training based on the Gradient Noise Scale (GNS) [68]. However, GNS does not theoretically capture the generalization of the model [68] and can only be efficiently approximated when there are more than one GPUs participating in training. Zeus, on the other hand, optimizes and trades off TTA and ETA by tuning the batch size *across* job recurrences and does not alter the model's convergence characteristics.

Energy measurement for Deep Learning. A recent line of research has analyzed the energy consumption [75] as well as the environmental impact [54, 85] for training large DNN

models inside a cluster. On the device-level, benchmarking efforts have been made to understand the energy efficiency and performance of training DNN on GPUs and other accelerators [93]. Several Python frameworks have been built for measurement [14, 40] and prediction [5] of energy consumption for DNN training. Zeus takes a similar software-based approach to measure power consumption via NVML [2], in order to perform JIT profiling of DNN training jobs.

Energy optimization for Deep Learning. Existing work has investigated energy-accuracy tradeoff in the context of DNN inference with new neural network architecture [89] and algorithm-hardware co-design [86], and training strategies such as warm-start [7] and gradient-matching-based data subset selection [50]. Other works optimize energy for DNN training on multiple GPUs with scheduling [47] and task mapping [52]. Zeus complements these solutions as it can be plugged in transparently into these frameworks.

Several works have studied the impact of GPU dynamic frequency and voltage scaling (DVFS) and power configuration on the energy consumption and performance of DNN training [11, 52, 87, 90, 101], wherein they focus on the tradeoff between the transient metric of system throughput and power consumption. While these work rely on offline modeling and profiling, Zeus focuses on a more realistic end-to-end metric of energy-to-accuracy and is fully online.

BatchSizer [71] introduces batch size as a control knob to optimize for energy efficiency of DNN inference. Zeus focuses on DNN training, and takes a holistic approach, optimizing both GPU and job configurations together.

9 Conclusion

In this work, we sought to understand and optimize the energy consumption of DNN training on GPUs. We identified the tradeoff between energy consumption and training time, and demonstrated that common practices can lead to inefficient energy usage. Zeus is an online optimization framework for recurring DNN training jobs that *finds* the Pareto frontier and allows users to *navigate* the frontier by automatically tuning the batch size and GPU power limit of their jobs. Zeus outperforms the state-of-the-art in terms of energy usage for diverse workloads and real cluster traces by continuously adapting to dynamic workload changes such as data drift. We earnestly hope that Zeus will inspire the community to consider energy as a first-class resource in DNN optimization.

C ETA w.r.t. Configurations for All Workloads

Figures 17 and 18 respectively show the ETA value when batch size and power limit are swept. Especially note the convexity of all BS-ETA curves, which justifies the design of our pruning exploration algorithm.

D Cumulative Regret of All Workloads

Figure 19 shows the cumulative regret of Zeus and Grid Search over job recurrences for all six workloads. In general, Zeus converges to a better knob than Grid Search while being faster.

E Search Paths for All Workloads

Figures 20 and 21 respectively show the search path of Zeus and Grid Search in the 2D configuration space. Thanks to the decoupling of batch size and power limit, Zeus is able to more efficiently navigate the search space and converge to a knob while consuming less energy and time during exploration.

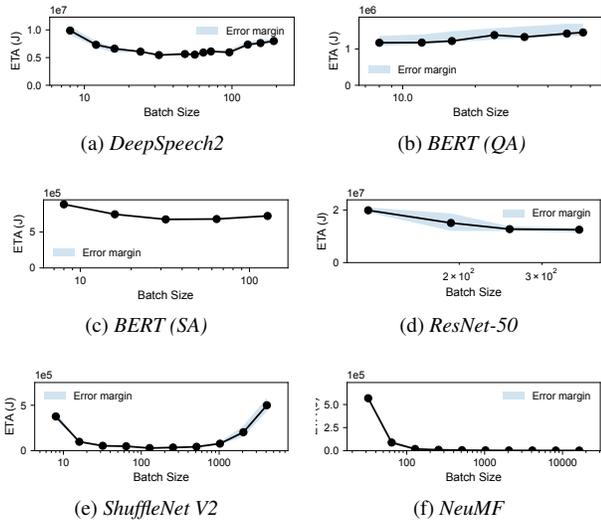

Figure 17: ETA w.r.t batch size of different DNN training workload. The blue shade shows the error margin across repeated runs.

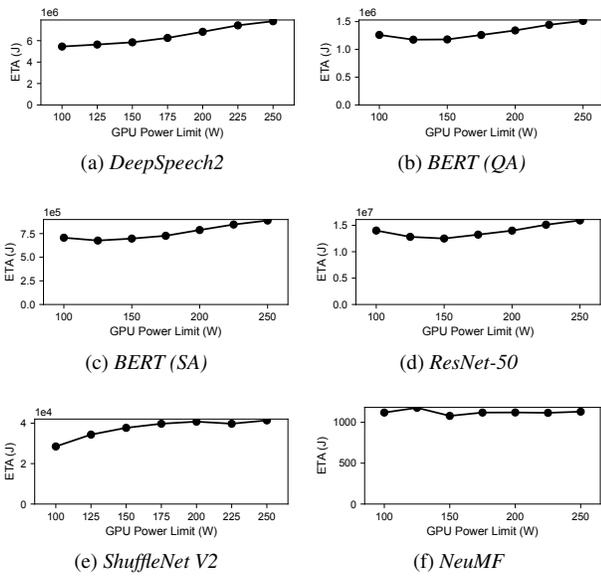

Figure 18: ETA w.r.t GPU power limit of different DNN training workload. Measured on an NVIDIA V100 GPU.

F Additional Sensitivity Analysis

Figure 22 compares both the energy consumption and training time for Zeus against Default. We also calculate and plot the geometric mean across all jobs. The result shows that with higher η , Zeus prioritizes reducing energy consumption over time, leading to higher improvement factor of energy, and vice versa.

G Performance of Zeus on All GPUs

Figure 23 presents the energy and time consumption of all workloads on four different generations NVIDIA GPUs: Ampere (A40), Volta (V100), Turing (RTX6000), and Pascal

Remote Procedure Call as a Managed System Service

Abstract

Remote Procedure Call (RPC) is a widely used abstraction for cloud computing. The programmer specifies type information for each remote procedure, and a compiler generates stub code linked into each application to marshal and unmarshal arguments into message buffers. Increasingly, however, application and service operations teams need a high degree of visibility and control over the flow of RPCs between services, leading many installations to use sidecars or service mesh proxies for manageability and policy flexibility. These sidecars typically involve inspection and modification of RPC data that the stub compiler had just carefully assembled, adding needless overhead. Further, upgrading diverse application RPC stubs to use advanced hardware capabilities such as RDMA or DPDK is a long and involved process, and often incompatible with sidecar policy control.

In this paper, we propose, implement, and evaluate a novel approach, where RPC marshalling and policy enforcement are done as a system service rather than as a library linked into each application. Applications specify type information to the RPC system as before, while the RPC service executes policy engines and arbitrates resource use, and then marshals data customized to the underlying network hardware capabilities. Our system, mRPC, also supports live upgrades so that both policy and marshalling code can be updated transparently to application code. Compared with using a sidecar, mRPC speeds up a standard microservice benchmark, DeathStarBench, by up to $2.5\times$ while having a higher level of policy flexibility and availability.

1 Introduction

Remote Procedure Call (RPC) is a fundamental building block of distributed systems in modern datacenters. RPC allows developers to build networked applications using a simple and familiar programming model [10], supported by several popular libraries such as gRPC [26], Thrift [84], and eRPC [39]. The RPC model has been widely adopted

*Jingrong Chen and Yongji Wu contributed equally.

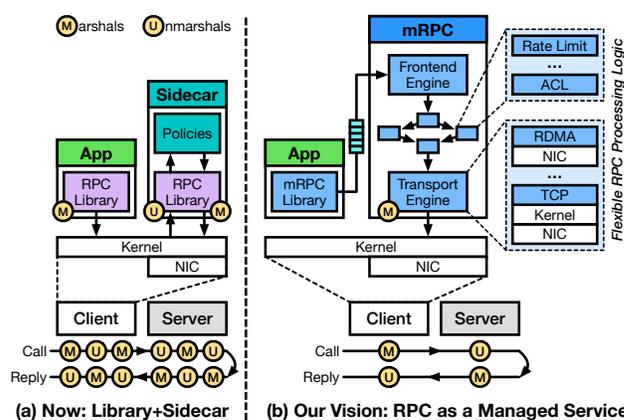

Figure 1: Architectural comparison between current (RPC library + sidecar) and our proposed (RPC as a managed service) approaches.

in distributed data stores [19, 41, 83], network file systems [24, 80], consensus protocols [68], data-analytic frameworks [2, 12, 16, 25, 55, 82, 94, 98], cluster schedulers and orchestrators [30, 50], and machine learning systems [1, 65, 72]. Google found that roughly 10% of its datacenter CPU cycles are spent just executing gRPC library code [42]. Because of its importance, improving RPC performance has long been a major topic of research [7, 8, 10, 14, 39, 52, 63, 81, 87, 95, 96].

Recently, application and network operations teams have found a need for rapid and flexible visibility and control over the flow of RPCs in datacenters. This includes monitoring and control of the performance of specific types of RPCs [62], prioritization and rate limiting to meet application-specific performance and availability goals, dynamic insertion of advanced diagnostics to track user requests across a network of microservices [22], and application-specific load balancing to improve cache effectiveness [6], to name a few.

The typical architecture is to enforce policies in a sidecar—a separate process that mediates the network traffic of the application RPC library (Figure 1a). This is often referred to as a service mesh. A number of commercial products have been developed to meet the need for sidecar RPC proxies, such as

Envoy [18], Istio [32], HAProxy [29], Linkerd [53], Nginx [67], and Consul [15]. Although some policies could theoretically be supported by a feature-rich RPC runtime linked in with each application, that can slow deployment—Facebook recently reported that it can take *months* to fully roll out changes to one of its application communication libraries [21]. One use case that requires rapid deployment is to respond to a new application security threat, or to diagnose and fix a critical user-visible failure. Finally, many policies are mandatory rather than discretionary—the network operations team may not be able to trust the library code linked into an application. Example mandatory security policies include access control, authentication/encryption [15], and prevention of known exploits in widely used network protocols such as RDMA [79].

Although using a sidecar for policy management is functional and secure, it is also inefficient. The application RPC library marshals RPC parameters at runtime into a buffer according to the type information provided by the programmer. This buffer is sent through the operating system network stack and then forwarded back up to the sidecar, which typically needs to parse and unwrap the network, virtualization, and RPC headers, often looking inside the packet payload to correctly enforce the desired policy. It then re-marshals the data for transport. Direct application-level access to network hardware such as RDMA or DPDK offers high performance but precludes sidecar policy control. Similarly, network interface cards are increasingly sophisticated, but it is hard for applications or sidecars to take advantage of those new features, because marshalling is done too high up in the network stack. Any change to the marshalling code requires recompiling and rebooting each application and/or the sidecar, hurting end-to-end availability. In short, existing solutions can provide good performance, or flexible and enforceable policy control, but not both.

In this paper, we propose a new approach, called RPC as a managed service, to address these limitations. Instead of separating marshalling and policy enforcement across different domains, we combine them into a single privilege and trusted system service (Figure 1b) so that marshalling is done **after** policy processing. In our prototype, mRPC for managed RPC, the privileged RPC service runs at user level communicating with the application through shared memory regions [4, 8, 58]. However, mRPC could also be integrated directly into the operating system kernel with a dynamically replaceable kernel module [61].

Our goals are to be fast, support flexible policies, and provide high availability for applications. To achieve this, we need to address several challenges. First, we need to decouple marshalling from the application RPC library. Second, we need to design a new policy enforcement mechanism to process RPCs efficiently and securely, without incurring additional marshalling overheads. Third, we need to provide a way for operators to specify/change policies and even change the underlying transport implementation without disrupting running applications.

We implement mRPC, the first RPC framework that follows

the RPC as a managed service approach. Our results show that mRPC speeds up DeathStarBench [23] by up to $2.5\times$, in terms of mean latency, compared with combining state-of-art RPC libraries and sidecars, i.e., gRPC and Envoy, using the same transport mechanism. Larger performance gains are possible by fully exploiting network hardware capabilities from within the service. In addition, mRPC allows for live upgrades of its components while incurring negligible downtime for applications. Applications do not need to be re-compiled or rebooted to change policies or marshalling code. mRPC has three important limitations. First, data structures passed as RPC arguments must be allocated on a special shared-memory heap. Second, while we use a language-independent protocol for specifying RPC type signatures, our prototype implementation currently only works with applications written in Rust. Finally, our stub generator is not as fully featured as gRPC.

In this paper, we make the following contributions:

- A novel RPC architecture that decouples marshalling/unmarshalling from RPC libraries to a centralized system service.
- An RPC mechanism that applies network policies and observability features with both security and low performance overhead, i.e., with minimal data movement and no redundant (un)marshalling. The mechanism supports live upgrade of RPC bindings, policies, transport, and marshalling without disrupting running applications.
- A prototype implementation of mRPC along with an evaluation on both synthetic workloads and real applications.

2 Background

In this section, we discuss the current RPC library architecture. We then discuss the emerging need for manageability and how manageability is implemented with existing RPC libraries.

2.1 Remote Procedure Call

To use RPC, a developer defines the relevant service interfaces and message types in a schema file (e.g., gRPC .proto file). A protocol compiler will translate the schema into program stubs that are directly linked with the client and server applications. To issue an RPC at runtime, the application simply calls the corresponding function provided by the stub; the stub is responsible for marshalling the request arguments and interacting with the transport layer (e.g., TCP/IP sockets or RDMA verbs). The transport layer delivers the packets to the remote server, where the stub unmarshals the arguments and dispatches the RPC request to a thread (eventually replying back to the client). We refer to this approach as *RPC-as-a-library*, since all RPC functionality is included in user-space libraries that are linked with each application. Even though the first RPC implementation [10] dates back to the 1980s, modern RPC frameworks (e.g., gRPC [26], eRPC [39], Thrift [84]) still follow this same approach.

A key design goal for RPC frameworks is efficiency. Google and Facebook have built their own efficient RPC frameworks, gRPC and Apache Thrift. Although primarily focused on portability and interoperability, gRPC includes many efficiency-related features, such as supporting binary payloads. Academic researchers have studied various ways to improve RPC efficiency, including optimizing the network stack [45, 69, 99], software hardware co-design [39, 41], and overload control [14].

As network link speeds continue to scale up [77], RPC overheads are likely to become even more salient in the future. This has led some researchers to advocate for direct application access to network hardware [5, 39, 73, 99], e.g., with RDMA or DPDK. Although low overhead, kernel bypass is largely incompatible with the need for flexible and enforceable layer 7 policy control, as we discuss next. In practice, multiple security weaknesses in RDMA hardware have led most cloud vendors to opt against providing direct access to RDMA by untrusted applications [48, 49, 58, 79, 95, 101].

2.2 The Need for Manageability

As RPC-based distributed applications scale to large, complex deployment scenarios, there is an increasing need for improved manageability of RPC traffic. We classify management needs into three categories: **1) Observability:** Provide detailed telemetry, which enables developers to diagnose and optimize application performance. **2) Policy Enforcement:** Allow operators to apply custom policies to RPC applications and services (e.g., access control, rate limits, encryption). **3) Upgradability:** Support software upgrades (e.g., bug fixes and new features) while minimizing downtime to applications.

One natural question to ask is: *is it possible to add these properties without changing existing RPC libraries?* For observability and policy enforcement, the state-of-the-art solution is to use a sidecar (e.g., Envoy [18] or Linkerd [53]). A sidecar is a standalone process that intercepts every packet an application sends, reconstructing the application-level data (i.e., RPC), and applying policies or enabling observability. However, using a sidecar introduces substantial performance overhead, due to redundant RPC (un)marshalling. This RPC (un)marshalling, for example, in gRPC+Envoy, including HTTP framing and protobuf encoding, accounts for 62-73% overhead in the end-to-end latency [102]. In our evaluation (§7), using a sidecar increases the 99th percentile RPC latency by 180% and decreases the bandwidth by 44%. Figure 1a shows the (un)marshalling steps invoked as an RPC traverses from a client to a server and back. Using a sidecar triples the number of (un)marshalling steps (from 4 to 12). In addition, the sidecar approach is largely incompatible with the emerging trend of efficient application-level access to network hardware. Using sidecars means data buffers have to be copied between the application and sidecars, reducing the benefits of having zero-copy kernel-bypass access to the network.

Finally, using sidecars with application RPC libraries does not completely solve the upgradability issue. While policy

can often be changed dynamically (depending on the feature set of the sidecar implementation), marshalling and transport code is harder to change. To fix a bug in the underlying RPC library, or merely to upgrade the code to take advantage of new hardware features, we need to recompile the entire application (and sidecar) with the patched RPC library and reboot. gRPC has a monthly or two-month release cycle for bug fixes and new features [27]. Any scheduled downtime has to be communicated explicitly to the users of the application or has to be masked using replication; either approach can lead to complex application life-cycle management issues.

We do not see much hope in continuing to optimize this RPC library and sidecar approach for two reasons. First, a strong coupling exists between a traditional RPC library and each application. This makes upgrading the RPC library without stopping the application difficult, if not impossible. Second, there is only weak or no coupling between an RPC library and a sidecar. This prevents the RPC library and the sidecar from cross-layer optimization.

Instead, we argue for an alternative architecture in which RPC is provided *as a managed service*. By decoupling RPC logic, e.g., (un)marshalling, transport interface, from the application, the service can simultaneously provide high performance, policy flexibility, and zero-downtime upgrades.

3 Overview

Our system, mRPC, realizes the *RPC-as-a-managed-service* abstraction while maintaining similar end-to-end semantics as traditional RPC libraries (e.g., gRPC, Thrift). The goals for mRPC are to be fast, support flexible policy enforcement, and provide high availability for applications.

Figure 2 shows a high-level overview of the mRPC architecture and workflow, breaking it down into three major phases: initialization, runtime, and management. The mRPC service runs as a non-root, user-space process with access to the necessary network devices and a shared-memory region for each application. In each of the phases, we focus on the view of a single machine that is running both the RPC client application and the mRPC service. The RPC server may also run alongside an mRPC service. In this case, mRPC-specific marshalling can be used. However, we also support flexible marshalling to enable mRPC applications to interact with external peers using well-known formats (e.g., gRPC). In our evaluation, we focus on cases where both the client and server employ mRPC.

The initialization phase extends from building the application to how the application binds to a specific RPC interface. **①** Similar to gRPC, users define a protocol schema. The mRPC schema compiler uses this to generate stub code to include in their application. We illustrate this using a key-value storage service with a single Get function. **②** When the application is deployed, it connects with the mRPC service running on the same machine and specifies the protocol(s) of interest, which are maintained by the generated stub. **③** The mRPC service also uses the protocol schema to generate,

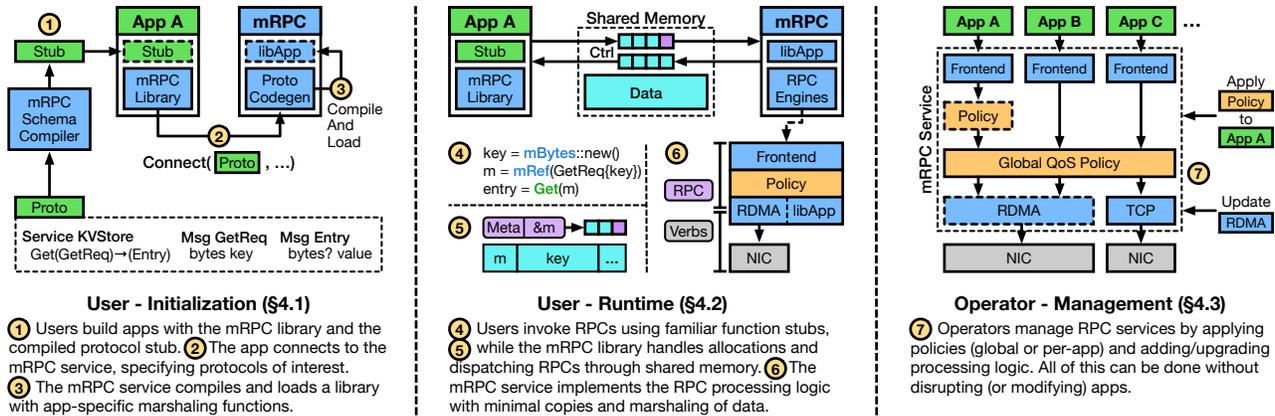

Figure 2: Overview of the mRPC workflow from the perspective of the users (and their applications) as well as infrastructure operators.

compile, and dynamically load a protocol-specific library containing the marshalling and unmarshalling code for that application’s schemas². This *dynamic binding* is a key enabler for mRPC to act as a long-running service, handling arbitrary applications (and their RPC schemas).³

At this point, we enter the runtime phase in which the application begins to invoke RPCs. Our approach uses *shared memory* between the application and mRPC, containing both control queues as well as a data buffer. **4** The application protocol stub produced by the mRPC protocol compiler can be called like a traditional RPC interface, with the exception that data structures passed as arguments or as return values must be allocated on a special heap in the shared data buffer. **5** Internally, the stub and mRPC library manage RPC calls and replies in the control queues along with allocations and deallocations in the data buffer. **6** The mRPC service operates over the RPCs through modular *engines* that are composed to implement the per-application *datapaths* (i.e., sequence of RPC processing logic); each engine is responsible for one type of task (e.g., application interface, rate limiting, transport interface). Engines do not contain execution contexts, but are rather scheduled by *runtimes* in mRPC that correspond to kernel-level threads; during their execution, engines read from input queues, perform work, and enqueue outputs. External-facing engines (i.e., frontend, transport) use asynchronous control queues, while all other engines are executed synchronously by a runtime. Application control queues are contained in shared memory with the mRPC service.

This architecture, along with dynamic binding, enables mRPC to *operate over RPCs rather than packets*, avoiding the high overhead of traditional sidecar-based approaches. Additionally, the modular design of mRPC’s processing logic enables mRPC to take advantage of fast network hardware

(e.g., RDMA and smartNICs) in a manner that is transparent to the application. A key challenge, which we will address in §4.2, is how to securely enforce operator policies over RPCs in shared memory while minimizing data copies.

Finally, mRPC aims to improve the manageability of RPCs by infrastructure operators. Here, we zoom out to focus on the processing logic across all applications served by an mRPC service. **7** Operators may wish to apply a number of different policies to RPCs made by applications, whether on an individual basis (e.g., rate limiting, access control) or globally across applications (e.g., QoS). mRPC allows operators to add, remove, update, or reconfigure policies at runtime. This flexibility extends beyond policies to include those responsible for interacting with the network hardware. A key challenge, which we will address in §4.3, is in supporting the *live upgrade* of mRPC engines without interrupting running applications (and while managing engines sharing memory queues).

4 Design

In this section, we describe how mRPC provides dynamic binding, efficient policy and observability support, live upgrade, and security.

4.1 Dynamic RPC Binding

Applications have different RPC schemas, which ultimately decide how an RPC is marshalled. In the traditional RPC-as-a-library approach, a protocol compiler generates the marshalling code, which is linked into the application. In our design, the mRPC service is responsible for marshalling, which means that the application-specific marshalling code needs to be decoupled from an RPC library and run inside the mRPC service itself. Failing to ensure this separation would allow arbitrary code execution by a malicious user.

Applications directly submit the RPC schema (and not marshalling code) to the mRPC service. The mRPC service generates the corresponding marshalling code, then compiles and dynamically loads the library. Thus, we rely on our mRPC service code generator to produce the correct marshalling code

²Note that such libraries may be prefetched and/or cached to optimize the startup time.

³The dashed box of "Stub" and "libApp" means they are generated code.

for *any* user-provided RPC schema. For the initial handshake between an RPC client and an RPC server, the two mRPC services check that the provided RPC schemas match, and if not, the client's connection is rejected.

There are three remaining questions. First, **what are the responsibilities of the in-application user stub and mRPC library?** In mRPC, applications rely on user stubs to implement the abstraction as specified in their RPC schema. This means we still need to generate the glue code to maintain the traditional application programming interface. Our solution is to provide a separate protocol schema compiler, which is untrusted and run by application developers, to generate the user stub code that does not involve marshalling and transport. The application RPC stub (with the help of the mRPC library) creates a message buffer that contains the metadata of the RPC, with typed pointers to the RPC arguments, on the shared memory heap. The message is placed on a shared memory queue, which will be processed by the mRPC service. The receiving side works in a similar way.

Second, **does this approach increase RPC connect/bind time?** Implemented naively, this design will increase the RPC connect/bind time because the mRPC service has to compile the RPC schema and load the resulting marshalling library when an RPC client first connects to a corresponding server (or equivalently when an RPC server binds to the service). However, this latency is not fundamental to our design, and we can mitigate it in the following way. The mRPC service accepts RPC schemas before booting an application, as a form of prefetching. Given a schema, it compiles and caches the marshalling code. At the time of RPC connect/bind, the mRPC service simply performs a cache lookup based on the hash of the RPC schema. If it exists within the cache, the mRPC service will load the associated library; otherwise, the mRPC service will invoke the compiler to generate (and subsequently cache) the library. This reduces the connect/bind time from several seconds to several milliseconds.

Third, **when new applications arrive, do existing applications face downtime?** The multi-threaded mRPC service is a single process that serves many RPC applications; however, the marshalling engines for different RPC applications are not shared. They are in different memory addresses and can be (un)loaded independently. We will describe in §4.3 how to load/unload engines without disrupting running applications.

4.2 Efficient RPC Policy Enforcement and Observability

We have one key idea to allow efficient RPC policy enforcement and observability: senders should marshal once (as late as possible), while receivers should unmarshal once (as early as possible). On the sender side, we want to support policy enforcement and observability directly over RPCs from the application, and then marshal the RPC into packets. The receiver side is similar: packets should be unmarshalled into RPCs, applying policy and observability operations, and then delivered directly to the application. Compared to

the traditional RPC-as-a-library approach with sidecars, this eliminates the redundant (un)marshalling steps (see Figure 1).

Data: DMA-capable shared memory heaps. Our design is centered around a dedicated shared memory heap between each application and the mRPC service. (Note that this heap is not shared across applications.) Applications directly create data structures, which may be used in RPC arguments, in a shared memory heap with the help of the mRPC library. Each application has a separate shared memory region, which provides isolation between (potentially mutually distrusting) applications. The mRPC library also includes a standard slab allocator for managing object allocation on this shared memory. If there is insufficient space within the shared memory, the slab allocator will request additional shared memory from the mRPC service and then map it into the application's address space. The mRPC service has access to the shared memory heap, allowing it to execute RPC processing logic over the application's RPCs, but also maintains a private memory heap for necessary copies.

Figure 3 shows an example workflow that includes access control for a key-value store service. Having the data structures directly in the shared memory allows an application to provide pointers to data, rather than the data itself, when submitting RPCs to the mRPC service. We call the message sent from an application to the mRPC service an *RPC descriptor*. If there are multiple RPC arguments, the RPC descriptor points to an array of pointers (each pointing to a different argument on the heap).

Let us say we have an ACL policy that rejects an RPC if the key matches a certain string. The mRPC service first copies the argument (i.e., key), as well as all parental data structures (i.e., GetReq), onto its private heap. This is to prevent time-of-use-to-time-of-check (TOCTOU) attacks. Since applications have access to DMA-capable shared memory at all times, an application could modify the content in the memory while the mRPC service is enforcing policies. Copying arguments is a standard mitigation technique, similar to how OS kernels prevents TOCTOU attacks by copying system call arguments from user- to kernel-space. This copying only needs to happen if the policy behavior is based on the content of the RPC. We demonstrate in §7.2 that even with such copying, mRPC's overhead for an ACL policy is much lower than gRPC + Envoy. The RPC descriptor is modified so that the pointer to the copied argument now points to the private heap. On the receiver side, the TOCTOU attack is not relevant, but we need to take care not to place RPCs directly in shared memory. If there is a receive-side policy that depends on RPC argument values, the mRPC service first receives the RPC data into a private heap; it copies the RPC data into the shared heap after policy processing. This prevents the application from reading RPC data that should have been dropped or modified by the policies. Note that we can bypass this copy when processing does not depend on RPC argument values (e.g., rate limits). During ACL policy enforcement, the RPC is dropped if the key argument is contained in a blocklist. Note that if an RPC is dropped, any further processing logic is never executed (including marshalling operations).

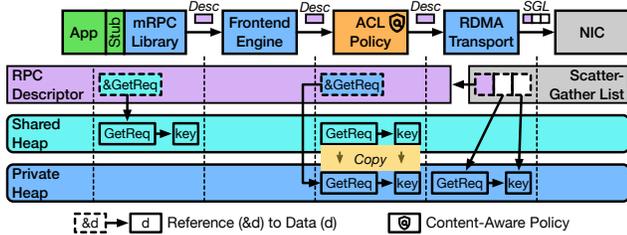

Figure 3: Overview of memory management in mRPC. Shows an example for the Get RPC that includes a content-aware ACL policy.

Finally, at the end of the processing logic, the transport adapter engine executes. mRPC currently supports two types of transport: TCP and RDMA. For TCP, mRPC uses the standard, kernel-provided scatter-gather (iovec) socket interface. For RDMA, mRPC uses the scatter-gather verb interface, allowing the NIC to directly interact with buffers on the shared (or private) memory heaps containing the RPC metadata and arguments. For both TCP and RDMA, mRPC provides disjoint memory blocks to the transport layer directly, eliminating excessive data movements.⁴

Control: Shared-memory queues. To facilitate efficient communication between an application and the mRPC service, we use shared memory control queues. mRPC allocates two unidirectional queues for sending and receiving requests from an application to the mRPC service. The requests contain RPC descriptors, which reference arguments on the shared memory heap. The mRPC service always copies the RPC descriptors applications put in the sending queue to prevent TOCTOU attacks. mRPC provides two options to poll the queues: 1) busy polling, and 2) eventfd-based adaptive polling. In busy polling, both the application-side mRPC library and the mRPC service busy poll on their ends of the queues. In the eventfd approach, the mRPC library and the mRPC service sends event notifications after enqueueing to an empty queue. After receiving a notification, the queue is drained (performing the necessary work) before subsequently waiting on future events. The eventfd approach saves CPU cycles when queues are empty. Other alternative solutions may involve dynamically scaling up (or down) the number of threads used to busy poll by the mRPC service; however, we chose the eventfd approach for its simplicity. In our evaluation, we use busy polling for RDMA and eventfd-based adaptive polling for TCP.

Memory management. We provide a memory allocator in the mRPC library for applications to directly allocate RPC data structures to be sent on a shared memory heap. The allocator invokes the mRPC service to allocate shared memory regions on behalf of the application (similar to how a standard

⁴For RDMA, if the number of disjoint memory blocks exceeds the limit of NIC’s capability to encapsulate all blocks in one RDMA work request, mRPC coalesces the data into a memory block before transmission. This is because sending a single work request (even with a copy) is faster than sending multiple smaller work requests on our hardware.

heap manager calls `mmap` or `sbrk` to allocate memory from an OS kernel). We need to use a specialized memory allocator for RPC messages (and their arguments), since RPCs are shared between three entities: the application, the mRPC service, and the NIC. A memory block is safe to be reclaimed only when it will no longer be accessed by any entity.

We adopt a notification-based mechanism for memory management. On the sender side, the outgoing messages are managed by the mRPC library within the application. On the receiver side, the incoming messages are managed by the mRPC service. When the application no longer accesses a memory block occupied by outgoing messages, the memory block will not be reclaimed until the library receives a notification from mRPC service that the corresponding messages are already sent successfully through the NIC (similar to how zero-copy sockets work in Linux). Incoming messages are put in buffers on a separate read-only shared heap. The receiving buffers can be reclaimed when the application finishes processing (e.g., when the RPC returns). To support reclamation of receive buffers, the mRPC library notifies the mRPC service when specific messages are no longer in use by the application. Notifications for multiple RPC messages are batched to improve performance. If the receiver application code wishes to preserve or modify the incoming data, it must make an explicit copy. Although this differs from traditional RPC semantics, in our implementation of Masstree and DeathStarBench we found no examples where the extra copy was necessary.

Cross-datapath policy engines. mRPC supports engines that operate over multiple datapaths, which may span multiple applications. For instance, any global policy (e.g., QoS) will need to operate over all datapaths (see §5). For this type of engine, we instantiate replicas of the engine for each datapath that it applies to. Replicas can choose to either communicate through shared state, which requires managing contention across runtimes, or support runtime-local state that is contention-free.

4.3 Live Upgrades

Although our modular engine design for the mRPC service is similar to Snap [58] and Click [47], we arrive at very different designs for upgrades. Click does not support live upgrades, while Snap executes the upgraded process to run alongside the old process. The old process serializes the engine states, transfers them to the new process, and the new process restarts them. This means that even changing a single line of code within a single Snap engine requires a complete restart for all Snap engines. This design philosophy is fundamentally not compatible with mRPC, as we need to deal with new applications arriving with different RPC schemas, and thus our upgrades are more frequent. In addition, we want to avoid fate sharing for applications: changes to an application’s datapath should not impact the performance of other applications. Ultimately, Snap is a network stack that does not contain application-specific code, whereas mRPC needs to be application-aware for marshalling RPCs.

We implement engines as plug-in modules that are dynamically loadable libraries. We design a live upgrade method that supports *upgrading, adding, or removing components of the datapath without disrupting other datapaths*.

Upgrading an engine. To upgrade one engine, mRPC first detaches the engine from its runtime (preventing it from being scheduled). Next, mRPC destroys and deallocates the old engine, but maintains the old engine’s state in memory; note that the engine is detached from its queues and not running at this time. Afterwards, mRPC loads the new engine and configures its send and receive queues. The new engine starts with the old engine’s state. If there is a change in the data structures of the engine’s state, the upgraded engine is responsible for transforming the state as necessary (which the engine developer must implement). Note that this also applies to any shared state for cross-datapath engines. The last step is for mRPC to attach the new engine to the runtime.

Changing the datapath. When an operator changes the datapath to add or remove an engine, this process now involves the creation (or destruction) of queues and management of in-flight RPCs. Changes that add an engine are straightforward, since it only involves detaching and reconfiguring the queues between engines. Changes that remove an engine are more complex, as some in-flight RPCs may be maintained in internal buffers; for example, a rate limiter policy engine maintains an internal queue to ensure that the output queue meets a configured rate. Engine developers are responsible for flushing such internal buffers to the output queues when the engines are removed.

Multi-host upgrades or datapath changes. Some engine upgrades or datapath changes that involve both the sender and the receiver hosts need to carefully manage in-flight RPCs across hosts. For example, if we want to upgrade how mRPC uses RDMA, both the sender and the receiver have to be upgraded. In this scenario, the operator has to develop an upgrade plan that may involve upgrading an existing engine to some intermediate, backward-compatible engine implementation. The plan also needs to contain the upgrade sequence, e.g., upgrading the receiver side before the sender side. Our evaluation demonstrates such a complex live upgrade, which optimizes the handling of many small RPC requests over RDMA (see §7.3).

4.4 Security Considerations

We envision two deployment models for mRPC: (1) a cloud tenant uses mRPC to manage its RPC workloads (similar to how sidecars are used today); (2) a cloud provider uses mRPC to manage RPC workloads on behalf of tenants. In both models, there are two different classes of principals: operators and applications. Operators are responsible for configuring the hardware/virtual infrastructure, deploying the mRPC service, and setting up policies that mRPC will enforce. Applications run on an operator’s infrastructure, interacting with the mRPC service to invoke RPCs. Applications trust operators, along with all privileged software (e.g., OS) and hardware that the

operators provide; both applications and operators trust our mRPC service and protocol compiler. In both deployment models, applications are not trusted and may be malicious (e.g., attempt to circumvent network policies).

In the first deployment model, mRPC service runs on top of a virtualized network that is dedicated to the tenant. Running arbitrary policy and observability code inside the mRPC service cannot attack other tenants’ traffic since inter-tenant isolation is provided by the cloud provider. In the second deployment model, our current prototype does not support running tenant-provided policy implementation inside mRPC service. How to safely integrate tenant-provided policy implementation and a cloud provider’s own policy implementation is a future work.

From the application point of view, we want to ensure that **mRPC provides equivalent security guarantees as compared to today’s RPC library and sidecar approach**, which we discuss in terms of: 1) dynamic binding and 2) policy enforcement. Our dynamic binding approach involves the generation, compilation, and runtime loading of a shared library for (un)marshalling application RPCs. Given that the compiled code is based on the application-provided RPC schema, this is a possible vector of attack. The mRPC schema compiler is trusted with a minimal interface: other than providing the RPC schema, applications have no control on the process of how the marshalling code is generated. We open source our implementation of the compiler so that it can be publicly reviewed.

As for all of our RPC processing logic, policies are enforced over RPCs by operating over their representations in shared memory control queues and data buffers. With a naive shared memory implementation, this introduces a vector of attack by exploiting a time-of-check to time-of-use (TOCTOU) attack; for instance, the application could modify the RPC message after policy enforcement but before the transport engine handles it. In mRPC, we address this by copying data into an mRPC-private heap prior to executing any policy that operates over the content of an RPC (as opposed to metadata such as the length). Similarly, received RPCs cannot be placed in shared memory until all policies have been enforced, since otherwise applications could see received RPCs before policies have a chance to drop (or modify) them. Shared memory regions are maintained by the mRPC service on a per-application basis to provide isolation.

5 Advanced Manageability Features

mRPC’s architecture creates an opportunity for advanced manageability features such as cross-application RPC scheduling. In this section, we present two such features that we developed on our policy engine framework to demonstrate the broader utility of our RPC-as-a-managed-service architecture.

Feature 1: Global RPC QoS. mRPC allows centralized RPC scheduling of cross-application workloads based on a global view of current outstanding RPCs. For example, mRPC can enforce a policy that prioritizes RPCs with earliest deadlines [86] across applications to support latency SLO or prioritizes

latency-sensitive workloads [101]. One challenge here is that a naive implementation may attempt to apply the QoS policy for datapaths spread over multiple runtimes (i.e., execution thread contexts). This would require the (replicated) policy engines on each datapath to share the state on outstanding RPCs, and thus impose synchronization overheads. Therefore, we adopt a similar strategy as used in the Linux kernel to apply the QoS policy on a per-runtime basis, which instead can use runtime-local storage without the need for synchronization. In our implementation, we support a QoS strategy that prioritizes small RPCs based on a configurable threshold size.

Feature 2: Avoiding RDMA performance anomalies. It is well known that RDMA workloads may not fully utilize the capability of a specific RDMA NIC without fine-tuning, and that particular traffic patterns can even cause performance anomalies [40, 49] (e.g., low RDMA throughput, pause frame storms). Previous work such as ScaleRPC [13] and Flock [63] have proposed techniques to utilize the RNIC more efficiently. However, their approaches are library-based and only work for single applications; therefore, they do not handle scenarios in which the *combination* of multiple application workloads causes poor RDMA performance. mRPC’s architecture enables us to have a global view of all RDMA requests and to avoid such performance anomalies.

We implement a global RDMA scheduler inside the RDMA transport engine, which translates RPC requests into RDMA messages and sends them to the RDMA NIC. In our implementation, we focus on addressing the performance degradation from interspersed small and large scatter-gather elements (which may be across RPCs as well as applications). We fuse such elements together with an explicit copy with an upper bound of 16 KB for the size of the fused element.

6 Implementation

mRPC is implemented in 32K lines of Rust: 3K lines for the protocol compiler, 6K for the mRPC control plane, 12K for engine implementations, and 11K for the mRPC library. The mRPC control plane is part of the mRPC service that loads/unloads engines.

The mRPC control plane is not live-upgradable. The mRPC library is linked into applications and is thus also not live-upgradable. We do not envision the need to frequently upgrade these components because they only implement the high-level, stable APIs, such as shared memory queue communication and (un)loading engines.

Engine interface. Table 1 presents the essential API functions that all engines must implement. Each engine represents some asynchronous computation that operates over input and output queues via `doWork`, which is similar in nature to Rust’s `Future`. mRPC uses a pool of runtime executors to drive the engines by calling `doWork`, where each runtime executor corresponds to a kernel thread. We currently implement a simple scheduling strategy inspired by Snap [58]: engines can be scheduled to

Operations

<code>doWork(in:[Queue], out:[Queue])</code>
<i>Operate over one or more RPCs available on input queues.</i>
<code>decompose(out:[Queue]) → State</code>
<i>Decompose the engine to its compositional states. (Optionally output any buffered RPCs)</i>
<code>restore(State) → Engine</code>
<i>Restore the engine from the previously decomposed state.</i>

Table 1: mRPC Engine Interface.

a dedicated or shared runtime on start. In addition, runtimes with no active engines will be put to sleep and release CPU cycles. The engines also implement APIs to support live upgrading: `decompose` and `restore`. In `decompose`, the engine implementation is responsible for destructing the engine and creating a representation of the final state of the engine in memory, returning a reference to mRPC. mRPC invokes `restore` on the upgraded instance of the engine, passing in a reference to the final state of the old engine. The developer is responsible for handling backward compatibility across engine versions, similar to how application databases may be upgraded across changes to their schemas.

Transport engines. We abstract reliable network communication of messages into transport engines, which share similar design philosophy with Snap [58] and TAS [45]. We currently implement two transport engines: RDMA and TCP. Our RDMA transport engine is implemented based on OFED libibverbs 5.4, while our TCP transport engine is built on Linux kernel’s TCP socket.

mRPC Library. Modern RPC libraries allow the user to specify the RPC data types and service interface through a language-independent schema file (e.g., `protobuf` for gRPC, `thrift` for Apache Thrift). mRPC implements support for `protobuf` and adopts similar service definitions as gRPC, except for gRPC’s streaming API. mRPC also integrates with Rust’s `async/await` ecosystem for ease of asynchronous programming in application development.

To create an RPC service, the developer only needs to implement the functions declared in the RPC schema. The dependent RPC data types are automatically generated and linked with the application by the mRPC schema compiler. The mRPC library handles all the rest, including task dispatching, thread management, and error handling. To allow applications to directly allocate data in shared memory without changing the programming abstraction, we implement a set of shared memory data structures that expose the same rich API as Rust’s standard library. This is done by replacing the memory allocation of data structures such as `Vec` and `String` with the shared memory heap allocator.

7 Evaluation

We evaluate mRPC using an on-premise testbed of servers with two 100 Gbps Mellanox Connect-X5 RoCE NICs and two Intel 10-core Xeon Gold 5215 CPUs (running at 2.5 GHz

base frequency). The machines are connected via a 100 Gbps Mellanox SN2100 switch. Unless specified otherwise, we keep a single in-flight RPC to evaluate latency. To benchmark goodput and RPC rate, we let each client thread keep 128 concurrent RPCs on TCP and 32 concurrent RPCs on RDMA.

7.1 Microbenchmarks

We first evaluate mRPC’s performance through a set of microbenchmarks over two machines, one for the client and the other for the server. The RPC request has a byte-array argument, and the response is also a byte array. We adjust the RPC size by changing the array length. RPC responses are an 8-byte array filled with random bytes. We compare mRPC with two state-of-the-art RPC implementations, eRPC and gRPC (v1.48.0). We deploy Envoy (v1.20) in HTTP mode to serve as a sidecar for gRPC. We use mRPC’s TCP and RDMA backends to compare with gRPC and eRPC, respectively. There is no existing sidecar that supports RDMA. To evaluate the performance of using a sidecar to control eRPC traffic, we implement a single-thread sidecar proxy using the eRPC interface. We keep applications running for 15 seconds to measure the result.

Small RPC latency. We evaluate mRPC’s latency by issuing 64-byte RPC requests over a single connection. [Table 2](#) shows the latency for small RPC requests. Note that since the marshalling of small messages is fast on modern CPUs, the result in the table remains stable even when the message size scales up to 1 KB. We use netperf and `ib_read_lat` to measure raw round-trip latency.

mRPC achieves median latency of 32.8 μ s for TCP and 7.6 μ s for RDMA. Relative to netperf (TCP) or a raw RDMA read, mRPC adds 11.8 or 5.1 μ s to the round-trip latency. This is the cost of the mRPC abstraction on top of the raw transport interface (e.g., socket, verbs).

We also evaluate latency in the presence of sidecar proxies. The sidecars do not enforce any policies, so we are only measuring the base overhead. Our results show that adding sidecars substantially increases the RPC latency. On gRPC, adding Envoy sidecars more than triples the median latency. The result is similar with eRPC. On mRPC, having a NullPolicy engine (which simply forwards RPCs) in the mRPC service has almost no effect on latency, increasing the median latency only by 300 ns.

Comparing the full solution (mRPC with policy versus gRPC/eRPC with proxy), mRPC speeds up the median latency by 6.1 \times (i.e., 33.4 μ s against 203.4 μ s) and the 99th percentile tail latency by 5.8 \times . On RDMA, mRPC speeds up eRPC by 1.3 \times and 1.4 \times in terms of median and tail latency (respectively). This is because the communication between the eRPC app and its proxy goes through the NIC, which triples the cost in the end-host driver (including the PCIe latency). In contrast, mRPC’s architecture shortcuts this step with shared memory.

In addition, to separate the performance gain from system implementation difference, we evaluate the latency of mRPC with full gRPC-style marshalling (protobuf encoding and

Transport	Solution	Median Latency (μ s)	P99 Latency (μ s)
TCP	Netperf	21.0	32.0
	gRPC	63.0	90.3
	mRPC	32.8	38.7
	gRPC+Envoy	203.4	251.1
	mRPC+NullPolicy	33.4	43.3
	mRPC+NullPolicy+HTTP+PB	49.8	61.9
RDMA	RDMA read	2.5	2.8
	eRPC	3.6	4.1
	mRPC	7.6	8.7
	eRPC+Proxy	11.3	15.6
	mRPC+NullPolicy	7.9	9.1

Table 2: **Microbenchmark [Small RPC latency]:** Round-trip RPC latencies for 64-byte requests and 8-byte responses.

HTTP/2 framing) in the presence of NullPolicy engines as an ablation study. Under this setting, compared with gRPC + Envoy, mRPC speeds up the latency by 4.1 \times in terms of both median and tail latency. We also observe that the mRPC framework does not introduce significant overhead. Even with the cost of protobuf and HTTP/2 encoding, mRPC still achieves slightly lower latency compared with standalone gRPC. In mRPC, we can choose a customized marshalling format, because we know the other side is also an mRPC service. In other cases, e.g., when interfacing with external traffic or dealing with endianness differences, we can still apply full-gRPC style marshalling. When mRPC is configured to use full-gRPC style marshalling, we only need to pay (un)marshalling costs between mRPC services. For gRPC + Envoy, in addition to the (un)marshalling costs between Envoy proxies, the communication between applications and Envoy proxies also needs to pay this (un)marshalling cost. In the remaining evaluations, we will use mRPC’s customized marshalling protocol. More results using gRPC-style marshalling are shown in [§A.1](#).

Large RPC goodput. The client and server in our goodput test use a single application thread. The left side of [Figure 4](#) shows the result. From this point on, when we discuss mRPC’s performance, we focus on the performance of mRPC that has at least a NullPolicy engine in place to fairly compare with sidecar-based approaches.

mRPC speeds up gRPC + Envoy and eRPC + Proxy, by 3.1 \times and 9.3 \times , respectively, for 8KB RPC requests. mRPC is especially efficient for large RPCs⁵, for which (un)marshalling takes a higher fraction of CPU cycles in the end-to-end RPC datapath. Having a sidecar substantially hurts RPC goodput both for TCP and RDMA. In particular, for RDMA, intra-host roundtrip traffic through the RNIC might contend with inter-host traffic in the RNIC/PCIe bus, halving the available bandwidth for inter-host traffic. mRPC even outperforms gRPC (without Envoy). mRPC is fundamentally more efficient in terms of marshalling format: mRPC uses `iovec` and incurs no data movement. [§A.1](#) shows an ablation study that demonstrates that even if mRPC uses a full gRPC-style marshalling engine, mRPC outperforms gRPC + Envoy due to a reduction in the number of (un)marshalling steps.

CPU overheads. To understand the mRPC CPU overheads, we measure the per-core goodput. The results are shown on

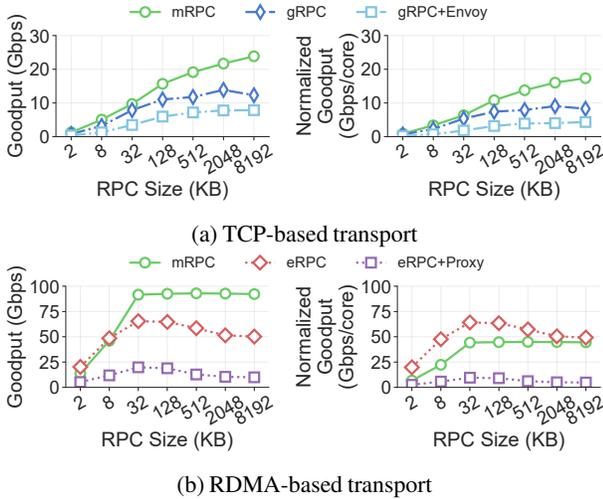

Figure 4: **Microbenchmark [Large RPC goodput]:** Comparison of goodput for large RPCs. Note that different solutions demand different amounts of CPU cores, so we also normalized the goodput to their CPU utilization, as shown in the right figures. The error bars show the 95% confidence interval, but they are too small to be visible.

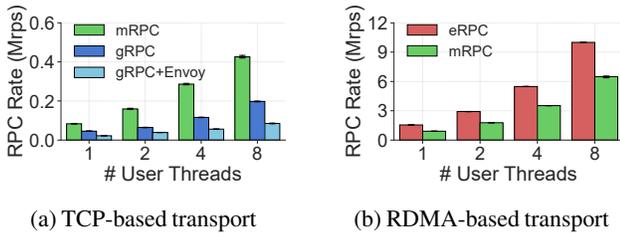

Figure 5: **Microbenchmark [RPC rate and scalability]:** Comparison of small RPC rate and CPU scalability. The bars show the RPC rate. The error bars show the 95% confidence interval.

the right side of Figure 4. mRPC speeds up gRPC + Envoy and eRPC + Proxy, by $3.8\times$ and $9.3\times$, respectively. This means mRPC is much more CPU-efficient than gRPC + Envoy and eRPC + Proxy. eRPC (without a proxy) is quite efficient, but converges to mRPC’s efficiency as RPC size increases.

RPC rate and scalability. We evaluate mRPC’s small RPC rate and its multicore scalability. We fix the RPC request size to 32 bytes and scale the number of client threads. We use the same number of threads for the server as the client, and each client connects to one server thread. Figure 5 shows the RPC rates when scaling from 1 to 8 user threads. All the tested solutions scale well. mRPC’s RPC rates scale by $5.1\times$ and $7.2\times$, on TCP and RDMA, from a single thread to 8 threads. As a reference, gRPC scales by $4.3\times$, gRPC + Envoy scales by

⁵Standalone eRPC exhibits relatively lower goodput on RoCE than on Infiniband. According to the eRPC paper [39], eRPC should achieve 75 Gbps on Infiniband for 8MB RPCs.

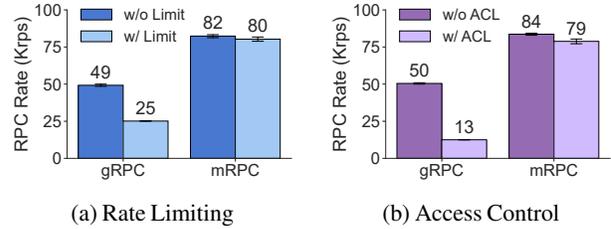

Figure 6: **Efficient Support for Network Policies.** The RPC rates with and without policy are compared. The bars of w/o Limit and w/o ACL for gRPC show its throughput when the sidecar is bypassed. The error bars show the 95% confidence interface.

$3.9\times$, and eRPC scales by $6.5\times$. mRPC achieves 0.43 Mrps on TCP and 6.5 Mrps on RDMA with 8 threads. gRPC + Envoy only has 0.09 Mrps, so mRPC outperforms it by $5\times$. We do not evaluate eRPC + proxy, because our eRPC proxy is only single-threaded. When we run eRPC + proxy with a single thread, it achieves 0.51 Mrps. So even if eRPC + proxy scales linearly to 8 threads, mRPC still outperforms it.

7.2 Efficient Policy Enforcement

We use two network policies as examples to demonstrate mRPC’s efficient support for RPC policies: (1) RPC rate limiting and (2) access control based on RPC arguments. RPC rate limiting allows an operator to specify how many RPCs a client can send per second. We implement rate limiting as an engine using the token bucket algorithm [91]. Our access control policy inspects RPC arguments and drops RPCs based on a set of rules specified by network operators. These two network policies differ greatly from traditional rate limiting and access control, which only limit network bandwidth and can only operate on packet headers.

We compare rate limit enforcement using an mRPC policy versus using Envoy’s rate limiter on gRPC workloads. To evaluate the performance overheads, we set the limit to infinity so that the actual RPC rate is never above the limit (allowing us to observe the overheads). Figure 6a shows the RPC rate with and without the rate limits. gRPC’s RPC rate drops immediately from 49K to 25K. This is because having a sidecar proxy (Envoy) introduces substantial performance overheads. For mRPC, the RPC rate stays the same at 82K. This is because having a policy introduces minimal overheads. The extra policy only adds tens to hundreds of extra CPU instructions on the RPC datapath.

We evaluate access control on a hotel reservation application in DeathStarBench [23]. The service handles hotel reservation RPC requests, which include the customer’s name, the check-in date, and other arguments. The service then returns a list of recommended hotel names. We set the access control policy to filter RPCs based on the customerName argument in the request. We use a synthetic workload containing 99% valid and 1% invalid requests. We again compare our mRPC policy

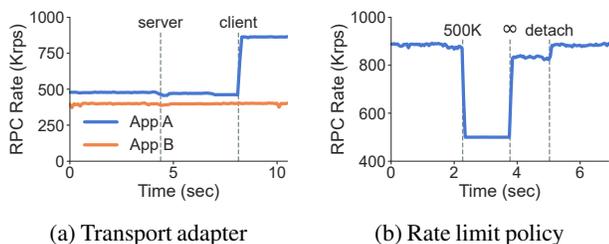

Figure 7: **Live upgrade.** In (a), the annotations indicate when the client of App A and server of A and B are upgraded. In (b), the annotations denote the specified rate and when the policy is removed.

against using Envoy to filter gRPC requests. We implement the Envoy policy using WebAssembly. gRPC’s rate drops from 50K to 13K. This is because of the same sidecar overheads and now Envoy has to further parse the packets to fetch the RPC arguments. On mRPC, the performance drop is much smaller, from 84K to 79K. Note that, on mRPC, the performance overhead of introducing access control is larger than rate limiting. For access control, the mRPC service has to copy the relevant field (i.e., `customerName`) to the private heap to prevent TOCTOU attacks on the sender side and has to copy the RPC from a private heap to the shared heap on the receiver side.

7.3 Live Upgrade

We demonstrate mRPC’s ability to live upgrade using two scenarios.

Scenario 1. During our development of mRPC, we realized that using the RDMA NIC’s scatter-gather list to send multiple arguments in a single RPC can significantly boost mRPC’s performance. In this approach, even when an RPC contains arguments that are scattered in virtual memory, we can send the RPC using a single RDMA operation (`ibv_post_send`). We use these two versions of our RDMA transport engine to demonstrate that mRPC enables such an upgrade without affecting running applications. Note that all other evaluations already include this RDMA feature. This upgrade involves both the client side’s mRPC service and the server side’s mRPC service, because it involves how RDMA is used between machines (i.e., transport adapter engine). gRPC and eRPC cannot support this type of live upgrade.

We run two applications (App A and App B). Both applications are sending 32-byte RPCs, and the responses are 8 bytes. A and B share the mRPC service on the server side. A’s and B’s RPC clients are on different machines. We keep 8 concurrent RPCs for B, forcing it to send at a slower rate, while using 32 for A. We first upgrade the server side to accept arguments as a scatter-gather list, and we then upgrade the client side of A. Figure 7a shows the RPC rate of A and B. When the server side upgrades, we observe a negligible effect on A’s and B’s rate. Neither A nor B needs recompilation or rebooting. When A’s client side’s mRPC service is upgraded, A’s performance

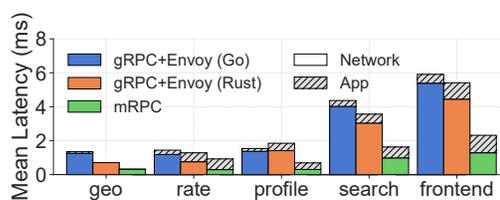

Figure 8: **DeathStarBench:** Mean latency of in-application processing and network processing of microservices. The latency of a microservice includes RPC calls to other microservices. The frontend latency represents complete end-to-end latency.

increases from 480K to 860K. B’s performance is not affected at all because B’s client side’s mRPC service is not upgraded.

Scenario 2. Enforcing network policies has performance overheads, even when they do not have any effect. For example, enforcing a rate limit of an extremely large throttle rate still introduces performance overheads just for tracking the current rate using token buckets. mRPC allows policies to be removed at runtime, without disrupting running applications.

We use the same rate limiting setup from §7.2 but on top of RDMA transport. Figure 7b shows the RPC rate. We start from not having the rate limit engine. We then load the rate limit engine and set the throttled rate to 500K. The RPC rate immediately becomes 500K. We then set the throttled rate to be infinite, and the rate becomes 840K. After we detach the rate limit engine, the rate becomes 890K.

Takeaways. There are two overall takeaways from these experiments. First, mRPC allows upgrades to the mRPC service without disrupting running applications. Second, live upgrades allow for more flexible management of RPC services, which can be used to enable immediate performance improvements (without redeploying applications) or dynamic configuration of policies.

7.4 Real Applications

We evaluate how the performance benefits of mRPC transform into end-to-end application-level performance metrics.

DeathStarBench. We use the hotel reservation service from the DeathStarBench [23] microservice benchmark suite. The reference benchmark is implemented in Go with gRPC and Consul [15] (for service discovery). Our mRPC prototype currently only supports Rust applications, and we thus port the application code to Rust for comparison. We use the same open-source services such as memcached [59] and MongoDB [64].

We distribute the HTTP frontend and the microservices on four servers in our testbed. The monolithic services (memcached, MongoDB) are co-located with the microservices that depend on them. We use a single thread for each of the microservices and the frontend. Further, we deploy an Envoy proxy as a sidecar on each of the servers (with no active policy). The pro-

	Median Latency	P99 Latency	Throughput
eRPC	16.8 μ s	21.7 μ s	8.7 MOPS
mRPC	22.5 μ s	33.1 μ s	7.0 MOPS

Table 3: **Masstree analytics**: Latency and the achieved throughput for GET operations. MOPS is Million Operations Per Second.

vided workload generator [23] is used to submit HTTP requests to the frontend. For a fair comparison, we also implemented a Rust version of the benchmark with Tonic [93], which is the de facto implementation of gRPC in Rust. We deploy the mRPC and Tonic implementations on bare metal, while the reference Go suite runs in Docker containers with a host network (which introduces negligible performance overheads compared to using bare metal [103]). All three solutions are based on TCP. We issue 20 requests per second for 250 seconds and record the latency of each request, breaking it down into the in-application processing time and network processing time for each microservice involved. In our evaluation, the dynamic bindings of the user applications are already cached in mRPC service, so the time to generate the bindings is not included in the result.

Figure 8 shows the latency breakdown. First, we validate that our own implementation of DeathStarBench on Rust is a faithful re-implementation. We can see that the original Go implementation and our Rust implementation have similar latency. Moreover, the amount of latency spent in gRPC is similar. Second, mRPC with a null policy outperforms by $2.5\times$ gRPC with a sidecar proxy in average end-to-end latency. §A.2 contains more details about the tail latency and the scenario without a sidecar.

Masstree analytics. We also evaluate the performance of Masstree [56], an in-memory key-value store, over both mRPC and eRPC [39] using RDMA. We follow the exact same workload setup used in eRPC, which contains 99% I/O-bounded point GET request and 1% CPU-bounded range SCAN request. We run the Masstree server on one machine and run the client on another machine. Both the server and the client use 10 threads, with each client thread using 16 concurrent requests. The test runs for 60 seconds. The result in Table 3 shows that eRPC outperforms mRPC, which makes sense since eRPC is a well-designed library implementation that is focused on high performance. mRPC enables many other manageability features in exchange for a slight reduction in performance. In this case, using mRPC instead of eRPC means that median latency increases by 34% and throughput reduces by 20%.

7.5 Benefits of Advanced Manageability Features

Next, we demonstrate the performance benefits of having centralized RPC management, through two advanced manageability features that we developed (see §5). We use synthetic workloads to test the advanced manageability features.

	Latency App		B/W App
	P95 Latency	P99 Latency	Bandwidth
w/o QoS	45.1 μ s	54.6 μ s	22.2 Gbps
w/ QoS	19.5 μ s	21.8 μ s	22.0 Gbps

Table 4: **Global QoS**: Performance of latency- and bandwidth-sensitive applications with and without a global QoS policy.

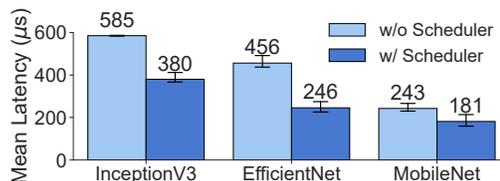

Figure 9: **RDMA Scheduler**: Mean RPC latency with or without RDMA scheduler. The error bars show the 95% confidence interval.

Global RPC QoS. We enable our cross-application QoS policy that reorders requests from multiple applications and prioritizes small RPC requests. We set up two applications and pin them to the same mRPC runtime. One application is latency-sensitive, sending 32-byte RPC requests with a single RPC in-flight; the other is bandwidth-sensitive, sending 32 KB requests with 64 concurrent RPCs. We measure the tail latency for the latency-sensitive application and the utilized bandwidth of the bandwidth-sensitive one.

Table 4 shows the result. Without the QoS policy, the bandwidth-sensitive application has a high bandwidth utilization; however, the latency-sensitive application suffers from a high tail latency. With the QoS policy in place, the small requests from the latency-sensitive application get higher priority and are sent first, improving P99 latency from 54.6 μ s to 21.8 μ s. Since small RPC requests consume negligible bandwidth, it barely affects the bandwidth-sensitive application (less than a 1% bandwidth drop).

RDMA Scheduler. Our RDMA scheduler batches small RPC requests into (at most) 16KB messages and sends requests using a single RDMA operation to reduce the load on the RDMA NIC. Our synthetic workload is based on BytePS [37], which uses RDMA for distributed deep learning. To synchronize a tensor to/from a server, BytePS prepends an 8-byte key and appends a 4-byte length to describe the tensor. The three disjoint memory blocks are placed in a scatter-gather list and submitted to the NIC, resulting in a small-large-small message pattern that triggers a performance anomaly [49]. This message pattern is quite common in real applications, as programs often need to describe a large payload with a small piece of metadata. We emulate BytePS’s RPC request pattern and generate RPCs from three widely-used models: MobileNet, EfficientNetB0, and InceptionV3 [31, 89, 90]. Each RPC call consists of an

8-byte key, a payload of tensor, and a 4-byte length. We use a single thread to make RPCs. Figure 9 shows the average RPC latency. The RDMA scheduler provides 30-90% latency improvement. This improvement differs for different neural networks, because of different RDMA message patterns.

8 Related Work

Fast RPC implementations. Optimizing RPC has a long history. Birrell and Nelson’s early RPC design [10] includes generating bindings via a compiler, interfacing with transport protocols, and various optimizations (e.g., implicit ACK). Bershad et al. showed how to use shared-memory queues to efficiently pass RPC messages between processes on the same machine [8]. mRPC’s shared-memory region leverages this idea but extends it to allow for marshalling code to be applied after policy enforcement. A similar use of shared-memory queues can be found with recent Linux support for asynchronous system calls [3] combined with scatter-gather I/O [54]; unlike traditional system calls, however, mRPC protocol descriptions can be defined at runtime.

Another line of work uses RDMA to speed network RPCs [13, 39, 41, 63, 87, 88]. These studies assume direct application access to network hardware and are thus susceptible to RDMA’s security weaknesses [79]. mRPC leverages ideas from RDMA RPC research but in a way that is compatible with policy enforcement and observability, by doing so as a service. Another line of work reduces the cost of marshalling, by using alternative formats [2, 9, 11, 20, 38, 66, 78, 92] or designing hardware accelerators [35, 43, 76, 97]. This work is largely orthogonal to our goal of removing unnecessary marshalling steps but could be applied to further improve mRPC performance.

Fast network stacks. Building efficient host network stacks is a popular research topic. MegaPipe [28], mTCP [36], Arrakis [73], IX [5], eRPC [39], and Demikernel [99] advocate building the network stack as a user-level library, bypassing the kernel for performance. In these systems, an application directly accesses the network interface, but they assume policy can be enforced by the network hardware and are thus vulnerable if the hardware has security weaknesses. mRPC can interpose policy on any RPC. Like mRPC, Snap [58] and TAS [45] implement the network stack as a service, but they stop at layer 4 (TCP and UDP) rather than layer 7 (RPC). Application RPC stubs must marshal data into shared memory queues to use Snap or TAS. Flexible policy engines are a key feature of Snap, but because Snap operates at layer 4, it can only apply layer 7 policies by unmarshalling and re-marshalling RPC data. A fast network stack like mRPC can also be implemented directly in the kernel. LITE [95] implements RDMA operations as system calls inside the kernel to improve manageability, and Shenango [69] interposes a specialized kernel packet scheduler for network messages.

Fast network proxies. There is a long line of work on improving the performance of network proxies [33, 34, 44, 46, 47,

51, 57, 60, 70, 71, 74, 75, 85, 100]. Much of this work considers the general case of a standalone proxy. Our work differs in two ways. First, our proposed technique is only for RPC traffic rather than generalized TCP traffic. Second, we co-design the application library stub and proxy, and thus, both must be co-located on the same machine for our shared memory queues to function. In today’s sidecar proxies (our baseline), this assumption holds, but it does not hold for generalized network proxies.

Live upgrades of system software. Being able to update system software without disrupting or restarting applications is key to achieving end-to-end high availability. Snap [58] provides live upgrade of the network stack running as a proxy; Bento [61] provides similar functionality for kernel-resident file systems. Relative to these systems, mRPC upgrades are more fine-grained. For example, Snap targets a maximum outage during upgrades of 200 milliseconds, by spawning another instance of itself and moving all connections to the new process. By contrast, our goal is near instantaneous changes and upgrades to RPC protocol definitions, policy engines, and marshalling code. We accomplish this by keeping the control plane intact and performing updates by loading and unloading dynamic libraries. eBPF is a Linux kernel extensibility mechanism that supports dynamic updates [17]; unlike eBPF, mRPC can dynamically change the execution graph of policy engines as well as the individual engines themselves.

9 Conclusion

Remote procedure call has become the de facto abstraction for building distributed applications in datacenters. The increasing demand for manageability makes today’s RPC libraries inadequate. Inserting a sidecar proxy into the network datapath allows for manageability but slows down RPC substantially due to redundant marshalling and unmarshalling. We present mRPC, a novel architecture to implement RPC as a managed service to achieve both high performance and manageability. mRPC eliminates the redundant marshalling overhead by applying policy to RPC data before marshalling and only copying data when necessary for security. This new architecture enables live upgrade of RPC processing logic and new RPC scheduling and transport methods to improve performance. We have performed extensive evaluations through a set of micro-benchmarks and two real applications to demonstrate that mRPC enables a unique combination of high performance, policy flexibility, security, and application-level availability. Our source code is available at <https://github.com/phoenix-dataplane/phoenix>.

A Appendix

A.1 mRPC with Full gRPC-style Marshalling

As gRPC uses protobuf [78] for encoding and HTTP/2 as the payload carrier, it has a memory copying and HTTP/2 framing cost. On the other hand, mRPC is agnostic to the marshalling format. Although mRPC’s default marshalling is zero-copy and is generally faster than gRPC-style marshalling, our main goal of the paper is to show that we can eliminate the redundant (un)marshalling steps while enabling network policies and observability for RPC traffic.

To isolate the performance benefits of using zero-copy marshalling and reducing the number of (un)marshalling steps, we evaluate mRPC with full gRPC-style marshalling (protobuf + HTTP/2). We implement an mRPC variant that applies encoding (decoding) code generated by the protobuf compiler and HTTP/2 framing for inter-host mRPC service communication.

We conduct the same large RPC goodput experiment in §7.1. The results are presented in Figure 10. We find that mRPC achieves performance comparable to gRPC after switching to using protobuf + HTTP/2. With full gRPC marshalling, mRPC still performs 2.6× and 3.7× as fast as gRPC + Envoy in terms of goodput and goodput per core. This is because mRPC reduces the number of (un)marshalling steps. The small RPC rate and scalability of mRPC with gRPC marshalling is also shown in Figure 11. Since encoding small RPCs with protobuf is relatively fast, the trend to the rate and scalability is similar to Figure 5a.

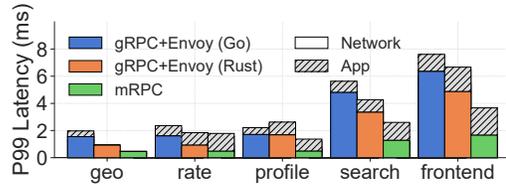

Figure 12: **DeathStarBench:** P99 latency of in-application processing and network processing of microservices, respectively. gRPC with Envoy and mRPC are compared. A null policy is applied for mRPC.

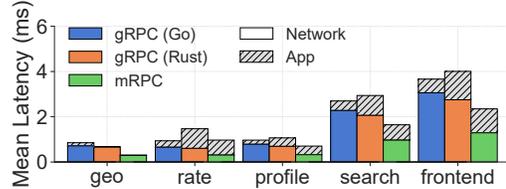

Figure 13: **DeathStarBench:** Mean latency of gRPC without proxy and mRPC.

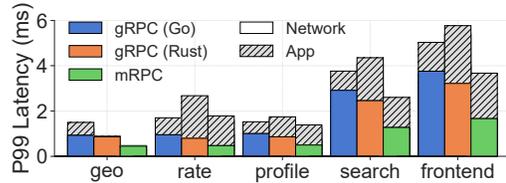

Figure 14: **DeathStarBench:** P99 latency of in-application processing and network processing of microservices, respectively. gRPC without proxy and mRPC are compared.

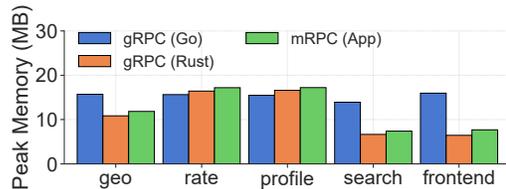

Figure 15: **DeathStarBench:** Peak memory usages of different services. gRPC without proxy and mRPC are compared.

A.2 Extended Evaluation for DeathStarBench

We report the P99 latency of DeathStarBench in Figure 12, comparing gRPC with Envoy and mRPC. The result is similar to the comparison of median latency in §7.4. mRPC speeds up gRPC+Envoy by 2.1× in terms of end-to-end P99 tail latency.

We also evaluate gRPC without proxy and mRPC without any policy enforced. Figure 13 and Figure 14 show the results for mean latency and P99 tail latency. We observe that mRPC speeds up gRPC by 1.7× and 1.6×, in terms of mean latency and P99 tail latency. Communication costs are substantial in the DeathStarBench applications, and thus reducing the communication latency can improve end-to-end application performance. This is consistent with the original

DeathStarBench paper's observation [23].

We further compare the memory usage of gRPC and mRPC. The peak memory consumption of gRPC and mRPC in DeathStarBench applications is illustrated in [Figure 15](#). For mRPC, we report the user application side memory usage, which also includes all the memory pages shared with the mRPC service. We observe that mRPC does not incur notable memory overhead compared to gRPC. On the other hand, we find a small and constant memory footprint of mRPC service across all machines at around 9 MB.

Canvas: Isolated and Adaptive Swapping for Multi-Applications on Remote Memory

Abstract

Remote memory techniques for datacenter applications have recently gained a great deal of popularity. Existing remote memory techniques focus on the efficiency of a single application setting only. However, when multiple applications co-run on a remote-memory system, significant interference could occur, resulting in unexpected slowdowns even if the same amounts of physical resources are granted to each application. This slowdown stems from massive sharing in applications' swap data paths. Canvas is a redesigned swap system that fully isolates swap paths for remote-memory applications. Canvas allows each application to possess its dedicated swap partition, swap cache, prefetcher, and RDMA bandwidth. Swap isolation lays a foundation for adaptive optimization techniques based on each application's own access patterns and needs. We develop three such techniques: (1) adaptive swap entry allocation, (2) semantics-aware prefetching, and (3) two-dimensional RDMA scheduling. A thorough evaluation with a set of widely-deployed applications demonstrates that Canvas minimizes performance variation and dramatically reduces performance degradation.

1 Introduction

Techniques enabling datacenter applications to use far memory [36, 39, 8, 62, 73, 91, 104, 90, 19] have gained traction due to their potential to break servers' memory capacity wall, thereby improving performance and resource utilization. Existing far-memory techniques can be roughly classified into two categories: (1) clean-slate techniques [90, 19] that provide new primitives for developers to manage remote memory, and (2) swap-based techniques [39, 91, 8, 104, 2] that piggyback on existing swap mechanisms in the OS kernel. Clean-slate techniques provide greater efficiency by enabling user-space far memory accesses, while swap-based techniques offer transparency, allowing legacy code to run *as is* on a far-memory system. This paper focuses on swap mechanisms as they are more practical and easier to adopt.

A typical swap system in the OS uses a *swap partition* and *swap cache* for applications to swap data between memory and external storage. The swap partition is a storage-backed swap space. The swap cache is an intermediate buffer between the *local memory* and storage—it caches *unmapped pages* that were just swapped in or are about to be swapped

out. Upon a page fault, the OS looks up the swap cache; a cache miss would trigger a *demand swap* and a number of *prefetching swaps*. Swaps are served by RDMA and all fetched pages are initially placed in the swap cache. The demand page is then mapped to a virtual page and moved out of the swap cache, completing the fault handling process.

Problems. Current swap systems run multiple applications over shared swap resources (*i.e.*, swap partition, RDMA, *etc.*). This design works for *disk-based swapping* where disk access is slow—each application can allow only a tiny number of pages to be swapped to maintain an acceptable overhead. This assumption, however, no longer holds under far memory because an application can place more data in far memory than local memory and yet still be efficient, thanks to RDMA's low latency and high bandwidth.

As such, applications have orders-of-magnitude more swap requests under far memory than disks. Millions of swap requests from different applications go through the same shared data path in a short period of time, leading to *severe performance interference*. Our experiments show that, with the same amounts of CPU and local-memory resources, co-running applications leads up to a 6× slowdown, an overhead unacceptable for any real-world deployment.

State of the Art. Interference is a known problem in datacenter applications and a large body of work exists on isolation of CPU [64, 16, 25], I/O [40, 96], network bandwidth [13, 37, 94, 87, 77, 53] and processing [59]. Most of these techniques build on Linux's `cgroup` mechanism, which focuses on isolation of traditional resources such as CPU and memory, *not* swap resources such as remote memory usage and RDMA. Prior swap optimizations such as `Infiniswap` [39] and `Fastswap` [8] focus on reducing remote access latency, overlooking the impact of swap interference in realistic settings. `Justitia` [113] isolates RDMA bandwidth between applications, but does not eliminate other types of interference such as locking and swap cache usage.

Contribution #1: Interference Study (§3). We conducted a systematic study with a set of widely-deployed applications on Linux 5.5, the latest kernel version compatible with Mellanox's latest driver (4.9-3.1.5.0) for our InfiniBand card. Our results reveal three major performance problems:

- **Severe lock contention:** Since all applications share a single swap partition, extensive locking is needed for swap entry allocation (needed by every swap-out), reduc-

* Contributed equally.

ing throughput and precluding full utilization of RDMA’s bandwidth. Our experience shows that in windows of frequent remote accesses, applications can spend **70%** of the windows’ time on swap entry allocation.

- **Uncontrolled use of swap resources (e.g., RDMA):** The use of the shared RDMA bandwidth is often dominated by the pages fetched for applications with many threads simultaneously performing frequent remote accesses. For example, aggressively (pre)fetching pages to fulfill one application’s needs can disproportionately reduce other applications’ bandwidth usage. Further, even within one application, prefetching competes for resources with demand swaps, leading to either prolonged fault handling or delayed prefetching that fails to bring back pages in time.
- **Reduced prefetching effectiveness:** Applications use the same prefetcher, prefetching data based on *low-level (sequential or strided) access patterns* across applications. However, modern applications exhibit far more diverse access patterns, making it hard for prefetching to be effective across the board. For example, co-running Spark and native applications reduces Leap [73]’s prefetching contribution by **3.19×**.

These results highlight two main problems. First, interference is caused by sharing a combination of swap resources including the swap partition/cache, and RDMA (bandwidth and SRAM on RNIC). Although recent kernel versions added support [47] for charging prefetched pages into `cgroup`, resolving interference requires a *holistic* approach that can isolate all these resources. Furthermore, interference stems not only from resource racing, but also from fundamental limitations with the current design of the swap system. For instance, reducing interference between prefetching and demand swapping requires understanding whether a prefetching request can come back in time. If not, it should be dropped to give resources to demand requests, which are on the critical path. This, in turn, requires a re-design of the kernel’s fault handling logic.

Second, cloud applications exhibit highly diverse behaviors and resource profiles. For example, applications with a great number of threads are more sensitive to locking than single-threaded applications. Furthermore, managed applications such as Spark often make heavy use of reference-based data structures while native applications are often dominated by large arrays. The *application-agnostic nature* of the swap system makes it hard for a one-size-fits-all policy (e.g., a global prefetcher) to work well for diverse applications. Effective per-application policies dictates (1) holistic swap isolation and (2) understanding application semantics, which is currently inaccessible in the kernel.

Contribution #2: Holistic Swap Isolation (§4). To solve the first problem, we develop Canvas, a *fully-isolated* swap system, which enables each application to have its dedicated swap partition, swap cache, and RDMA usage. In doing so,

Canvas can charge each application’s `cgroup` for the usage of all kinds of swap resources, preventing certain applications from aggressively invading others’ resources.

Contribution #3: Isolation-Enabled Adaptive Optimizations (§5). To solve the second problem, we develop a set of adaptive optimizations that can tailor their policies and strategies to application-specific swap behaviors and resource needs. Our adaptive optimizations bring a *further boost* on top of the isolation-provided benefits, making co-running applications even *outperform* their individual runs.

(1) Adaptive Swap Entry Allocation (§5.1) Separating swap partitions reduces lock contention at swap entry allocations to a certain degree, but the contention can still be heavy for multi-threaded applications. For example, Spark creates many threads to fully utilize cores and these threads need synchronizations before obtaining swap entries. The synchronization overhead increases dramatically with the number of cores (§6.4.1), creating a scalability bottleneck. We develop an adaptive swap entry allocator that dynamically balances between the degree of lock contention (i.e., time) and the amount of swap space needed (i.e., space) based on each application’s memory behaviors.

(2) Adaptive Two-tier Prefetching (§5.2) Current kernel prefetchers build on low-level access patterns (e.g., sequential or strided). Although such patterns are useful for applications with large array usages, many cloud applications are written in high-level, managed languages such as Java or Python; their accesses come from multiple threads or exhibit pointer-chasing behavior as opposed to sequential or strided patterns. As effective prefetching is paramount to remote-memory performance, Canvas employs a two-tier prefetching design. Our *kernel-tier prefetcher* prefetches data for each application into its private swap cache based on low-level patterns. Once this prefetcher cannot effectively prefetch data, Canvas adaptively forwards the faulty address up to the *application tier* via a modified `userfaultfd` interface, enabling customized prefetching logic at the level of reference-based or thread-based access patterns.

(3) Adaptive RDMA Scheduling (§5.3) Isolating RDMA bandwidth alone for each application is insufficient. As there could be many more *prefetching* requests than *demand swap requests*, naively sending all to RDMA delays demand requests, increasing fault-handling latency. On the other hand, naively delaying prefetching requests (as in FastSwap [8]) reduces their *timeliness*, making prefetched pages useless. We built a *two-dimensional* RDMA scheduler, which schedules packets not only between applications but also between prefetching and demand requests for each application.

Results. Our evaluation (§6) with a set of 14 widely-deployed applications (including Spark [109], Cassandra [10], Neo4j [79], Memcached [4], XGBoost [23, 22], Snappy [38], etc.) demonstrates that Canvas improves the overall application performance by up to **6.2×** (average **3.5×**) and reduces applications’ performance variation (i.e.,

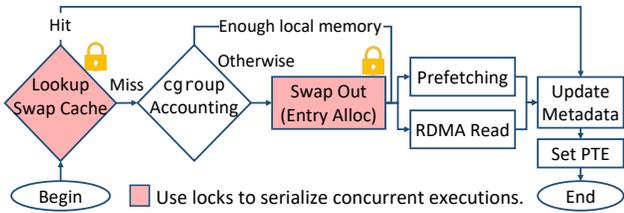

Figure 1: The kernel’s remote-access data path.

standard deviation) by $7\times$, from an overall of **1.72** to **0.23**. Canvas improves the overall RDMA bandwidth utilization by $2.8\times$ for co-run applications. Canvas is available at <https://github.com/uclsystem/canvas>.

2 Background

This section presents the necessary background in Linux 5.5, which is the latest kernel version compatible with Mellanox’s latest driver for our InfiniBand adapter.

Figure 1 illustrates the kernel’s remote access data path where remote memory is mapped into the host server as a swap partition where applications access remote memory via page faults. The swap partition is split into a set of 4KB *swap entries*, each mapping to an actual remote memory cell and has a unique entry ID. Upon a page fault, the kernel uses the swap entry ID contained in the corresponding page table entry (PTE) to locate the swap entry that stores the page.

The first step in handling the fault is to look up the swap cache, which is a set of radix trees, each containing a number of cached and unmapped pages for a block (*e.g.*, 64MB) of swap entries. These pages were either just swapped in due to demand swapping or prefetching, or are about to be swapped out. If a page can be found there, it gets mapped to a virtual page and removed from the swap cache. Otherwise, the kernel needs to perform a *demand swap-in*.

Before issuing the request, the kernel first does *cgroup* accounting to understand if there is enough physical memory to swap in the page. If there is, the kernel issues an RDMA read request, which is then pushed into RDMA’s dispatch queue. As the demand swap occurs, the kernel prefetches a number of pages that will likely be needed in the future. This number depends on the swap history at the past few page faults. For example, if the pages fetched follow a sequential or strided pattern, the kernel will use this pattern to fetch a few more pages. If no pattern is found, the kernel reduces the number of prefetched pages until it stops prefetching completely. Once these demand and prefetched pages arrive, they are placed into the swap cache. Their swap entries in remote memory are then freed.

If *cgroup* accounting deems that local memory is insufficient for the new page, the kernel uses an LRU algorithm to evict pages. Evicting a page *unmaps* it and pushes it into the swap cache. When memory runs low, the kernel releases existing pages from the swap cache to make room for newly

fetched pages. Clean pages can be removed right away and dirty pages must be written back. To write back a page, the swap system must first allocate a swap entry using a free-list-based allocation algorithm. Finally, an RDMA write request is generated and the page is written into the entry via RDMA.

In each remote access, extensive locking is needed for swap entry allocation—shared allocation metadata (*e.g.*, free list) must be protected when multiple applications/threads request swap entries simultaneously. Although there are active efforts [48, 46] in the Linux community to optimize swap entry allocation, their performance and scalability is unsatisfactory for cloud workloads (see Appendix B).

3 Motivating Performance Study

To understand the impact of interference, we conducted a study with a set of widely-deployed applications including Apache Spark [109], Neo4j [79], XGBoost [23] (*i.e.*, a popular ML library), Snappy [38] (*i.e.*, Google’s fast compressor/decompressor), as well as Memcached [4]. Spark and Neo4j are managed applications running on the JVM, while the other three are native applications. They cover a spectrum of cloud workloads from data storage through analytics to ML. In addition, they include both batch jobs (such as Spark) and latency-sensitive jobs (such as Memcached). Co-running them represents a typical scenario in a modern datacenter where operators fill left-over cores unused by latency-sensitive tasks with batch-processing applications to improve CPU utilization [15]. For example, in a Microsoft Bing cluster, batch jobs are colocated with latency-sensitive services on over 90,000 servers [49]. Google also reported that 60% of machines in their compute cluster co-run at least five jobs [112].

We ran these programs, individually *vs.* together, on a machine with two Xeon(R) Gold 6252 processors, running Linux 5.5. Another machine with two Xeon(R) CPU E5-2640 v3 processors and 128GB memory was used for remote memory. Each machine was equipped with a 40 Gbps Mellanox ConnectX-3 InfiniBand adapter and interconnected by one Mellanox 100 Gbps InfiniBand switch. Using *cgroup*, the same amounts of CPU and local memory resources were given to each application throughout the experiments. RDMA bandwidth was *not* saturated for both application individual runs and co-runs. The amount of local memory configured for each application was 25% of its working set.

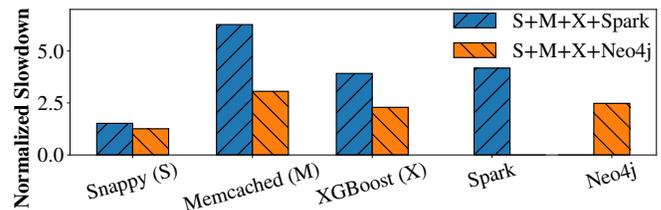

Figure 2: Slowdowns of co-running applications compared to running each individually.

Performance Interference and Degradation. To understand the overall performance degradation and how it changes with different applications, we used two managed applications: Spark and Neo4j. Figure 2 reports each application’s performance degradation when co-running with other applications compared to running alone. The blue/orange bars show the slowdowns when the three native applications co-run with Spark/Neo4j. Clearly, co-running applications significantly reduces each application’s performance. We observed an overall $3.9/2.2\times$ slowdown when native applications co-run with Spark/Neo4j. Spark persists a large RDD in memory and keeps swapping in/out different parts of the RDD, while Neo4j is a graph database and holds much of its graph data in local memory and thus does not swap as much as Spark.

Another observation is that the impact of interference differs significantly for different applications. Applications that generate high swap throughputs aggressively invade swap and RDMA resources of other applications. In our experiments, Memcached, XGBoost, and Spark all need frequent swaps. However, Spark runs many more threads (>90 application and runtime threads) than Memcached (4) and XGBoost (16), resulting in a much higher swap throughput. As such, Spark takes disproportionately more resources, leading to severe degradation for Memcached and XGBoost.

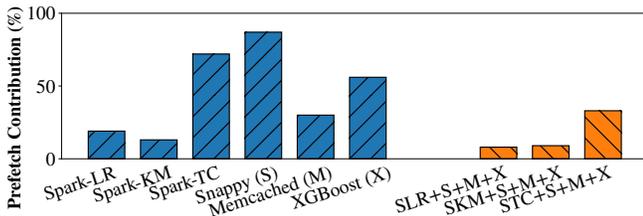

Figure 3: Prefetching contribution of Leap: the percentage of page faults served by Leap-prefetched pages (%).

Reduced Prefetching Effectiveness. Sharing the same prefetching policy reduces the prefetching effectiveness when multiple applications co-run. Figure 3 reports *prefetching contribution*—the percentage of page faults served by prefetched pages—the higher the better; if a prefetched page is never used, prefetching it would only incur overhead. We used Leap [73] as our prefetcher. The left six bars report such percentages for the applications running individually. When applications co-run, the rightmost three bars report the average percentages across applications. As shown, co-running dramatically reduces the contribution.

Note that Leap [73] uses a majority-vote algorithm to identify patterns across multiple applications. However, when applications that exhibit drastically different behaviors co-run, Leap cannot adapt its prefetching mechanism and policy to each application. Furthermore, Leap is an aggressive prefetcher—even if Leap does not find any pattern, it always prefetches a number of contiguous pages. However, aggressive prefetching for applications such as Spark with

garbage collection (GC) is ineffective—*e.g.*, prefetching for a GC thread has zero benefit and only incurs overhead. Detailed evaluation of prefetching can be found in §6.4.

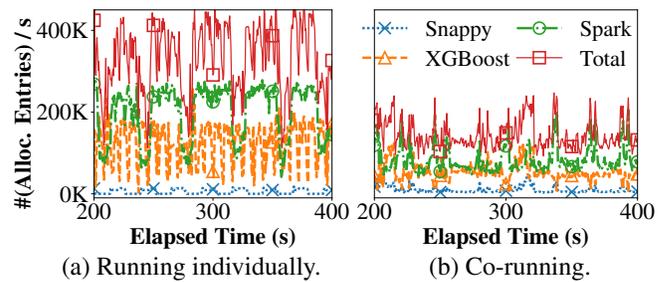

Figure 4: Swap entry allocation throughput when applications run individually (a) and together (b).

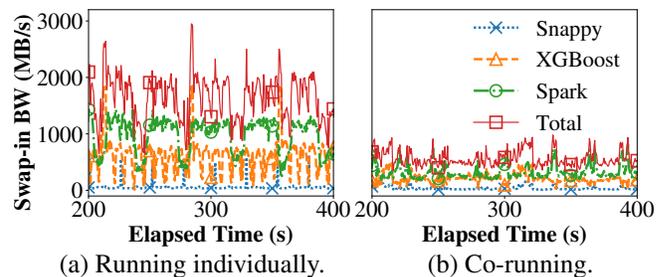

Figure 5: RDMA swap-in bandwidth when applications run individually (a) and together (b).

Lock Contention. We observed severe lock contention in the swap system when applications co-run, particularly at swap entry allocation associated with each swap-out.

We experimented with Spark (Logistic Regression), XGBoost, and Snappy. Our results show that in windows of frequent remote accesses, co-running applications can spend up to **70%** of the window time on obtaining swap entries. Lock contention leads to significantly reduced swap-entry allocation throughput, reported in Figure 4. The total lines in Figure 4(a) and (b) show the total throughput (*i.e.*, the sum of each application’s allocation throughput). The co-running throughput (b) is drastically reduced compared to the individual run’s throughput (a) (*i.e.*, $\sim 450\text{Kps}$ to $\sim 200\text{Kps}$).

Reduced RDMA Utilization. Figure 5 compares the RDMA read bandwidth (for swap-ins) when applications run individually and together. Similarly, the total line represents the sum of each application’s RDMA bandwidth. The total RDMA utilization is constantly below $\sim 1000\text{MBps}$ in Figure 5(b), which is $3.28\times$ lower than that in Figure 5(a) due to various issues (*e.g.*, locking, reduced prefetching, *etc.*). The RDMA write bandwidth degrades by an overall of $2.80\times$.

Demand v.s. Prefetching Interference. Optimizations such as Fastswap [8] improve swap performance by dividing the RDMA queue pairs (QP) into sync and async. The high-priority synchronous QP is used for demand swaps, while the low priority async QP is used for prefetching requests.

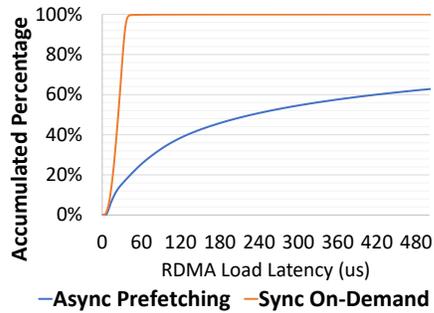

Figure 6: Latency of prefetching and on-demand swapping.

This separation reduces head-of-line blocking incurred by prefetching. However, when applications co-run, this design adds a delay for prefetching. Figure 6 depicts the CDF of the latency of RDMA packets from demand and prefetching requests, when the four applications co-run on Leap. As shown, 99% of the on-demand requests are served within $40\mu\text{s}$. However, the latency of 36.9% of prefetching requests is longer than $512\mu\text{s}$ and it can reach up to 52ms! Long latency renders prefetched pages useless because prefetching is meant to load pages to be used soon. Our profiling shows that among the prefetched pages that are actually accessed by the application, 90% are accessed within $70\mu\text{s}$, indicating that $\sim 70\%$ of the pages prefetched return too late. A late prefetch of a page would subsequently block a demand request of the page when it is accessed by the application. This problem motivates our two-dimensional RDMA scheduling (§5.3).

Takeaway. The root cause of performance degradation is that multiple applications, whose resource needs and swap behaviors are widely apart, all run on a global swap system with the same allocator and prefetcher. Table 1 summarizes these problems, their performance impact, and our solutions.

4 Swap System Isolation

Canvas extends `cgroup` for users to specify size constraints for swap partition, swap cache, and RDMA bandwidth. We discuss the kernel support to enforce these new constraints, laying a foundation for adaptive optimizations in §5.

Swap Partition Isolation. In Linux, remote memory is managed via a swap partition interface, shared by all applications. If there are multiple available swap partitions, they are used in a *sequential manner* according to their priorities. As a result, data of different applications are mixed and stored in arbitrary locations.

Canvas separates remote memory of each `cgroup` to isolate capacity and performance. The user creates a `cgroup` to set a size limit of remote memory for an application. Canvas allocates remote memory in a demand-driven manner—upon a pressure in local memory, Canvas allocates remote memory and registers it as a RDMA buffer. Canvas enables per-`cgroup` swap partitions by creating a swap partition interface and attaching it to each `cgroup`. For each `cgroup`, a

separate swap-entry manager is used for allocating and freeing swap entries. Swap entry allocation can now be charged to the `cgroup`, which controls how much remote memory each application can use. Our adaptive swap entry allocation algorithm is discussed in §5.1.

Canvas explicitly enables a private swap cache for each `cgroup` (a default value of 32MB), whose size is charged to the *memory budget* specified in the `cgroup`. As a result, the size of an application’s swap cache changes in response to its own memory usage, without affecting other applications.

For each demand swap-in, Canvas first checks the `mapcount` of the page, which indicates how many processes this page has been mapped to before. If the page belongs only to one process, it is placed in its private swap cache. Otherwise, it has to be placed in a global swap cache (discussed shortly). To release pages (*e.g.*, when the application’s working set increases, pushing the boundary of the swap cache), Canvas scans the swap cache’s page list, releasing a batch of pages to shrink the cache.

RDMA Bandwidth Isolation. For each `cgroup`, Canvas isolates RDMA bandwidth with a set of *virtual* RDMA queue pairs (VQPs) and a centralized packet scheduler. Users can set the swap-in/swap-out RDMA bandwidth of a `cgroup` with our extended interface. Our RDMA scheduler works in two dimensions. The *first dimension* schedules packets across applications, while the *second dimension* schedules on a per-application basis—each `cgroup` has its *sub-scheduler* that schedules packets that belong to the `cgroup` between demand swapping and prefetching.

VQPs are high-level interfaces, implemented with lock-free linked lists. Each `cgroup` pushes its requests to the head of its VQP, while the scheduler pops requests from their tails. At the low level, our scheduler maintains three physical queue pairs (PQP) per core, for *demand swap-in*, *prefetching*, and *swap-out*, respectively. The scheduler polls all VQPs and forwards packets to the corresponding PQPs, using a *two-dimensional* scheduling algorithm (see §5.3).

Handling of Shared Pages. Processes can share pages due to shared libraries or memory regions. These pages cannot go to any private swap cache. Canvas maintains a global swap partition and cache for shared pages. When a page is evicted and unmapped, Canvas checks its `mapcount` and adds it to the global swap cache if the page is shared between different processes. All pages in the global swap cache will be eventually swapped out to the global partition using the original lock-based allocation algorithm. Conversely, pages swapped in (and prefetched) from the global swap partition are all placed into the global swap cache. For typical cloud applications such as Spark, Cassandra and Neo4j, the number of shared pages is much smaller than process-private pages, using locks in a normal way would not incur a large overhead. We cannot charge applications’ `cgroups` for pages in the global swap cache, because which process(es) share these pages is unknown before they get mapped into pro-

Problem Description	Performance Impact	Canvas’s Solution
Unlimited use of swap and RDMA resources	Apps generating higher swap thrupt use disproportionately more resources	Holistic isolation of swap system RDMA isolation and scheduling (§4, §5.3)
Lock conten. at swap entry alloc.	Reduced swap-out thrupt	(1) Swap parti. isolation (§4); (2) adaptive entry alloc. (§5.1)
Single low-level prefetcher	Increased fault-handling latency	Two-tier adaptive prefetching (§5.2)
prefetching v.s. demand interfere	Increased fault-handling latency	Two-dimensional RDMA scheduling (§5.3)

Table 1: Summary of major issues and Canvas’s solution.

cesses’ address spaces. Canvas allows users to create a special `cgroup`, named `cgroup-shared`, to limit the size of the global swap cache/partition.

One limitation of our `cgroup`-based approach is that `cgroup` can only partition resources statically while applications’ resource usage may change from time to time and static partitioning could lead to resource underutilization. However, the focus of this paper is to ensure isolation and future work could incorporate max-min fair allocation to improve resource utilization.

5 Isolation-Enabled Swap Optimizations

On top of the isolated swap system, we develop three optimizations, which dynamically adapt their strategies to each application’s resource patterns and semantics.

5.1 Adaptive Swap Entry Allocation

As discussed in §3, swap entry allocation suffers from severe lock contention under frequent remote accesses—allocation is needed at every swap-out. To further motivate, we use a simple experiment by running Memcached alone on remote memory with different core numbers. As the number of cores increases, the average entry allocation time grows super-linearly—it grows from $10\mu\text{s}$ under 16 cores quickly to $130\mu\text{s}$ under 48 cores due to increased lock contention (see Figure 16). Creating a per-application swap partition mitigates the problem to a certain degree. However, applications like Spark run more than 90 threads; frequent swaps in these threads can still incur significant locking overhead.

To further reduce contention, we develop a novel swap entry allocator that adapts allocation strategies in response to each application’s own memory access/usage. Our first idea is to enable a *one-to-one* mapping between pages and swap entries. At the first time a page is swapped out, we allocate a new swap entry using the original (lock-protected) algorithm. Once the entry is allocated, Canvas writes the entry ID into the page metadata (*i.e.*, `struct page`). This ID remains on the page throughout its life span. As a result, subsequent swap-outs of the page can write data directly into the entry corresponding to this ID. We pay the locking overhead *only once* for each page at its first swap-out.

This approach requires a swap entry to be reserved for each page. For example, if the local memory size is S and the remote memory allocation is $3S$, with one-to-one mapping the remote memory allocation would be $4S$ (*i.e.*, each

page residing in local memory also has a remote page, resulting in a 33% overhead). However, this overhead may not be necessary. For example, modern applications exhibit strong epochal behaviors. Under the original allocator, swap entries for pages accessed in one epoch can be reused for those in another epoch. Under this approach, however, all pages in all epochs must have their dedicated swap entries throughout the execution, which can lead to an order-of-magnitude increase in remote memory usage.

Our key insight is: we should trade off *space for time* if an application has much available swap space, but *time for space* when its space limit is about to be reached. As such, when the remote memory usage is about to reach the limit specified in `cgroup` (*i.e.*, 75% in our experiments), Canvas starts removing reservations to save space. The next question is which pages we should consider first as our candidates for reservation removal. Our idea is that we should first consider “hot pages” that always stay in local memory and are rarely swapped. This is because hot pages (*i.e.*, data on such pages are frequently accessed) are likely to stay in local memory for a long time; hence, locking overhead is less relevant for them. On the contrary, “cold” pages whose accesses are *spotty* are more likely to be swapped in/out and hence swap efficiency is critical. Here “hot” and “cold” pages are relatively defined as they are specific to execution stages—a cold page swapped out in a previous stage can be swapped in and become hot in a new stage.

To this end, we develop an *adaptive allocator*. Canvas starts an execution by reserving swap entries for *all* pages to minimize lock contention. Reservation removal begins when remote-memory pressure is detected. Canvas adaptively removes reservations for hot pages. We detect hot pages *for each application* by periodically scanning the application’s *LRU active list*—pages recently accessed are close to the head of the active list. Each scan identifies a set of pages from the head of the list; a page is considered “hot” if it appears in a consecutive number of sets recently identified.

Removing the reservation for a hot page can be done by (1) removing the entry ID from the page metadata and (2) freeing its reserved swap entry in remote memory, adding the entry back to the free list. Once a hot page becomes cold and gets evicted, it does not have a reservation any more, and hence, it goes through the original (lock-protected) allocation algorithm to obtain an entry. In this case, the page

receives a new swap entry and remembers this new ID in its metadata.

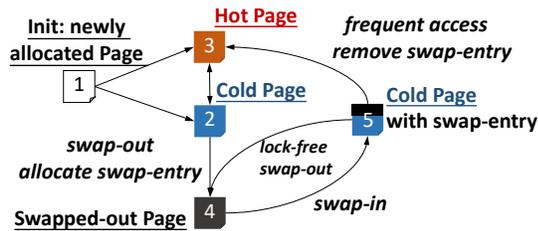

Figure 7: FSM describing our page management when remote-memory pressure is detected.

Figure 7 shows the page state machine, which describes the page handling logic. A cold page (to be evicted) can be in one of the two states: state 2 and state 5. A page comes to state 2 if it is (1) a brand new page that has never been swapped out or (2) previously a hot page but has not been accessed for long. Once it reaches state 2, the page does not have a reserved swap entry ID and hence, swapping out this page goes through the normal allocation path. In the case of swap-in (state 5), the swap entry ID is already remembered on the page. The next swap-out will directly use this entry and be lock-free. If the page becomes hot (from state 5 to 3), Canvas removes the entry ID and releases the entry reservation. The entry is then added back to the free list.

Performance Analysis. To understand the performance of the adaptive entry allocation algorithm, let us consider the following two scenarios. In the first scenario, the application performs uniformly random accesses. As a result, Canvas cannot clearly distinguish hot/cold pages, and thus randomly cancels their reservations. However, due to the random process, when a page is swapped out, it has a certain probability of still possessing a reserved swap entry (depending on the ratio of remaining reservations) and hence Canvas can still improve the allocation performance.

In the second scenario, the application follows a repetitive pattern of accessing a page a few times (making it hot) and then moving on to accessing another page; it will not come back to the page in a long while. Under our allocation algorithm, every page will be identified as a hot page, leading to the cancellation of its reservation. However, each page will be swapped out when it is cold enough; at each swap-out, the page has to go through the original allocation algorithm. This is the worst-case scenario, and even in this case, Canvas has the same (worst-case) performance as the original Linux allocator, which allocates an entry at each swap-out.

Some of the recent patches submitted to the Linux community also attempt to reduce lock contention for swap entry allocation. A detailed description of how Canvas differs from these patches can be found in Appendix B.

5.2 Two-tier Adaptive Prefetching

Problems with Current Prefetchers. Current prefetchers all focus on low-level (streaming or strided) access pat-

terns. While such patterns exist widely in native array-based programs, applications written in high-level languages such as Python and Java are dominated by reference-based data structures—operations over such data structures involve large amounts of pointer chasing, making it hard for current prefetchers to identify clear patterns.

Furthermore, cloud applications such as Spark are heavily multi-threaded. Modern language runtimes, such as the JVM, run an additional set of auxiliary threads, *e.g.*, for GC or JIT compilation. How these user-level threads map to kernel threads is often implemented differently in different runtimes. Consequently, kernel prefetchers such as Leap [73] cannot distinguish patterns from different threads.

To develop an adaptive prefetcher, Canvas employs a two-tier design, illustrated in Figure 8. At the low (kernel) tier, Canvas uses an existing kernel prefetcher that prefetches data for each application into its own private swap cache (unless data comes from the global swap partition). A kernel prefetcher is extremely efficient and can already cover a range of (array-based) applications. For applications whose accesses are too complex for the kernel prefetcher to handle, we forward the addresses up to the application level, letting the application/runtime analyze semantic access patterns at the level of threads, references, arrays, *etc.*

Prefetching Logic. In Canvas, we adopt the sync/async separation design in Fastswap [8], which prevents head-of-line blocking. As stated earlier, we use three PQPs per core, one for swap-out, one for (sync) demand swap-in, and one for (async) prefetching. Canvas polls for completions of critical (demand) operations, while configuring *interrupt completions* for asynchronous prefetches.

Canvas determines whether to use an application-tier prefetcher based on *how successful kernel-tier prefetching is*. If the number of pages prefetched for an application is lower than a threshold at the most recent $N (=3$ in our evaluation) faults consecutively, Canvas starts forwarding the faulting addresses up to the application-tier prefetcher (discussed shortly) although the kernel-tier prefetcher is still used as the first-line prefetcher.

Canvas stops forwarding whenever the kernel-tier prefetcher becomes effective again. Our key insight is: the kernel-tier prefetcher is efficient without needing additional compute resources (as it uses the same core as the faulting thread), while the application-tier prefetcher needs extra compute resources to run. As such, we disable application-tier prefetchers as long as the kernel-tier prefetcher is effective. To pass a faulting address to the application, we modify the kernel’s `userfaultfd` interface, allowing applications to handle faults at the user space. Our modification makes the kernel forward the faulting address only if the kernel’s prefetcher continuously fails to prefetch pages.

Runtime Support for Application-tier Prefetching. A major challenge is how to develop application-tier prefetchers. On the one hand, application-tier prefetchers should conduct

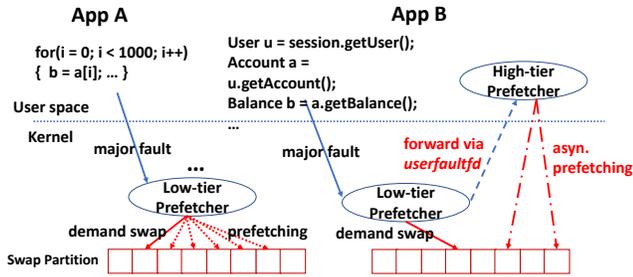

Figure 8: Canvas’s two-tier prefetcher: App A is an array-based program while B is a modern web application that uses reference-based data structures. The low-tier prefetcher successfully prefetches pages for A, but not for B. Hence, Canvas forwards the addresses up to B’s high-tier prefetcher.

prefetching based on *application semantics*, of which the kernel is unaware. On the other hand, application developers may not be familiar with a low-level activity like prefetching; understanding memory access patterns and developing prefetchers can be a daunting task for them.

Our insight is: applications that benefit from application-tier prefetching are mostly written in high-level languages and run on a managed runtime such as the JVM. Inspired by previous work on using language runtime to solve memory efficiency problems for data analytics applications [81, 78, 82, 80, 72], Canvas currently supports application-tier prefetching for the JVM as a platform. However its support could be easily extended to other managed runtimes for high-level languages like Go and C#. Leveraging language runtime solves both problems discussed above—it has access to semantic information such as how objects are connected and the number of application threads; furthermore, the burden of developing an application-tier prefetcher is shifted from application developers to runtime developers. Thus, it is not necessary to supply a custom application-tier prefetcher per application, but define it once for each language runtime.

In this work, we develop an application-tier prefetcher in Oracle’s OpenJDK as a proof-of-concept. It works for all (Java, Scala, Python, *etc.*) programs that run on the JVM. Our JVM-based prefetcher considers two *semantic patterns*: (1) *reference-based* (*i.e.*, accessing an object brings in pages containing objects referenced by this object) and (2) *thread-based* (*i.e.*, accesses from different application threads are separately analyzed to find patterns).

For (1), we modify the JVM to add support that can quickly find, from a faulting address, *the object* in which the address falls. We use write barrier, a piece of code instrumented by the JVM at each object field write, as well as the garbage collector to record references between pages. For example, for each write of the form $a.f = b$, if the objects referenced by a and b are on different page groups, we record an edge on a *summary graph* where each node represents a consecutive group of pages and each edge represents references between groups. During prefetching, we traverse

the graph from the node that represents the accessed page and prefetch pages that can be reached within 3 hops. The traversal does not follow cycles and its overhead is negligible. This approach is suitable for applications that store a large amount of data in memory, such as Spark and Cassandra.

For (2), we leverage the JVM’s user-kernel thread map. For each faulting address, Canvas additionally forwards the thread information (*i.e.*, pid) to the JVM, which consults the map to filter out non-application (*e.g.*, GC, compilation, *etc.*) threads and segregate addresses based on Java threads (as opposed to kernel threads). Segregated addresses allow us to analyze (sequential/strided) patterns on a per-thread basis (using Leap’s majority-vote algorithm [73]). Once patterns are found, the prefetcher sends the prefetching requests to the kernel via `async_prefetch`.

For native programs that directly use kernel threads (*e.g.*, `pthread`), the thread information is straightforward and immediately visible to Canvas. We can easily segregate addresses accessed from different threads and analyze patterns based upon addresses from each individual thread.

Policy. To improve effectiveness, the JVM uses a search tree to record information about large arrays. Upon the allocation of an array whose size exceeds a threshold (*i.e.*, 1MB in our experiments), the JVM records its starting address and size into the tree. The JVM runs a daemon prefetching thread. Once receiving a sequence of faulting addresses, we determine which semantic pattern to use based on *how many application threads are running* and *whether the faulting addresses fall into a large array*. If there are many threads and the faulting addresses fall into arrays, the JVM uses (2) to find per-thread patterns. If either condition does not hold, the JVM uses (1) to prefetch based on references. For native applications, we only enable (2), as we observed that our native programs do not use many deep data structures.

5.3 Two-Dimensional RDMA Scheduling

To provide predictable performance for applications sharing RDMA resources, our RDMA scheduling algorithm should provide four properties: (1) weighted fair bandwidth sharing [18, 30] across applications; (2) high overall utilization; (3) treating demand and prefetching requests with different priorities; and (4) timely handling of prefetching requests.

Canvas performs two-dimensional scheduling by extending existing techniques. Canvas uses max-min fair scheduling to assign bandwidth across applications, and priority-based scheduling with *timeliness* to schedule prefetching and demand requests within each application. Although these scheduling techniques are not new themselves, Canvas combines them in a unique way to solve the interference problem. Canvas maintains three PQPs on each core, respectively, for swap-outs, demand swap-ins, and prefetching swap-ins. Swap-outs are only subject to fair scheduling while swap-ins are subject to both fair and priority-based scheduling.

Vertical: Fair Scheduling. Under max-min fairness, each application receives a fair share of bandwidth. If there is extra bandwidth, we give it to the applications in the reverse order of their bandwidth demand until bandwidth is saturated. The high overall utilization of bandwidth is achieved by redistributing unconsumed bandwidth proportionally to the weights of unsatisfied applications. Canvas implements weighted fair queuing with virtual clock [84, 30, 110].

Horizontal: Priority Scheduling with Timeliness. Within each `cgroup`, Canvas schedules demand requests with a higher priority than prefetching requests. However, this could lead to long latency for prefetching requests. To bound the latency of prefetching, our scheduler employs a history-based heuristic algorithm to identify and drop outdated prefetching requests. In particular, Canvas maintains the *timeliness distribution* of prefetched pages per `cgroup`. Timeliness is a metric that measures the time between a page being prefetched and accessed. We attach a timestamp to each request when pushing it into a VQP. The scheduler maintains packets statistics on-the-fly to estimate the round-trip latency and arrival time of each prefetching request. Requests are dropped if the estimated arrival time exceeds the estimated timeliness threshold.

Special care must be taken to drop prefetching requests. Before issuing a prefetching request, the kernel creates a page in the swap cache and sets up its corresponding PTE. The page is left in a *locked* state until its data comes back. However, a thread that accesses an address falling into the page may find this locked page in the swap cache and block on it. Dropping prefetching requests may cause the thread to hang. To solve the problem, we detect threads that block on prefetching requests for too long and generate new *demand requests* for them.

We rely on a per-entry timestamp to efficiently detect threads that block on prefetching requests. In Canvas, we attach a timestamp field to the swap entry metadata. Canvas’s scheduler records the timestamp every time it enqueues a prefetching request into VQP. If another thread faults on the same page later, it will retrieve the same swap entry from the PTE. If the swap entry contains a timestamp, the faulting thread knows that a prefetching request has already been issued. Next, the faulting thread calculates the time elapsed since the timestamp, and compares it with a timeout threshold (maintained by the RDMA scheduler based on page-fetching latencies). If it exceeds the timeout threshold, the faulting thread drops the prefetching request. The drop operation is elaborated below:

Before issuing each (demand or prefetching) request, the kernel first allocates a physical page in the swap cache and locks the page until the request returns. Upon the return of the data, the data is written into the page; the page is unlocked and mapped into the page table. In order to safely drop a request, we add another field *valid* in the swap entry metadata, indicating whether the prefetching request on

the go is valid. Once a faulting thread identifies a delayed prefetching request (by using the timestamp as discussed above), it sets the *valid* field in the swap entry to `false` and then creates a new physical page in the swap cache. The thread goes ahead and issues another (demand) I/O request based on this new page. When the delayed prefetching request returns, it checks the *valid* field and discards itself once it sees the false value. The field is then set back to `true`.

When a demand request is issued, Canvas clears the timestamp field in its corresponding swap entry. If a thread faults on the same page, it will block on the request instead of issuing a new one due to the empty timestamp (indicating that the request on the go is a demand one).

6 Evaluation

It took us 17 months to implement Canvas in Linux 5.5. The application-tier prefetcher was implemented in OpenJDK 12.

Application	Workload	Dataset	Size / (E , V)
Managed			
Cassandra	5M read, 5M insert	YCSB[26]	10M records
Neo4j	PageRank	Baidu[5]	(17M, 2M)
Spark	PageRank (SPR)	Wikipedia[5]	(57M, 1.5M)
	KMeans (SKM)	Wikipedia[5]	188M points
	Logistic Regression (SLR)	Wikipedia[5]	188M points
	Skewed Groupby (SSG)	synthetic	256K records
	Triangle Counting (GTC)	synthetic	(1.5M, 384K)
MLlib	Bayes Classifiers (MBC)	KDD [3]	1.5M instances
GraphX	Connected Components (GCC)	Wikipedia[5]	(188M, 9M)
	PageRank (GPR)	Wikipedia[5]	(188M, 9M)
	Single Src. Shortest Path (GSP)	synthetic	2M vertices
Native			
XGBoost	Binary Classification	HIGGS[12]	22M instances
Snappy	Compression	enwik9 [1]	16GB
Memcached	45M gets, 5M sets	YCSB[26]	10M records

Table 2: Programs and their workloads.

Setup. We included a variety of cloud applications in our experiments, including managed (Java) applications such as Spark [109], Cassandra [10] (a NoSQL database), Neo4j [79] (a graph database), as well as three native applications: XGBoost [23], Snappy [38], and Memcached [4]. Spark, Cassandra, Neo4j, Memcached, and XGBoost are multi-threaded while Snappy is single-threaded. The Spark applications span popular libraries such as GraphX and MLlib.

We co-ran different combinations of programs. The same application in different combinations receives the same amount of local (CPU and memory) resources. To simplify performance analysis, we let each combination of applications co-run contain one managed (Spark, Cassandra, or Neo4j) application and the three native programs, which consume less resources. These experiments were conducted on two machines, one used to execute applications and a second to provide remote memory. The configurations of these machines was reported earlier in §3. We carefully configured Linux with the following configuration to achieve the best performance for Linux: (1) SSD-like swap model, (2) per-VMA prefetching policy, and (3) cluster-based swap en-

try allocation. We disabled hyper-threads, CPU C-states, dynamic CPU frequency scaling, transparent huge pages, and the kernel’s mitigation for speculation attacks.

For each combination, we limited the amounts of CPU resources for the managed application, XGBoost, Memcached, and Snappy to be 24, 16, 4, and 1 core(s). For local memory, we used two ratios: 50% and 25%, meaning each application has 50/25% of its working set locally. When using Canvas, we additionally limited the sizes of swap partitions in such a way that for each application the total size of its swap partition and assigned local memory is slightly larger than its working set. In doing so, each application has just enough (local and remote) memory to run and reservation cancellation (§5.1) is triggered in all executions.

The swap cache size for each application starts at 32MB and changes dynamically. The global swap cache size (configured by `cgroup-share`) was also set to 32MB. Canvas uses max-min fair scheduling to assign bandwidth across applications, and their initial weights are proportional to their swap partition assignments. We ran each application 10 times. Their average execution times (with error bars) are reported in all experiments throughout this section.

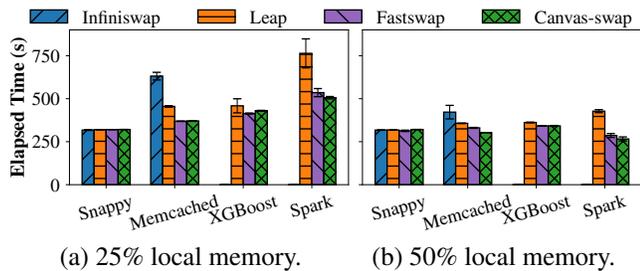

Figure 9: Performance of different swap systems.

6.1 Basic Swap Systems

We used Fastswap [8] as our underlying swap system, with a small amount of code changes to port Fastswap (originally built against Linux 4.11) to Linux 5.5. We first compared the performance of each individual application running on basic swap systems including Infiniswap [39], Infiniswap with Leap [73], the original Fastswap [8], and Canvas’s ported Fastswap (without isolation and optimizations). We could not run LegoOS [91] as it does not support network-related system calls, which are required for applications such as Spark. LegoOS implements swaps with RPCs as opposed to paging, but our idea (*i.e.*, isolation and adaptive swapping) is applicable to this approach as well.

We ran Infiniswap and Leap on Linux 4.4, and Fastswap on Linux 4.11. The results are reported in Figure 9. Infiniswap hung on XGBoost and Spark, and its corresponding bars are thus not reported in Figure 9. Since Canvas-swap was built off Fastswap, they have similar performance.

6.2 Overall Performance

Next, we demonstrate the overall performance when applications co-run together under Canvas. Each experiment ran the same set of three native programs with one managed application: Spark-LR, Spark-KM, Cassandra, or Neo4j. The results for the 25% and 50% local memory configurations are reported in Figure 10(a) and (b), respectively.

The four bars in each group represent an application’s performance when running alone on Linux 5.5, co-running with other applications on Linux 5.5, co-running on the original Fastswap, and co-running on Canvas (with all optimizations enabled). Across all experiments, Canvas improves applications’ co-run performance by up to $6.2\times$ (average $3.5\times$) and up to $3.8\times$ (average $1.9\times$) under the two memory configurations. Canvas enables Spark and Neo4j to even outperform their individual runs due to the optimizations that could also improve single-application performance.

6.3 Isolation Reduces Degradation and Variation

This experiment measures the effectiveness of isolation alone. We used a variant of Canvas with the isolated swap system and RDMA bandwidth (*i.e.*, vertical scheduling between applications) but without our swap-entry optimization, two-tier prefetcher, and horizontal RDMA scheduling.

Degradation Reduction. We ran the same set of experiments under 25% local memory. As shown in Figure 11, isolation reduces the running time by up to $5.2\times$, with an average of $2.5\times$. Isolation is particularly useful for applications that do not have many threads but need to frequently access remote memory, such as Memcached, which has 4 threads and cannot compete for resources with managed applications such as Spark and Cassandra, which have more than 90 (application and runtime) threads. As such, its performance is improved by $3.3\times$ with dedicated swap resources. Isolation improves the average RDMA utilization by $2.8\times$ from 692MB/s to 1908MB/s, making the peak bandwidth reach 4494MB/s.

Table 3: Performance variations of three native applications when co-running with each of the 11 managed applications under 25% local memory (Canvas / Linux 5.5 / Fastswap).

Program	Mean			Min			Max			σ		
Snappy	1.07	1.28	1.23	1.03	1.10	1.08	1.23	1.69	1.46	0.07	0.20	0.14
Memcached	1.45	3.24	3.76	1.30	1.48	2.05	1.91	6.05	8.17	0.20	1.82	2.14
XGBoost	1.05	3.17	2.81	1.01	1.38	1.91	1.13	6.13	4.76	0.04	1.59	1.11
Overall	1.21	2.56	2.60	1.01	1.10	1.08	1.91	6.13	8.17	0.23	1.64	1.72

Variation Reduction. One significant impact of interference is performance variation—the same application has drastically different performance when co-running with different applications (as shown in Figure 2). To demonstrate our benefits, we co-ran the three native applications with each of the eleven managed applications listed in Table 2, which cover a wide spectrum of computation and memory access behaviors. Table 3 reports various statistics of their perfor-

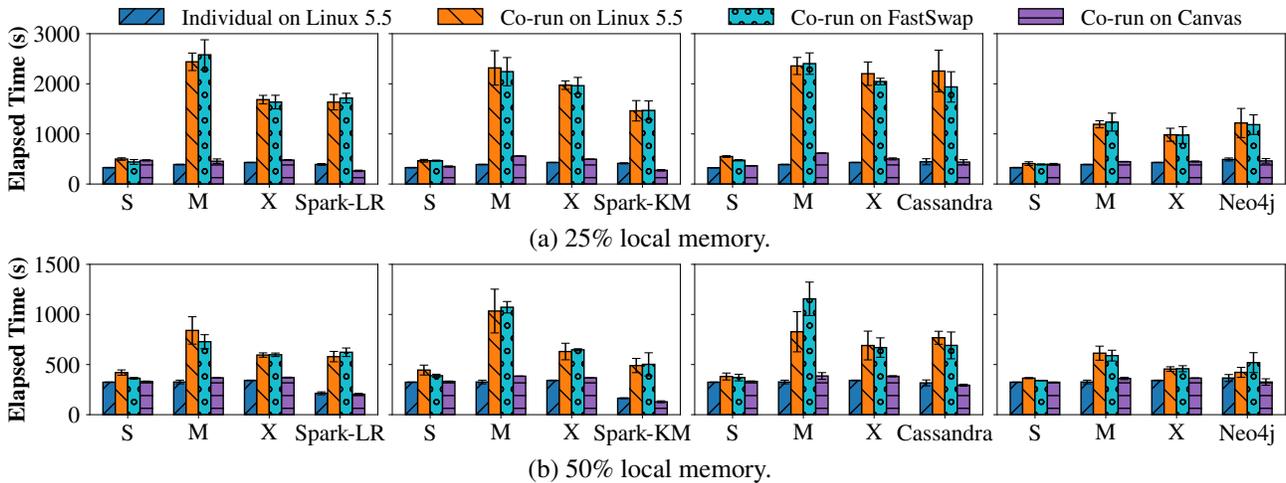

Figure 10: Performance of each program under 25% and 50% local memory when the three native programs, Snappy (S), Memcached (M), and XGBoost (X), co-run with a managed application. Canvas ran with all optimizations enabled.

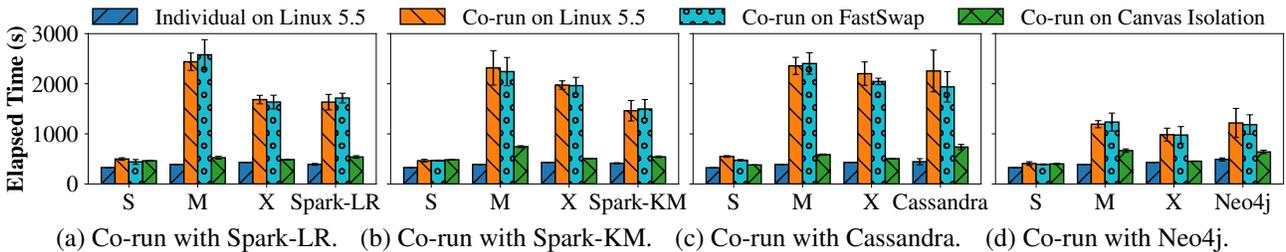

Figure 11: Performance of native applications co-run with different managed applications under 25% local memory; for Canvas, only isolation was enabled (*i.e.*, without adaptive optimizations).

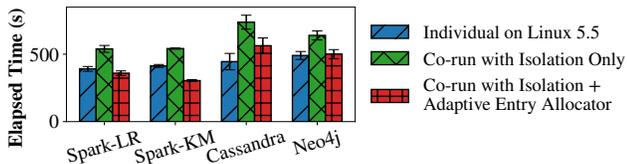

Figure 12: Benefit of adaptive swap entry allocation. Compared are the times of the application running individually on Linux 5.5, co-running on Canvas with adaptive entry allocation disabled, and enabled.

mance including the mean, minimum, maximum, and standard deviation of their slowdowns (compared to their individual runs). Clearly, the performance of the three programs is much more stable (indicated by a small σ) under Canvas than Linux—variations are reduced by $7\times$ overall.

6.4 Effectiveness of Adaptive Optimizations

This subsection evaluates the benefit of each swap optimization *on top of the isolated swap system* by turning it on/off.

6.4.1 Adaptive Swap Entry Allocator

Isolation already reduces lock contention at swap entry allocation because each process has its own swap entry manager. However, for multi-threaded applications such as Spark and

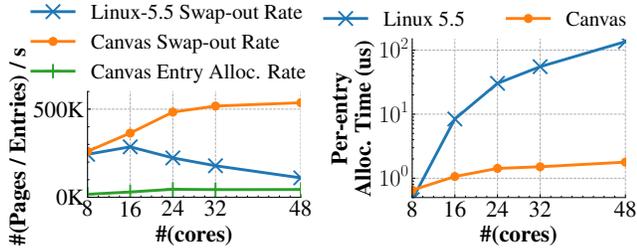

Cassandra, their processing threads still have to go through the locking process. In this subsection, we focus on managed applications due to their extensive use of threads. Figure 12 shows the performance of Spark LR, Spark KM, Cassandra, and Neo4j when they each co-run with the other three native programs. On average, our adaptive allocation enables an *additional* boost of $1.50\times$ for Spark LR, $1.77\times$ for Spark KM, $1.31\times$ for Cassandra, and $1.28\times$ for Neo4j.

Table 4: Swap-out throughput w/ and w/o adaptive swap-entry allocation when native programs co-run with Spark.

Thruput (KPages/s)	Linux 5.5	Canvas w/o adap. alloc.	Canvas w/
Avg. Spark apps	98	164	295
Avg. all apps	185	309	468

Table 4 reports the swap-out throughput when the native applications co-run with Spark. As shown, isolation improves the throughput by $1.67\times$ while adaptive allocation provides an additional boost of $1.51\times$. This benefit is obtained after applying all optimizations in Linux 5.5.

Effectiveness of Entry Reservation. We compared our adaptive allocation algorithm with the original allocator in Linux 5.5 by running Memcached with varying (8 – 48) cores under 25% local memory. As shown in Figure 13(a), for Canvas,

(a) Swap-out and entry alloc rates. (b) Per-entry alloc time.

Figure 13: Entry allocation comparison between the allocation algorithm in Canvas and Linux 5.5 for Memcached under 25% local memory. The Y-axis in (b) is log-scaled.

(1) the swap-out rate increases with the core number (showing good scalability) and (2) the swap entry allocation rate remains low. This is due to Canvas’s entry reservation algorithm that effectively reuses a significant number of swap entries for page swap-outs. On the contrary, in Linux 5.5, the swap-out rate (which is the same as its entry allocation rate) decreases when more cores are used. This is because each entry allocation takes significantly longer, reducing the swap-out throughput. A comparison of per-entry allocation time can be seen in Figure 13(b). We additionally compared the allocation algorithm between Canvas, Linux 5.5, and Linux 5.14; these results are reported in Appendix B.

6.4.2 Prefetching Effectiveness

Our baseline is the kernel’s default prefetcher on the isolated swap system with adaptive swap allocator *enabled*. Since application-tier prefetching is designed primarily for high-level languages, here we focus on managed programs.

Time. We compare the running time for three Spark applications LR, KM, TC, and Neo4j, between the kernel’s prefetcher over Canvas’s isolated swap system and Canvas’s two-tier prefetcher, when each managed application co-runs with the three native applications under the 25% local memory configuration. Application-tier prefetching brings **33%**, **17%**, **19%**, and **8%** additional performance benefits on top of the kernel prefetching with the isolated swap system. All the four managed applications benefit from the thread-level pattern analysis while the managed applications have seen 5-9% contributions from using the reference-based pattern. The thread-level pattern analysis we added for native programs brings a 5% and 11% improvement for Memcached and XGBoost.

We have also run Leap [73], a prefetcher that aggressively prefetches a number of contiguous pages if it cannot find any pattern. This approach may work for native applications because these applications access arrays; hence, the contiguous pages aggressively prefetched are likely to be useful for array accesses. However, it works poorly for high-level language applications such as Spark and Neo4j, which use deep data structures and run graph-traversal GC tasks (which exhibit neither sequential nor strided patterns). Aggressively

prefetching useless pages wastes the RDMA bandwidth and the swap cache. Leap slows down our managed applications by 1.4 \times , compared to the kernel’s default prefetcher.

Table 5: Prefetching contribution and accuracy when different Spark and Neo4j co-run with native applications.

Contribution	Spark-LR	Spark-KM	Spark-TC	Neo4j
Leap	23.4%	25.8%	42.2%	67.0%
Kernel	63.3%	68.0%	65.9%	41.1%
Canvas Two-tier	79.2%	79.3%	75.3%	45.0%
Accuracy	Spark-LR	Spark-KM	Spark-TC	Neo4j
Leap	16.8%	17.2%	35.9%	6.1%
Kernel	95.6%	96.4%	93.9%	80.4%
Canvas Two-tier	94.3%	94.8%	94.9%	87.1%

Prefetching Contribution and Accuracy. Table 5 compares prefetching *contribution* and *accuracy* for the four managed applications when each of them co-runs with the same three native applications. Contribution is defined as a ratio between the number of page faults hitting on the swap cache and the total number of page faults (including both cache hits and demand swap-ins). Accuracy is defined as a ratio between the number of page faults hitting on the swap cache and the total number of prefetches. Clearly, contribution has a strong correlation with performance while accuracy measures the pattern recognition ability of a prefetcher. For example, for a conservative prefetcher that prefetches pages only if a pattern can be clearly identified, it can have a high accuracy (*i.e.*, prefetched pages are all useful) but a low contribution (*i.e.*, the number of prefetches is small).

Here we report prefetching contribution and accuracy for three prefetchers: Leap (on our isolated swap system), the kernel prefetcher (also on our isolated swap system), and Canvas’s two-tier prefetcher. Among the three prefetchers, for all but Neo4j, Leap has the lowest accuracy and contribution because it is an aggressive prefetcher. Leap keeps prefetching pages even when it cannot detect any patterns, which greatly reduces the prefetching accuracy. Second, due to the limited swap cache, the useless pages prefetched can cause previously prefetched pages to be released before they are accessed, hurting contribution. The kernel prefetcher and Canvas have comparable accuracy because the kernel prefetcher is much more conservative than Leap. It stops prefetching when no clear pattern can be observed. However, Linux has lower contribution than our two-tier prefetcher since Canvas prefetches more useful pages using semantics.

6.4.3 RDMA Scheduling

We evaluate our two-dimensional RDMA scheduling. For the vertical dimension, we use the weighted min-max ratio (WMMR) $\frac{\min(x_i/w_i)}{\max(x_i/w_i)}$ [96] as our bandwidth fairness metric (the closer to 1, the better), where x_i is the bandwidth consumption of the application i , and w_i is its weight. We set the

weight proportionally to the average bandwidth of each application when running individually. Our vertical scheduling achieves an overall of **0.88** WMMR.

The horizontal dimension (*i.e.*, priority scheduling with timeliness) is our focus here because interference between prefetching and demand swapping is a unique challenge we overcome in this work. We ran GraphX Connected Components (GraphX-CC) with the three native applications. Figure 14 compares the latency of sync vs. async swap-in requests with and without the horizontal scheduling of RDMA.

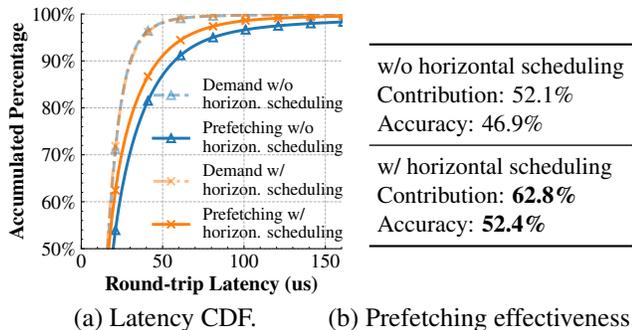

Figure 14: Horizontal scheduling effectiveness for GraphX-CC: (a) prefetching latency reduced, and (b) prefetching contribution and accuracy improved.

As shown, our scheduler does *not* incur overhead for the synchronous, demand requests but reduces the (90th percentile) latency of the asynchronous prefetching requests by $\sim 5\%$. Note that these results were obtained with Canvas’s two-tier prefetcher enabled, which already generates precise prefetching requests. With the Leap prefetcher, the (90th percentile) latency reduction can be as high as $9\times$. To understand how the latency reduction improves prefetching effectiveness, we have also compared the prefetching contribution and accuracy with and without the horizontal scheduling, as shown in Figure 14(b). Due to the high timeliness requirement of prefetching requests, even 5% latency reduction can lead to noticeable improvements in prefetching—*e.g.*, the contribution/accuracy of GraphX-CC increases by **10.7%** and **5.5%** on top of the two-tier prefetcher—which ultimately translate to a **7-12%** overall improvement.

7 Related Work

Remote Memory. The past few years have seen a proliferation of remote-memory systems that built on the kernel’s swap mechanisms (including recent works such as LegoOS [91], Infiniswap [39], Fastswap [8], and Semeru [104] as well as earlier attempts [32, 6, 31, 34, 28, 45, 61, 105]). Remote memory is part of a general trend of resource disaggregation in datacenters [43, 21, 36, 14, 11, 66, 65, 58, 7, 9, 83, 95], which holds the promise of improving resource utilization and simplifying new hardware adoption. Under disaggregated memory, application data are stored on memory servers, making swap interference a more serious problem.

Resource Isolation. Interference exists in a wide variety of settings [29, 69, 111] and resource isolation is crucial for delivering reliable performance for user workloads. There is a large body of work on isolation of various kinds of resources including compute time [64, 16, 25], processor caches [35, 57, 106], memory bandwidth [67, 68, 71, 50, 107], I/O bandwidth [40, 96, 70, 74, 97, 103, 108], network bandwidth [13, 41, 37, 94, 87, 77, 53], congestion control [27, 44], as well as CPU involved in network processing [59]. Techniques such as IX [17] and MTCP [52] isolate data-plane and application processing at the core granularity.

Prefetching. Prefetching has been extensively studied, in the design of hardware cache [101, 42, 114, 100, 76], compilers [98, 63, 89, 86, 60, 33], as well as operating systems [102, 73]. Detecting spatial patterns [75] is a common way to prefetch data. For example, various hardware techniques [93, 54, 51] have been developed to identify patterns (*i.e.*, sequential or stride) in addresses accessed. Leap [73] is a kernel prefetcher designed specifically for applications using remote memory. Swap interference can reduce the effectiveness of any existing prefetchers, let alone that none of them consider complex (semantic) patterns. Early work such as [85, 20] proposes application-level prefetching for efficient file operations on slow disks. Our prefetcher is, however, designed for a new setting where applications trigger page faults frequently and read pages from fast remote memory, with much tighter latency budgets.

RDMA Optimizations. There is a body of recent work on RDMA scheduling [88, 92] and scalability improvement [99, 24, 56, 55, 113]. These techniques focus more on scalability when RDMA NICs are shared among multiple clients.

8 Conclusion

We observed swap resources must be isolated when multiple applications use remote memory simultaneously. As such, Canvas isolates swap cache, swap partition, and RDMA bandwidth to prevent applications from invading each other’s resources. Now that resource accounting is done separately for applications, Canvas offers three optimizations that adapt kernel operations such as swap-entry allocation, prefetching, and RDMA scheduling to each application’s resource usage, providing additional performance boosts.

A Extended Motivation

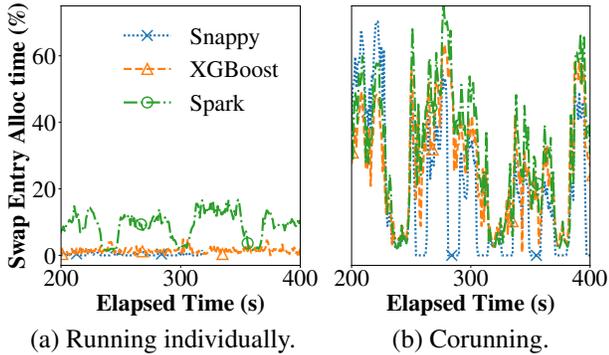

Figure 15: Percentage of time spent on swap entry allocation when applications run individually (a) and together (b).

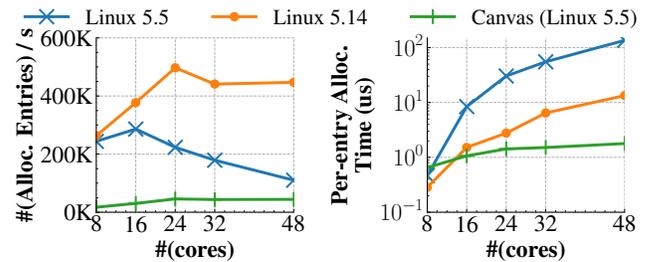

Figure 15 compares the percentage of time spent on swap entry allocation between individual runs and co-runs under Linux 5.5. As shown, each application, when co-run with other applications, spend significantly more time on allocating swap entries due to the increased locking time.

B Recent Kernel Development

As an optimization in Linux 5.5, the kernel keeps swap entries for clean pages—when clean pages are evicted, they do not need to be written back if their swap entries are not released for other allocations. Once a page becomes dirty, its swap entry must be immediately released. Clearly, this approach works for read-intensive applications where most pages are clean, but not for write-intensive workloads such as Spark. We tried various entry-keeping thresholds (*i.e.*, entry keeping starts when the percentage of available swap entries exceeds this threshold) between 25% and 75%, and saw only marginal performance differences (<5%) across our programs.

We have closely followed the kernel development since the release of Linux 5.5 and found two recent patches related to our approach. These two patches, submitted by Intel and merged into the kernel at 5.8, also attempt to optimize locking overhead at swap entry allocation. The idea of the first patch [48] is using fine-grained locking—dividing swap entries into *clusters* and assigning each core a random cluster upon an allocation request. The second patch [46] performs batch entry allocation by scanning more swap entries while holding the lock to make each batch larger. Note that our adaptive allocation algorithm solves a much bigger problem than these patches—Canvas *avoids* allocating entries for most swap-outs, while these patches reduce the overhead of locking for each allocation. As such, Canvas is completely lock-free for reserved entries while these patches must still go through the allocation path, requiring locking if multiple cores are assigned the same cluster (*i.e.*, core collision).

In fact, the probability of collision increases quickly with the number of cores. As shown below in Figure 16, the allocation performance of these patches degrades super-linearly when the number of cores exceeds 24. Another major drawback is that none of these patches build on isolated swap partitions. Lack of swap partition isolation makes applications search for swap entries globally, which can still result in interference—applications such as Spark can quickly saturate these clusters with all its executor threads, making other applications wait before they can obtain the locks. By reserving entries, our algorithm significantly reduces the number of entry allocation requests (due to entry reusing) and the cost of each allocation (due to reduced lock contention).

(a) Swap entry allocation rate. (b) Per-entry allocation time.

Figure 16: Entry allocation comparison between Canvas and the allocation algorithm when Memcached runs on Linux 5.14 on RAMDisk.

Comparison with Linux 5.5 and Linux 5.14. As the kernel is fast evolving and our latest InfiniBand driver is only compatible with Linux 5.5, we compared the swap-entry allocation performance between Canvas, Linux 5.5, and the latest Linux 5.14 over RAMDisk, by running Memcached with varying (8 – 48) cores.

As Figure 16(a) shows, our adaptive entry reservation algorithm reduces the allocation rate by several orders of magnitude compared to Linux 5.14. Note that the allocation rate under Linux 5.5 drops as the number cores increases because each allocation takes much longer and hence the swap-out throughput (*i.e.*, allocation throughput) reduces (*i.e.*, the application runs slower).

Figure 16(b) compares our algorithm with Linux 5.5 and Linux 5.14 on per-entry allocation time. As shown, the optimization in [48, 46] is unscalable—as the number of cores increases, the per-entry allocation cost increases significantly. In fact, the allocation cost grows superlinearly after 24 cores due to core collision. On the contrary, Canvas’s per-entry allocation cost remains low and stable. With 48 cores, our algorithm outperforms Linux 5.14’s entry allocator (that uses [48, 46]) by 13×.

Hermit: Low-Latency, High-Throughput, and Transparent Remote Memory via Feedback-Directed Asynchrony

Abstract

Remote memory techniques are gaining traction in datacenters because they can significantly improve memory utilization. A popular approach is to use kernel-level, page-based memory swapping to deliver remote memory as it is transparent, enabling existing applications to benefit without modifications. Unfortunately, current implementations suffer from high software overheads, resulting in significantly worse tail latency and throughput relative to local memory.

Hermit is a redesigned swap system that overcomes this limitation through a novel technique called *adaptive, feedback-directed asynchrony*. It takes non-urgent but time-consuming operations (*e.g.*, swap-out, `cgroup` charge, I/O deduplication, *etc.*) off the fault-handling path and executes them asynchronously. Different from prior work such as Fastswap, Hermit collects runtime feedback and uses it to direct how asynchrony should be performed—*i.e.*, whether asynchronous operations should be enabled, the level of asynchrony, and how asynchronous operations should be scheduled. We implemented Hermit in Linux 5.14. An evaluation with a set of latency-critical applications shows that Hermit delivers low-latency remote memory. For example, it reduces the 99th percentile latency of Memcached by **99.7% from 36 ms to 91 μ s**. Running Hermit over batch applications improves their overall throughput by **1.24 \times** on average. These results are achieved without changing a single line of user code.

1 Introduction

Techniques enabling datacenter applications to use remote memory [10, 17, 28, 29, 36, 43, 52, 53, 57] have gained traction due to their potential to break servers' memory capacity wall, thereby significantly improving datacenters' resource utilization. Compared to clean-slate techniques [17, 52] that provide new primitives for developers to efficiently manage remote memory, swap-based techniques [3, 10, 29, 53, 57, 58] that piggyback on existing paging/swap mechanisms in the OS kernel are more practical as they offer transparency, allowing legacy code to run *as is* on a far-memory system.

The main drawback of swap-based remote access is the overhead incurred by the kernel's paging system. For ex-

ample, when running Memcached using Fastswap [10], the current state-of-the-art swapping system for Linux, a remote access takes an average of 14μ s, of which only 9μ s are spent on network (RDMA) operations—the software-induced overhead is *above 50%*! This large fault-handling overhead significantly increases operation latency, precluding the use of remote memory with latency-critical applications.

In addition, long remote-access time can further block subsequent instructions dependent on these accesses, leading to substantial reductions in application throughput. For example, the performance of garbage collection in a managed language runtime is highly sensitive to memory access latency due to its pointer-chasing nature. Reductions in GC performance can lead to delayed object creations, dramatically reducing the application's overall throughput [42, 57, 58].

The underlying reason for such high overhead is a mismatch in the design of today's swap-based paging systems, which originally targeted slow, disk-based storage, and modern datacenter networks (*e.g.*, 100-400 GbE) that can deliver pages much faster. For example, through profiling, we reveal the following performance bottlenecks that persist in Linux (§3):

- **Page reclamation blocks the critical path:** To make room to fault in new pages, the OS must reclaim memory by swapping out cold pages. Linux is designed to handle this asynchronously by swapping out pages in a separate thread. However, when Linux fails to keep up with the demand for new pages, the page fault handler must block and wait for reclamation to finish.
- **Duplication checks are too conservative:** Linux is designed to never make duplicate I/O requests for the same page. Although this occasionally prevents wasted bandwidth, it comes at a high cost in terms of synchronization overhead, such as during swap cache lookup and insertion.
- **Opportunities for batching are not exploited:** Batching can be an effective optimization when it does not harm page fault handling latency. For example, when Linux performs page reclamation, it first selects a set of victim pages and then swaps out each page individually. A better strategy would be to process victim pages in batches, reducing the cost of TLB shootdowns, I/O writes, and `cgroup` accounting.

State of the Art. The conventional wisdom is that software overheads can be overcome by bypassing the ker-

*Part of the work was done when Yifan Qiao interned at Alibaba Group.
◇Corresponding authors.

nel [48, 52, 63]. This approach typically requires application-level modifications or the use of custom APIs, making it impractical to deploy transparently across all applications. Our aim is to answer the following question instead: *Can we eliminate performance bottlenecks in the kernel directly, allowing the benefits of fast remote memory to be exposed to all applications transparently?*

Recent work, such as Fastswap [10] and InfiniSwap [29], has made some progress in optimizing the kernel’s swap subsystem, such as the use of RDMA to deliver remote pages more efficiently. Fastswap, the current state-of-the-art, also modifies the Linux Kernel to offload page reclamation to a dedicated core and executes it asynchronously. This increases swap-out efficiency, and reduces the time that a page fault handler must block waiting for reclamation to finish. However, Fastswap leaves other opportunities for asynchrony on the table. In addition, a single, dedicated core is insufficient to accommodate changes in demand for swap-out throughput under time-varying memory pressure, limiting the conditions where Fastswap can perform well (§3).

Insights. This work builds on three insights, all centering around asynchrony. First, asynchrony can be used to reduce the latency of page fault handling. For example, during a page fault, the kernel first looks for the page in the swap cache. If the page is present, it will be mapped at the faulting address and the kernel does not need to issue a fetch. However, this check is protected by a lock, which incurs a non-trivial overhead. Instead, fetching a page via RDMA, even if the page is already in the swap cache, is extremely fast: its only penalty is slightly wasted network bandwidth (*i.e.*, bandwidth is rarely saturated). By always issuing the fetch asynchronously and overlapping it with the check, we can reduce the fault-handling latency.

Second, only page faults handlings are latency critical, so it is safe to aggressively optimize all other operations for throughput via batching. For instance, when TLB shoot-downs are batched, it reduces the number of interrupts that have to be sent across cores. As another example, RDMA writes of multiple swapped-out dirty pages can be batched into a single transfer. These opportunities are only possible because such operations are conducted asynchronously; otherwise, batching would delay critical swap-in operations.

Third, to achieve optimal performance, the use of asynchrony (*e.g.*, number of cores) must be adjusted dynamically. For example, it is critical that swap-out throughput is perfectly balanced with swap-in throughput. If swap-out throughput is too low, the page fault handler will block and delay the application. If it is too high, it will leave a substantial portion of local memory underutilized, impacting application performance. This is especially challenging because the swapping rate depends on the workload, its inputs, and even the different phases within its execution.

Hermit. This paper presents Hermit, a new paging/swap system that exploits these (previously-unknown) opportuni-

ties for asynchrony. Hermit employs *feedback-directed asynchrony* as the major principle in the paging system design, simultaneously enabling full code transparency (*i.e.*, any legacy code can run *as is*), low remote access latency, and high application throughput. Hermit employs different types of asynchrony to tackle the three bottlenecks (*i.e.*, blocked swap-ins, conservative checks, lack of batching), as elaborated below:

First, page reclamation is moved into a set of reclaim threads, which eagerly evict (least-recently used) pages and aggressively batch expensive operations involved in each swap-out (§4.2). In particular, Hermit batches page unmapping, TLB shutdown, RDMA writes, polling, and `cgroup` uncharging in swap-out threads, reducing the amounts of computation involved in swap-outs and improving their throughput (§4.4).

Second, Hermit opportunistically bypasses the swap-in duplication check and issues I/O read requests eagerly, delaying such checks to the synchronous PTE update stage. Since only one thread can successfully update the PTE, all other competing threads will eventually release their duplicate pages, guaranteeing safety (§4.3).

Third, inspired by optimistic locking [4], Hermit makes page I/O fully asynchronous during swap-in to further reduce latency. We split the swap-in procedure into two components: one that can still successfully run and is reversible even if there are concurrent updates, and a second that may either abort or create irreversible side effects in the presence of concurrent updates. Hermit moves the first component out of the critical section to overlap it with the page I/O (details are in Figure 4). Hermit checks the validity before the critical section finishes (*i.e.*, whether concurrent updates have occurred) and if they have, reverts the speculatively executed operations.

Finally, we create a feedback control system for each type of asynchronous operation, using execution profiles to adjust whether and how asynchrony should be applied. In particular, we use (1) *page turnaround* (*i.e.*, time between a page’s swap-in and previous swap-out), (2) *page-in/-reclamation throughput*, and (3) *conflict rates* (*i.e.*, how often concurrent updates occur), as metrics to adjust our asynchrony in dealing with reclamation timing, reclamation intensity, eager swap-in, conservative checks, respectively. Hermit profiles and collects these signals throughout the execution to dynamically adapt to the application’s changing behaviors.

Results. Hermit was implemented in Linux 5.14 (released August 2021). We have carefully inspected all relevant kernel patches made since then and confirmed that none of them are directly related to Hermit.

We evaluated Hermit with a set of real-world applications including both latency critical (Memcached, SocialNet, and Gdnsd) and batch processing applications (Apache Spark, XGBoost, and Apache Cassandra). Our evaluation on Memcached demonstrates that Hermit outperforms Fastswap [10]

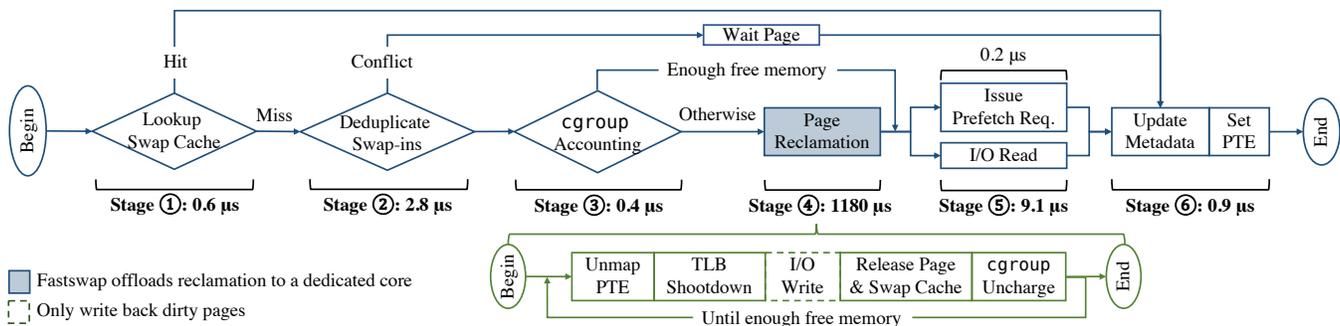

Figure 1: The life cycle of a remote memory page fault in Linux swap.

by **99.7%** in latency, reducing the 99th percentile latency **from 36 ms to 91 μs**. For batch processing applications, Hermit improves throughput by up to **1.87×** with a geometric mean of **1.24×**. Hermit also scales much better with the number of cores than Fastswap. These results demonstrate that low tail latency and high throughput can be achieved at the same time without bypassing kernel, making Hermit a practical solution for enabling remote memory. Hermit is available at <https://github.com/uclastem/hermit>.

2 Background

Today’s datacenter applications expose high load variability and diurnal patterns [13, 14, 47]. Despite low average load, operators have to provision resources for peak demand to avoid violating service-level agreements. Memory is an especially challenging resource because it is *uncompressable*, meaning that running out of it causes tasks to be killed, which can be very disruptive to overall performance [56]. This is a major contributing factor to low memory utilization in today’s datacenters [41, 56].

Remote memory offers a promising solution to improving memory utilization. Its key idea is to break the hardware boundary and unstrand the idle memory of remote machines through fast datacenter networking. Existing systems have demonstrated the feasibility of utilizing remote memory with good performance [10, 17, 52]. Among different approaches to realizing remote memory, the kernel-based approach offers a unique advantage of transparency. It enables existing applications to run as is over remote memory using commodity hardware. This is very attractive to datacenter operators as it significantly lowers the bar for adoption.

The kernel-based approach achieves transparency through paging, an idea that dates back to the 1960s. Originally, paging was designed to extend the addressable memory space with a slow but large secondary storage (usually a mechanical disk). Under memory pressure, the kernel pages out cold pages to disk and marks them as absent from memory. Later, if a process accesses any of those pages, the memory management unit (MMU) raises a page fault exception which transparently traps the control flow into the kernel to page in the data and update the corresponding page table entry (PTE).

Linux implements paging in its swap subsystem, which is often used as the last resort for preventing out-of-memory (OOM) killing. Swap can serve as a temporary mechanism that buys operators time to solve memory pressure, *e.g.*, by migrating or killing processes. The architecture of the paging/swap subsystem has remained relatively stable since its inception. However, in the context of remote memory, fast network-attached memory (4 μs, 12 GB/s) can be used as a secondary storage device as opposed to a slower disk (10 ms, 200 MB/s). Due to this huge performance gap, the legacy swap system is a bottleneck in accessing remote memory. For example, when running Memcached on Fastswap (*i.e.*, the state-of-the-art swap system) with a high local memory ratio (70%), we see a 4× throughput drop.

3 Understanding Existing Swap Systems

3.1 The Life Cycle of Remote Memory Access

The legacy design of Linux swap imposes high overheads on accessing remote memory. To better understand the root cause of its inefficiencies, we conducted a performance study by running Memcached on Fastswap [10] (the state-of-the-art swap system). Figure 1 shows the stages of a remote memory access and breaks down their costs. We discuss each stage in more detail as follows:

- ① **Lookup swap cache.** The swap cache serves as a centralized component that prevents race conditions. It tracks the information of swapped-in pages and ongoing swap-out requests. First, the faulting page may have been fetched by another process or the OS prefetcher. By looking up the swap cache, Linux detects this and jumps to stage ⑥. Second, it is possible that the faulting page is being swapped out by another process. In this case, naively fetching the remote page will see the stale copy. With the swap cache, Linux detects the race and cancels the ongoing swap-out. Looking up the swap cache takes an average of 0.6 μs.
- ② **Deduplicate swap-ins.** At the same time, there can be multiple threads swapping in the same page. Linux guarantees that only one thread can succeed by synchronizing with lock primitives. The remaining threads will be busy waiting until the page gets fetched. This design saves I/O bandwidth

but impacts latency and hurts scalability. This stage takes an average of 2.8 μ s.

③ **cgroup accounting.** Before fetching the page, Linux must ensure that the current process has sufficient free memory by performing cgroup accounting. For the lucky process with enough memory, it jumps to stage ⑤ directly. The accounting stage takes an average of 0.4 μ s. Otherwise, Linux must go through stage ④ to reclaim pages to make room, as elaborated below.

④ **Direct page reclamation.** Linux iteratively reclaims pages until the size of the available local memory is above the low-water mark. Linux swaps out a single page for each iteration. Swap-out is expensive as it involves operations such as TLB shutdown, PTE unmapping, *etc.* This stage exists only when the local memory runs low, but it is also the longest one that takes an average of 1180 μ s. To reduce direct reclamation, Fastswap performs this stage asynchronously with a dedicated core.

⑤ **Fetch and prefetch page.** Linux issues an I/O request to fetch the faulted page. Meanwhile, it may issue multiple prefetching requests. This stage takes an average of 9.1 μ s.

⑥ **Update metadata.** Finally, Linux updates kernel metadata, including page table entries (PTEs), swap entries, and page reverse mapping (`rmap`). This stage takes 0.9 μ s.

3.2 Root Causes of Inefficiencies

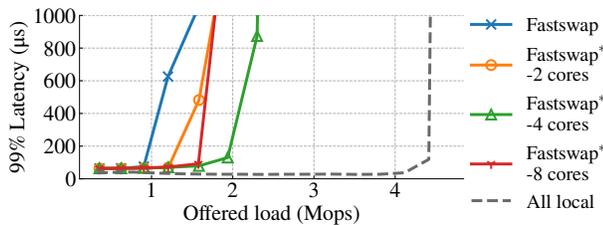

Figure 2: 99th percentile latency with respect to offered load of Memcached on Fastswap under 70% local memory.

To understand the bottleneck imposed by Fastswap’s single, dedicated reclamation core, we ran several experiments with Memcached. Figure 2 shows Memcached’s 99th percentile latency with respect to its offered load when running with 70% local memory. The baseline for comparison is Memcached running locally (100% local memory without swapping), which is the rightmost curve and achieves >4.4 Mops load throughput with good tail latency. Memcached on Fastswap (the blue curve), however, can only offer \approx 1 Mops load before the dedicated core gets saturated and its latency increases dramatically. The reason is that Fastswap’s single dedicated core cannot keep up with the increasing demand for page reclamation. We then modified Fastswap’s original implementation to offload page reclamation onto multiple cores, denoted as `Fastswap*` in the figure, as a naïve strawman approach.

Using more dedicated cores can indeed help reduce the direct reclamation ratio, as shown in Figure 3. With 4 dedicated cores, `Fastswap*` is able to eliminate direct page

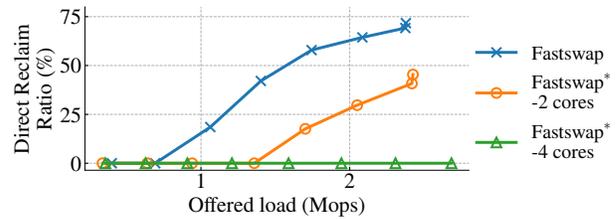

Figure 3: Direct page reclamation ratio of Memcached on Fastswap under 70% local memory.

reclamation, thus providing the highest throughput among all Fastswap variants. However, Fastswap uses static core provisioning, which is insufficient in practice due to the phased behaviors and shifts in load that occur within datacenter applications. First, the number of required dedicated cores depends on the application’s working set, the available local memory, and the swap-in intensity, making it impossible for a statically determined number to work universally for different applications or even different phases of the same application. Second, over-provisioning dedicated cores does not always lead to greater end-to-end performance; in many cases, using more cores only shifts the bottleneck from page reclamation to the application itself, as more dedicated cores for reclamation imply fewer available cores for application threads. As shown in Figure 2, increasing the number of dedicated cores in Fastswap from 1 to 4 (`Fastswap* -4 cores`) improves performance, but further allocating cores degrades performance (`Fastswap* -8 cores`). Furthermore, although `Fastswap* -4 cores` eliminates direct page reclamation (*i.e.*, reducing latency), it still loses \sim 45% performance (*i.e.*, reducing throughput). The performance loss is due to three major kinds of inefficiencies induced by Linux swap, as elaborated below.

Swap-out blocks swap-in. As explained earlier, Memcached experiences high memory access latency when running short of local memory, as it has to reclaim pages. Page reclamation is expensive as it requires finding victim pages and unmapping them, followed by a number of expensive operations for consistency such as TLB shutdown. This significantly impacts its tail latency, leading to violations of the service-level agreement (SLA).

Fastswap tackles this issue by allocating a dedicated core to reclaim pages asynchronously in the background. However, as discussed earlier, it is nearly impossible to statically identify the optimal number of cores due to load variability.

Unoptimized for fast I/O. Linux swap was designed for slow secondary storage like hard-disk drives whose performance is two to three orders of magnitude lower than today’s remote memory in both bandwidth and latency. Since disk bandwidth is often the bottleneck, Linux applies aggressive optimizations in its page fault handling path to reduce I/O traffic (stage ②). While they were effective in the era of slow disks, these optimizations become irrelevant in the context of remote memory whose bandwidth is close to the bandwidth of main memory. Even worse, the outdated op-

timization generates an adversarial performance impact; it prolongs remote memory access latency, hurting scalability (*e.g.*, due to synchronization). For latency-critical applications like Memcached, prolonged remote memory accesses can significantly increase the time for serving incoming requests, imposing super-linear effects on tail latency. Modeled by queueing theory [24], for instance, 10% longer service time can potentially double the 99th percentile latency, leading to vast SLA violations.

Additionally, since the disk latency (ms-scale) is significantly higher than the CPU time in page fault handling (μ s-scale), Linux adopts a serial-execution model for simplicity. As shown in Figure 1, the I/O read stage is executed separately from other stages; after issuing the I/O read request, Linux either busy waits for the I/O response or re-schedules the faulting thread (which hurts latency of fast I/O requests), relinquishing the opportunity of overlapping the waiting period with other stages.

Unoptimized for CPU overhead. Linux swap is a mechanism aimed at avoiding OOM killing. Inherently, treating swapping as a rare event, it was designed to optimize for responsiveness, *not* for CPU efficiency. For example, during page reclamation (stage ④), Linux swaps out only one page at a time, under the assumption that by releasing the space more timely it can unblock the OOM process sooner. Unfortunately, this amplifies the CPU usage as it must invoke expensive operations such as TLB shutdown for *every reclaimed page*. While overhead is acceptable when swapping is rare, it grows significantly in the scenario of remote memory (which is swapping-intensive). In the case of Memcached, 12.6% of the total CPU time is spent on reclaiming pages, not on application tasks. To make matters worse, Linux swap heavily relies on locks to synchronize page reclamation and scales poorly. Hence, the overhead will further increase with the number of concurrent swapping operations.

Key takeaway. Linux swap imposes high overheads to remote memory access primarily due to the above three issues. Fastswap, the state-of-the-art swap system, partially tackles the first issue, but neglects the last two. For the first issue, Fastswap uses statically provisioned cores to run swap-out tasks; as shown in Figure 2, static core provisioning cannot adapt to dynamic load changes, leading to either insufficient or wasted CPU resources.

4 Hermit Design

4.1 Design Overview

To overcome the aforementioned inefficiencies, we developed Hermit, a new swap system based on the principle of *feedback-directed asynchrony*. Our key insight is that asynchrony should be used aggressively (to overlap nonurgent and urgent operations to reduce latency), but this must be done in a controlled manner—whenever asynchrony cannot

bring benefits, we should switch back to the conventional synchronous design. Figure 4 illustrates Hermit’s design.

First, Hermit optimizes tail latency of accessing remote memory by moving page reclamation from the critical path into the background (§4.2). Instead of following the design of Fastswap, which statically reserves a certain number of dedicated cores, Hermit relies on a *reclaim scheduler* to dynamically schedule reclaim threads. The scheduler leverages feedback from `cgroup` counters to determine the right timing and the appropriate number of cores for reclamation.

Second, the swap-in path of Hermit was designed with fast remote memory in mind (§4.3)—for remote memory, it is reasonable to trade off network usage for end-to-end performance as modern datacenter network offers abundant bandwidth (100-400 Gbps). In the common case, Hermit detects idle network bandwidth and opportunistically bypasses swap-in duplication checks (stage ② in §3) to improve scalability and reduce latency. This bypassing has a consequence: in the (rare) case that multiple threads are fetching the same page at the same time, they will all transfer the same page over the network. Note that this will *not* lead to correctness issues because only one copy will be mapped by the PTE in the last stage, and any other requests will abort and release their page. However, it may potentially waste some network bandwidth when duplicate pages are requested. Therefore, instead of bypassing blindly, we use the conflict rate (in the last stage) as a control signal to determine whether it is beneficial to enable bypassing. To further optimize the critical-path latency, Hermit also overlaps the I/O read stage with other swap-in operations (*e.g.*, `cgroup` accounting, meta-data updating, *etc.*).

Finally, we structured Hermit to operate in a swap-intensive environment to match the reality of using remote memory (§4.4). Hermit carefully optimizes the CPU usage of page reclamation so that more CPU resources are available for applications. Enabled by Hermit’s reclaim scheduler, which reduces the “urgency” of reclamation tasks, Hermit opportunistically handles reclamation requests *in batches* to amortize the overhead. In addition, Hermit bypasses the expensive reverse mapping operation when swapping out a private page (which is common). As a result, Hermit not only reduces the remote access latency but also significantly improves the application’s throughput.

4.2 Reclaim Scheduling

In Linux swap, the direct page reclamation in the swap-in path significantly impacts the tail latency of accessing the remote memory. To reduce tail latency, Hermit moves reclamation off the critical path into background threads; the reclaim scheduler monitors the free memory size and *proactively* starts reclamation before memory exhaustion. The scheduler uses the application’s swap throughput as a feedback signal to auto-tune the number of reclaim threads.

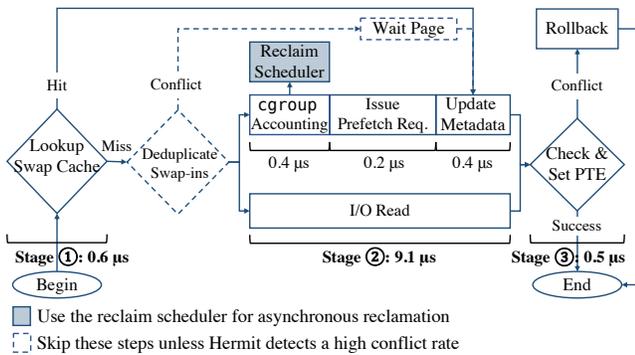

Figure 4: The life cycle of a remote memory page fault in Hermit.

Designing such a scheduler is challenging because it must determine both the right *timing* and the appropriate *amount of CPU resources* for reclamation. (1) As for the timing, if the scheduler starts reclamation too early, a substantial portion of local memory would be underutilized, impacting application performance; on the flip side, if the scheduler starts reclamation too late, the application would exhaust the local memory and suffer from direct reclamation. (2) As for CPU resources, under-provisioning cores for reclamation (*i.e.*, the case of Fastswap) make it unable to keep up with the local memory consumption rate, leading to memory exhaustion, while over-provisioning cores is also undesired as it contends with the application and reduces its performance.

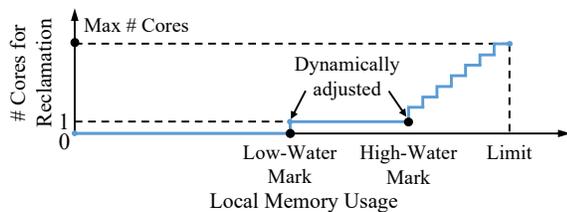

Figure 5: Adaptive reclaim scheduler.

Figure 4 shows the design of the reclaim scheduler, which leverages counters from `cgroup` to schedule reclamation. Since the timing for reclamation is critical to performance, our reclaim scheduler has to be very reactive to free memory size changes (in μs -level). Instead of using a dedicated core to poll the memory usage which waste CPU cycles, Hermit adopts a *decentralized* reclaim scheduler; it inlines the scheduler code into the `cgroup` charging, an indispensable step for swap-ins. This design enables us to discover any sudden change in the free memory size with only a few CPU cycles.

Hermit’s scheduling policy follows the conventional wisdom of random early detection [26] to gradually increase its asynchronous reclaim throughput. Specifically, Hermit starts asynchronous reclamation when application’s memory budget is running low, but Hermit will only enable a small number of reclaim threads first and gradually increase the number of reclaim threads after observing constantly increasing memory usage. The intention of the design is to handle a burst of swap-ins within the memory limit with as few re-

claim threads as possible, and thus minimizing asynchronous reclamation’s interference to the application.

On the other hand, when the application is about to run out of memory, Hermit must unleash the full power of asynchronous reclaim threads to match the reclaim throughput to swap-in throughput to avoid direct reclamation, offering the application maximum swap performance. Figure 5 depicts Hermit’s adaptive scheduling policy, which determines the number of cores for page reclamation given the application’s current local memory usage. The curve can be divided into three phases, marked by the low-water mark and the high-water mark to differentiate the urgency of asynchronous reclamation.

When the application does not swap intensively and its local memory usage is below the low-water mark, the number of reclamation cores is zero, indicating that the asynchronous page reclamation is disabled now to let application threads have all CPU cores. When the application’s local memory usage is between the low-water mark and the high-water mark, it indicates that the application is under memory pressure, and the scheduler will assign one core for asynchronous reclamation to relieve the memory pressure with minimal compute to minimize its interference to application’s threads.

Finally, when the application hits the high-water mark, it indicates that the application is about to run out of memory. Page reclamation is an urgent task now to prevent the application from triggering direct page reclamation. As such, the reclaim scheduler must assign more cores for reclamation to match the reclaim throughput with application’s swap-in throughput. As Figure 5 shows, during this phase, the number of cores assigned for reclamation is proportional to the local memory usage, reaching the maximum value when the local memory usage equals the memory limit.

Hermit leverages the kernel’s runtime statistics to auto-tune the low and high memory watermarks, as elaborated below.

High memory watermark. Hermit dynamically adjusts the high memory watermark based on the application’s current *swap intensity*. We define swap intensity as the overall swap-in throughput divided by the per-core page reclamation throughput, representing the number of cores needed for reclamation to match the swap-in speed. Intuitively, when the swap intensity increases, we should lower the high-water mark to start ramping up reclamation earlier; and when the swap intensity decreases, we should raise the high-water mark accordingly. Hermit sets the high-water mark as $MEM_LIMIT - \alpha \cdot SWAP_INTENSITY$, where $\alpha = 128$ works well in practice.

Low memory watermark. Initially, Hermit sets the low-water mark to be the same as the high-water mark. Then it gradually probes its optimal value based on the average page turnaround time (APT), defined as the average duration for swapped-out pages to remain untouched. When APT does not increase, Hermit attempts to lower the low-

water mark, as now it can potentially start reclamation earlier without impacting the application performance. However, when APT increases, Hermit immediately raises back the low-water mark to revert the negative impact on the application performance.

4.3 Adapt Swap-in to Fast Remote Memory

As shown in Figure 4, Hermit re-architects the swap-in path for the fast remote memory with two main innovations.

Eager swap-in. Hermit opportunistically bypasses the swap-in duplication check to minimize latency. As such, it is now possible that multiple threads issue swap-in requests for the same page. To ensure that only one of them will succeed, Hermit synchronizes them in the final stage (updating PTE) using a fine-grained lock. All other failed threads will release their swapped-in pages—CPU cycles consumed by them are wasted and considered as penalty. Hermit collects the conflict rate and the penalty as feedback to reassess whether it is still beneficial to enable eager swap-in and disable it if it impacts performance.

Asynchronous I/O. Hermit further shortens the critical path of swap-ins by overlapping the I/O read with other operations, for example, `cgroup` charging. If later the `cgroup` check shows no memory, Hermit discards the I/O read response and updates the failure counter. Hermit falls back into synchronous I/O when the failure ratio is high. This happens very rarely in practice thanks to Hermit’s asynchronous reclamation (§4.2).

4.4 CPU-Efficient Page Reclamation

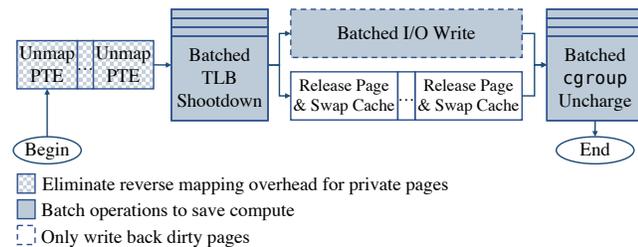

Figure 6: Hermit’s asynchronous page reclamation path.

As shown in Figure 6, Hermit carefully optimizes the CPU overheads of page reclamation to minimize its performance impact to applications.

Batched reclamation. As illustrated in §3, Linux’s page reclamation is mainly designed for slow disk devices where swapping occurs infrequently—it trades off CPU efficiency for responsiveness by only swapping out one page at a time. However, Hermit overcomes the responsiveness loss with its asynchronous reclamation design, which relaxes the responsiveness requirement of page reclamation, thereby creating opportunities for batching. As depicted in Figure 6, Hermit batches expensive operations, including TLB shutdowns, I/O writes, and `cgroup` accountings—to amortize their overheads in the asynchronous page reclamation path.

Reverse mapping elimination. To avoid race conditions during reclamation, Linux has to ensure that the page is immutable before writing it back to remote memory. Linux achieves this goal by using `rmap` (reverse page mapping) to identify and unmap all the virtual pages mapped to the reclaimed physical page. `rmap` walk is expensive as it involves several memory accesses and lock synchronizations. A key observation in Hermit is that most reclaimed pages are private pages (*i.e.*, only referenced by one virtual page). For private pages, Hermit eliminates the expensive `rmap` walk by inlining the virtual page address into the physical page metadata in Linux. This approach trades a tiny portion of local memory (0.2% in the worst case) for better performance.

5 Implementation

We implemented Hermit atop Linux 5.14, the latest release when we started the project. We have been carefully examining every new release to ensure that no patch is directly related to our techniques. We added or modified 9704 lines of kernel code, mainly re-implementing Linux’s swap-in and swap-out code paths.

We built our RDMA-based swap backend atop Fastswap’s implementation. The original Fastswap uses Linux’s `frontswap` interface which only supports blocking I/O. We extended it with an asynchronous I/O interface to enable asynchronous batched I/O writes during page reclamation.

For the swap-in path, we stored the feedback signals `swap_stats`, used by Hermit to decide whether to bypass the swap-in deduplication, in Linux’s process context `mm_struct`. `swap_stats` contains two atomic counters representing the numbers of successful and aborted swap-ins respectively. The page fault handler reads and updates `swap_stats` when swapping in the page.

For the swap-out path, we implemented per-`cgroup` reclaim threads as Linux kernel threads. We stored the feedback signals `swap_ctrl`, used by Hermit to decide the swap-out timing, in Linux’s memory `cgroup` `mem_cgroup`. `swap_ctrl` contains two counters representing the total number of charged pages and reclaimed pages. Hermit updates `swap_ctrl` during `cgroup` charging and page reclamation. The reclaim scheduler reads `swap_ctrl` periodically (per 128 charges in our implementation) to calculate the swap intensity for updating the high-water mark. We use Linux’s existing mechanism of tracking the page re-fault distance to calculate the average page turnaround (APT) for updating the low-water mark. Hermit batches 32 pages per NUMA node for its asynchronous page reclamation to keep low amortized overheads while ensuring most reclamations can finish timely (within 1 ms). To batch reclamation while ensuring consistency, we carefully ordered the operations (see Figure 6). Hermit first selects and unmaps a batch of pages, and then issues a single TLB flush before writing all dirty pages to remote memory. After which, Hermit rechecks each page to ensure it remains untouched and free it. Other-

wise, the page must have been faulted on and re-mapped into the process' page table, so Hermit skips freeing this page and returns it back to the application. To bypass the `rmap` walk, we stored the virtual address of private pages using a global array. We did not directly embed the virtual address into Linux's per-page metadata to avoid breaking its cache alignment.

6 Evaluation

Our evaluation seeks to answer the following questions:

1. Can Hermit maintain low tail latency (§6.2) and high throughput (§6.3) while delivering remote memory?
2. How does Hermit's performance compare to standard Linux and Fastswap [10]? (§6.2-§6.3)
3. What contributes to Hermit's better performance? (§6.4)

Setup. We ran experiments in a cluster with one CPU server and one memory server, connected by a 100 GbE network. Each server equips a 24-core AMD 7402P CPU and 128 GB memory. Both Hermit and Fastswap ran on Ubuntu 20.04 with Linux 5.14. For latency-critical applications, we generated load from another server, which connects to the CPU server via a 25 GbE network. We followed common practices to tune these servers for low latency [47], including disabling CPU frequency scaling, machine-check exceptions, and transparent hugepages. We also disabled OS security mitigations as recent CPUs have fixed these vulnerabilities. We enabled hyperthreading as it improves the performance of remote memory systems.

Methodology. We compared Hermit with the ideal system that only uses local memory and the state-of-the-art kernel-based remote memory system, Fastswap [10]. To enable a fair comparison, we also ported Fastswap to Linux 5.14, the same kernel version that Hermit uses.

6.1 Real-world Applications

We used six real-world datacenter applications for evaluation, as shown in Table 1.

Category	Application	Dataset	Size
Latency-Critical	Memcached [7]	Facebook's <code>USR</code> [14] like	32M KVs
	SocialNet [27]	Socfb-Penn94 [51]	41.5K nodes, 1.4M edges
	Gdnsd [1]	Custom	75M sites
Batch	Spark [62]	Wikipedia EN [8]	188M points
	XGBoost [21]	HIGGS [15]	21M instances
	Cassandra [9]	YCSB [22]	20M records

Table 1: Applications used in the evaluation.

Latency-critical applications. Memcached [7] is a popular in-memory key-value store. It only performs a hash table lookup for each request, leading to a small per-request memory footprint. It has low compute intensity and poor spatial locality. We followed Facebook's `USR` distribution to generate load with 99.8% GET and 0.2% PUT [14]. SocialNet (a

part of the DeathStarBench [27]) is a twitter-like interactive web application built with microservices. It has a fan-out pattern in which each client request is served by multiple microservice instances. This leads to a larger per-request memory footprint than Memcached. It has medium compute intensity and poor spatial locality. We rewrote DeathStarBench's python-based load generator using C++ to increase its throughput. Gdnsd is an authoritative-only DNS server. It performs a tree lookup for each DNS query. It has a small per-request memory footprint and low compute intensity. Different from previous applications, Gdnsd has good spatial locality. We generated queries with random domain names for evaluation. For all three applications, we generated requests with keys followed Zipf distribution using the skewness parameter $s = 0.99$, to be consistent with the standard YCSB benchmark suite [22].

Batch applications. Apache Spark [62] is a big data analytics engine. We used the logistic regression model from its official example suite for evaluation, in which Spark trains the model iteratively by scanning the dataset to update the model parameters. It has high compute intensity and a large memory footprint. XGBoost is a gradient boosting library for machine learning. We ran binary classification for evaluation. It initializes a group of decision trees and trains them iteratively by splitting the tree leaves with input data. It has dynamic parallelism and a medium memory footprint. Apache Cassandra [9] is a large-scale NoSQL database. It uses a storage structure similar to a log-structured merge tree, which has medium compute intensity and good spatial locality. Different from other batch applications, it also periodically persists in-memory data to disk. We used YCSB [22] as its workload for evaluation. Both Spark and Cassandra are Java-based and run atop OpenJDK-11. Java's garbage collection makes them more memory intensive. XGBoost is a native C++ application.

6.2 Tail Latency of Latency-Critical Applications

To better quantify the tail latency overhead introduced by Hermit, we use low-latency applications enabled by Shenango (a recent datacenter library OS) [47], for evaluation. With Shenango's low-latency threading runtime and network stack, these applications achieve sub-millisecond tail latency, making it an extremely challenging case for swap systems. We also rerun the same applications with their vanilla (Linux-based) versions. The results (in Appendix A) show similar trends but with higher tail latency for all systems, including the ideal local-only case. This stems from the higher overhead of the kernel's threading and network stack. Following previous studies [34, 49, 63], we primarily focus on applications' 99th percentile latency in our evaluation. The results of other percentiles (including median and 99.9th) can be found in Appendix C.

We first ran applications with a fixed load (50% of load capacity measured with only using local memory) and varying

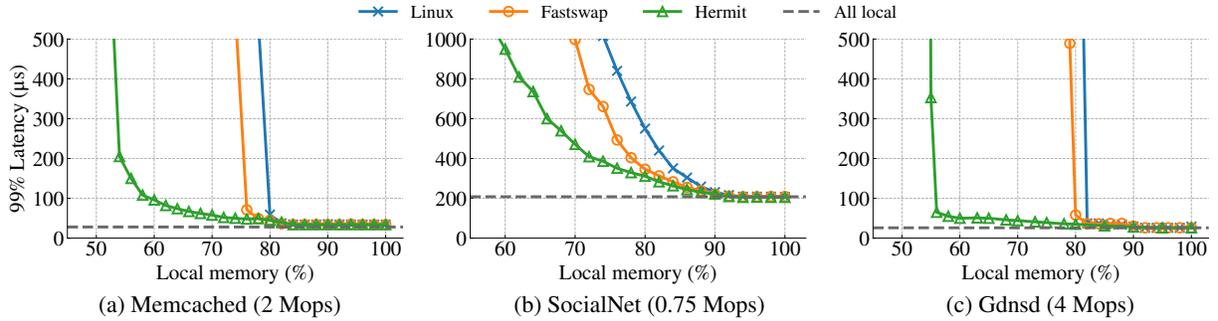

Figure 7: Hermit significantly outperforms Fastswap and Linux in terms of 99% latency under the same fixed load and varying local memory ratio. Hermit enables applications to operate in a more challenging regime of less local memory while still maintaining $< 500 \mu\text{s}$ 99% latency.

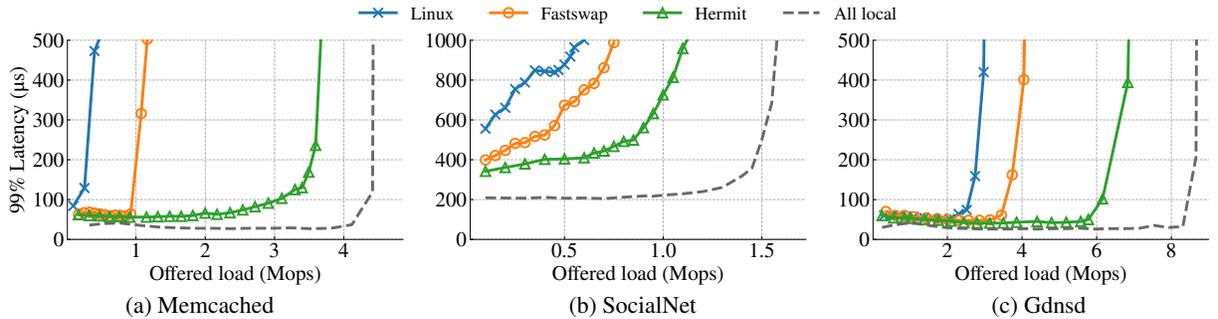

Figure 8: Hermit achieves significantly lower 99% latency than Fastswap and Linux under the same fixed local memory ratio and varying load. For Memcached and Gdnspd, Hermit achieves 99% latency close to the ideal local-only case. SocialNet is more challenging due to its higher per-request memory footprint, but Hermit still achieves 74% load capacity of the ideal case.

local memory ratios. We measured the application performance on Linux, Fastswap, Hermit, and the ideal setup that only uses local memory (see Figure 7). The original Linux does not have an RDMA-based swap backend. To enable a fair comparison, we extended it to use Fastswap’s RDMA backend. On Figure 7, the X-axis shows the ratio of the local memory provisioned; the Y-axis shows the 99th percentile latency achieved by Linux, Fastswap, Hermit, and the ideal setup.

Intuitively, both Fastswap and Hermit achieve ideal performance when only using local memory. When we decrease the local memory ratio, latency increases as remote accesses become more frequent. However, Hermit’s latency increases slower than Fastswap, revealing it is more tolerant to remote accesses. This is because Hermit’s overhead of accessing remote memory is lower, thanks to its shorter swap-in path and its reclaim scheduler that eliminates direct reclamation (§6.4.1). As Hermit adaptively changes the number of reclaim threads to match the reclamation rate with the swap-in rate, it can result in competition for CPU resources if the local memory ratio is small enough. Eventually, both systems encounter a “hockey-stick” when they cannot handle the excessive remote memory accesses. Compared to Fastswap, Hermit enables applications to operate in a more challenging regime of less local memory while still maintaining $< 500 \mu\text{s}$ 99th percentile latency.

Specifically, the low compute intensity of Memcached and Gdnspd aligns with Hermit’s optimizations well; they only re-

quire a few CPU cores for serving load, leaving the rest of the cores for reclamation. Moreover, thanks to their small per-request memory footprints, they only require a small number of reclaim threads. For Memcached, Hermit has to rely on more than four reclaim threads to keep up with frequent swap-ins when Memcached runs under $< 60\%$ local memory ratio. The CPU contention gets more severe when local memory gets smaller, and the system reaches 70% CPU utilization under 58% local memory ratio. Afterward, Hermit’s reclaim threads can heavily interfere and block Memcached’s threads, thus ramping up the tail latency. Similarly, Gdnspd on Hermit used $\sim 72\%$ CPU cycles when running under 56% local memory ratio, and the system can no longer maintain low 99th percentile latency afterward. Fastswap’s single dedicated core fails to keep up with the increasing page reclamation demand when local memory ratio is lower than 76% and 82% for Memcached and Gdnspd, respectively, which ramps up their 99th percentile latency. To conclude, Hermit pushes the operating regime in terms of local memory ratio from 75% (*i.e.*, Fastswap) to 55% for Memcached, and from 80% to 55% for Gdnspd. Gdnspd has a slightly better result due to its better spatial locality. SocialNet is a more challenging application that has a higher compute intensity and a larger per-request memory footprint. It requires more reclaim threads which compete with application threads more heavily under low local memory ratios. The system used 70% of its CPU resources under 65% local memory ratio, and saturated all CPU cores under 60% local memory ratio. Hermit pushes its

regime from 75% local memory ratio to 65%. In summary, Hermit enables applications to store an average of 20% more working set in remote memory without breaking the tail latency target, thereby harnessing stranded memory resources more efficiently.

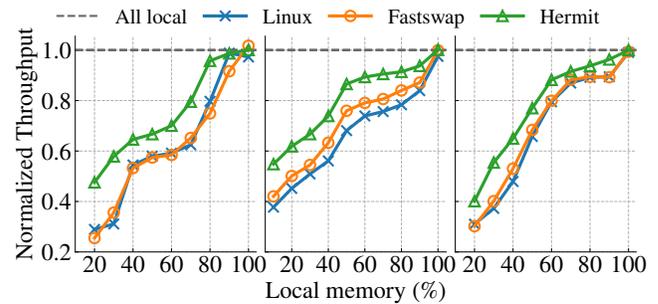

Next, we fixed the local memory ratio to 70% and measured the tail latency of applications with varying load (see Figure 8). Under low load, both Fastswap and Hermit encounter higher latency than the local-only case due to additional remote memory accesses. Hermit delivers lower latency than Fastswap due to the cheaper remote accesses it offers. For Memcached and Gdnsd whose per-request memory footprint is smaller, Hermit reduces 99th percentile latency by 3–9 μ s, whereas for SocialNet, Hermit reduces latency by 43–86 μ s.

Under high load, the latency gap becomes wider because of the CPU contention between application and asynchronous reclaim threads. In this case, application threads access remote memory intensively, therefore triggering memory reclamation frequently. The asynchronous reclaim threads impact application performance by contending CPU resources. Hermit experiences lower performance degradation because of its asynchronous and more CPU-efficient design of memory reclamation (§6.4.2). By eliminating blocking induced by direct reclamation and shifting more CPU resources from reclamation to application, Hermit handles higher load than Fastswap under the same local memory ratio while still maintaining < 500 μ s 99th percentile latency. Hermit improves the load capacity by 3.2 \times (from 1.1 Mops to 3.5 Mops) for Memcached, and 1.7 \times (from 4.0 Mops to 6.8 Mops) for Gdnsd. Notably, compared to the ideal local-only case, Hermit enables these applications to enjoy the benefit of remote memory with only an average of 20% decrease in their load capacity. It is more challenging to handle SocialNet well due to its larger per-request memory footprint and higher compute intensity. As a result, the number of reclaim threads needed increases quickly with the load, deteriorating the contention with application threads. Even though, Hermit still improves SocialNet’s capacity by 1.5 \times (from 0.75 Mops to 1.15 Mops).

6.3 Throughput of Batch Applications

In this section, we evaluate the throughput of batch applications under varying local memory ratios (see Figure 9). Hermit outperforms both Fastswap and Linux. It only requires 45%–70% local memory to achieve at least 80% of the ideal throughput for all applications. In contrast, Fastswap (*i.e.* the better baseline) has to use an average of 20% more local memory to achieve the same throughput. Even under the extremely challenging case of 20% local memory, Hermit is still able to preserve 40%–60% of applications’ ideal throughput. This leads to 1.23 \times –1.87 \times improvement over Fastswap.

When Spark runs atop Fastswap, its throughput drops significantly when running with < 40% local memory. Our profiling reveals that swapping becomes extremely frequent in this case, triggering the scalability bottleneck in kernel’s page reclamation path. Hermit does not suffer from the same issue due to two reasons. First, Hermit significantly reduces the direct reclamation ratio by performing reclamation asynchronously and timely. Therefore, it confines reclamation into a small number of reclaim threads rather than all the application threads (in direct reclamation). Second, Hermit’s CPU-efficient reclamation design reduces the number of threads needed, further alleviating the scalability issue.

(a) Spark (68.4s) (b) XGBoost (42.2s) (c) Cassandra (72.6s)
 Figure 9: We measured the throughput of batch applications achieved by different swap systems normalized to the ideal local-only setup. Hermit outperforms other baselines. The number in the parenthesis shows the ideal execution time.

6.4 Design Drill-Down

We now evaluate specific aspects of Hermit’s design to understand their individual contributions to overall performance.

6.4.1 Remote Memory Access Latency

Hermit reduces remote memory access latency by shortening the critical path of swap-ins. Figure 10 breaks down the improvements brought by specific optimizations, including bypassing deduplication and using asynchronous I/O. The results are measured using Memcached. Without Hermit’s optimizations, the original Linux spends 2.8 μ s on swap-in deduplication. Hermit eliminates this overhead entirely by opportunistically bypassing the deduplication, see Figure 11. After enabling asynchronous I/O, Hermit further overlaps I/O read with other swap-in operations (*e.g.*, `cgroup` accounting and metadata updating), reducing the swap-in latency by another 0.9 μ s. With both optimizations turned on, Hermit reduces the page fault handling latency by 35%, from 13.8 μ s to 10.2 μ s. The RDMA backend spends 9 μ s on performing a 4KiB-page I/O. This indicates that Hermit reduces the overhead of the swap system by a factor of four, from 4.8 μ s to only 1.2 μ s.

6.4.2 Page Reclamation Efficiency

To demonstrate Hermit’s improvements on page reclamation efficiency, we ran Memcached and measured the per-thread

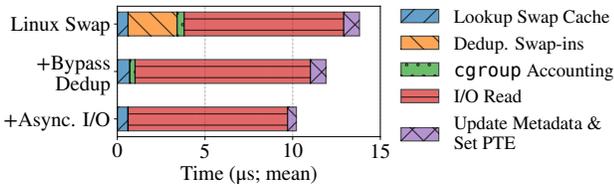

Figure 10: Hermit reduces the remote memory access latency in Memcached from 13.8 μ s to 10.2 μ s with two optimizations, *i.e.*, bypassing deduplication and using asynchronous I/O.

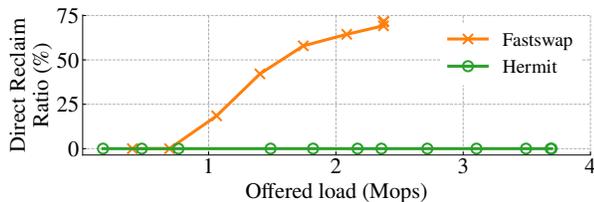

Figure 11: Hermit entirely eliminates direct reclamation for Memcached, thanks to its asynchronous reclamation design. Fastswap fails to serve > 2.4 Mops load due to CPU congestion.

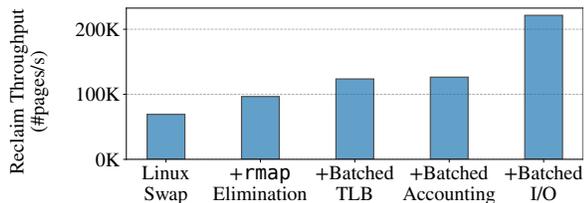

Figure 12: Eliminating reverse mappings and enabling more batching makes reclamation 2.9 \times more efficient.

reclamation throughput, see Figure 12. As shown by the left-most bar, the original Linux achieves 77K pages/s reclamation throughput. Hermit’s `rmap` elimination optimization effectively improves the throughput by 37%, as most of pages are private in Memcached. Batching TLB shutdowns and `cgroup` accountings amortizes their overheads and brings an additional 27% and 3% improvement, respectively. Finally, Hermit batches I/O writes for dirty pages and overlaps them with the page release phase. This significantly reduces the time wasted on polling for the write completion, generating a 75% further improvement. Our further profiling reveals that Hermit reduces the per-page overhead of `rmap` by 59% from 1.70 μ s to 0.69 μ s, TLB shutdown by 92% from 2.45 μ s to 0.20 μ s, and I/O writes by 88% from 6.47 μ s to 0.76 μ s. To summarize, Hermit improves the single-thread page reclamation throughput from 77K pages/s to 221K pages/s, making reclamation 2.9 \times more efficient.

6.4.3 Effectiveness of Feedback-directed Asynchrony

To demonstrate the importance of Hermit’s feedback-directed asynchrony, we modified Hermit’s reclaim scheduler to use Fastswap’s static scheduling policy. The new version `Hermit*` uses a fixed number of reclaim threads and starts reclamation only when the free local memory size falls below 8 MiB. Figure 13 shows the results of Memcached.

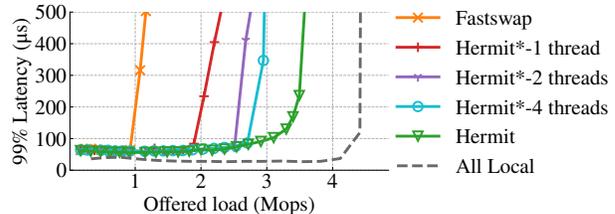

Figure 13: Hermit’s feedback-directed asynchrony is indispensable for achieving superior performance. Hermit considerably outperforms all `Hermit*`s—the modified versions that adopt Fastswap’s static scheduling policy for reclamation.

Hermit consistently outperforms all variants of `Hermit*`, regardless of the number of reclaim threads statically configured. Our further profiling reveals that the memory pressure during Memcached’s execution varies over time. In most cases, it only requires ≤ 2 reclaim threads to mitigate the pressure. However, upon sudden bursts of requests, it needs up to 4 threads to fully keep up with the demand. Hermit’s reclaim scheduler dynamically adjusts the number of reclaim threads to adapt to the changes in demand, thereby achieving superior performance to its static counterparts.

6.4.4 Breaking Down End-to-End Speedup

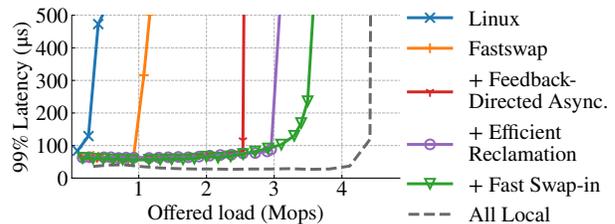

Figure 14: All three of Hermit’s optimizations work in tandem to improve Memcached’s latency and throughput. Results are measured with 70% local memory.

We evaluated the individual contribution of each of the three optimizations (§6.4.1–§6.4.3) to the overall application performance.

For latency-critical applications, we used Memcached as the representative. We re-ran Memcached with the same configuration as Figure 8 (a) with optimizations enabled incrementally. Figure 14 reports the results. Linux even fails to handle low load of 0.5 Mops under 70% local memory, as it frequently triggers direct reclamation which can easily prolong Memcached’s 99th percentile latency by hundreds of microseconds. Fastswap outperforms Linux by offloading reclamation to a dedicated core. However, the application quickly saturates the core’s reclamation capacity once the load reaches 1.1 Mops, and starts to trigger direct reclamation again (see Figure 11). This prevents Fastswap from maintaining low 99th percentile latency afterward.

With the reclaim scheduler (§4.2), Hermit can handle a much higher load, 2.5 Mops, before the latency starts to spike. This is because Hermit’s reclaim scheduler proactively and timely starts asynchronous reclamation, eliminat-

ing the blocking caused by direct reclamation. Optimizations in the reclamation path (§4.4) reduce the amount of CPU resources required. This alleviates the contention between reclaim threads and application threads, adding 0.4 Mops to the load capacity. Finally, optimizations in the swap-in path (§4.3) make remote memory accesses faster and reduce the per-request processing time, thereby enabling Memcached to achieve higher load with the same amount of compute. Putting them all together, Hermit helps Memcached reach 3.5 Mops using 70% local memory while maintaining 99th percentile latency under 250 μ s.

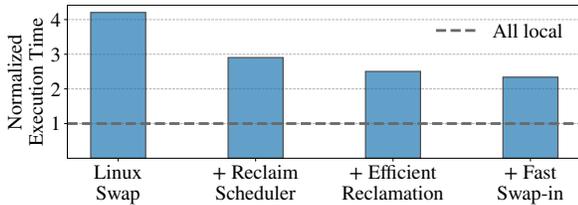

Figure 15: All three of Hermit’s optimizations collectively improve Spark’s throughput. The Y-axis shows the execution time normalized to the ideal local-only time (68.4s). Results are measured under 20% local memory.

For batch applications, we used Spark as the representative and re-ran it under 20% local memory with the same configuration as Figure 9(a). Figure 15 breaks down the performance improvements. Our reclaim scheduler again improves the application throughput by a large margin (31%) due to the following reasons. First, batch applications usually follow the epochal hypothesis [46], whose compute and memory behaviors vary during an epoch but repeat across epochs. Asynchronous reclamation unleashes the hidden parallelism by speculatively reclaiming pages, making it possible for reclaim threads to efficiently harness idle compute resources in each epoch. Second, Linux swap frequently triggers massive direct reclamations instantaneously, causing severe lock contentions between page faults handlings (swap-in) and reclamation. Hermit avoids the burst of reclamation and greatly alleviates the contention by reclaiming asynchronously and proactively. Further, optimizations on the page reclamation path and the swap-in path collectively improve the swap efficiency: they yield an additional 10% and 4% throughput improvement, respectively.

6.4.5 Resource Consumption of Swap Operations

Network Bandwidth. Hermit performs swap operations eagerly to improve performance. It opportunistically bypasses swap-in deduplication to reduce swap-in latency (§4.3) and proactively schedules asynchronous reclaim threads to avoid direct reclamation (§4.2). These optimizations offer performance benefits potentially at the cost of additional network usage. For example, Hermit might swap in the same page several times in the presence of concurrent page faults. To confirm that Hermit does not incur excessive network traffic, we measure the network bandwidth used for

swap-ins and swap-outs, and compare it with Fastswap’s usage.

Figure 16 shows the results when running Memcached. The X-axis shows the offered load while the Y-axis shows the average network bandwidth. The error bar quantifies the bandwidth fluctuation during the application’s execution. With higher offered load, both Fastswap and Hermit use more network bandwidth as Memcached swaps memory more frequently. The bandwidth usage in swap-outs is lower than in swap-in as clean pages do not need to be written back during reclamation.

For swap-in, Hermit incurs similar network bandwidth usage compared to Fastswap. This is consistent with our further investigation which reveals that the conflict rate (*i.e.* the ratio of concurrent page faults that swap in the same page) is less than 0.07%. Therefore, Hermit’s swap-in optimization barely introduces any extra network overhead in practice.

For swap-out, we break down the total bandwidth consumption into the usage of asynchronous swap-out and direct swap-out. Hermit is able to constantly perform asynchronous reclamation without using additional network bandwidth compared to Fastswap. This makes sense as Hermit’s optimizations to reclamation timing and efficiency do not inflate the number of reclaimed pages.

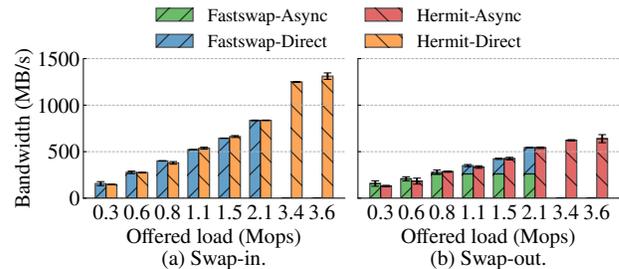

Figure 16: Hermit’s optimizations do not incur additional network usage during swap-ins/-outs compared to Fastswap.

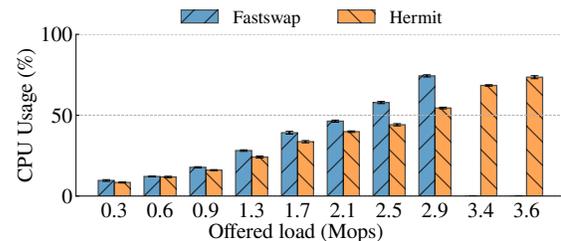

Figure 17: Hermit saves ~30% CPU cycles under varying load compared with Fastswap, which is the key enabler to achieve low 99th percentile latency under high load.

CPU Cycles. We also profiled the CPU usage of applications running on Fastswap and Hermit, revealing that Hermit can serve much higher load with the same amount of CPU resources. Figure 17 depicts the total CPU usage of Memcached and Hermit’s reclaim threads under 70% local memory ratio and varying load. When increasing load, both Fastswap and Hermit use more CPU cycles as Memcached

swaps more frequently. We observed that Memcached fails to use > 70% CPU cycles due to its internal lock contention on hot slabs under skewed workloads. Even though Hermit can spawn more reclaim threads than Fastswap (when needed), it uses 20%–30% fewer CPU resources overall, thanks to its feedback-directed asynchrony and more effective use of batching. Therefore, Hermit is able to offer 32% higher load capacity for Memcached compared to Fastswap.

7 Related Work

Resource Disaggregation. Datacenters today suffer from poor average resource utilization due to overprovisioning [41, 56]. Resource disaggregation, an idea that dates back to 1990s [12, 23, 31, 45, 61], has gained renewed interest, thanks to the high performance of modern datacenter networks [16, 19, 28]. Its key idea is to break the server boundary and unstrand idle resources of remote servers over the network. Existing systems have demonstrated the feasibility of disaggregating various types of resources, including storage [32, 35, 37], accelerators [6, 20], and memory [10, 43, 52, 57]. Some other systems focus on improving the reliability of disaggregated datacenters [33, 64]. We focus on memory disaggregation (*i.e.*, remote memory) in this paper.

Kernel-based Remote Memory. To provide transparency to existing applications, the kernel-based approach leverages OS paging to access and manage remote memory. Most kernel-based systems build upon Linux, including Hermit. Infiniswap [29] is an early work that integrates Linux’s swap subsystem with an RDMA-based block device backend. Later, Fastswap [10] leverages the lightweight `frontswap` interface of Linux to reduce overhead and offloads page reclamation to a dedicated core. Leap [43] improves Linux’s prefetcher to achieve a higher local memory hit ratio. Canvas [59] isolates swap paths for co-running applications. The ongoing advances of Linux’s virtual memory subsystem from the kernel community also benefit Linux-based remote memory. These include, but are not limited to multi-generational LRU [55], speculative page faults [4], maple-tree-based VMAs [2], and DAMON-based proactive page reclamation [5]. Finally, LegoOS [53] makes larger changes to both the kernel and hardware with the goal of achieving better performance through a clean-slate approach.

Library-based Remote Memory. Library-based approaches bypasses the OS to reduce kernel overhead and overcome the granularity restrictions imposed by paging. They trade application transparency for performance; application developers often have to modify their code to use new remote memory APIs. FaRM [25] and KVDirect [38] expose remote memory with an external key-value store interface which mismatches with the construction of existing applications. Distributed shared memory (*e.g.*, [40, 44]), on the other hand, provides an object-oriented interface that is more user-friendly. AIFM [52] proposes a higher-level abstraction of remote-able data structure, but

but it still requires effort to port applications. Semeru [57], Mako [42], and MemLiner [58] are JVM-based remote memory runtimes, offering transparency to Java applications by co-designing the JVM with the kernel.

Hardware-accelerated Remote Memory. Another type of work proposes novel hardware designs, thereby unlocking new opportunities for optimizing remote memory. While Hermit focuses on the software layer, it could benefit from advances to the underlying hardware. PBerry [18] and Kona [17] overcome the granularity restriction of paging and enable cache-line-level remote memory access. Clio [30], StRoM [54], and RMC [11] reduce the expensive network traffic by offloading tasks into the customized hardware of the memory server. Finally, the emerging CXL bus [39] may lower the performance cost of accessing remote memory by delivering lower latency and near-local-DRAM throughput.

Multi-tiered Memory System. Recent research has focused on overcoming DRAM’s capacity wall through the use of slower memory/storage devices—such as compressed memory, non-volatile memory (NVM), NVMe SSD, *etc.* Two examples of such systems are TMO [60] and HeMem [50], which transparently offload main memory to slower tiers. TMO focuses on developing a policy for determining which data to offload and how much, whereas Hermit aims at building an efficient offloading mechanism. HeMem targets improving throughput for batch applications. Therefore, it treats page offloading as a time-insensitive operation and performs it in the background. In contrast, Hermit optimizes for both batch and latency-critical applications by conducting page reclamation timely and proactively.

8 Conclusion

In this paper, we presented Hermit, a re-architected swap system that is based on adaptive, feedback-directed asynchrony. Our evaluation shows that Hermit significantly outperforms Fastswap (the state-of-the-art swap system) in real data center applications; it reduces the 99th percentile tail latency by 99.7% and improves the throughput by 1.24× on average. Hermit defies the conventional wisdom about kernel-based remote memory, demonstrating that it is possible to achieve both full transparency and high performance simultaneously.

A Tail Latency of Linux-Based Applications

In this section, we evaluate Hermit using the vanilla Linux-based Memcached as opposed to the Shenango-enhanced Memcached (§6.2). Figure 18(a) shows 99th percentile latency with fixed load (1 Mops) and varying local memory ratios. Figure 18(b) shows latency with a fixed local memory ratio (70%) and varying load. Hermit still significantly outperforms other baseline systems. The results show a similar trend to the results of Shenango-enhanced Memcached.

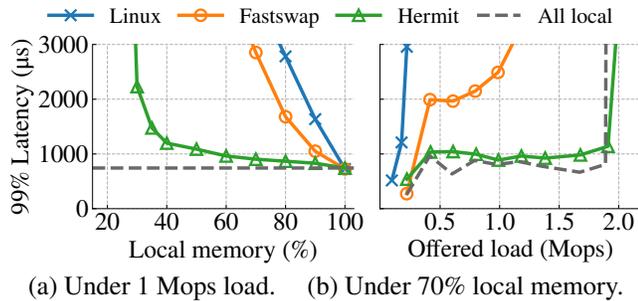

Figure 18: For the vanilla Linux-based Memcached, Hermit still significantly outperforms other baseline systems.

B CPU Usage of Other Applications

This section reports and compares the CPU usage of Social-Net and Gdnsd running on Fastswap and Hermit under the same setting as in Figure 8. Figure 19 shows the results. Thanks to its efficient swap design, Hermit consistently uses 10%–40% fewer CPU cycles than Fastswap, even though it invokes more reclaim threads.

C Tail Latency in Other Percentiles

This section reports the median and 99.9th percentile latency of all three latency-critical applications. Figure 20 depicts the results when running applications with a fixed load and varying local memory ratios. The results exhibit a similar trend to Figure 7. All three systems sustain low median latency when local memory is not too scarce, while Hermit slightly outperforms Fastswap and Linux. When local memory continues to decrease, applications have to spend more CPU cycles on frequent remote memory accesses. The CPU congestion consequently ramps up the median latency. Thanks to the CPU-efficient swap design, Hermit’s median latency increases slower than Fastswap, allowing applications to serve higher load, particularly when local memory is scarce. With regards to 99.9th percentile latency, Hermit again significantly outperforms Fastswap and Linux. It enables applications to put on average 20% more working set in remote memory without violating the tail latency agreement.

Next, we repeated the experiment shown in Figure 8 by fixing the local memory ratio to 70% and measured the median and 99.9th percentile latency of applications with vary-

ing load (see Figure 21). Hermit is able to deliver low median latency close to the ideal setup and much lower tail latency. Since 99.9th percentile latency is more susceptible to direct page reclamation, Fastswap experiences significant performance degradation once its single dedicated core gets saturated. Hermit, in contrast, is able to offer high load (> 60% compared to the ideal all-local setup) and maintain low 99.9th percentile latency under 70% local memory ratio.

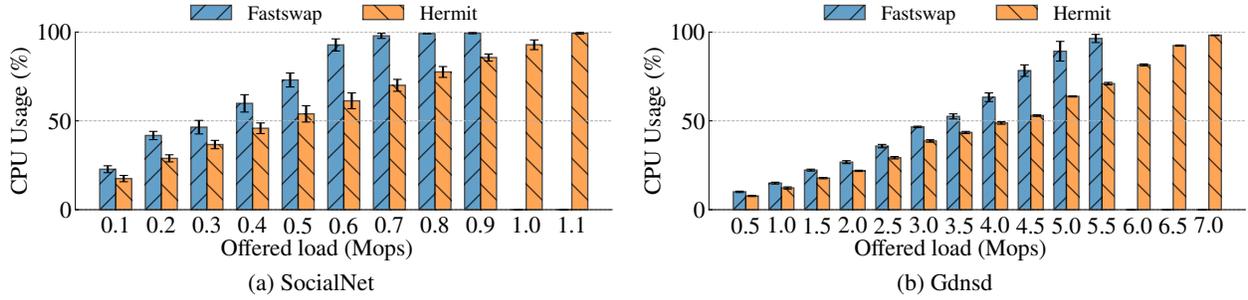

Figure 19: For SocialNet and Gdnzd, Hermit still saves 10%–40% CPU cycles under varying load compared with Fastswap, which is the key enabler it can achieve low tail latency under high load.

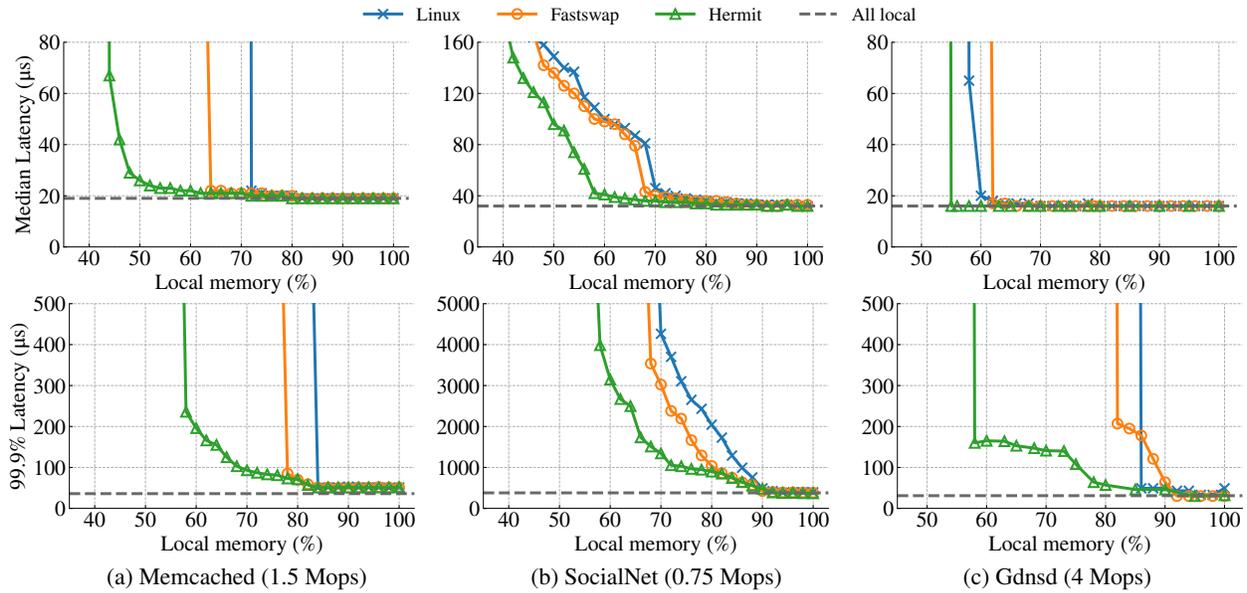

Figure 20: Hermit still significantly outperforms Fastswap and Linux in terms of median and 99.9% latency under the same load and varying local memory ratio.

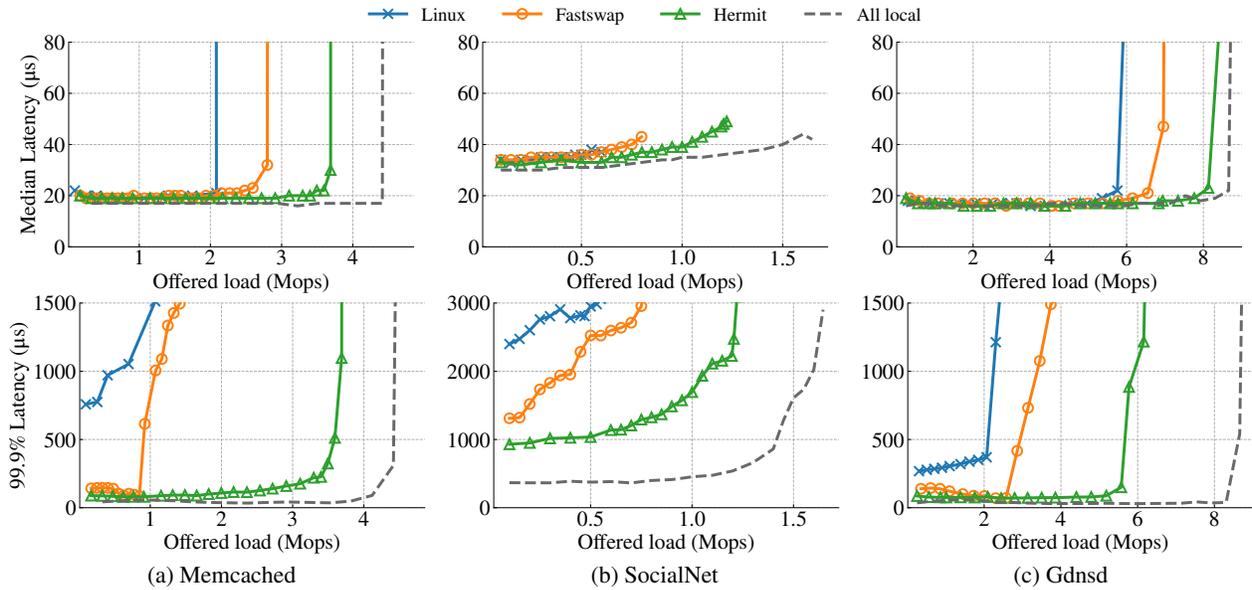

Figure 21: Hermit also achieves significantly lower median and 99.9% latency than Fastswap and Linux under 70% local memory ratio and varying load. As we used a closed-loop load generator for SocialNet, it reaches the maximum load capacity before its median latency spikes.

NetRPC: Enabling In-Network Computation in Remote Procedure Calls

Tsinghua University

Abstract

People have shown that in-network computation (INC) significantly boosts performance in many application scenarios include distributed training, MapReduce, agreement, and network monitoring. However, existing INC programming is unfriendly to the normal application developers, demanding tedious network engineering details like flow control, packet organization, chip-specific programming language, and ASIC architecture with many limitations. We propose a general INC-enabled RPC system, NetRPC. NetRPC provides a set of familiar and lightweight interfaces for software developers to describe an INC application using a traditional RPC programming model. NetRPC also proposes a general-purpose INC implementation together with a set of optimization techniques to guarantee the efficiency of various types of INC applications running on a shared INC data plane. We conduct extensive experiments on different types of applications on the real testbed. Results show that using only about 5% or even fewer human-written lines of code, NetRPC can achieve performance similar to the state-of-the-art INC solutions.

1 Introduction

The recent programmable switches like Barefoot Tofino [16] and Cisco Silicon One [5] can execute user-specified stateful packet processing at line rate. The evolution has sparked a surge of proposals to offload application functions into the network. The trend is called *in-network computation (INC)*.

INC has been widely applied in various applications including distributed ML training [11, 22, 29, 31, 37], cache [19, 25], agreement [6, 18, 40], and network monitoring [12, 17, 26, 27]. The tremendous bandwidth and low latency on switches lead to huge performance gains. For example, ATP [22] accelerates distributed training throughput by 38% ~ 66%; P4xos [6] reduces the end-to-end delay by more than 90%; NetCache [19] improves throughput by 3-10 times compared with a host-only software solution. However, developing INC applications involves too much arcane knowledge in networking that is far

from application programmers' (we refer to them as *users* in this paper) expertise and willingness to learn.

First, the INC program centers on individual packets. Users need to handle network functions such as packet parsing, flow table installation, forwarding, routing, reliable transmission, and congestion control as part of the application.

Second, users need to learn chip-specific languages like P4 [3] and NPL [28]. Even the high-level programming models like Lyra [7] and C3 [20] still focus on packet processing and require too much network knowledge (e.g., transmission windows and protocol fields) for software engineers.

Third, users need to understand low-level chip design details and limitations. Familiar data types and operations like floating points are missing, and users have to design approximations [13, 22, 31] manually. Even harder, users need to place their program on a pipeline of *stages* with isolated memory and deal with limitations, like once-only memory access per stage and a limited number of tables and rule entries.

Last but not least, users need to *statically* decide switch memory layout, table/register arrangement, etc., as the switch hardware can only modify them at boot time. Therefore, users need to reset the switch to start/remove an INC application, causing minute-level service interruption.

As a result, existing projects use INC only as a single application accelerator instead of a shared infrastructure. Even a simple application involves thousands of lines of code on both switches and hosts (Table 4 in Section 6). The development and operation difficulties prevent wide INC adoption.

In comparison, traditional software uses two abstraction layers to decouple application code from network details: 1) a *Socket layer* providing connection/session management, resource sharing, reliable communication, and byte stream abstraction; and 2) a *remote procedure call (RPC) layer* providing high-level data types and call interfaces. In the popular gRPC framework [10], users write a language-independent *interface definition language (IDL)* (e.g., `protobuf` [9]) specifying types of parameters and return values, and the gRPC compiler generates client and server *stubs* that users can integrate into application code. The stubs automatically marshal/un-

marshal arguments and handle underlying Socket connections. RPCs prove to be a powerful interface to build modern distributed systems. Unfortunately, neither layer exists in INC, leaving tedious network details to user applications.

We propose NetRPC to add both missing layers — an *INCLayer* and an *RPCLayer* — to bridge application programming and network packet processing, allowing users to leverage INC features to develop a diverse set of distributed applications using the familiar RPC interfaces.

The *RPCLayer* provides a high-level RPC interface. It is built on gRPC with two extensions: *INC-enabled data types (IEDTs)* and a *NetFilter*. IEDTs include basic types like integers and floating points, and collections like arrays and maps. Users define RPC services using the same `protobuf` language, just replacing vanilla gRPC types with IEDTs to allow NetRPC to recognize and process these data fields. In addition, users provide a *NetFilter* to specify the computation with INC, in terms of five *reliable INC primitives (RIPs)*. RIPs implement high-level operations on IEDTs such as arithmetics, reading/writing a map/array of arbitrary size, and synchronization primitives. RIPs also guarantee reliability, i.e., under various network conditions, RIPs eventually complete as long as the client/server processes survive.

RPCLayer also provides automatic data parallelism for calls with large arguments. NetRPC breaks up a call into subtasks, executes these subtasks concurrently, and sends out multiple *concurrent flows*. We offer it as a built-in feature to save programmers from handcrafting concurrent flows or co-flows to fully utilize the 100+ Gbps links in INC switches.

Analogous to the Socket, the *INCLayer* handles all flows from the *RPCLayer*. In addition to the basic guarantees of the Socket-like connection, reliable transport and congestion control, the *INCLayer* implements the RIPs using a set of protocols involving both the INC switches and the end-hosts.

We build NetRPC as a *general* INC-enabled RPC system. This is different from existing INC projects that only need to find one workaround for the switch hardware limitations as they target only a single application. The first design trade-off we need to make is between *generality (i.e., how programmable the network is)* and *simplicity (i.e., how easy it is to program it)*. Instead of building yet another general INC language, NetRPC chooses to provide only the necessary set of network-independent primitives and the simple *NetFilter* specification. Observing INC projects in the past ten years, we find only a handful successful types (Section 3.1). We design the primitives so that users can easily develop applications of all these types and enjoy the INC performance boosts.

New challenges for NetRPC include, from low level to high level: 1) efficiently managing the switch memory and pipeline stages to support the high-level array and map types; 2) hiding the switch hardware limitations from high-level programs; 3) supporting reliable transmission for different INC scenarios; 4) running multiple INC applications concurrently on a shared data plane; and 5) allowing users to define INC operations for

their applications in the familiar gRPC abstraction.

We have many innovative designs to solve the above challenges. 1) Using a fallback mechanism, the end-host agents can take over all cases that the INC switches fail to handle; 2) Using an INC-compatible transport protocol, we can correctly handle packet retransmission and congestion control, maintaining both correctness and throughput; 3) Adapting a novel memory management scheme, we map from *keys* to unified 32-bit *logical addresses* that further map to switch *physical addresses*, allowing us to optimize the switch memory management much like normal caches; 4) By providing only a limited interface *NetFilter*, we abstract all obscure hardware limitations into a single high-level limitation (i.e., the primitives *NetFilter* supports).

We implement NetRPC using a testbed with two Barefoot Tofino [16] switches and eight machines. Using four non-trivial applications (Paxos, network monitoring, distributed training, and MapReduce) as examples, we show that 1) we reduce the *line of code (LoC)* on the end host to about 1/20, using less than two dozen network-related LoC per application; 2) NetRPC code is completely the same as vanilla gRPC code; and 3) we can offer the same or even better INC speedup.

In summary, our contributions include:

1) As a programming interface, NetRPC is the first framework to integrate INC acceleration into the RPC framework, reducing the bar of INC adoption in software.

2) As an INC system, NetRPC proposes a set of INC primitives applicable to different INC application types and innovative design elements to efficiently implement them, including reliable transport, memory management, and synchronization, as well as enabling a multi-application INC data plane.

3) Using four common INC application types on a real testbed, we demonstrate that we can offer the same INC performance boost with far fewer lines of code.

2 Related Work

Most existing INC applications make a network-software co-design. Even with the “network programming languages”, users still have to handle many network engineering details.

Network-software co-design of INC. People have recently demonstrated many promising INC-accelerated applications, such as NetCache [19] and distCache [25] for caching, P4xos [6], NetChain [18] and NetLock [40] for agreement, SwitchML [31], SHARP [11], and ATP [22] for distributed ML training, and ElasticSketch [38], SilkRoad [26] and Sonata [12] for network monitoring. These solutions are similarly constructed as the network-software co-design — user interfaces, customized protocols, switch programs, rule installation, and endpoint agents — to achieve full-stack optimization and higher switch resource efficiency.

Chip-specific Programming Languages. People have proposed several chip-specific programming languages [3, 28,

32, 33] to support data plane customization. Existing programming languages are tightly coupled with corresponding ASICs. For example, Trident-4 [28] only supports NPL, while P4 programs can run on Tofino and Silicon One. P4 [3], arguably the most popular one for recent INC solutions, follows a *reconfigurable match table* (RMT) architecture. P4 programs first define packet headers and corresponding parsers and then process extracted header fields in a pipeline. Programmers must specify the actions on header fields, persistent switch registers at each pipeline stage, and drive actions by match-action tables. Also, users must define a *deparser* to reconstruct the packet for forwarding.

High-level network programming abstractions. There have been efforts to simplify the INC programming. E.g., Lyra [7] offers a one-big-pipeline abstraction that allows programmers to express their intent with simple statements; NCL [20] imports a window-based abstraction over packets as the basic processing units. μ P4 [34] provides a lightweight logical architecture that abstracts away the structure of the underlying hardware pipelines for better program composition. NetVRM [42] allows developers to virtualize switch memory with a few modifications to existing P4 code. Chipmunk [8] adopts a domain-specific program synthesis technique to generate faster packet-processing code at the cost of longer compilation time. However, these high-level abstractions still revolve around networking details, such as (de)packetization, connection maintenance, and protocol stacks. The semantic gap between the software and network programming model is still a significant obstacle for ordinary software developers.

3 Design Overview

We design NetRPC to allow software developers to enjoy the performance benefits of INC without tedious network programming. We want NetRPC to be general enough to support typical INC application scenarios.

3.1 INC Application Types

INC accelerates applications primarily in two ways: optimizing bandwidth usage (reducing the *number of bytes* to servers) or reducing latency (removing the server from the round trip). People have proposed many INC applications. Table 3.1 summarizes the four types of applications.

The first two types handle large data sets with optimizing bandwidth as the main goal: (1) synchronous aggregation (SyncAtgr) for distributed machine learning (ML) training; (2) asynchronous aggregation (AsyncAtgr) for general MapReduce-type applications. The difference between these two types is that SyncAtgr aggregates only a fixed-sized array (e.g., the gradient updates) and works in iterations, i.e., we can proceed only *after* all clients send the updates. In contrast, AsyncAtgr aggregates over an arbitrary number of keys as they come in and allows accessing results at any time.

The other two types only use small data, with the main goal to optimize latency by avoiding sending packets to the server: (3) key-value cache (KeyValue) that require frequent queries and responses; and (4) Voting (Agreement) that involve counting votes from different clients until reaching a threshold. Unlike (1) and (2), each request is small, but the challenge is how to achieve a latency smaller than client-to-server RTT by not involving the server at all.

3.2 Challenges and Solution Overview

Providing a reliable data stream for general INC application types. Different from traditional networks, there are *side effects* when packets go through an INC switch, such as updating a map. Thus, when a packet goes through a switch twice in retransmission, the computation is no longer *idempotent*, violating the computation correctness. Prior solutions are application-specific, e.g., ATP [22] requires explicit server ACKs. It works in SyncAtgr, but not in the other three types because involving the server defeats latency optimization. We design an efficient and general retransmission mechanism that maintains the per-flow state on the switch using only a few bits in switch memory. We also design an effective flow and congestion control protocol (Section 5.1).

Making “normal path” efficient: Supporting memory-efficient arrays and maps on INC switches. Arrays and maps are core data structures in many applications, and INC significantly accelerates operations on them with parallel element processing. E.g., training applications use arrays to store the aggregated gradients, and monitoring applications keep the aggregates in a map, one key per metric. In both cases, the switch can add up all values in parallel. Existing systems either require pre-determined encoding of keys (e.g., knowing all the keys at compile time) or waste precious switch memory and packet header space to store the long keys. We leverage the host agents to generate a *two-level mapping* from keys of arbitrary lengths to a unified 32-bit *logical address space* and then map it to the switch physical memory. We also design a cache management algorithm running on the server agent to improve switch memory utilization efficiency (Section 5.2.2).

Making “corner cases” correct: Hiding switch hardware limitations from the upper-level program. We still need to handle switch hardware limitations. Our key idea is to use all *host agents* as a fallback mechanism. The host agents emulate all switch operations in software and thus can always provide correct INC results to the `RPCLayer` regardless of the switch’s ability or resource. NetRPC supports two kinds of fallbacks: 1) arithmetic overflows that may happen in floating-point computation and accumulations (Section 5.2.1); and 2) insufficient memory on the switch (Section 5.2.2).

Supporting multi-application data plane. Prior arts support only a single application, and the life span of the switch program does not exceed that of the application. How-

Table 1: Four Common INC Application Scenarios and Primitives They Need

Type	Applications and Existing Systems	IEDT	Primitives
SyncAgr	Distributed ML training (ATP [22], SHARP [11], SwitchML [31])	Array	Map.get, Map.addTo, Map.clear, CntFwd
AsyncAgr	MapReduce (ASK [2], NetAccel [23], Cheetah [36])	Map	Map.get, Map.addTo, Stream.modify
KeyValue	Cache (NetCache [19], DistCache [25]), Monitoring (ElasticSketch [38])	Map	Map.get, Map.addTo
Agreement	Synchronization (P4xos [6], NetChain [18], NetLock [40])	Integer	Map.get, Map.addTo, Map.clear, CntFwd

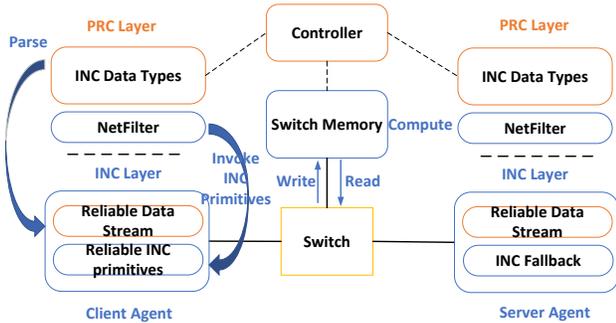

Figure 1: NetRPC system architecture.

ever, the RPC servers are long-running daemons, and server start/stop/restart events are common. It is prohibitively expensive to reset the switch on such events. We solve the problem with three designs: 1) letting all applications share the same set of RIPs; 2) sharing the same set of switch memory blocks among applications by partitioning the key spaces among them; 3) providing three choices of memory eviction behaviors to fit different applications (Section 5.2.2).

Interface INCLayer primitives with RPLayer without breaking protobuf abstraction. Users need to tell NetRPC *what* to process in INC and *how* to process them. We need to add the INC specification to `protobuf` language, but we decide *not* to change the language to keep the learning curve low for users. Thus, we design the `NetFilter` as a configuration instead of a program. We only allow users to specify a fixed set of RIPs with at most one instance for each kind as a filter to process arguments and return values. The limitation simplifies NetRPC design yet still allows implementing all four common types of INC applications (Section 4).

The NetRPC contains a controller, host agents, and switch programs as in Figure 1. The system-wide *controller* is a dedicated process that handles registration and name lookups at initialization, while at runtime, it manages configurations on both switches and host agents. The *host agents* run on each client/server. Each host agent maintains a fixed number of connections (configurable) with the switch, even without running tasks. These connections are essential for the reliable communication (Section 5.1). A single *switch program* starts each INC switch at boot time and executes all primitives. The switch receives configurations from the controller to run applications without resetting the switch program (to avoid interrupting the network). If the switch fails to handle

```

a primitive due to resource or functionality limitations, the primitive execution falls back to the server agents.

4 RPC Layer in NetRPC

In this section, we first introduce the NetRPC programming interface using gradient aggregation in the distributed training application as a concrete example. Then we briefly introduce interface implementation in the `RPLayer`.

protobuf definition. Like in vanilla gRPC, users first provide a `protobuf` definition that compiles into the client and server stubs. Figure 2 shows an example `protobuf` file. The messages are user-defined types, and `service` is the RPC definition using `messages` as arguments and return values. The only modification to vanilla `protobuf` is the `filter` clause allowing users to provide the `NetFilter` file name (see below).

NetRPC data types. Users declare all variables that they want to process in INC using *INC-enabled data types (IEDTs)* defined by NetRPC. E.g., line 3 and 5 in Figure 2 defines variables (both `tensor`) as a `netrpc.FPArray` (floating point

```

1  shared_ptr<Channel> channel =
    CreateCustomChannel(server_ip,
        InsecureChannelCredentials());
2  unique_ptr<Stub> stub_(NewStub(channel));
3  void PushPull(double* data, int length) {
4      NewGrad request;
5      AgtrGrad reply;
6      ClientContext context;
7      request.mutable_tensor()->mutable_data()
8          ->Add(data, data+length);
9      Status status = stub_
10         ->Update(&context, request, &reply);
11     memcpy(data, reply.tensor().data(),
12         length * sizeof(double))
13     train(data);
14 }

```

Table 2: NetRPC Primitive Semantics

Primitive	Args	Semantics
Map.addTo	stream	map[stream.key] += stream.value
Map.get	stream	stream.value = map[stream.key]
Map.clear	empty	map[stream.key] = 0
Stream.modify	op,para	stream.value = op(stream.value, para)
CntFwd	key,th,tgt	cnt[key]++; if cnt[key] == th then forward(tgt) else drop

array) IEDT. Optionally, user can add normal gRPC data fields to the same messages, and NetRPC simply passes them to the server without processing.

Collections (Array and Map) are core data types in NetRPC. The item value can be integers or floating points, and keys can be integers or strings. NetRPC enables 1) automatically applying the user-defined NetFilter on every value in these collections and 2) accessing the *global INC map* using keys.

Life of a NetRPC call. In NetRPC, when a client initiates a call, the *client stub* marshals the arguments and sends them through one of two channels: messages with IEDT through the INC channel established by the per-host *client agent* and normal messages through the original gRPC Socket. In this paper, we only focus on the *data streams* in the INC channel. The underlying *INCLayer* processes the data stream and optionally interacts with the *INC map*. The INC map is a NetRPC abstraction of unlimited global memory addressable using keys or array indices. INC map is implemented on both switches and host agents (in Section 5.2.2). The return path is similar: the *server stub* marshals the return value and sends it through either the INC channel or the normal Socket.

The NetFilter and reliable INC primitives (RIPs). In addition, users need to specify their INC operations. Here, we have a choice in terms of what kind of operations NetRPC should provide. We want to find the sweet spot in the trade-off between generality and simplicity. We also want to provide a reconfigurable switch program to serve new applications. Therefore, we pick five primitives that we can compose together in a similar layout to implement existing types of INC

operations (Section 3.1). Figure 5 displays this layout and its implementation on the switch. The users only need to provide configurations for these five primitives in their NetFilter file (Figure 3) to specify their INC operation of interest.

The NetFilter is a JSON configuration file. It contains a *AppName* that uniquely identifies an application, a *Precision* field that specifies the floating-point precision (number of digits after the decimal point). Lower precision allows INC to process more data without falling back to the host.

The more interesting part in NetFilter is the next five fields that allow users to provide arguments to RIPs, including three map-access primitives, Map.addTo, Map.get, and Map.clear, one data stream manipulation primitive, Stream.modify, and one synchronization primitive, CntFwd. Table 2 summarizes the parameters and semantics of these primitives.

Map.addTo *accumulates* data items from the stream to the map according to their keys/indices, and Map.get reads out the values of a specific key from the map. In Figure 3, we add the values of the *NewGrad.tensor* array to the INC map to aggregate the gradient, and on the return path, we read out the results from the INC map into the *AgtrGrad.tensor* array.

Map.clear defines how to clear a value from the INC map. In the example, *copy* means backing up the aggregates to the server before clearing it out to handle packet losses. We introduce other possible options in Section 5.2.2.

Stream.modify performs arithmetics on the stream. It only modifies the stream without accessing the INC map. In Figure 3, we set it to *nop*, as we do not modify streams. Table 8 in Appendix A lists all operations we support for Stream.modify.

The CntFwd is the most interesting primitive. It accumulates values on one or more keys (specified with CntFwd.key) in the INC map until the accumulator reaches the specified threshold (CntFwd.threshold). Then it forwards out the message to the destination(s) specified at CntFwd.to. The CntFwd primitive is essential to control both *how many* packets to forward to the clients/servers and *when* to forward them, and thus essential for SyncAgtr and Agreement applications. In this example, we set key to a single ClientID, meaning that we only need one counter for the number of unique clients who have sent gradient updates. In this case, only when exactly two unique clients have sent a stream, will the network aggregate the items and send back AgtrGrad to ALL clients.

There are other use cases for CntFwd. Setting the CntFwd.threshold to one makes the CntFwd behave as the *test&set* primitive in many instructions sets, useful to implement distributed mutual exclusion. Also, by providing a collection in the data stream, we can use a map of counters to track multiple votes in concurrent ballots, a widely-used functionality in distributed agreement protocols. CntFwd allows the switch to notify the clients only when enough votes arrive. Appendix D provides more examples of CntFwd primitive.

Table 1 summarizes the primitives used in each INC application type. Figure 5 illustrates a RIP pipeline running the example code in Figure 3. A SyncAgtr application pushes

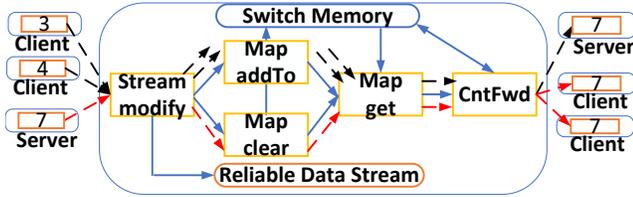

Figure 5: RIP pipeline in switches.

data into the network by its clients (black arrows) for on-switch aggregation and on-server backup. The server sends back the computation results (red arrows) to clients and clears the switch memory. The same switch program (and the RIP pipeline) completes all INC functions in the round trip without reconfiguring the switch.

Using RPC calls to build the application. With the `protobuf` and `NetFilter` definition, the remaining process is exactly the same as normal gRPC. The `protobuf` compiler generates client and server stubs, and users include stubs in their application. Figure 4 provides the client code using the RPC service defined in Figure 2. Note that the code is completely identical to vanilla gRPC, hiding INC details from the users.

Automatic data parallelism on RPCs with large arguments. There could be multiple concurrent NetRPC applications/channels and procedure calls in the runtime. The stub submits calls as tasks to the host agents. A task contains the application data (i.e., arguments or returned values, encoded as protobuf messages), the metadata (e.g., network program configurations), and the routing information.

The host agents maintain a thread pool of worker threads to process tasks. NetRPC automatically partitions the task into subtasks and dispatches them onto multiple worker threads for load balance. The worker threads serve the subtasks in their queue on a First-Come-First-Serve (FCFS) basis. The worker threads serialize the subtask’s data into a sequence of packets (Appendix B.1) and send them over the user-level network stack we implement using DPDK [15].

Limitation of RIP abstraction. RIP abstraction targets simplifying programming in general INC scenarios where different INC applications regularly start and stop to share the infrastructure. It lacks logical semantics like looping and branching and thus can not implement complex algorithms (e.g., DHS [41]) or data structure (e.g., NetChain [18] queue). Adding more RIPs will extend the functionality but reduce the source available for each RIP. We leave further extensions and a customizable set of RIPs as future work.

5 INC Layer in NetRPC

`INCLayer` provides a reliable layer to support RIPs. There are two design objectives: 1) efficiently utilize INC switch resources to support a multi-application data plane with full

INC performance boost; 2) provide an end-host software-based fallback mechanism to support reliable byte streams and INC primitives for the `RPCLayer`. As a result, `RPCLayer` can safely assume that the data stream is delivered reliably, and the `NetFilter` is fully executed in various network conditions.

In this section, we first introduce how we can build a general reliable data stream abstraction. Then we introduce the essential RIPs, including map access, arithmetics, and `CntFwd`. Finally, we briefly introduce the switch implementation.

5.1 Reliable Data Stream

Encoding IEDTs into sequences of packets. Client agents receive data streams containing multiple key-value pairs from the `RPCLayer`. Then the client agent encodes these pairs into separate packet headers using a user-level networking stack written in DPDK [15] and sends them out. Each packet contains a fixed number of key-value pairs (32 in the current setting), a sequence number, a *global application ID* (GAID), as well as other state information we will introduce in this section. Figure 14 in Appendix B.1 illustrates the packet header structure. The packet can optionally contain the normal payload with non-INC types for the application. NetRPC only processes the key-values encoded in the header.

Idempotent packet retransmission. In case of packet loss, traditional transport simply retransmits the lost packet. However, INC complicates the retransmission because the retransmitted packet can cause *side effects* on the switch, such as incrementing a map value again. In other words, naive retransmission is not *idempotent* and may lead to incorrect INC results. Switches need extra information to detect which packets are retransmitted. Traditional networking doctrine tells us that we shall avoid keeping states on switches. Thus, some INC designs choose to keep extra states on the sever [22] and let the server to ACK each packet. The ACK informs the switches about processed packets. This design requires the server to ACK every packet. It works on applications like gradient aggregation, where the INC is primarily used for reducing *server bandwidth* by only forwarding the results to the server to ACK while completing aggregation on the switch only. However, this design does not fit applications like `KeyValue` and `Agreement`, as server ACKs defeat the purpose of latency reduction via sub-RTT switch response.

To design a general protocol, we observe that 1) we send/receive all INC flows using host-agents under NetRPC control; 2) the INC switches have a relatively large memory, and the retransmission states are almost negligible compared to the INC map. Thus, we can safely keep the per-flow state on the switch as long as we can limit the number of agent flows.

We further design our protocol to minimize per-flow switch memory usage, allowing a switch to only keep a *bit array* of size w_{max} per flow, where w_{max} is the max sending window size. The switch initializes all bits to 1. Every packet contains a sequence number (`seq`), and a `flip` bit that is set to

$(seq/w_{max})\%2$. On receiving the packet, the switch checks the $(seq\%w_{max})$ -th bit in the bit array. If the bit is the same as the `flip` in the packet header, the switch considers it as a retransmitted packet and thus skips updating the INC map. Otherwise, the packet is new, and the switch sets its corresponding bit to the `flip` and processes the packet normally.

We show that this simple protocol guarantees idempotent execution, i.e., 1) a packet's first appearance flips the bit, and 2) a packet's later appearance (retransmission) equals the bit. We prove it by *induction*. For sending window 0, all `flip` bits in packets are 0s, and the switch bitmap is all 1s. Since each packet only sets the bitmap to 0 once, at the end of window 0, all bits become 0. Then assuming the two properties hold for window $t - 1$, we show that they still hold for window t . Recall that the client agent sends out the i -th packet in window t (denoted as P) only after the i -th packet in window $t - 1$ (denoted as P') is ACKed. Therefore, when P first appears, P' should already set the bit as P' 's `flip`. As P and P' are opposite in `flip`, P 's first appearance flips the bit. P 's later appearance would not flip the bit, and the window controls packets out of the window not to appear (and falsely flip the bit) between P 's appearances. Thus, the two properties hold in window t . By induction, it is correct for all sending windows.

We can use $N \times w_{max}$ bits of switch memory to support N concurrent reliable flows on each agent. We experimentally set $w_{max} = 256$ and find it sufficient to achieve a per-flow bandwidth of 20+ Gbps.

Flow control and congestion control. Note that w_{max} is a fixed value. We still need to deal with the flow control and congestion control due to resource contentions on either the end hosts or switches. We use the same mechanism to handle both flow and congestion control by automatically setting a congestion window $cw \leq w_{max}$.

Traditional congestion control, like the one in TCP, relies on round-trip-time (RTT) and duplicate ACKs to adjust cw . However, in INC primitives like `CntFwd`, these signals may not reflect the real network congestion as the receiver needs to wait for the slowest sender before ACKing.

Thus, NetRPC adopts an ECN (i.e., explicit congestion notification)-based congestion control mechanism. The switches set the ECN when the ingress port length exceeds the threshold. Meanwhile, it writes the ECN information to the INC map under a special key. Thus, all retransmission packets carry ECN until cleared like other map values. This prevents ECN signal loss due to packet loss. Otherwise, the client agents adjust the cw using the same *additive increase multiplicative decrease (AIMD)* policy as prior arts [22]. Experiments show that this design allows multiple flows to achieve both high goodput and fairness in bandwidth sharing.

Other transport protocols. Several recent transport protocols have affected the design of `INCLayer`. MTP [35] proposes a message-based protocol to customize congestion control, load balancing and resource isolation for INC. However, it requires maintaining per-pathlet states on both packet headers

and end hosts, importing extra overhead to hurt the system's performance. DCTCP [1] imports a more fine-grained congestion window adjustment based on the ECN proportion. This approach is inapplicable to INC scenarios because we have to count the maximum number of ECNs in a single (i.e., the most congested) path instead of the total ECN proportion due to incast. This consumes more resources on the switch and will reduce the stream goodput, so we utilize AIMD to simplify implementation and will extend the protocol in future work (Section 7).

5.2 Reliable INC Primitive Designs

5.2.1 Computation and arithmetic overflows

Floating point arithmetic by quantization. INC switches only have limited 32-bit arithmetic functionality, yet INC applications like training require floating-point (FP) arithmetic. The standard practice uses quantization to fit the FP numbers into 32-bit integers (aka, fixed-point numbers). NetRPC quantizes an FP value in the client agent by multiplying it with a scaling factor (the `precision` field in `NetFilter`) and maps the value back to FP before handing it to the `RPCLayer`.

Handling overflows. While people have shown that the precision loss might not cause problems in many applications, 32-bit fixed-point numbers do not offer enough *representable range* in many cases, and thus overflow is unavoidable. Even without FP numbers, just using the `Map.addTo` to accumulate values may also lead to overflow. Thus, we need a way to handle occasional overflows.

When the switch detects an overflow during computation, it sets the overflowed value to `MAX_INT` or `MIN_INT` and forwards the packet normally. When a host agent receives a packet with `MAX_INT/MIN_INT` value, it suspects there is an overflow¹ and gives up the result. Then the client agents mark and resend these overflow packets, causing the switch to skip the processing and directly forward them to the server agent. The server agent computes the correct result using 64-bit integers or FP numbers in software.

Fallback on network fabrics without INC support. A similar fallback mechanism works when there are no programmable switches or data-plane resources reach capacity. If the controller fails to assign the INC application to any switch, the server agent will execute RIPv in software using the same switch failure handling mechanism. Therefore, the application is guaranteed to derive the correct results with the transparent fallback, only losing performance benefits from INC.

¹Strictly speaking, there is one possibility of a false positive where the result is exactly `MAX_INT/MIN_INT`. The false positive only slightly affects performance leading to an extra retry, but not correctness.

5.2.2 Memory: INC map-access primitives

Memory address spaces in INCLayer. The RPCLayer supports maps with arbitrary keys, while the INCLayer only provides a 32-bit *logical* address space per application. The client agent hashes keys with different types and lengths into the 32-bit address space. We handle all collisions by putting the colliding keys into the payload to bypass the switch INC and let the server agent to process them. We choose not to use a larger logical space as we find it sufficient to support multiple applications with acceptable collisions. A short address saves bits in packets, increasing the effective bandwidth.

INCLayer maps the 32-bit address space onto the *physical* address space on switches. Each physical address corresponds to a *register* on a switch. Switches may have different numbers of registers. E.g., the switch we use has about 160K registers available per pipeline stage, and we use eight stages to support map-related primitives.

It is not trivial to map the logical address to a physical switch address. The above hashing approach does not work here because switch registers are a valuable resource we want to make full use of, but when the utilization is high, the collision rate increases fast, causing many fallbacks to servers. In fact, we need to pack the physical memory tightly. Also, we want to avoid keeping the logical-physical address mapping on switches; otherwise, it wastes switch memory.

In some applications, such as distributed training (as in ATP [22]) in SyncAgr, it is simple as every client has the same set of keys. Each of them only needs to sort the keys and give each key a sequence number. However, it does not work in general cases, such as AsyncAgr, where each client might have a different set of keys.

Multiple clients of a single application. We solve the problem by letting the server agent, shared by multiple clients, decide and maintain the mapping for all its clients. The first time a client uses a new logical address, it sends packets to the server without INC. If there is switch memory available, the server agent will piggyback a mapping for this address on the returning ACK. Then the client can send subsequent packets with the physical address set in the packet for the switch. If the switch memory is full, the server will not return the mapping, and thus clients keep sending subsequent packets to the server without INC. With the method, we ensure all clients calling the same server use a consistent mapping.

Handling multiple applications. According to the applications' requests, the controller reserves switch memory at application registration time. When an application gets no switch memory, they fall back to using server agents. We use a simple FCFS policy for the static allocation among different applications and leave advanced memory scheduling as future work. Note that although the controller reserves memory at registration time, the actual allocation only happens when the clients plan to send out data streams. Thus we can avoid holding memory unnecessarily.

Cache replacement policies. The switch memory serves as a cache for certain keys, and we need a replacement policy at the server agent. We take an approximation to the *least-recently-used* (LRU) policy. Each client agent counts the uses of each logical address within a *cache update window*, and at the end of the window, they send the counter to the server, allowing the server to compute the most-used keys in the last window. Then in the next period, the server evicts less used values. We also evaluate other popular cache replacement policies in Section 6, and we show that this periodic counting-based LRU policy works well.

Optimization for synchronous aggregation. In addition to the general logical-physical mapping, we realize that the SyncAgr (i.e., distributed training) applications like SwitchML [31] only require access to large continuous arrays. It is more memory-efficient to be able to allocate such arrays in a few *circular buffers* instead of many individual addresses. NetRPC supports such buffers of a fixed size of 256 keys.

Preventing switch memory leaks on host failures. Unlike existing INC designs that serve only a single application, NetRPC is a shared infrastructure supporting many applications. Thus, we need to take care of potential switch memory leaks resulting from the crashing of user programs or host machines before they can explicitly release the memory. We address this issue with a *two-level timeout* mechanism.

NetRPC processes a packet with an *admission rule* that checks the GAID. We keep a timestamp of the last time the rule runs for each GAID. The controller periodically polls the switch for these timestamps. If it finds a stale timestamp, it triggers the *first-level timeout* by notifying the server agent to retrieve the application's INC map. After a longer period, the server agent triggers the *second-level timeout*, sending the saved data items to the user-defined stub or deleting them if the stub no longer exists. As switch memory is small and precious, we want to reclaim it quickly with a small *first-level timeout*. However, the small timeout unavoidably introduces false positives, hurting the correctness of programs with low communication frequency, such as monitoring infrequent events. In fact, these applications will benefit little from INC anyways, and the timeout mechanism allows them to run just like normal applications. Servers have much larger memory and thus can keep user maps longer, providing the correctness of such programs similar to software.

The Map.clear primitive. The switch memory only supports Map.addTo instead of directly overwriting the value. Thus, to start a new accumulation (e.g., a new iteration of training, restarting a vote, etc.), the user program needs to execute three steps: 1) Map.get the accumulator value to the hosts, and 2) Map.clear the memory and 3) start to Map.addTo new values. However, there is a risk that the packets get dropped *en-routing* to the host. In this case, the memory is already cleared, so the value is permanently lost.

NetRPC provides different methods to prevent this loss, as

there is a latency-throughput tradeoff. We decide to allow users to choose from three clear policies in `NetFilter`.

1) [Copy]: The client-call stream first carries the map’s value to the server, and then the return stream from the server will `Map.get` and `Map.clear` the values. Thus we guarantee the server has a backup in case the return packet is lost. This policy requires no extra switch memory at the cost of forwarding more data to the server and thus higher latency.

2) [Shadow]: The switches double memory allocation. The data stream uses two memory segments alternatively: `Map.get` from one and `Map.clear` the other. This approach reduces latency at the cost of doubling memory usage and thus is only suitable for latency-sensitive applications with few data items.

3) [Lazy]: The `Map.clear` primitive only lets the host agents to save the current value and let the switch to keep accumulating without clearing. The host agent subtracts the saved value to compute the accumulated value since the last clear. When the accumulator eventually overflows, we fall back to the server agent using the same overflow logic and clear the switch memory. If the application (e.g., voting) has a slow-increasing counter, lazy policy involves little overhead.

The multiple `clear` policies allow users to better customize their INC applications according to their SLA requirements and workload features. We compare the performance of the three policies in Section 6.

Implementation on the switch. We allow 32 key-value pairs per packet. We use four register groups per stage and 8 out of the 12 stages on the switch to implement the INC map access. This design fits the switch hardware limitation: a packet can only access each group of registers in the switch once per trip. For the same reason, we arrange `Map.get/Map.addTo` and `Map.clear` to execute in the opposite direction of a packet round trip. These primitives are organized in a flow chart on the switch pipeline (Figure 15 in Appendix C). Appendix D displays a number of example settings of `NetFilter` in different application types.

5.2.3 Forwarding: the `CntFwd` primitive

The `CntFwd` primitive requires two extra pieces of logic in the switch. First, the switch needs to recognize the packet is a `CntFwd` packet, and then the packet goes through the normal map-access pipeline to increase and read the values in the accumulator. We implement different computation logic for the accumulator (`test&set` or `accumulate`) by applying different match-action tables according to the `CntFwd.threshold`. Finally the packet enters the last stage on the switch that decides whether to `drop`, `send`, or `multicast` the packet.

6 Evaluation

In this section, we show that NetRPC achieves the following desirable properties: 1) NetRPC supports four kinds of INC applications; 2) NetRPC significantly reduces the amount of

Table 3: Workload and Baseline in Experiments

App Type	App	INC Baselines	Dataset
SyncAgr	Distributed Training	ATP [22] SwitchML [31]	ImageNet [14]
AsyncAgr	WordCount	ASK [2]	Yelp [39]
KeyValue	Network Monitoring	ElasticSketch [38]	CAIDA Anonymized Internet Trace [4]
Agreement	Paxos	P4xos [6]	Synthetic workload

application code; 3) NetRPC achieves the same performance as handcrafted INC applications; 4) NetRPC handles situations like packet loss, congestion, etc. In addition, we evaluate the effects of policy settings (clear and caching).

6.1 Experiment Settings

NetRPC implementation. We implement NetRPC switch logic on a 12-stage programmable switch. The NetRPC switch pipeline contains 32 read-write memory segments corresponding to the 32 key-value pairs in the NetRPC packet. Each memory segment contains 40k 32-bit units to restore INC states or the INC map. Depending on the service configuration, we vary packet lengths from 192 to 320 bytes.

NetRPC includes four modules: $\sim 4K$ lines of P4 code for the switch logic, $\sim 2K$ lines of Python code for the remote controller, $\sim 2K$ lines of C++ code as the plugin of gRPC++ [10], and $\sim 3K$ lines of C++ code for the NetRPC end-host agents using DPDK. We also implement four types of INC applications with only 200 \sim 500 lines of code each.

Testbed. We run NetRPC on a testbed of 8 GPU machines and two programmable switches. The devices form a dumbbell topology: two connected switches, each with four machines. In the experiment, we use “X-to-Y” to denote a topology with X clients and Y servers. The switch contains a Barefoot Tofino chip and provides 32×100 Gbps ports. Each machine has a Mellanox ConnectX-5 dual-port 100 Gbps NIC. Each machine is equipped with two NVIDIA GeForce RTX 2080Ti GPUs, 56 CPU cores at 2.20GHz, and 192GB RAM. The machines install NVIDIA driver 430.34, CUDA 10.0, Mellanox driver OFED 4.7-1.0.0.1, and Ubuntu 18.04.

Workloads and baselines. Table 3 shows the workloads and baselines we use. We run various typical models (VGG, ResNet, AlexNet) for SyncAgr. We also implement each application’s pure software version as baselines using DPDK.

6.2 Reducing User Code Complexity

We compare the user-written lines of code (LoC) of NetRPC applications with existing INC arts. Table 4 shows that NetRPC reduces the overall human-written code by over 97% in all four application types. To enable INC in an RPC, the application developers only need to configure the `NetFilter` to enable/disable RIPs on the switch without writing any switch

Table 4: LoC Comparisons: NetRPC vs. Prior INC Arts

	NetRPC		Prior INC Arts	
	Endhost	Switch	Endhost	Switch
SyncAggr	173	13	3394	5329
AsyncAggr	166	26	3278	4258
KeyValue	162	26	898	2360
Agreement	1453	26	5441	931

code. `NetFilter` results in a huge LoC reduction (12-21 LoCs in NetRPC v.s. 931-5329 in prior arts). On the host, NetRPC also reduces the LoC of host programs by 95%, 95%, 73%, and 82% for the four applications compared with existing INC applications, as NetRPC users only write code to process data-stream as call arguments, avoiding the tedious network functions like (de)packetization, reliability, etc.

6.3 End-to-end Application Performance

Distributed ML training. We set up eight worker machines for this evaluation. We use two existing INC frameworks, SwitchML [31] and ATP [22], and a pure software solution, BytePS, as baselines. We implement the NetRPC version on BytePS with only 500 LoC modifications. All INC versions use a single parameter server (PS), while the software version uses eight to provide enough throughput.

Figure 6 shows the average training speed per worker. We have the following observations: 1) INC solutions outperform non-INC ones for most models because they avoid incast to the PS. NetRPC, ATP, and SwitchML are 42%, 42%, and 11% faster than BytePS in VGG16; 2) For all models, NetRPC performs similar to ATP (97% to 100% of ATP), and at most 28% faster than SwitchML; 3) the training speeds on ResNet are similar because they are computation-intensive, and communication does not affect the overall performance much.

We believe the performance gain in NetRPC over existing systems is from the automatic parallel streams. As a side benefit, NetRPC uses only a single port (or one pipeline) instead of recirculation like ATP or SwitchML. Using fewer ports is essential for the multi-application data plane. SwitchML-RDMA [30] uses even more pipelines by chaining four pipelines together to achieve a performance gain over ATP. We do not adopt the design because resource efficiency is one of our key considerations.

Paxos. We use NetRPC to implement a Paxos [21] consensus system, offloading the leader and vote counting functions to switches. The implementation only contains about 700 LoC changes. We use an INC baseline, P4xos [6], and two software ones, `libpaxos` [24] and DPDK Paxos [6]. We run two proposers, two acceptors, and three learners in all cases.

Figure 7 summarizes the results on both throughput and 99th-percentile latency to achieve one consensus. Key findings include: 1) NetRPC achieves a maximum throughput of 503K messages/second, 12% higher than P4xos, and $7.86\times$

Table 5: Microbenchmark on Basic INC Functions

Metrics	NetRPC	Prior Arts	DPDK
SyncAggr Goodput(Gbps)	50.55	46.44 (ATP)	40.11
AsyncAggr Goodput(Gbps)	72.31	73.96 (ASK)	45.88
Voting Delay(μ s)	20	22 (P4xos)	92
Monitor Delay(ms)	3.52	3.26 (ElasticSketch)	4.05
Packet Processing Capacity(Mpps)	>1000	>1000	83.47

and $4.93\times$ higher than the two software solutions. INC solutions are much faster because they offload packet processing to the switch to alleviate the CPU bottleneck on servers. NetRPC has higher throughput than P4xos because it only sends the final results to the learners, reducing the workload on servers and saving the traffic on learner links. 2) The 99th-percentile latency of NetRPC is 311 ms and 96 ms shorter than software but 42 ms higher than P4xos. This is because we choose not to run the acceptors on switches like P4xos and thus need an extra round trip to the software acceptor. We believe the location and replication flexibility of the acceptor is a worthwhile tradeoff for the extra latency, given that it is still much faster than pure software.

6.4 Micro-benchmarks

To better understand NetRPC performance impact, we conduct a series of micro-benchmarks, focusing on INC-related functions only. We also use both prior INC arts and pure software DPDK implementation as comparison baselines.

Throughput. We perform SyncAtgr and AsyncAtgr on a 2-to-1 testbed and measure the *sender goodput*, using ATP and ASK as INC baselines.

The first row in Table 5 shows the result. NetRPC offers 9% higher throughput than ATP. The reason is that NetRPC does not apply recirculation (we use `copy` policy in this experiment) as ATP and SwitchML, which costs extra ports or pipelines on the switch. Instead, it relies on the parallel message sending (Section 4) to increase the goodput. Not surprisingly, both INC solutions outperform software solutions, e.g., NetRPC offers 26% higher goodput than pure DPDK. In fact, the end-to-end training results (42% faster, see Section 6.3) show an even larger improvement than the micro-benchmark, as in SyncAtgr, the shorter latency also improves GPU utilization as we spend less time waiting for the aggregation results.

The second row shows the goodput in AsyncAtgr. NetRPC achieves a similarly high throughput as ASK (about 73 Gbps). Unlike SyncAtgr, the keys count as part of a valid payload in this case, and thus the goodput is higher. Both INC solutions have 37% higher throughput than the pure DPDK.

Latency. We measure the average latency for the two latency-sensitive applications: Agreement and KeyValue, using P4xos voting and ElasticSketch [38] (monitoring) as baselines. The third row in Table 5 shows the average voting latency. Both NetRPC and P4xos outperform DPDK with a 76% latency

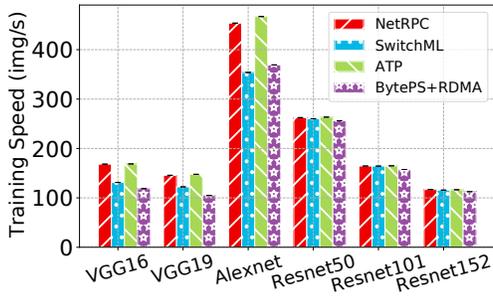

Figure 6: Deep Learning Training Speed

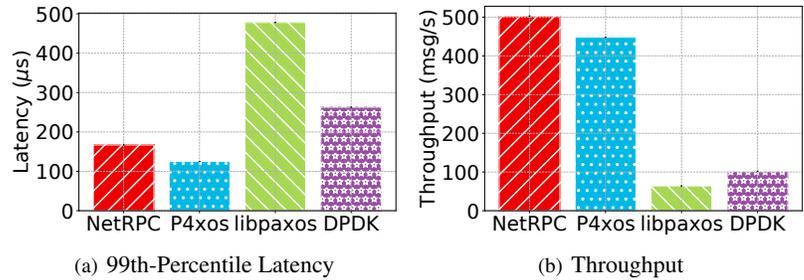

Figure 7: End-to-end Performance of Paxos Systems.

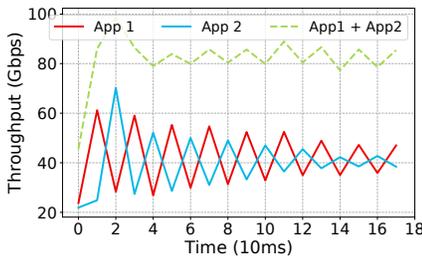

Figure 8: Congestion Control: Fairness

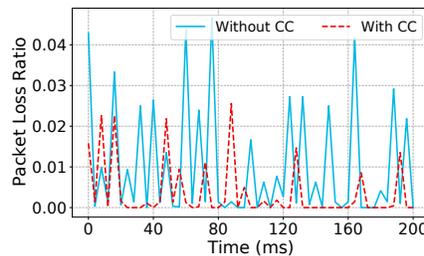

Figure 9: Congestion Control: Packet Loss

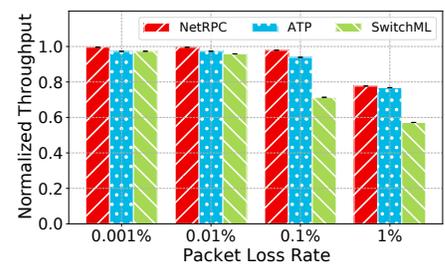

Figure 10: Packet Loss Rates vs. Throughput

reduction. NetRPC and P4xos offer similar latency, showing that NetRPC abstraction layers do not add extra latency.

The last two rows of Table 5 compares performance for Key-Value types, specifically in *flow counting*. Both NetRPC and ElasticSketch have lower latency than DPK, by 13% and 20%, respectively. Notably, the last row of Table 5 also shows a 10× packet processing capacity increase from DPK. NetRPC is about 0.26 ms (9%) slower than ElasticSketch because we do not have the same application-specific optimization that avoids modifying packets. We believe a less-than-10% latency increase is a reasonable price to pay for the general programming model by omitting the optimization.

Congestion control performance. To evaluate the effects of congestion control in NetRPC, we concurrently run two applications: a SyncAggr and an AsyncAggr on the same data plane (i.e., the same switch, host, and links), each having two clients and one server. Figure 8 shows the throughput over a short time period. We observe that the throughput quickly converges within 200 ms, and the combined bandwidth reaches 77% to 89% of the 100Gbps link. Also, the two application fairly shares the available bandwidth. Figure 9 shows the packet loss ratio over a short time period with/without congestion control. We can see that our ECN-based congestion and flow control reduces packet loss by about 63%, as it automatically adjusts the sending window to avoid overwhelming both the link and the server agent (Section 5.1).

Reliability mechanisms. To evaluate how NetRPC handles packet losses, we inject packet losses at different rates to emulate unreliable network. We run three INC applications

NetRPC, ATP, and SwitchML and verified that all three correctly handles packet loss. Figure 10 shows the normalized throughput. NetRPC performs retransmission correctly under packet loss, using on-switch states only. At a high loss rate, NetRPC has a more graceful performance degradation. Compared with the no-loss case, NetRPC, ATP, and SwitchML’s throughput decrease by 22%, 23%, and 43%, respectively. With 1% loss, NetRPC shows significantly less performance degradation than SwitchML because it adopts out-of-order ACKs and thus learns and reacts to packet loss faster.

Handling overflows. We run SyncAggr under synthetic workload varying overflow ratios from 0.001% to 1%. Figure 11 plots the throughput vs. overflow ratios. In all experiments, we check the computation results to ensure that NetRPC detects and corrects the overflow as we expect. When the overflow ratio exceeds 0.1%, we notice throughput degradation due to the software fallback. NetRPC still achieves about 65 Gbps throughput at 1% overflows. Note that the overflow ratio in real workload is far less than 1% with a reasonable quantization scaling factor for floating-point numbers. In contrast, the pure software solution only achieves a max of 40 Gbps.

Performance of `clear` policies. NetRPC offers three ways to handle `Map.clear` in `NetFilter` (Section 5.2.2). We measure the performance of a 2-to-1 SyncAggr using three `Map.clear` policies, and Table 6 summarizes the results. `Lazy` policy performance depends on the ratio of arithmetic overflow, and we use three ratios of 0%, 1%, and 10%. `Copy` policy achieves the highest throughput without extra memory cost but also has the highest latency because it relies on servers to backup

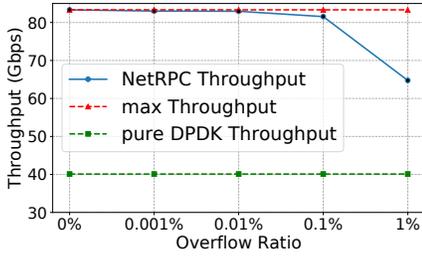

Figure 11: Overflow Ratio vs. Throughput

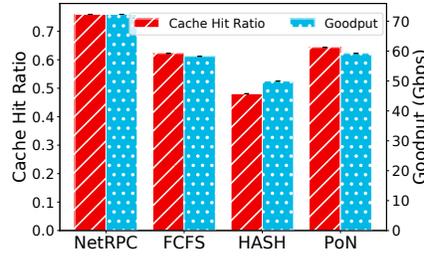

Figure 12: Caching Policy Comparison

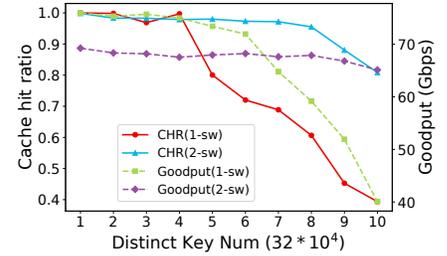

Figure 13: NetRPC on Two Switches

Table 6: Clear Policy Impact on Performance

	Latency	Memory	Throughput
copy	74 μ s	1x	83.11Gbps
shadow	24 μ s	2x	50.41Gbps
lazy (0%)	22 μ s	1x	83.31Gbps
lazy (1%)	23 μ s	1x	64.75Gbps
lazy (10%)	30 μ s	1x	34.82Gbps

the cleared states for reliability. `Shadow` policy offers a good latency of 24 μ s but doubles memory usage and has the lowest throughput because it needs to recirculate the packet and keep an extra copy. `Lazy` policy achieves both the highest throughput and lowest latency with no overflows. But as the overflow ratio increases, both metrics degrade. The actual accumulator overflow ratio depends on the data. Thus, we leave them as a user configuration in the `NetFilter`.

Cache policy. As we discuss in Section 5.2.2, a good cache policy alleviates traffic incast at the server and improves performance. We evaluate multiple cache policies. The experiment uses $32 \times 4K$ switch memory with 2-to-1 traffic. Comparison baselines are FCFS, hash-based caching (HASH), and Power of N (PoN). HASH policy uses the hash key as the index to address the switch memory (like ASK [2] and ATP [22]) and falls back to the server agent on hash collisions. PoN is a classic policy in sketches [38]: it only caches the hot keys whose hit number exceeds a threshold N and gives up caching when the switch memory is full. We tune the hyper-parameter N to maximize the performance experimentally.

Figure 12 shows the result. First, the CHR is positively correlated with the goodput, indicating the need for cache policy optimization. NetRPC’s periodic cache update outperforms other cache policies by 18% ~ 57% on cache hit ratio (CHR) and 22% ~ 44% on goodput. HASH performs the worst because it ignores the locality of keys in the same packet: if some keys are cached, but their adjacent keys in the same stream are not due to hash collision, the entire packet will never hit the cache. PoN and FCFS behave similarly as they stop caching new hot keys if the cache has been fully filled. Compared with these baselines, NetRPC catches up the locality better and adapts to high-skewed key distribution better

Table 7: Concurrent Application Throughput and Latency

Metrics	1APP	4APP	4APP \times 5
Sync Goodput (Gbps)	50.55	24.88	24.84
Async Goodput (Gbps)	72.31	36.01	36.60
Goodput Sum (Gbps)	N/A	60.89	61.44
KeyValue Delay (ms)	3.52	3.56	3.85
Agreement Delay (μ s)	20	21	24

because it always caches the recent hot keys and periodically updates the switch cache to make up space for newer ones.

6.5 Multiple Concurrent Applications

An important goal of NetRPC is to support a multi-application data plane without switch rebooting. To evaluate the performance, we run multiple instances of all four application types in a 2-to-1 topology. We evaluate using three concurrency settings: 1) running a single application instance (“1APP”); 2) running one instance per type (“4APP”); and 3) running five instances per type (“4APP \times 5”). Table 7 shows the total goodput and average latency. In all cases, we measure and report the throughput of SyncAgtr and AsyncAgtr and the latency of KeyValue and Agreement. In the 4APP \times 5 case, we take the average of all instances of the measured type.

When concurrent applications increase from 4 to 20, we observe that the total bandwidth of SyncAgtr and AsyncAgtr stays roughly the same. Although KeyValue and Agreement do not use much bandwidth, they do contend for switch PPS (packets per second) and queue up in sending threads. The experiments show that small applications have little impact on bandwidth-heavy ones. We observe only a 20% latency increase compared to the 1APP case. These results demonstrate the successful resource sharing ability of NetRPC.

6.6 Running on Multiple Switches

Limited by available hardware, we only validate NetRPC’s cross-switch capability with two-switches. We chain the two switches into a longer pipeline, and thus a packet can carry more key-value pairs. The NetRPC server agent decides which

key to put on which switch. We compare the performance of running 2-to-1 MapReduce on the testbed with one / two switches. We loop through the distinct keys multiple times, and thus a cache smaller than the number of distinct keys will suffer cache misses. Then we measure the CHR and the goodput varying with the number of distinct keys as an indicator of how well NetRPC is using memory on both switches.

Figure 13 shows the result. Each switch stores $M = 32 \times 40K$ values with distinct keys. We confirm that the goodput starts to drop at M using one switch, but $2M$ with two. The peak goodput decreases slightly with more switches (from 75 Gbps to 69 Gbps), mainly because of the increased host workload to encode more keys into the packet. Beyond the switch memory capacity, the goodput first decreases slightly (5.3% of peak throughput with 1.5M keys for one switch) and then dramatically (22% with 2M keys). This is because offering a 75 Gbps workload, there is little hope that the server CPU can handle many cache misses. Nevertheless, the two-switch setting shows a 1.63 \times improvement over the one-switch case when handling 2.5M distinct keys, showing that NetRPC can efficiently utilize memory on multiple switches.

7 Conclusion and Future Work

In-network computation (INC) comes from software-defined networking (SDN), but INC is fundamentally different from SDN because it mainly provides *computation* service instead of *communication*. Thus, we need a new programming model for INC to *better describe computation*. We need high-level data structures, collections, memory, and procedure calls that center around end-hosts instead of packets, headers, tables, and pipelines that center around switches. On the other hand, we recognize that the INC data plane is still a shared network infrastructure, not an application-specific accelerator. Thus, both generality and multi-application support are essential.

NetRPC, to our knowledge, is the first framework that integrates INC into the familiar RPC programming model. NetRPC allows users to implement different types of INC applications using the familiar gRPC framework and run them on a single shared INC data plane. NetRPC achieves 97% of LoC deduction for INC applications and offers similar or better performance boosts than handcrafted systems.

Current NetRPC mainly focuses on *mechanisms* of INC + RPC integration. In future work, we will focus on *policies*, such as scheduling among different applications, efficient sharing between INC workload and other SDN or traditional network traffic, efficient end-host CPU, GPU, and INC co-scheduling. We will also explore NetRPC on more complex topologies, especially those with oversubscribed links. We will extend NetRPC congestion control with more fine-grained window adjustment. We will open source NetRPC on the publication of this paper to benefit the INC community.

A Arithmetic in NetRPC

We list the arithmetic operators of `Stream.modify` and their semantics supported by NetRPC in Table 8.

B NetRPC Protocol

B.1 Packet Format

The packet contains three kinds of fields. The key-value pairs encode the application data with the format of an array of $\langle \text{key/index}, \text{value} \rangle$ tuples; computation control fields encode the `NetFilter` configurations and guide the switch program for the computation; transport control fields maintain the channel connection.

Key-value pairs. Each NetRPC packet carries 32 key-value pairs. These pairs are either processed on the switch or the server agent by the selected primitives. The computation results are also carried back in the same position.

Computation Control Fields. The control flag bits contain the basic information about primitives selection. Current bits in use can indicate the following choices: whether any overflow happens (`isOf`); whether to use `CntFwd` (`isCnf`); whether to clear the target memory (`isClr`).

`OpType` indicates the type of arithmetic operation on key-value pairs. NetRPC supports various line-rate on-packet computation as we discuss in Appendix A. In `bitmap` field, the i -th bit in the bitmap indicates whether the switch should process the i -th key-value pair. The `CntFwd` fields only come into effect when the `isCnf` flag is set. `counter index` tells the switch which counter (register) to increase; when the register value equals to the `counter threshold`, the switch should forward the packet instead of dropping it.

Transmission Control Fields. Concurrent NetRPC connections (de)multiplex the network, and NetRPC distinguishes the flows by the GAID. On hosts, received packets are classified to the applications; on the switch, the GAID is also used for admission control. In NetRPC, each sending thread maintains a short-term connection to serve applications' calls/tasks and thus assigns a sequence number (starting from zero) for each packet. In addition, the reliability control requires sending threads to maintain a long-term connection (cross the tasks) with the switch. The field `State Register of Reliable Transmission SRRT` is the switch memory address to store the state, and the `flip bit` is the reliable state to store. Some bits in the `Control Flag` also controls the routing: whether the packet should cross the switch to the server agent (`isCross`); ECN indicates whether the switch is experiencing congestion (queue buildup); whether the packet comes from the server agent (`isSA`); whether to multicast the packet (`isMcast`).

Optimization. Some optional fields will be removed if unnecessary in the computation to improve the network bandwidth efficiency and the goodput. (1) If we address the key-value or value stream linearly to the switch memory, we can eliminate the key fields and indicate the starting index of the memory segment by the `counter index` field. (2) If the computation does not need `CntFwd`, we can eliminate the `CntFwd` fields.

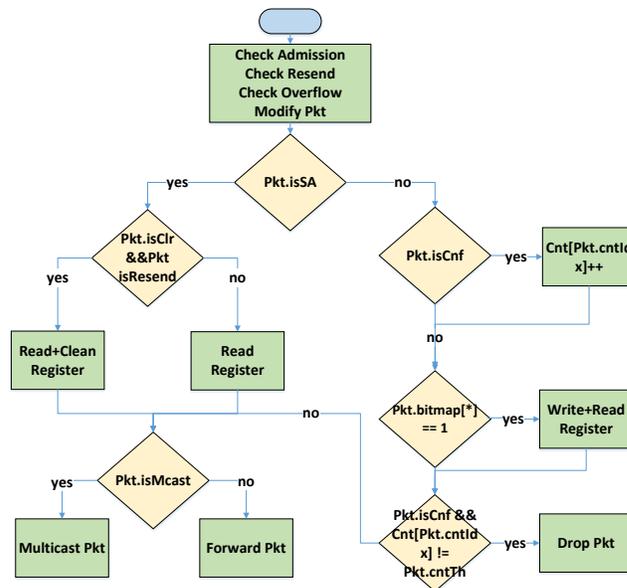

Figure 15: NetRPC Switch Logic

C Switch pipeline details

There is a 12-stage pipeline in our switch, and we use 8 to implement the map access primitives. The remaining four stages handle the reliable transmission, flow and congestion control, as well as `Stream.modify` and the `CntFwd` primitive. Figure 15 illustrate the flowchart for switch logic.

When the switch receives a NetRPC packet, it will first check whether the corresponding application (GAID) has registered. Unregistered packets will be forwarded as normal ones. Moreover, the switch checks whether it receives the packet for the first time. Otherwise, it avoids `Map.addTo/Map.clear` primitives on the switch memory but still `Map.get` values from registers into the packets. An overflow packet will be forwarded directly for fallback without on-switch processing.

For packets to the server, the switch first executes `Stream.modify` and `CntFwd` if required, then processes key-value pairs in the packet: `Map.addTo` the switch registers and `Map.get` the computation results back to replace the value. The switch drops those packets that enable `CntFwd` but do not reach the threshold and forwarded/multicast the rest packets.

For packets from the server, the switch first `Map.get` register values into the packet and then decides whether to clear the corresponding registers. The switch will forward/multicast the packets according to control flags and routing rules.

D NetRPC Implementation Examples

We enumerate some NetRPC implementation of classic INC applications: MapReduce, lock server, and network monitoring in Figure 16 to 24.

```

Bolt: Sub-RTT Congestion Control for Ultra-Low Latency

Abstract

Data center networks are inclined towards increasing line rates to 200Gbps and beyond to satisfy the performance requirements of applications such as NVMe and distributed ML. With larger Bandwidth Delay Products (BDPs), an increasing number of transfers fit within a few BDPs. These transfers are not only more performance-sensitive to congestion, but also bring more challenges to congestion control (CC) as they leave little time for CC to make the right decisions. Therefore, CC is under more pressure than ever before to achieve minimal queuing and high link utilization, leaving no room for imperfect control decisions.

We identify that for CC to make quick and accurate decisions, the use of precise congestion signals and minimization of the control loop delay are vital. We address these issues by designing Bolt, an attempt to push congestion control to its theoretical limits by harnessing the power of programmable data planes. Bolt is founded on three core ideas, (i) Sub-RTT Control (SRC) reacts to congestion *faster* than RTT control loop delay, (ii) Proactive Ramp-up (PRU) *foresees* flow completions in the future to promptly occupy released bandwidth, and (iii) Supply matching (SM) explicitly matches bandwidth demand with supply to maximize utilization. Our experiments in testbed and simulations demonstrate that Bolt reduces 99th-p latency by 80% and improves 99th-p flow completion time by up to 3× compared to Swift and HPCC while maintaining near line-rate utilization even at 400Gbps.

1 Introduction

Data center workloads are evolving towards highly parallel, lightweight applications that perform well when the network can provide low tail latency with high bandwidth [5]. Accordingly, the Service Level Objectives (SLOs) of applications are becoming more stringent, putting increasing responsibility on network performance. To support this trend, the industry is inclined towards increasing line rates. 100Gbps links are already abundant, 200Gbps is gaining adoption, and industry standardization of 400Gbps ethernet is underway [24].

*Work done as a student researcher at Google

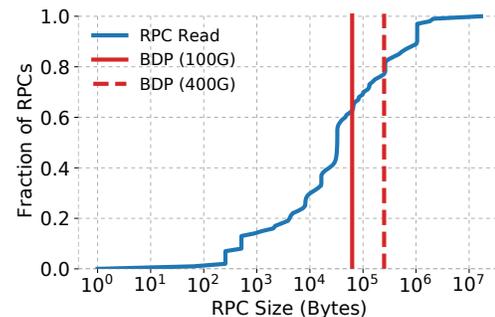

Figure 1: RPC size distribution for READ operations

With the increasing line rates, CC needs to make decisions with *higher quality and timeliness* over a *burstier workload*. We illustrate this based on a recent analysis of RPC sizes in our data centers with respect to BDP sizes at 100Gbps and 400Gbps (calculated using a typical base delay/RTT in data centers). Our findings are presented in Figure 1.

The fraction of RPCs that fit within 1 and 4 BDP increases from 62% and 80% at 100Gbps to 80% and 89% at 400Gbps. These RPCs are performance-sensitive to queuing and under-utilization. Ultimately, even a single incorrect or slow CC decision may end up creating tens of microseconds of tail queuing [12], or cause under-utilization [53] which prolongs the flow completion time by a few RTTs. Therefore, an increasing fraction of such RPCs raises the bar for the quality and timeliness of CC.

Concomitantly, at higher bandwidth, the workload becomes burstier and thus harder to control. Figure 1 also reveals that a 400Gbps link with just 40% load sees an RPC arrival or completion roughly every RTT! Hence, it becomes more difficult to control queuing and under-utilization as they arrive and finish quickly at RTT timescales. We expect these numbers to be even more challenging for upcoming workloads such as disaggregated memory and ML.

We identify two key aspects of CC that are important to address the challenges of achieving higher CC quality and timeliness on burstier workloads:

First, granular feedback about the location and severity of

congestion allows avoiding over/under-reaction [3]. A precise CC algorithm would receive the exact state of the bottleneck to correctly ramp down during congestion and ramp up during under-utilization. This congestion information would intuitively involve telemetry such as the current queue occupancy and a measure of link utilization [35]. Then, end-hosts would be able to calculate the exact number of packets they can inject into the network without creating congestion.

Second, the **control loop delay** is a determinant of how sensitive a control algorithm can be. It is defined as the delay between a congestion event and the reaction from the senders arriving at the bottleneck. Smaller the control loop delay, the more accurate and simpler decisions a control system can make [41]. The state-of-the-art CC algorithms in production are reported to work well to the extent their control loop delay allows [30, 35, 60]. However, even a delay of one RTT will be too long to tolerate for future networks because of the increasing BDPs [58]. We conjecture that the inevitable next step is to reduce the control loop delay to sub-RTT levels.

Fortunately, the flexibility and precision provided by programmable switches [7, 11, 22] allow designing new mechanisms to reduce the control loop delay and increase the granularity of control algorithms. These state-of-the-art switches can generate custom control signals to report fine-grained telemetry so that flows don't need to rely on end-to-end measurements for detecting congestion at the bottleneck link.

In this work, we present Bolt, our effort of harnessing the power of programmable data planes to design an extremely precise CC for ultra-low latency at very high line rates. Bolt collects congestion feedback with absolute minimum (sub-RTT) delay and ramps up flows proactively to occupy available bandwidth promptly. To achieve this, it applies the "packet conservation" principle [25] onto the traffic with accurate per-packet decisions in P4 [9]. Small per-packet `cwnd` changes, combined with the fine-grained in-network telemetry, help limit the effects of noise in the instantaneous congestion signal. With Bolt, end-hosts do not make implicit estimations about the severity and exact location of the congestion or the number of competing flows, freeing them from manually tuned hard coded parameters and inaccurate reactions.

The main contributions of Bolt are:

1. A discussion for the fundamental limits of an optimal CC algorithm with minimal control loop delay.
2. Description of 3 mechanisms that collectively form the design of Bolt – an extremely precise CC algorithm with the shortest control loop possible.
3. Implementation and evaluation of Bolt on P4 switches in our lab which achieves 86% and 81% lower RTTs compared to Swift [30] for median and tail respectively.
4. NS-3 [48] implementation for large scale scenarios where Bolt achieves up to $3\times$ better 99th-p flow completion times compared to Swift and HPCC [35].

The remainder of the paper describes the rationale behind the design of Bolt in §2, design details in §3, and implementation insights in §4. Further evaluations and benchmarks are provided in §5 followed by practical considerations in §6. Finally, a survey of related work is presented in §7.

2 Towards Minimal Control Loop Delay

Timely feedback and reaction to congestion are well understood to be valuable for CC [42]. With Bolt, we aim to push the limits on minimizing the control loop delay that is composed of two elements: (1) *Feedback Delay* (§2.1) is the time to receive any feedback for a packet sent, and (2) *Observation Period* (§2.2) is the time interval over which feedback is collected before `cwnd` is adjusted. Most CC algorithms send a window of packets, observe the feedback reflected by the receiver over another window, and finally adjust the `cwnd`, having a total control loop delay that is even longer than an RTT [1, 10, 19, 30, 35, 60]. In this section, we describe both *Feedback Delay* and *Observation Period* in detail and discuss how these elements can be reduced to their absolute minimum motivating Bolt's design in §3.

2.1 Feedback Delay

There are two main types of feedback to collect for congestion control purposes: (i) *Congestion Notification* and (ii) *Under-utilization Feedback*.

2.1.1 Congestion Notification

The earliest time a CC algorithm can react to drain a queue is when it first receives the notification about it. Traditionally, congestion notifications are reflected by the receivers with acknowledgments [1, 8, 30, 35, 42, 47, 60]. We call this the RTT-based feedback loop since the delay is exactly one RTT.

To demonstrate how notification delay affects performance, we run an experiment where the congestion notification is delivered to the sender after a constant configured delay (and not via acknowledgments). Setting this delay to queuing delay plus the propagation time in the experiment is equivalent to RTT-based control loops described above. The experiment runs two flows with Swift CC [30] on a dumbbell topology¹ where the second flow joins while the first one is at a steady state. The congestion signal is the RTT the packet will observe with current congestion. Figure 2 (left) shows the time to drain the congested queue for different notification delays. Clearly, smaller notification delay helps mitigate congestion faster as senders react sooner to it.

More importantly, in addition to traveling unnecessary links, traditional RTT-based feedback loops suffer from the congestion itself because the notification waits in the congested queue before it is emitted. Adding the queuing delay

¹RTT is 8 μ s and all the links are 100Gbps.

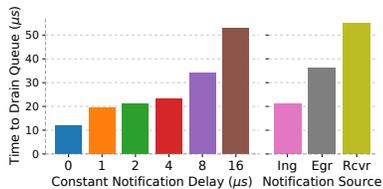

Figure 2: Effect of notification delay on queue draining time

to the notification delay hinders tackling congestion even more. During severe congestion events, this extra delay can add multiples of the base RTT to the feedback delay [30].

To understand this more, we also measure the congestion mitigation time of scenarios where the notification is generated at different locations in the network in Figure 2 (right). "Rcvr" represents the RTT-based feedback loop where the congestion notification is piggybacked by the receiver. "Egr" is when the switch sends a notification directly to the sender from the egress pipeline, after the packet waits in the congested queue. "Ing" is when the notification is generated at the ingress pipeline, as soon as a packet arrives at the switch. As expected, generating the congestion notification as soon as possible improves performance by more than $2\times$.

Correspondingly, we stress that in order to reduce the notification delay to its absolute minimum, the congestion notification should travel directly from the bottleneck back to the sender without waiting in the congested queue.

2.1.2 Under-utilization Feedback

While flow arrival events add to congestion in the network, flow completion events open up capacity to be used by other flows. When a flow completes on a fully utilized link with zero queuing, the packets of the completing flow leave the network and the link will suddenly become under-utilized until the remaining flows ramp up (Figure 3a). As traffic gets more dynamic, such under-utilization events become more frequent, reducing the total network utilization. Therefore, in addition to detecting congestion, a good control algorithm should also be able to detect any under-utilization in order to capture the available bandwidth quickly and efficiently [44].

In practice, CC schemes deliberately maintain a standing queue under a steady state, so that when a flow completes, the packets in the queue can occupy the bandwidth released by the finished flow until the remaining flows ramp up [34, 40]. For example, while HPCC was designed to keep near-zero standing queue, the authors followed up that in practice, HPCC target utilization should be set to 150% to improve network utilization [36], which implies half a BDP worth of standing queue. Other CC schemes used in practice also maintain standing queues by filling up the buffers to a certain level before generating any congestion signal [1, 30, 60].

Figure 4 demonstrates how Swift behaves upon a flow com-

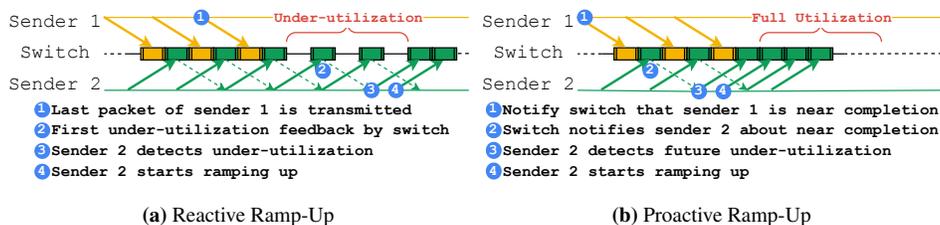

Figure 3: Under-utilization feedback

pletion when a long enough standing queue is not maintained. There are two flows in the network² and one of them completes at $t = 200\mu s$. The remaining flow's $cwnd$ takes about 25 RTTs to occupy the released bandwidth as per the additive increase mechanism in Swift. During this time interval, under-utilization happens despite the non-zero queuing at a steady state. This under-utilization can also be observed when there are a larger number of flows if the standing queue size is not adjusted appropriately [53].

Ideally, any remaining flow should immediately capture the $cwnd$ of the completing flow without under-utilizing the link. Therefore we conclude that an optimal congestion control algorithm would detect flow completions early enough, **proactively**, to ramp up as soon as the spare capacity becomes available (Figure 3b).

2.2 Observation Period

In addition to the feedback delay, the total control loop delay is usually one RTT longer for window-based data center CC schemes. Namely, once the sender adjusts its $cwnd$, the next adjustment happens only after an RTT to prevent reacting to the same congestion event multiple times. We call this extra delay the *observation period* and illustrate it in Figure 5.

Once-per-window semantics is very common among CC schemes where the per-packet feedback is aggregated into per-window observation. For example, DCTCP [1] counts the number of ECN markings over a window and adjusts $cwnd$ based on this statistics once every RTT. Swift compares RTT against the target every time it receives an ACK but decreases $cwnd$ only if it has not done so in the last RTT. Finally, HPCC picks the link utilization observed by the first packet of a window to calculate the reference $cwnd$ which is updated once per window. As a consequence, flows stick to their $cwnd$ decision for an RTT even if the feedback for a higher degree of congestion arrives immediately after the decision.

Updating $cwnd$ only once per window removes information about how dynamic the instantaneous load was at any time within the window. This effect, naturally, results in late and/or incorrect congestion control decisions, causing oscillations between under and over-utilized (or congested) links when flows arrive and depart. Consider the scenario² in Figure 6

²The dumbbell topology from Figure 2 (RTT: $8\mu s$, 100Gbps links).

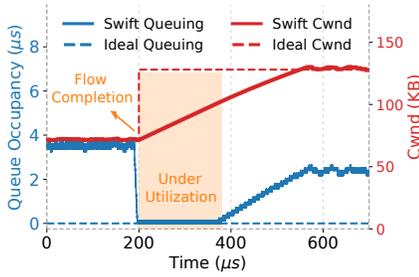

Figure 4: cwnd of the remaining Swift flow and queue occupancy after a flow completion.

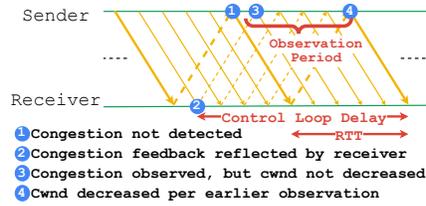

Figure 5: Observation period adds up to an RTT to the control loop delay.

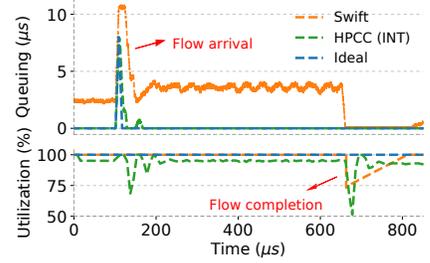

Figure 6: HPCC and Swift’s reaction to flow arrival and completion.

where a new flow joins the network at $t = 100\mu\text{s}$ while another flow is at its steady state. HPCC drains the initial queue built up in a couple of RTTs, but immediately oscillates between under-utilization and queuing for a few iterations. Moreover, the completion of a flow at $t = 650\mu\text{s}$ again causes oscillations. Under highly dynamic traffic, such oscillations may increase tail latency and reduce network utilization.

An alternative way to avoid oscillations would be to react conservatively similar to Swift. It also reduces cwnd only once in an RTT during congestion but uses manually tuned parameters (i.e. α and β) to make sure reactions are not impulsive. Although oscillations are prevented this way, Figure 6 shows that Swift takes a relatively long time to stabilize.

We conclude that once per RTT decisions can lead to either non-robust oscillations or relatively slow convergence. This is especially problematic in high-speed networks where flow arrivals and completions are extremely frequent. Ideally, the shortest observation period would be a packet’s serialization time because it is the most granular decision unit for packet-switched networks. Yet, the per-packet CC decisions should only be incremental to deal with the noise from observations over such a short time interval.

3 Design

Bolt is designed for ultra-low-latency even at very high line rates by striving to achieve the ideal behavior shown in Figures 4 and 6. The design aims to reduce the control loop delay to its absolute minimum as described in §2. *First*, the congestion notification delay is minimized by generating notifications at the switches and reflecting them directly to the senders (§3.1). *Second*, the flow completion events are signaled by the senders in advance to hide the latency of ramp-up and avoid under-utilization (§3.2). *Third*, cwnd is updated after each feedback for quick stabilization where the update is at most one per packet to be resilient to noise. Together, these three ideas allow for a precise CC that operates on a per-packet basis minimizing incorrect CC decisions.

Prior works have separately proposed sub-RTT feedback [17, 50, 57], flow completion signaling [18], and per-packet

cwnd adjustments [16, 27] which are discussed in §7. Bolt’s main innovation is weaving these pieces into a harmonious and precise sub-RTT congestion control that is feasible for modern high-performance data centers. The key is to address congestion based on the *packet conservation principle* [25] visualized in Figure 7 where a network path is modeled as a pipe with a certain capacity of packets in-flight at a time. When the total cwnd is larger than the capacity by 1, there is an excess packet in the pipe which is queued. If the total cwnd is smaller than the capacity by 1, the bottleneck link will be under-utilized by 1 packet per RTT. Therefore, as soon as a packet queuing or under-utilization is observed, one of the senders should *immediately* decrement or increment the cwnd, without a long observation period.

Bolt’s fundamental way of minimizing feedback delay and the observation period while generating precise feedback for per-packet decisions is materialized with 3 main mechanisms:

1. **SRC (Sub-RTT Control)** reduces congestion notification delay to its absolute minimum. (§3.1)
2. **PRU (Proactive Ramp Up)** hides any feedback delay for foreseen under-utilization events. (§3.2)
3. **SM (Supply Matching)** quickly recovers from unavoidable under-utilization events. (§3.3)

To realize these 3 mechanisms, Bolt uses 9 bytes of transport-layer header detailed in listing 1. We explain the purpose of each field as we describe the design of Bolt whose switching logic is summarized in Algorithm 1.

3.1 SRC - Sub-RTT Control

As discussed in §2.1.1, a smaller feedback delay improves the performance of CC. Therefore, Bolt minimizes the delay of the feedback by generating control packets at the *ingress* pipeline of the switches and sending them directly *back to the sender*, a mechanism available in programmable switches such as Intel-Tofino2 [32]. While in spirit, this is similar to ICMP Source Quench messages [45] that have been deprecated due to feasibility issues in the Internet [33], Bolt’s SRC mechanism exploits precise telemetry in a highly controlled data center environment.

Figure 8 depicts the difference in the paths traversed by the traditional ACK-based feedback versus the SRC-based feedback mechanism. As SRC packets are generated at ingress, they establish the absolute minimum feedback loop possible by traveling through the shortest path between a congested switch and the sender. Moreover, to further minimize the

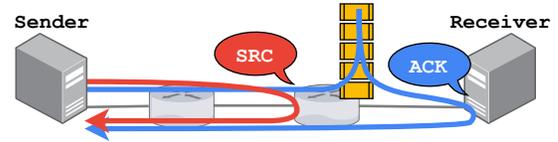

Figure 8: Path of ACK-based vs. SRC-based feedback

feedback delay, Bolt prioritizes ACK and SRC packets over data packets at the switches.

Bolt generates SRC packets for every data packet that arrives when the queue occupancy is greater than or equal to the $CCTHRESH$ which is trivially set to a single MTU for minimal queuing. Yet, if there are multiple congested switches along the path of a flow, generating an SRC at each one of them for the same data would flood the network with an excessive amount of control packets. To prevent flooding switches mark the DEC flag of the original data packet upon generation of an SRC packet, such that no further SRC packets at other hops can be generated due to this packet (lines 5 and 10 in Algorithm 1). This implies that the number of SRC packets is bounded by the number of data packets in the network at any given time. In practice, however, we find that the actual load of SRC packets is extremely lower (§5.2.1) and present an approximation for the additional load of SRC packets in Appendix A.

When there are multiple congested hops, and the flow receives SRC packets only from the first one, the $cwnd$ decrement still helps mitigate congestion at all of them. Consequently, even if congestion at the first hop is not as severe as the others, Bolt would drain the queue at the first hop and quickly start working towards the subsequent hops.

Bolt stamps two vital pieces of information on the SRC packets – the current queue occupancy and the capacity of the link. In addition, it reflects the TX timestamp of the original data packet (lines 6-8 in Algorithm 1). As the sender receives this packet, it runs the decision logic shown in Algorithm 2. First, rtt_{src} is calculated as the time between transmitting the corresponding data packet and receiving an SRC packet for it. This is the congestion notification delay for Bolt which is always shorter than RTT and enables sub-RTT control. The reflection of the TX timestamp enables this computation without any state at the sender. Next, $reaction_factor$ is calculated as a measure of this flow’s contribution to congestion. Multiplying this value with the reported queue occupancy gives the amount of queuing this flow should aim to drain. All the flows aiming to drain only what they are responsible for organically help for a fair allocation.

Finally, $\frac{rtt_{src}}{target_q}$ gives the shortest time interval between two consecutive $cwnd$ decrements. This interval prevents over-reaction because switches keep sending congestion notifications until the effect of the sender’s $cwnd$ change propagates to them. For example, if the target queue has a single packet, the sender decrements its $cwnd$ only if rtt_{src} has elapsed since the last decrement. However, if the queue is larger, Bolt allows

Algorithm 2: BOLT LOGIC AT THE SENDER HOST

```
1 HandleSrc ( $pkt_{src}$ ):
2    $rtt_{src} \leftarrow now - pkt.t_{tx\_data}$ 
3    $reaction\_factor \leftarrow flow.rate / pkt_{src}.link\_rate$ 
4    $target_q \leftarrow$   $\triangleright$  in number of packets
5      $pkt_{src}.queue\_size \times reaction\_factor$ 
6   if  $\frac{rtt_{src}}{target_q} \leq now - last\_dec\_time$  then
7      $cwnd \leftarrow cwnd - 1$ 
8      $last\_dec\_time \leftarrow now$ 
9 HandleAck ( $pkt_{ack}$ ):
10  if  $pkt_{ack}.inc$  then  $\triangleright$  Capacity available
11     $cwnd \leftarrow cwnd + 1$ 
12  if  $pkt_{ack}.seq\_no \geq seq\_no\_at\_last\_ai$  then
13     $cwnd \leftarrow cwnd + 1$   $\triangleright$  per-RTT add. inc.
14     $seq\_no\_at\_last\_ai \leftarrow snd\_next$ 
```

more frequent decrements to equalize the total $cwnd$ change to the target queue size in exactly one rtt_{src} . As the required $cwnd$ adjustments are scattered over rtt_{src} , Bolt becomes more resilient to noise from any single congestion notification.

Events such as losses and timeouts do not happen in Bolt as it starts reacting to congestion way in advance. However, due to the possibility of such events occurring, say due to mis-configuration or packet corruption, handling retransmission timeouts, selective acknowledgments, and loss recovery are kept the same as in Swift [30] for completeness.

3.2 PRU - Proactive Ramp Up

Bolt explicitly tracks flow completions to facilitate Proactive Ramp Up (PRU). When a flow is nearing completion, it marks outgoing packets to notify switches, which plan ahead on distributing the bandwidth freed up by the flow to the remaining ones competing on the link. This helps remaining Bolt flows to *proactively ramp up* and eliminate the under-utilization period after a flow completion (see Figure 3b).

When flows larger than one BDP are sending their last $cwnd$ worth of data, they set the *LAST* flag on packets to mark that they will not have packets in the next RTT. Note that this does not require knowing the application-level flow size. In a typical transport like TCP, the application injects a known amount of data to the connection at each `send` API call, denoted by the `len` argument [29]. Therefore, the amount of data waiting to be sent is calculable. *LAST* is marked only when the remaining amount of data in the connection is within $cwnd$ size. Our detailed implementation is described in §4.2.

A switch receiving the *LAST* flag, if it is not congested, increments the *PRU token* value for the associated egress port. This value represents the amount of bandwidth that will be freed in the next RTT. The switch distributes these tokens to packets without the *LAST* flag, i.e. flows that have packets to send in the next RTT, so that senders can ramp up proactively.

However, only flows that are not bottlenecked at other hops should ramp up. To identify such flows, Bolt uses a greedy approach. When transmitting a packet, senders mark the *INC* flag on the packet. If a switch has PRU tokens (line 14 in Algorithm 1) or has free bandwidth (line 16 in Algorithm 1, explained in §3.3), it keeps the flag on the packet and consumes a token (line 15 and 17, respectively). Else, the switch resets the *INC* flag (line 19), preventing future switches on the path to consume a token for this packet. Then, if no switch resets the *INC* flag along the path, it is guaranteed that all the links on the flow's path have enough bandwidth to accommodate an extra packet. The receiver reflects this flag in the ACK so that the sender simply increments the $cwnd$ upon receiving it (lines 10-11 in Algorithm 2). There are cases where the greedy approach can result in wasted tokens and we discuss the fallback mechanisms in §3.3.

Flows shorter than one BDP are not accounted for in PRU calculations. When a new flow starts, its first $cwnd$ worth of packets are not expected by the network and contribute to the extra load. Therefore, the switch shouldn't replace these with packets from other flows once they leave the network. Bolt prevents this by setting the *FIRST* flag on packets that are in the first $cwnd$ of the flow. Switches check against the *FIRST* flag on packets before they increment the *PRU token* value (line 12 of Algorithm 1).

Note that PRU doesn't need reduced feedback delay via SRC packets, because it accounts for a flow completion in the *next* RTT by design. A sender shouldn't start ramping up earlier as it can cause extra congestion before the flow completes. Therefore, the traditional RTT-based feedback loop is the right choice for correct PRU accounting.

3.3 SM - Supply Matching

Events like link and device failures or route changes can result in under-utilized links without proactive signaling. In addition, *PRU tokens* may be wasted if assigned to a flow that can not ramp up due to being already at line rate, or bottlenecked by downstream switches. For such events, conventional CC approaches rely on gradual *additive* increase to slowly probe for the available bandwidth which can take several tens of RTTs [1, 30, 42, 60]. Instead, Bolt is able to probe *multiplicatively* by explicitly matching utilization demand to supply through *Supply Matching* (SM) described below.

Bolt leverages stateful operations in programmable switches to measure the instantaneous utilization of a link. Each switch keeps track of the mismatch between the supply and demand for the link capacity for each port, where the number of bytes the switch can serialize in unit time is the supply amount for the link; and the number of bytes that arrive in the same time interval is the demand for the link. Naturally, the link is under-utilized when the supply is larger than the demand, otherwise, the link is congested. Note the similarity to HPCC [35] that also calculates link utilization, albeit from

Algorithm 3: Supply Token calculation at the ingress pipeline for each egress port of the switch

```

1 CalculateSupplyToken (pkt) :
2    $inter\_arrival\_time \leftarrow now - last\_sm\_time$ 
3    $last\_sm\_time \leftarrow now$ 
4    $supply \leftarrow BW \times inter\_arrival\_time$ 
5    $demand \leftarrow pkt.size$ 
6    $sm\_token \leftarrow sm\_token + supply - demand$ 
7    $sm\_token \leftarrow \min(sm\_token, MTU)$ 

```

an end-to-end point of view which restricts it to make once per RTT calculations. Bolt offloads this calculation to the switch data plane so that it can capture the precise instantaneous utilization instead of a coarse-grained measurement.

When a data packet arrives, the switch runs the logic in Algorithm 3 to calculate the *supply token* value (*sm_token* in the algorithms) associated with the egress port. The token accumulates the mismatch between the supply and demand in bytes on every packet arrival for a port. A negative value of the token indicates queuing whereas a positive value means under-utilization. When the token value exceeds one MTU, Bolt keeps the *INC* flag on the packet and permits the sender to inject an additional packet into the network (lines 16-17 in Algorithm 1). The *supply token* value is then decremented by an MTU to account for the inflicted future demand.

If a switch port doesn't receive a packet for a long time, the *supply token* value can get arbitrarily large, which prohibits capturing the instantaneous utilization if a burst of packets arrive after an idle period. To account for this, Bolt caps the *supply token* value at a maximum of one MTU. Details on how this feature is implemented in P4 are provided in §4.

As noted earlier, there are cases where there can be wasted tokens, i.e. a switch consumes a token (either PRU or SM) to keep *INC* bit, but is reset by downstream switches. In such cases, SM will find the available bandwidth in the next RTT. In the worst case, this happens for consecutive RTTs and Bolt falls back to additive increase similar to Swift [30] (lines 12-14 in Algorithm 2). Namely, *cwnd* is incremented once every RTT to allow flows to probe for more bandwidth and achieve fairness even if they do not receive any precise feedback as a fail-safe mechanism.

4 Implementation

We implemented Bolt through Host (transport layer and NIC) and Switch modifications in our lab. We used Snap [38] as our user-space transport layer and added Bolt in 1340 LOC in addition to the existing Swift implementation. Plus, the switch-side implementation consists of a P4 program – *bolt.p4* – in 1120 LOC. Figure 9 shows the overview of our lab prototype as a whole and we provide details below.

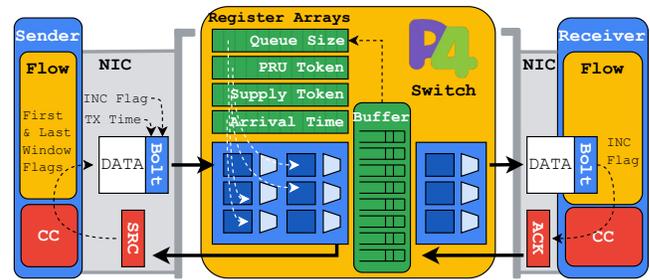

Figure 9: Bolt system overview

4.1 Switch Prototype

We based our implementation on the programmable data plane of Intel Tofino2 [11] switches in our lab as they can provide the queue occupancy of the egress ports in the ingress pipelines and generate SRC packets [32]. This is crucial for Bolt to minimize the feedback delay incurred by SRC packets as they are not subject to queuing delay at congested hops.

When congestion is detected in the ingress pipeline, the switch mirrors this packet to the input port while forwarding the original one along its path. The mirroring configuration is determined with a lookup table that matches the ingress port of the packet and selects the associated mirroring session.

The mirrored packet is then trimmed to remove the payload and the flow identifiers (i.e. source/destination addresses and ports) are swapped. Finally, *SRC* flag is set on this packet to complete its conversion into an SRC packet.

The entire *bolt.p4* consists mainly of register array declarations and simple if-else logic as shown in Algorithm 1. There are 4 register arrays for storing queue occupancy, token values, and the last packet arrival time. All of the register arrays are as large as the number of queues on the switch because the state is maintained per queue. In total, only 3.6% and 0.6% of available SRAM and TCAM, respectively, are used for the register arrays, tables, and counters.

The switch keeps the last packet arrival time for every egress port to calculate the supply for the link. On each data packet arrival, the difference between the current timestamp and the last packet arrival time is calculated as the inter-arrival time. This value should ideally be multiplied with the link capacity (line 4 of Algorithm 3) to find the supply amount. However, since floating point arithmetic is not available in PISA pipelines, we use a lookup table indexed on inter-arrival times to determine the supply amount. We set the size of this lookup table as 65536 where each entry is for a different inter-arrival time with a granularity of a nanosecond. Consequently, if the inter-arrival time is larger than 65 microseconds, the *supply token* value is directly set to its maximum value of 1 MTU which triggers *INC* flag to be set. We find that, at a reasonably high load, 65 microseconds of inter-arrival time is rare enough for links greater than 100Gbps such that any longer value can be safely interpreted as under-utilization.

Our prototype is based on a single HW pipeline. Therefore,

we implemented Bolt entirely at the ingress pipeline to make it easier to understand and debug its logic. However, since PRU and SM maintain state per egress port, they could also be implemented at the egress pipeline with minor modifications. This way, the state for packets from multiple ingress pipelines would naturally be aggregated.

4.2 Host Prototype

Our transport layer uses the NIC hardware timestamps to calculate rtt_{src} as described in Algorithm 2. When a sender is emitting data, the TX timestamp is stamped onto the packet. The switch reflects this value back to the sender, so that rtt_{src} is the difference between the NIC time when the SRC packet is received (RX timestamp) and the reflected TX timestamp. This precisely measures the network delay to the bottleneck without any non-deterministic software processing delays.

The transport layer also multiplexes RPCs meant for the same server onto the same network connection. Then, the first `cwnd` bytes of a new RPC isn't necessarily detected as the *first* window of the connection. To mitigate this issue, our prototype keeps track of idle periods of connections and resets the *bytes-sent counter* when a new RPC is sent after such a period. Therefore the *FIRST* flag is set on a packet when the counter value is smaller than `cwnd`.

Finally, the *last* window marking for PRU requires determining the size of the remaining data for each connection. In our prototype, the connection increments *pending bytes counter* by the size of data in each `send` API call from the application. Every time the connection transmits a packet into the network, the counter value is decremented by the size of the packet. Therefore the *LAST* flag is set on a packet when this counter value is smaller than `cwnd`.

4.3 Security and Authentication

Getting Bolt to work for encrypted and authenticated connections was a key challenge in our lab. Our prototype uses a custom version of IPsec ESP [23, 28] for encryption atop the IP Layer. However, switches need to read and modify CC information at the transport header without breaking end-to-end security. The *crypt_offset* of the protocol allows packets to be encrypted only beyond this offset. We set it such that the transport header is not encrypted, but is still authenticated.

In addition, switches cannot generate encrypted packets due to the lack of encryption and decryption capabilities. To remedy this, we generate SRC packets on switches as unreliable datagrams per RoCEv2 standard by adding IB BTH and DETH headers while removing the encryption header.

The RoCEv2 packets have the invariant CRC calculated over the packet and appended as a trailer. Fortunately, Tofino2 provides a CRC extern that is capable of this calculation over small, constant-size packets [31]. As a result, NICs are able to forward the SRC packets correctly to the upper layers based on the queue pair numbers (QPN) on the datagrams.

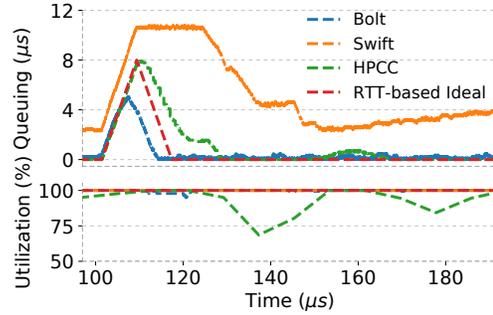

Figure 10: Bolt’s reaction to flow arrival versus the ideal behavior.

5 Evaluation

We evaluate Bolt on NS3 [48] micro-benchmarks to demonstrate its fundamental capabilities in §5.1 followed by sensitivity and fairness analysis in §5.2 and §5.3. Then, in §5.4, we run large-scale experiments to measure the end-to-end performance of the algorithm, i.e. flow completion time slow-downs. Finally, we evaluate our lab prototype in §5.5.

5.1 Micro-Benchmarks

5.1.1 Significance of SRC

The only way for Bolt to decrease `cwnd` is through SRC whose effectiveness is best observed during congestion. Therefore, we repeat the same flow arrival scenario described in Figure 6 with Bolt.³ Typically, with conventional RTT-based congestion control algorithms, a new flow starting at line rate emits BDP worth of packets until it receives the first congestion feedback after an RTT. If the network is already fully utilized before this flow, all emitted packets end up creating a BDP worth of queuing even for an RTT-based ideal scheme. Then, the ideal scheme would stop sending any new packets to allow draining the queue quickly which would take another RTT. This behavior is depicted as red in Figure 10 where a new flow joins at 100 μ s.

HPCC’s behavior in Figure 10 is close to the ideal given that it is an RTT-based scheme with high precision congestion signal. As the new flow arrives, the queue occupancy rises to 1 BDP. However, the queue is drained at a rate slower than the link capacity because flows continue to occasionally send new packets while the queue is not completely drained.

Bolt, on the other hand, detects congestion earlier than an RTT. Therefore it starts decrementing `cwnd` before the queue occupancy reaches BDP and completely drains it in less than 2 RTTs, even shorter than the RTT-based ideal scheme.

In addition, HPCC’s link utilization drops to as low as 75% after draining the queue and oscillates for some time, which is due to the RTT-long observation period (§2.2). Bolt’s per-packet decision avoids this under-utilization.

³The dumbbell topology with two flows (8 μ s RTT at 100Gbps).

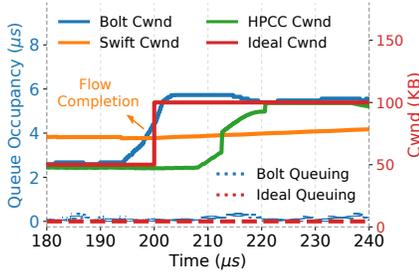

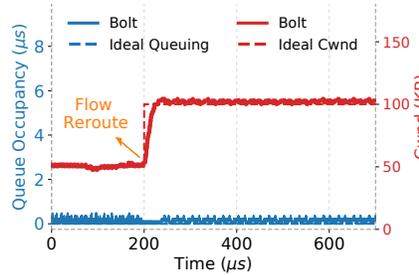

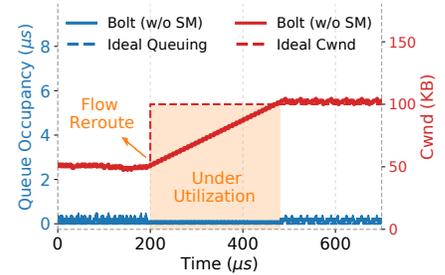

Figure 11: $cwnd$ of the remaining flow and queue occupancy after a flow completion.

(a) Bolt

(b) Bolt (without SM)

Figure 12: $cwnd$ of the remaining flow and queue occupancy after a flow is rerouted.

Utilization (%)		PRU OFF	PRU ON
SM	OFF	90.46	97.38
	ON	92.41	98.54

Table 1: Effectiveness of PRU and SM on the bottleneck utilization.

5.1.2 Significance of PRU

Flow completions cause under-utilization without proactive ramp-up or standing queues because conventional congestion control algorithms take at least an RTT to react to them (§2.1.2). Moreover, as shown in Figure 4 for Swift, a standing queue might not be enough to keep the link busy if the $cwnd$ of the completing flow is larger than the queue size

We repeat the same scenario with Bolt to test how effective proactive ramp-up can be upon flow completions against Swift and HPCC. Figure 11 shows the $cwnd$ of the remaining flow and the queue occupancy at the bottleneck link. When a Bolt flow completes at $t=200\mu s$, the remaining one is able to capture the available bandwidth in $1\mu s$ because it starts increasing $cwnd$ (by collecting PRU tokens) one RTT earlier than the flow completion. Moreover, neither queuing nor under-utilization is observed. HPCC, on the other hand, takes $20\mu s$ ($> 2 \times RTT$) to ramp up for full utilization because it needs one RTT to detect under-utilization and another RTT of observation period before ramping up. Finally, Swift takes more than $370\mu s$ to reach the stable value due to the slow additive increase approach which doesn't fit into Figure 11. The complete ramp-up of Swift is shown in Figure 4.

Although PRU and SM seem to overlap in the way they quickly capture available bandwidth, PRU is a faster mechanism compared to SM because it detects under-utilization proactively. To demonstrate that, we create a star topology with 100Gbps links and a base RTT of $5\mu s$, where 5 senders send 500KB to the same receiver. Flows start $15\mu s$ apart from each other to complete at different times so that PRU and SM can kick in. We repeat while disabling PRU or SM and measure the bottleneck utilization to observe how each mechanism is effective at achieving high throughput.

Table 1 shows the link utilization between the first flow completion and the last one. When only PRU is disabled, the

utilization drops by 6% despite having SM. On the other hand, disabling SM alone causes only a 1% decrease. This indicates that PRU is a more powerful mechanism compared to SM when under-utilization is mainly due to flow completions in the network. Together, they increase utilization by 8%.

5.1.3 Significance of SM

Unlike flow completions, events such as link failure or rerouting are not hinted in advance. Then, PRU doesn't kick in, making Bolt completely reliant on SM for high utilization. To demonstrate how SM quickly captures available bandwidth, we use the same setup from Figures 4 and 11, but reroute the second flow instead of letting it complete.

Figure 12 shows the $cwnd$ of the remaining flow after the other one leaves the bottleneck. Thanks to SM, $cwnd$ quickly ramps up to utilize the link in $23\mu s$ (12a). When SM is disabled, the only way for Bolt to ramp up is through traditional additive increase which increases $cwnd$ by 1 every RTT (12b). Therefore it takes more than 33 RTTs to fully utilize the link.

5.2 Sensitivity Analysis

5.2.1 Overhead of SRC

To mitigate congestion, Bolt generates SRC packets in an already loaded network. In order to understand the extra load created by SRC, we measure the bandwidth occupied by SRC packets at different burstiness levels. For this purpose, we use the same star topology from §5.1.2. The number of senders changes between 1 and 63 to emulate different levels of burstiness towards a single receiver at 80% load. The traffic is based on the READ RPC workload from Figure 1.

Figure 13 shows the bandwidth occupied by the SRC packets (top) and the 99th-p queue occupancy at the bottleneck (bottom) with a different number of senders. When there are multiple senders, the SRC bandwidth is stable at 0.33Gbps (0.33% of the capacity). Similarly, the tail queuing is also bounded below $6.4\mu s$ for all the experiments. Therefore, we conclude that Bolt is able to bound congestion with a negligible amount of extra load in the network. In §5.5, we show that the overhead is negligible for the lab prototype as well.

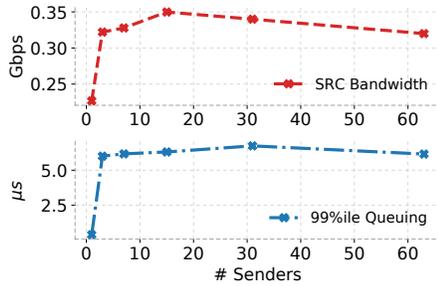

Figure 13: SRC overhead and sensitivity for different levels of burstiness

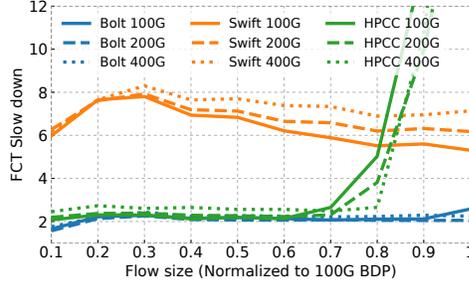

Figure 14: 99^{th} - p Slowdown for messages smaller than BDP

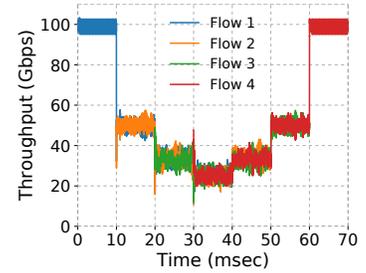

Figure 15: Fair allocation by Bolt

Metric	Swift	HPCC	Bolt
99^{th} - p Queuing (msec)	23.543	23.066	13.720
99^{th} - p FCT Slowdown	7017	5037	5000

Table 2: Tail queuing, and FCT slowdown for 5000-to-1 incast.

5.2.2 Robustness Against Higher Line Rates

One of the goals of Bolt is to be robust against ever-increasing line rates in data centers. To evaluate the performance at different line rates, we repeat the simulations from §5.2.1 with 63 senders where we increase the link capacity from 100Gbps to 200Gbps and 400Gbps. This way, the burstiness of the senders increases, making it difficult to maintain small queuing at the switches. Therefore, flow completion time (FCT) slowdown [14]⁴ of small flows are affected the most, whereas throughput oriented large flows would trivially be better off with higher line rates.

Accordingly, we plot the 99^{th} - p FCT slowdown for flows that are smaller than BDP (at 100 Gbps) in Figure 14. Swift’s performance monotonically decays with higher link rates due to the increasing burstiness. Similarly, HPCC at 400Gbps achieves 25% worse performance compared to the 100Gbps scenario for flow sizes up to 0.7 BDP. For the rest of the workload, HPCC makes a leap such that it performs worse than other algorithms irrespective of the line rates. Bolt on the other hand is able to maintain small and steady tail slowdowns for all the small flows despite the increasing line rates.

5.3 Fairness Analysis

To test the fairness of Bolt, we run an experiment on a dumb-bell topology with 100Gbps links. We add or remove a new flow every 10 milliseconds and measure the throughput of each flow which is shown in Figure 15. Our results indicate that Bolt flows converge to the new fair share quickly when the state of the network changes.

⁴FCT slowdown is flow’s actual FCT normalized by its ideal FCT when the flow sends at line-rate (e.g., when it was the only flow in the network).

5.4 Large Scale Simulations

One of the most challenging cases for CC is a large-scale incast. To evaluate Bolt’s performance in such a scenario, we set up a 5000-to-1 incast on the star topology described earlier where each one of 50 senders starts 100 same size flows at the same time. Table 2 presents the 99^{th} - p queue occupancy and FCT slowdown for the incast. Since Bolt detects congestion as early as possible, it bounds tail queuing to a 41% lower level compared to Swift and HPCC. In addition, the tail FCT slowdown for Bolt is 5000, indicating full link utilization. Moreover, the bandwidth occupied by the SRC packets is as low as 0.77Gbps throughout the incast. This is only twice the overhead for 80% load in §5.2.1, despite the extreme bursty arrival pattern of the incast.

We also evaluate the performance of Bolt on a cluster-scale network where 64 servers are connected with 100Gbps links to a fully subscribed fat-tree topology with 8 ToR switches. All the other links are 400Gbps and the maximum unloaded RTT is 5μ s. We run traffic between servers based on two workloads at 80% load: (i) the READ RPC workload described in Figure 1 represents traffic from our data center, (ii) the Facebook Hadoop workload [49]. Figure 16 and 17 show the median and 99^{th} - p FCT slowdown for the workloads. Note that the Hadoop workload is relatively more bursty where 82% of the flows/RPCs fit within a BDP in the given topology. Hence a large fraction of the curves in Figure 17 is flat where all the RPCs in this region are extremely small (i.e. single packet).

For both of the workloads, Bolt performs well across all flow sizes. Specifically, Bolt and HPCC achieve very low FCT for short flows (<7KB) because of a few design choices: First, they maintain zero standing queues. Plus, Bolt’s SRC reduces the height of queue spikes after flow arrivals. HPCC, on the other hand, tends to under-utilize the network upon flow completions (§2.1.2), statistically reducing queue sizes.

FCT of median-size flows (a few BDPs) starts to degrade for HPCC due to under-utilization described in §2.1.2 and §2.2. Bolt performs up to $3\times$ better in this regime by avoiding under-utilization thanks to PRU and SM. Swift’s standing queues prevent under-utilization, but FCTs are high because

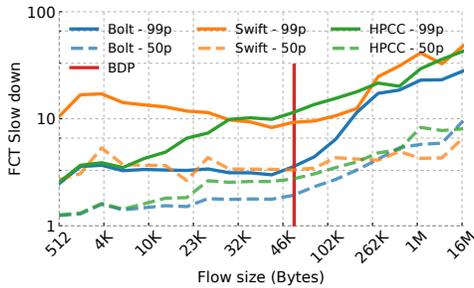

Figure 16: FCT slowdown for READ RPC Workload from Figure 1

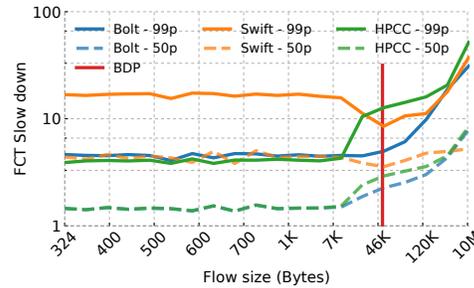

Figure 17: FCT slowdown for Facebook Hadoop Workload

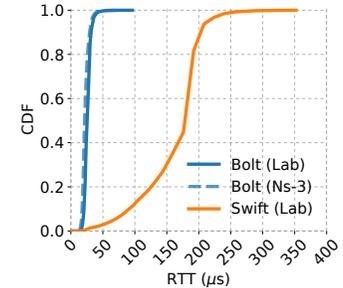

Figure 18: Bolt's lab prototype matches its simulator

median-size flows are also affected by the queuing delay.

The impact of queuing diminishes and utilization becomes the dominant factor for long flows. Therefore Bolt and Swift perform better than HPCC. In addition, Bolt is slightly better at the tail compared to Swift, while Swift is slightly better at the median, suggesting that Bolt is fairer.

5.5 Bolt in the Lab

Our lab testbed consists of 2 servers and 2 Intel Tofino2 [11] switches. Each server runs 4 packet processing engines running Snap [38] that provide the transport layer with the Bolt algorithm. Each engine is scheduled on a CPU core that independently processes packets so that we are able to create a large number of connections between the servers. Links from the servers to the switches are 100Gbps and the switches are connected to each other with a 25Gbps link to guarantee that congestion takes place within the network. The base-RTT in this network is $14\mu\text{s}$ and we generate flows between the servers based on the READ RPC workload.

We evaluate Bolt on two scenarios. First, we run 100% (of 25Gbps) load to see if our prototype can saturate the bottleneck. Then, we run 80% load to compare the congestion mitigation performance of Bolt against Swift in a more realistic scenario. Finally, we verify that our results from the lab and the simulations match to verify our implementations.

The median and the 99th-p RTT at 100% load for Swift are $189\mu\text{s}$ and $208\mu\text{s}$ respectively. These numbers are high because Swift maintains a standing queue based on the configured base delay to fully utilize the link even after flow completions. Bolt on the other hand, attains $27\mu\text{s}$ and $40\mu\text{s}$ of median and tail RTT, 86% and 81% shorter than Swift. In the meantime, it achieves 24.7Gbps which is only 0.8% lower compared to Swift despite the lack of a standing queue.

We repeat the same experiment with 80% load and observe that both Swift and Bolt can sustain 80% (20Gbps) average link utilization. Figure 18 shows the CDF of measured RTTs throughout the experiment. Similar to the 100% load case, the median and tail RTTs for Bolt are $25\mu\text{s}$ and $40\mu\text{s}$, 86% and 83% lower compared to Swift respectively⁵.

⁵For Swift we set $50\mu\text{s}$ base target delay as specified in the paper [30] and $200\mu\text{s}$ as flow scaling range. Swift's average RTT in Figure 18 is higher than

Moreover, we measure that the bandwidth occupied by the SRC packets in our lab is 0.13Gbps, 0.536% of the bottleneck capacity. This is consistent with our observation in §5.2 despite the larger SRC packets with custom encapsulations.

Finally, we simulate the 80% load experiment in NS3 [48] with the same settings to verify that our simulator matches our observations in the lab. Figure 18 also shows the CDF of RTTs measured throughout the simulation. The median and tail RTTs from our simulations are $21\mu\text{s}$ and $39\mu\text{s}$, within 15% and 0.025% of the lab results respectively.

6 Practical Considerations

Typically, new products are deployed incrementally in data centers due to availability, security, or financial concerns. As a consequence, the new product (i.e. the CC algorithm) lives together with the old one for some time called brownfield deployment. We identify three potential issues that Bolt could face during this phase and address them below.

First, some switches in the network may not be capable of generating SRC packets while new programmable switches are being deployed. Unfortunately, the vanilla Bolt design can not control the congestion at these switches. This can be addressed by running an end-to-end algorithm on top of Bolt. For example, imagine the Swift algorithm calculates a fabric $cwnd$ as usual in parallel with Bolt's calculation of $cwnd$ using SRC packets. Then, the minimum of the two is selected as the effective $cwnd$ for the flow. When an older generation switch is congested, SRC packets are not generated, but Swift adjusts the $cwnd$. Consequently, flows benefit from ultra-low queuing at the compatible switches while falling back to Swift when a non-programmable switch becomes the bottleneck.

Second, hosts would also be migrated to Bolt incrementally. Therefore, Bolt would need to coexist with the prior algorithm. Studying the friendliness of algorithms with Bolt through frameworks such as [26] and [56] remains a future work. For example, TCP CUBIC would not coexist well with Bolt as it tries to fill the queues until a packet is dropped while Bolt would continuously decrement its $cwnd$ due to

Swift paper's value ($\sim 50\mu\text{s}$), because of two reasons. First, this workload is burstier than the ones in Swift paper. Second, the 25Gbps bottleneck implies a higher level of flow scaling than with 100Gbps links.

queuing. Instead, we propose the use of QoS (Quality of Service) queues to isolate Bolt traffic from the rest. Appendix B describes a baseline approach for such deployment.

Finally, scenarios where packet transmissions are batched (say by the NIC) even when the `cwnd` is smaller than BDP can still trigger SRC generation, inhibiting flows to increase `cwnd` to the right value. We find that transport offloading on modern smart NICs uses batching to sustain high line rates. Bolt alleviates such bursts with a higher CC_{THRESH} that tolerates batch size worth of queuing at the switches.

7 Related Work

In addition to HPCC [35] and Swift [30] that serve as our primary comparison points, several other schemes have similar ideas or goals.

FastTune [59] uses programmable switches for precise congestion signal. Similar to HPCC, it calculates link utilization over an RTT to multiplicatively increase or decrease `cwnd`. For shorter feedback delay, it pads the INT header onto ACK packets in the reverse direction instead of data packets. ExpressPass [10] utilizes the control packets in the reverse direction as well. Nonetheless, forward and reverse paths for a flow are not always symmetrical due to ECMP-like load balancing or flow-reroutes. Therefore, Bolt chooses to explicitly generate SRC packets with little overhead (§5.2).

FastLane [57] is one of the early proposals to send notifications from switches directly to the senders. However, notifications are generated only for buffer overflows which is late for low latency CC in data centers. Annulus [50], on the other hand, uses standard QCN [21] packets from switches with queue occupancy information. Yet these packets are not L3 routable, so Annulus limits its scope only to detecting bottlenecks one hop away from senders. Bolt brings the best of both worlds and controls congestion at every hop while knowing the precise state of congestion.

XCP [27] and RCP [13] also propose congestion feedback generated by the switch. Switches wait for an average RTT before calculating CC responses that are piggybacked on the data packet and reflected on the ACK. As discussed in §2.2, this implies a control loop delay of two RTTs in total.

FCP [18] uses budgets and prices to balance the load and the traffic demand. FCP switches calculate the price of the link based on the demand while senders signal flow arrivals or completions similar to SM and PRU in Bolt. However, the required time series averaging and floating-point arithmetic make the calculation infeasible for programmable switches while consuming bytes on the header. In contrast, Bolt is based on the packet conservation principle with a simple, yet precise logic implementable in P4 and requires only 3 bits on the header (*FIRST*, *LAST*, and *INC*) for SM and PRU.

Switch feedback has also been studied for wireless settings. For instance, ABC [16] marks packets for `cwnd` increments or decrements with an RTT-based control loop for congestion

mitigation. On the other hand, Zhuge [39] modifies the wireless AP to help senders detect congestion quicker. However, since it is challenging to modify schemes in WAN, Zhuge relies on the capabilities of existing schemes for the precision of the congestion signals, i.e. delayed ACKs for TCP.

Receiver-driven approaches such as NDP [19], pHost [15], and Homa [43] require receivers to allocate/schedule credits based on the demand from senders. They work well for congestion at the last hop because receivers have good visibility into this link. For example, when an RPC is fully granted, the Homa receiver starts sending grants for the next one without the current RPC being finished to proactively utilize the link. This is similar to PRU in Bolt despite being limited to the last hop. Unfortunately, the last hop is not always the bottleneck for a flow especially when the fabric is over-subscribed [52].

Schemes that use priority queues [2, 4, 20, 43] are proposed to improve the scheduling performance of the network to approximate SRPT [51] like behavior. We find deploying such schemes to be rather difficult because, typically, QoS queues in data centers are reserved to separate different services.

On-Ramp [37] is an extension for CC which proposes to pause flows at the senders when the one-way delay is high. Bolt can also benefit from its flow control mechanism. We leave evaluating Bolt with this extension as future work.

There are also per-hop flow control mechanisms such as BFC [17] and PFFC [55] that pause queues at the upstream switches via early notifications from the bottleneck. The deadlock-like issues of PFC [54] are resolved by keeping the per-flow state on switches, which we find challenging in our data centers as switches have to implement other memory or queue-intensive protocols, e.g., routing tables or QoS. Therefore, we scope Bolt to be an end-to-end algorithm with a fixed state similar to other algorithms in production [30, 35, 60].

8 Conclusion

Increasing line rates in data centers is inevitable due to the stringent SLOs of applications. Yet, higher line rates increase burstiness, putting more pressure on CC to minimize queuing delays for short flows along with high link utilization for long flows. We find that two key aspects of CC need to be pushed to their boundaries to work well in such highly dynamic regimes based on experience with our data centers.

Bolt addresses these aspects thanks to the flexibility and precision provided by programmable switches. First, it uses the most granular congestion signal, i.e. precise queue occupancy, for a per-packet decision logic. Second, it minimizes the control loop delay to its absolute minimum by generating feedback at the congested switches and sending them directly back to the senders. Third, it hides the control loop delay by making proactive decisions about foreseeable flow completions. As a result, accurate `cwnd` is calculated as quickly as possible, achieving more than 80% reduction in tail latency and 3× improvement in tail FCT.

Appendix

A Approximating SRC Overhead

Bolt switches generate SRC packets for every data packet they receive as long as there is queuing, given that the data packet is not marked with the *DEC* flag. Then the number of

SRC packets depend on how long queuing persisted and how many packet are received in this time interval.

At steady state where no new RPCs join the network, we can estimate the fraction of time queuing persist on a bottleneck. Congestion at this regime happens only due to the once-per-RTT additive increase of 1 by each flow.

As described in §3.1, senders pace c_{wnd} decrements such that the total number of decrements equals the queue occupancy after 1 rtt_{src} . This implies that any queuing will persist for 1 rtt_{src} , but will be completely drained after. Since a new congestion is not inflicted until the next RTT, we conjecture that the fraction of time that the switch has non-zero queuing is governed by the following golden ratio:

$$\text{fraction of time switch is congested} = \frac{rtt_{src}}{rtt} \quad (1)$$

which is always less than 1.

Note that equation 1 is an approximation for congestion interval since it doesn't incorporate traffic load, new RPC arrivals or multi bottleneck scenarios. Nonetheless, we can calculate the number of SRC packets generated at a bottleneck with it.

$$\# \text{ of SRC pkts} = \# \text{ of DATA pkts} \times \frac{rtt_{src}}{rtt} \quad (2)$$

Finally, we map equation 2 to the bandwidth occupied by the SRC packets by incorporating the link capacity and the packet sizes:

$$\text{SRC Bandwidth} = C \times \frac{p_{src}}{p_{data}} \times \frac{rtt_{src}}{rtt} \quad (3)$$

Where C is the rate at which the traffic is flowing through the bottleneck link, p_{src} is the size of SRC packets and p_{data} is the size of data packets, i.e. MTU.

When we calculate the bandwidth of SRC packets according to equation 3 for the simulation in §5.2.1, we find 0.37Gbps which is within 12% of the simulation result of 0.33Gbps. Moreover, equation 3 gives 0.10Gbps for our lab setup in §5.5 which is within 23% of the measured value of 0.13Gbps.

B Bolt with QoS

The relationship between congestion control algorithms and QoS has always been contradictory. An ideal congestion control algorithm aims to mitigate any queuing at the switch, whereas a QoS mechanism always needs enough queuing to be able to differentiate packet priorities and serve one before the other. Put another way, QoS only takes effect when the arrival rate at a link is greater than the capacity such that it causes queue build-up. Yet, QoS is vital for commercial networks in order to be able to differentiate applications or tenants for business related reasons [6]. This is particularly true for unavoidable transient congestion events, i.e. incast.

Algorithm 4: Supply Token calculated for QoS queue i at the switch with n QoS levels serving the same egress port

```

1 Function CalculateSupplyToken ( $pkt$ ):
2    $inter\_arrival\_time \leftarrow now - last\_sm\_time$ 
3    $last\_sm\_time \leftarrow now$ 
4    $w_{effective} \leftarrow 0$ 
5   for  $j \leftarrow 0$  to  $n$  do
6     if  $i = j$  ||  $q\_size_j \neq 0$  then
7        $w_{effective} \leftarrow w_{effective} + w_j$ 
8      $supply \leftarrow BW \times inter\_arrival\_time \times (\frac{w_i}{w_{effective}})$ 
9      $demand \leftarrow pkt.size$ 
10     $sm\_token \leftarrow sm\_token + supply - demand$ 
11     $sm\_token \leftarrow \min(sm\_token, MTU)$ 

```

Fortunately, the way Bolt reports queue occupancy is QoS-agnostic such that it can generate SRC packets with the occupancy of the queue assigned by the QoS mechanism. Consequently, it would try to minimize queuing at that particular queue. Similarly, the way PRU token are calculated would be queue specific instead of being egress port specific. For example, if there are P ports on a switch and n QoS levels per port, the size of the register array that maintains the token values would be of $P \times n$ and flows would only be able to proactively ramp-up if another flow with the same QoS level is about to finish.

On the other hand, accounting for the $supply$ token requires the service rate for the associated queue (§3.3) which would be a dynamic value depending on the current demand for different QoS levels. We identify two approaches for maintaining $supply$ tokens correctly and implementing a QoS aware version of Bolt on programmable switches.

B.1 Ideal Approach

Imagine a scenario where weighted fair queuing [46] is applied for QoS purposes. Then, Bolt would need to be able to increment the $supply$ token value based on the weight associated to the QoS level (w_i) and the link capacity (C) as well as the demand for each QoS level. For example, when all QoS levels have at least 1 packet in their queue, a packet arriving at QoS level i should increment the token value by $C \times w_i \times t_{inter-arr}$.

If a QoS queue is empty, its weight is distributed to other QoS levels in proportion to each level's own weight. Therefore, Bolt should adjust the $supply$ token value of QoS level i based on the logic presented in Algorithm 4.

Note that in order to be able to determine the service rate of each queue, queue occupancy of other queues would be required. This requirement creates a challenge for P4 switches since only one queue's occupancy can be read at a time. A workaround to this would be to create shadow register arrays

for each priority queue where they get updated whenever a value is not being read from them. Moreover the calculation at the line 8 of Algorithm 4 requires floating point arithmetic which could be address via lookup tables.

B.2 Heuristic Approach

A simpler mechanism to enable QoS on Bolt switches would be to introduce probabilistic SRC generation where higher priority traffic has lower probability to generate a SRC packet. This would naturally keep the rates of high priority flows high while throttling others. Yet, an extensive empirical study would be required to determine the probabilities such that the queuing for all the QoS levels are bounded to some extent.

Understanding the impact of host networking elements on traffic bursts

Erfan Sharafzadeh¹, Sepehr Abdous¹, Soudeh Ghorbani^{1,2}

¹Johns Hopkins University, ²Meta

Abstract

Conventional host networking features various traffic shaping layers (e.g., buffers, schedulers, and pacers) with complex interactions and wide implications for performance metrics. These interactions can lead to large bursts at various time scales. Understanding the nature of traffic bursts is important for optimal resource provisioning, congestion control, buffer sizing, and traffic prediction but is challenging due to the complexity and feature velocity in host networking.

We develop Valinor, a traffic measurement framework that consists of eBPF hooks and measurement modules in a programmable network. Valinor offers visibility into traffic burstiness over a wide span of timescales (nanosecond- to second-scale) at multiple vantage points. We deploy Valinor to analyze the burstiness of various classes of congestion control algorithms, qdiscs, Linux process scheduling, NIC packet scheduling, and hardware offloading. Our analysis counters the assumption that burstiness is primarily a function of the application layer and preserved by protocol stacks, and highlights the pronounced role of lower layers in the formation and suppression of bursts. We also show the limitations of canonical burst countermeasures (e.g., TCP pacing and qdisc scheduling) due to the intervening nature of segmentation offloading and fixed-function NIC scheduling. Finally, we demonstrate that, far from a universal invariant, burstiness varies significantly across host stacks. Our findings underscore the need for a measurement framework such as Valinor for regular burst analysis.

1 Introduction

Measurement studies show that traffic is bursty across a wide range of timescales in diverse contexts such as Ethernet LANs [38], WANs [56], data centers [25], and WWW traffic [21]. In particular, microsecond-scale congestion events, sometimes called *microbursts*, have been the focus of numerous measurement and control papers recently [13, 18, 19, 25, 33, 37, 72]. However, the modulating effect of host networking on traf-

fic burstiness at various timescales is relatively less investigated. This paper addresses this gap. We ask *what causes the traffic to emerge from hosts in bursts?* Is burstiness an *scale-invariant* property of traffic, i.e., does the traffic retain its burstiness across a wide range of timescales, or do the microbursts become smooth at coarse timescales? Are canonical burst countermeasures such as TCP pacing and packet scheduling effective in curtailing bursts?

These questions have far-reaching implications for network performance and design. Controlling bursts at different timescales requires deploying mechanisms that operate at the corresponding pace. Microbursts, for instance, require real-time techniques with sub-RTT control loops, whereas bursts at longer timescales can be more effectively managed by resource provisioning techniques such as topology engineering and routing that take seconds to minutes to complete [71].

Unfortunately, studying the impact of host networking on bursts is complex. Take the Linux network stack as an example: the egress traffic that originates from the Linux kernel stack passes through many layers and optimizations before arriving at the wire. Transport protocol internals like initial window size, cumulative acknowledgments, queueing disciplines (qdiscs), driver rings, segmentation offloading, and hardware packet scheduler at the NIC all handle the traffic. All these elements and their complex interactions can play a role in forming or suppressing bursts at various timescales. These challenges are further compounded by the heterogeneity, scale, and the velocity of evolution in today's networks that constantly change in response to increasing demand and the rollout of new services [26, 46, 73].

To address this challenge, we build Valinor, a high-resolution traffic measurement framework that enables network operators to systematically and periodically dissect the elements of host networking, their impact on traffic burstiness in isolation, and importantly, their interactions with the emergent traffic patterns, all at different timescales. To ensure visibility into the impact of the software stack and the shape of the traffic on the wire through time, Valinor is composed of two main components: 1) An in-host timestamping frame-

work (Valinor-H) based on eBPF that collects egress packet metadata nearly at the last stage of software stack processing. 2) An in-network packet timestamping framework (Valinor-N) that captures packet arrival timestamps in the programmable switch data plane immediately after the NIC, and sends the timestamp data to offline servers for collection, storage, and burstiness analysis.

Our analysis of the impact of host networking on the shape of traffic using Valinor reveals some surprising results. As an example, classical work paints a unifying and consistent picture of scale-invariant burstiness, i.e, they show the same degree of variability across a wide range of timescales in a variety of different network types [21, 38, 56]. It has also been established that this scale-invariant burstiness is primarily caused by *application layer* characteristics such as long-tailed flow size distributions and is “robust”: it holds for a variety of transport protocols (e.g., TCP Reno, Vegas, and flow controlled UDP) and various network configurations [23, 53].

In contrast, our investigations paint a more nuanced and complex picture. We show that burstiness at various timescales varies significantly across host configurations (hardware configurations, transport protocols, scheduling, etc.). We also show the pronounced modulating effect of below application layer elements on bursts. This implies that, for the same heavy-tailed flow size distribution, the ultimate shape of traffic on the wire depends heavily on the host configuration such as the NIC scheduler. Plus, Valinor’s analysis of newer reliable transport protocols (e.g., Homa [47], DCTCP [9], and BBR [17]) reveals the high degree of variability of burstiness for these protocols. As an example, BBR is less bursty not just at fine timescales (a result that is consistent with the literature [47, 52]) but also at coarse timescales. The latter finding (new to the best of our knowledge) implies that techniques such as topology engineering [71] and multi-timescale congestion control [66]—premised on the long-range burstiness of traffic—may yield limited performance improvements under these new protocols.

Finally, given the impact of some variants of transport protocols on bursts, we quantify the effectiveness of TCP pacing and active queue management paradigms such as CoDel [49] in qdiscs (software packet schedulers) in mitigating bursts. Our results show the pronounced impact of lower-layer functions (residing in the driver and NIC) on forming the ultimate shape of traffic on the wire relative to the higher-layer software operations of the TCP/IP stack and qdiscs. As an example, active queue management techniques such as CoDel and RED in the Linux kernel try to prevent the formation of large and lasting bursts. However, our results show that their impact is effectively erased by offloading (TSO, serialization, etc.) and the NIC scheduler. For example, while in isolation, the frequency of large 300 KB bursts under CoDel is 500 times lower than FIFO, this difference is barely visible on the wire after packets pass through the multi-queue NIC with segmentation offloading. Moreover, TCP pacing enforced in the

qdiscs generates between $1.8 \times 10^{-19} \times$ larger bursts when NIC scheduler and offloading are in action compared to when in isolation.¹ This result indicates that the countermeasures for controlling bursts should be moved further down the packet processing pipeline at the end hosts.

Our results on the variability of burstiness (based on hardware configurations, transports, etc.)—combined with the ever-evolving workloads and features in today’s networks—highlight the need for periodic traffic measurement and analysis. To facilitate this, we have released Valinor’s sources and artifacts as open-source software.² We next introduce the mathematical notions developed for capturing bursts across time, present their practical implications in networks (§2), provide some background on host networking and the design space of burst measurement frameworks (§3), and present the design of Valinor (§4) before delving into our findings (§5).

2 Background: scale-invariant burstiness

Measurements of the Internet traffic show periods of sustained greater-than-average or lower-than-average traffic rates across a wide range of timescales [21, 24, 38, 53, 56]. This behavior, sometimes called *scaling* or *self-similarity*, has broad implications for performance. In this section, we first formalize the notion of self-similarity and re-introduce the Hurst exponent, a mathematical representation of self-similarity, before discussing the implications of self-similarity and characterizing bursts at fine timescales such as microbursts.

Self-similarity. Self-similarity is a notion pioneered by Benoit Mandelbrot [45] which refers to a phenomenon where a certain property of an object (such as an image or a time-series) is preserved with respect to scaling in space and/or time. If an object is self-similar, its parts, when magnified, resemble the shape of the whole [55].

More formally, let $(X_t)_{t \in \mathbb{Z}_+}$ be a timeseries, e.g., this time-series can represent a traffic trace measured at some fixed time granularity. The aggregated series $X_i^{(m)}$ is defined as

$$X_i^{(m)} = 1/m(X_{im-m+1} + \dots + X_{im})$$

In other words, X_t is partitioned into blocks of size m , their values are averaged, and i denotes the index of these blocks.

Autocorrelation is a mathematical representation of the degree of similarity between a timeseries X_t and a time-shifted version of X_t over successive time intervals. It measures the relationship between the current value of a timeseries and its

¹ Despite making the traffic bursty and hard to manage, these low-level functions are essential for reducing the processing overhead and meeting the increasingly high link rates. For example, disabling TCP segmentation offload results in a $3 \times$ increase in CPU utilization, 71% lower throughput, and a 46% increase in median packet RTTs for a multi-flow *Iperf* test. Relatedly, disabling MQ results in a 4% decline in the throughput of the same workload.

²<https://hopnets.github.io/valinor>

future values. A strong positive autocorrelation for a traffic volume timeseries, for example, suggests that if the volume is high (i.e., higher than average) now, then it is likely to be also high in the next time slot, whereas a strong negative autocorrelation implies that a high-volume slot is likely to be followed by a low volume one.

Let $r(k)$ and $r^{(m)}(k)$ denote, respectively, the autocorrelation functions (ACFs) of X_t and $X_t^{(m)}$ where k is the time shift from the original timeseries. We say that X_t is *self-similar*, or more accurately *asymptotically second-order self-similar*, if these conditions hold:

$$r(k) \sim c \times k^{-\beta} \quad (1)$$

$$r^{(m)}(k) \sim r(k) \quad (2)$$

for large k and m , where $0 < \beta < 1$ and c is a constant, and $f(x) \sim g(x)$ as $x \rightarrow a$ means that $\lim_{x \rightarrow a} f(x)/g(x) = 1$ [66]. X_t is self-similar in the sense that its ACF $r(k)$ behaves hyperbolically with $\sum_{k=0}^{\infty} r(k) = \infty$ (Eq. 1). This property is also referred to as *long-range dependence*. Equation 2 implies that for self-similar timeseries, the autocorrelation structure is preserved with respect to time aggregation.

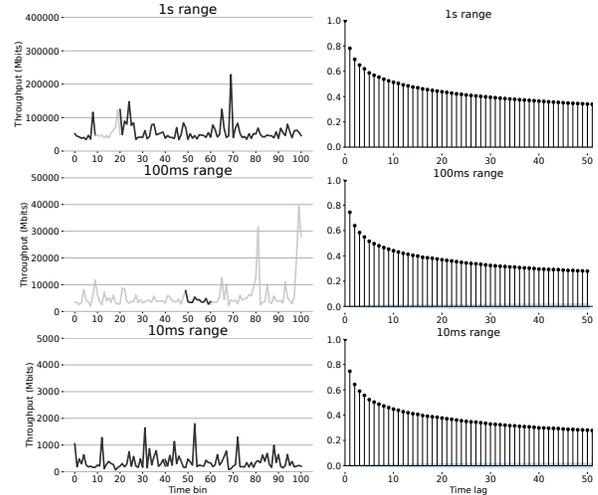

In networks, the traffic is called self-similar if the aggregated traffic over varying timescales remains bursty, regardless of the granularity of the timescale.

The Hurst exponent. Let $H = 1 - \beta/2$. H is called the *Hurst exponent*. The Hurst exponent, a number in the $(0, 1)$ range that is sometimes referred to as the *index of long-range dependence*, is a measure of the long-term memory of a timeseries. It characterizes the self-similarity and long-range dependence of the timeseries:

- $0.5 < H < 1$ indicates a self-similar timeseries with long-term positive autocorrelations, i.e., a high value in the series (e.g., higher than average traffic volume) is likely to be followed by another high value. Plus, the values a long time into the future also tends to be high. It follows from Eq. (1) above that the closer H is to 1, the more long-range dependent X_t is. Conversely, H values closer to 0.5 show weaker long-range dependence.
- $H = 0.5$ indicates a completely uncorrelated series.
- $0 < H < 0.5$ indicates a *mean-reverting* timeseries, i.e., one with long-term switching between high and low values in adjacent pairs of time slots. That is, a single high value in the timeseries is likely to be followed by a low value.³

Various techniques (e.g., rescaled-range analysis and Peridogram [67]) exist for estimating H for an empirical dataset. Similar to the seminal work on Bellcore Ethernet traffic self-similarity [38], we use the rescaled-range, R/S , for the results presented in this paper. The details of this method are presented in Appendix §A.

³Note that the $0 < \beta < 1$ condition in the equations above is a requirement for self-similar, and not mean-reverting, series.

(a) Time-series (b) Auto-correlation
Figure 1: A self-similar timeseries with $H=0.88$.

Example: Figure 1a (the first row) shows a simulated scenario where 32 TCP connections generate a synthetic workload using Pareto flow size distribution with a mean of 4200 KB and $\alpha = 1.05$ and exponential arrivals that create 6 Gbps offered load. We plot the traffic rate (in Mbps) against time where time granularity is 1s. A data point is the aggregated traffic volume over a 10ms interval. The second row of the same figure depicts the same traffic series where a randomly selected second interval in the first timeseries (the highlighted segment in the first row) is magnified by a factor of ten, resulting in a granularity of 100ms in the truncated timeseries. The last row similarly rescales a randomly selected slot by $10\times$. The figures show that this trace is self-similar: when traffic is aggregated over varying timescales, the aggregate traffic pattern remains bursty, regardless of the granularity of the timescale. This visual scaling is confirmed by the Hurst coefficient, $H = 0.88$, and the autocorrelation functions of the trace (Figure 1b) that show positive, slow (almost polynomial) decaying, and consistently shaped correlations across various timescales. Slow-decaying ACFs signify long-range dependence in a timeseries.

Practical implications of self-similarity. Self-similarity has broad implications on network design and performance, e.g., it is shown to lead to increased delay and loss [5, 6, 22, 42, 50, 53, 66]. We next discuss some of the key implications of self-similarity:

- **Queueing performance and buffer sizing.** Self-similarity greatly influences queueing performance. From a queueing theory standpoint, the defining characteristic of self-similarity is that the queue length distribution decays much more slowly than short-range-dependent traffic (polynomially vs. exponentially under short-range dependent traffic, e.g., Poisson processes) [66]. For strongly self-similar traffic, the mean queue

length increases with the buffer size [54]. This implies that networks with strongly self-similar traffic should deploy small buffers to control the queuing delay.

- **Throughput and latency trade-off.** Prior work [53, 54] shows that jointly provisioning low delay and high throughput is adversely affected by self-similarity.
- **Traffic prediction and burst countermeasures.** The correlation structures present in self-similar traffic can be detected and exploited to predict future traffic over timescales larger than an RTT [66].⁴ Traffic prediction at long timescales, in turn, is invaluable for designing the appropriate burst countermeasures. For instance, resource provisioning techniques with control loops larger than an RTT (e.g., multi-scale congestion control [66], re-routing, and topology rewiring [71]) enhance the performance of self-similar traffic.

Microbursts. Given their ubiquity and impact, in particular in data centers, microsecond-scale traffic surges, known as *microbursts* [13, 41, 72], have been the focus of many recent proposals [4, 19, 27, 37, 41, 70].

The intensity of a microburst has often been measured implicitly based on buffer utilization, or in more extreme cases, packet loss. Related work also quantifies microbursts as the number of packets from one flow that occupy a buffer at a time snapshot [33], the evolution of switch queue length over time [63], an uninterrupted sequence of packets with gaps of smaller than a threshold [35], and/or sequence size of larger than a threshold [68]. Using metrics that are independent of network queues allows us to perform universal measurements in the entire network, i.e., both at the hosts and the switches. Yet, measurement systems intending to quantify microbursts can leverage all the above definitions to provide a holistic view of burstiness behavior.

From the technical perspective, we define a burst as the cumulative sum of packet bytes whose inter-arrivals are smaller than a threshold τ . Setting the minimum value for τ initially depends on link speeds and MTUs. For example, in a fully utilized 40 Gbps link with MTU = 1500 bytes, packets arrive 300 ns apart. Therefore, an initial τ of 2-10 \times of this value is small enough to detect microbursts and large enough not to miss consecutive packets from flows. To ensure that τ is not affected by the network configuration and the internal characteristics of the workloads, we repeat our measurement with a wide range of values for τ .

3 Approaches to measuring traffic bursts

In this section, we provide a brief background on host networking and present the design space of burst measurement frameworks before discussing Valinor in §4.

⁴The prediction methods span diverse domains such as regression theory, neural networks, and estimation theory [66].

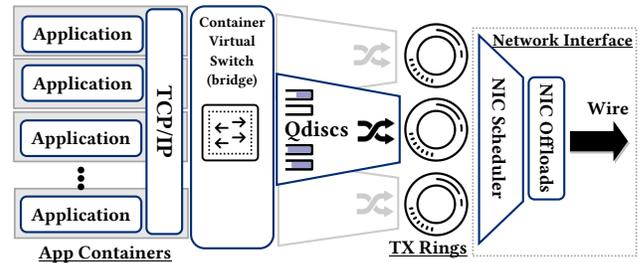

Figure 2: Conventional network processing stack architecture in a containerized Linux deployment.

3.1 Conventional host networking

Conventional network stacks consist of various processing layers glued together via several optimization techniques. In Linux, application data is passed to socket interfaces (buffering in the userspace), and then to the transport protocol processing (transport buffers, short queues [20]). Transport protocols populate *sk_buffs*,⁵ a collection of data pointers and header information. After performing routing, *sk_buffs* eventually make their way towards interface *qdiscs*, the hierarchical packet schedulers in Linux. *qdiscs* operate in parallel on all CPU cores and forward the scheduled *sk_buffs* towards driver rings where another layer of buffering is performed before notifying the NIC [65]. Finally, with the conventional offloading features enabled, the NIC performs scatter/gather [58], segmentation, checksum, and sends the packets on the wire [16]. Figure 2 depicts an overview of the packet’s path through the network processing pipeline in a Linux host.

3.2 Capturing timestamps

High-resolution timestamping is essential for burst analysis. Various techniques exist for capturing packet arrivals:

NIC timestamps. Hardware timestamping is available in all commodity NICs. This feature is supported by the Linux kernel via ancillary socket data. When a user requests timestamping through a socket option, the transmission timestamps are generated in the hardware before sending the packet on the wire and are eventually sent to the source socket. Therefore, the application is responsible for polling the error queue and reading the timestamps. Hardware timestamping supports most TCP and UDP connections, however, it suffers from two main shortcomings. First, if the operating system fails to poll the timestamp registers of the NIC in time, e.g., in higher packet rates, the timestamp will be overwritten by that of the next packet. Plus, modifying the network application to receive timestamps may impact the application’s workload pattern, and thus must be performed with extra care.

⁵*sk_buff* stands for "Socket buffer" and is used to represent the socket data that eventually is shaped into the packet. *sk_buffs*, therefore, may contain a single or multiple packets.

Modifying networking stack software. To study realistic network traffic with higher arrival rates, hardware timestamping is not ideal due to the need to change the application internals and high overheads. An alternative solution is to directly capture the timestamps closer to the packet processing, e.g., the NIC driver, and either add the timestamps to the packet payload or re-route them to the userspace. Alas, accessing and modifying the packet data requires offloading features such as scatter-gather IO and Segmentation Offloading to be turned off. Additionally, timestamps that are at *sk_buff* granularity may not imitate the inter-packet gaps on the wire due to the intervention of lower layers.

eBPF hooks. eBPF offers a series of hooks inside the Linux kernel and the NIC driver that allows fast execution of arbitrary data plane logic. An eBPF program consists of a data plane and a control-plane code targeting a specific hook on the RX or TX path (XDP hook in the receive path of NIC driver and traffic control (*tc*) hook on the TX path of the qdisc subsystem are two examples). eBPF *tc* programs are registered to the kernel using the *tc* command and are executed inside a lightweight RISC virtual machine. eBPF also provides fast data structures that enable shared state between the kernel and the userspace. This allows us to perform burst measurements offline with any workload configuration without modifying the kernel source or packet payloads.

While eBPF relieves us from directly modifying the packet processing code in the kernel, it presents two shortcomings. First, eBPF, similar to the previous solution, works at *sk_buff* granularity since packet segmentation is almost always offloaded to the NIC. Therefore, the eBPF framework can only measure the gaps between larger chunks of data, not packets. Additionally, our measurements show that each eBPF invocation incurs up to 1 μ s of delay, mostly due to memory accesses. While this overhead may be acceptable at the *sk_buff* granularity, the framework will lose its visibility into nanosecond-scale events. Ultimately, eBPF provides a convenient solution to plug into the network data path with minor interference. Making it a viable burstiness probing point on the egress path. We present the design and implementation of the Valinor eBPF framework, Valinor-H, in §4.1.

Timestamping in the switch data-plane. A holistic method to capture the behavior of all host networking components (including the NIC) is to perform measurements immediately after transmitting the packets on the wire, i.e., at the first network hop. Fortunately, the rise of programmable switch architectures with high-resolution timestamping enables capturing packet arrival timestamps and sending this data off the critical communication path for offline processing. This further ensures zero interference with the

ongoing communication and the ability to track the entire egress host networking components. We describe the design of our in-network measurement system, Valinor-N, in §4.2.

Programmable NICs share many of the strengths of in-network measurements (e.g., timestamping close to the wire, low overhead, and no interference) but do not provide visibility into in-network queue occupancies. Plus, our experience with commodity DPUs [15] shows inconsistencies in the capabilities of existing devices. General-purpose SoC NICs [15] are either bound to their slow ARM CPUs or do not offer per-packet timestamping capabilities on their fast path. Due to these practical issues as well as the greater visibility that in-network measurements offer, alongside its host module, Valinor currently leverages programmable networks for capturing bursts on the wire.

4 Valinor measurement framework

For designing Valinor, we have three goals in mind:

1. Offering visibility into the host networking traffic, as well as the shape of the traffic on the wire.
2. Offering high-resolution timestamping of packet arrivals in line with the increasing link bandwidths and faster packet processing pipelines.
3. Providing insights on traffic shape and burstiness at different scales and time ranges.

We design and implement Valinor, a measurement framework that consists of two main timestamping prongs to study packet arrivals from the host and network vantage points. First, we design Valinor-H to study the host's view of its egress traffic by choosing *tc* eBPF hooks. For capturing the external picture of traffic burstiness, we design Valinor-N, a timestamping module for programmable fabric.

4.1 Valinor-H: burst measurement in hosts

Valinor-H offers visibility into the impact of the software stack on traffic, immediately before the traffic is passed to the NIC. The insight into the characteristics of the traffic entering the hardware can help the design of the functions offloaded to the NIC. This becomes increasingly important as more and more functions migrate to the NIC, driven by the dire need to reduce software overhead.⁶

Figure 3 presents the design of our eBPF framework. Our framework consists of two separate programs. The data plane program follows a strict set of C-like instructions that are executed at the *tc* qdisc, every time a *sk_buff* arrives. We design

⁶As network speeds increase at a faster pace than CPU speeds, software overhead is increasingly the performance bottleneck [52]. This has motivated the offloading of various functions such as segmentation, serialization, scheduling, and even transport protocol processing to the NIC [11, 58, 64].

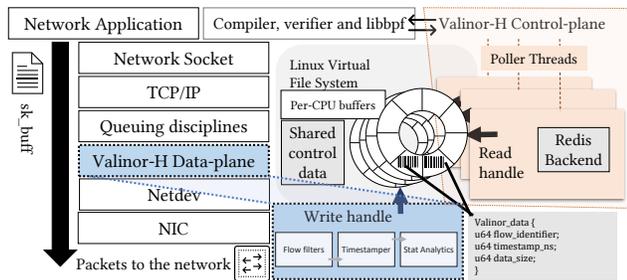

Figure 3: The eBPF measurement framework’s architecture. Valinor-h consists of a data plane and a control plane, communicating via lock-free ring buffers.

circular buffers capable of storing up to 2^{16} arbitrary data entries shared with the control plane. Then, the *write handle* determines the correct location for adding new timestamp entries and updates the data structure. In the control plane, we initialize the data plane and the circular buffer and start polling the buffer for new data. The data entries carry the *sk_buff* lengths as well as the flow hash and protocol header information. The *read handle*, retrieves the timestamp entries one by one and hands them to the Redis workers for persistent storage.

One challenge that arises when using a shared data structure is synchronization between the data plane and the control plane. This scenario generally needs locking mechanisms to prevent a race condition, however, the nature of the timestamping data, being strictly increasing, lifts this heavy burden. Therefore, in the control plane, Valinor-H only reads and increments its write handle if the timestamp value is larger than the previous value read. Another synchronization issue arises when multiple CPUs attempt to store packet metadata in the shared memory. Luckily, eBPF offers per-CPU structures to prevent race conditions in the data plane. The Valinor-H control plane uses separate threads to read from per-CPU buffers simultaneously.

With the in-host measurement framework, network operators can verify the operation of higher-level network processing layers on the transmission path of the sender hosts. Valinor-H, at this stage, can capture the ingress traffic into the NIC which includes the traffic egress from qdiscs, the transport layer, and the applications. To capture the traffic behavior in the core of the network, and on a per-packet granularity, we introduce Valinor-N in the following section.

4.2 Valinor-N: in-network burst measurement

Software-based measurements in the host stack are bound to the coarse-grained *sk_buff* arrivals and are implemented before NIC functions (i.e., ring schedulers and segmentation offloads). Hence, the captured traffic behavior might not match that of the wire. To fill this gap, we introduce the in-network variant of Valinor based on programmable switch

data planes. Valinor-N consists of three pieces: 1) the switch component, 2) the collector data plane, and 3) the analysis component. Valinor-N is able to I) capture per-packet arrival timestamps with zero overhead outside the critical path, II) collect and store timestamp entries arriving at line rate, and III) perform various analyses on timestamp data to provide an in-depth image of the traffic burstiness at different scales.

Valinor Switch. The switch data plane program uses *mirroring* and *timestamping* functionalities available in the PISA architecture. For every packet that matches user-defined flow filters, Valinor-N appends the arrival timestamp, queuing delay, and the size of the original packet along with its layer 1-4 header information to a special IP packet with a pre-defined Valinor header. The packet is then sent to a collector server. The server machine, deployed outside the critical path of the communication between traffic endpoints, aggregates the timestamp information and performs the offline analysis.

Timestamp collection. The collector machine features a userspace packet processing framework based on DPDK that parses the arrived packets and stores the timestamp information along with flow metadata into an in-memory Redis [3] instance. Analysis of the timestamp data is then performed by querying the data store. Receiving timestamp packets at line rate and storing them in persistent storage poses several scalability challenges to the design of the collector component. To ensure that software can drain NIC buffers at line rate, we designate multiple worker threads to read and process the incoming packets. After parsing timestamp headers, the worker threads extract the timestamp data and send them to additional worker threads that are responsible for communicating with Redis. The stored metadata is then retrieved by the analysis framework to perform burst analysis using timestamps.

Valinor-N’s Redis workers issue batched commands during idle periods to minimize interference with packet processing workers. We use Redis sorted sets to store timestamp entries sorted by arrival times since the packets that arrive at the collector may have a different order from the packets that arrive at the Valinor-N switch data plane. We use 1G *hugepages* and large memory pools to ensure that timestamp packets are not dropped at higher rates (Up to 40 Gbps in our testbed).

Offline timestamp processing. The last piece of Valinor’s design is the offline timestamp analysis framework that queries the Redis data structures and performs analysis on timestamp data. Our framework is able to report various statistics on traffic burstiness by measuring the packet inter-arrivals. For example, in the next section, we report our findings on the scaling behavior, caused by various packet processing components in the sender machine. We

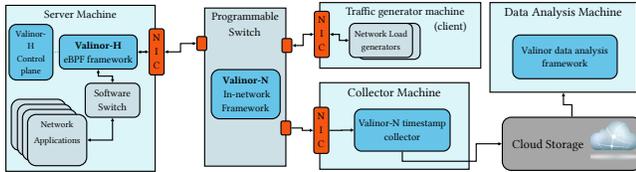

Figure 4: Deployment overview of Valinor framework.

report actual burst sizes in bytes, inter-arrival distributions, queuing delays, and various burstiness time series analyses. We implement the offline processing framework in Python.

5 Findings

We deploy Valinor to analyze the burstiness of various workloads and configurations. Our results show:

- Host networking, largely overlooked in prior self-similarity studies, plays a major role in forming and suppressing bursts.
- Lower layers of the network processing stack (such as segmentation offloading and NIC scheduling) compromise the effectiveness of software-based traffic shaping and active queue management solutions.
- Software pacing has major limitations. For workloads with a mixture of short and large flows, lower layers of the network processing stack mask the impact of software-based traffic pacing. For workloads with very short flows, software pacing can blunt bursts but leads to a major increase in RTT and significant throughput reduction.
- NIC driver buffer sizing and process scheduling can re-shape bursts.

Experiment setup. Figure 4 demonstrates how Valinor framework components come together in a basic deployment. For evaluating Valinor, we use a wide range of workload distributions. We deploy Iperf instances alongside Homa’s open-source load generator [47] inside Linux containers and configure the workload generators to simulate different trace-driven workload patterns including Facebook’s ETC, Google search, aggregated Google data center, DCTCP’s web search, and Facebook’s intra-cluster and intra-rack Hadoop traces [9, 12, 47, 60]. Unless stated otherwise, all application containers are connected via an OVS [2] virtual bridge to the external interface. Our testbed consists of servers featuring Intel Xeon E5-2620 v4 processors, 64 GB of memory, and Intel XL710 40G NICs. We connect the servers via a Wedge-100 Tofino switch running Valinor-N timestamping framework. We deploy Valinor-H on Linux kernel 5.17 with the latest version of *libbpf* and *iproute2* installed. The collector machine features

Setting	Default Value	Parameter Range
Transport	TCP cubic	cubic, reno, BBR, DCTCP, Homa
Qdisc	fq	fq, fq_codel, pfifo_fast, HHF, SFQ
Byte Queue Limit	Dynamic	[100B-10MB]
MTU	1500	1500, 9000
Process scheduler	CFS	CFS, FIFO, Microquanta

Table 1: Default system configuration and tested parameter ranges.

Valinor’s userspace data plane based on *DPDK* v20. We disable idle states on all servers and set the frequency governor to *performance* to minimize the interference of power-saving features on networking performance. The default settings for the evaluated components are summarized in Table 1.

Finally, to calculate microburst lengths, since we use 40Gbps links, we set the burst inter-arrival threshold to 500ns for the presented results (see §2). Valinor also computes microburst lengths for other threshold settings (ranging from 5ns to 10µs). While the threshold setting impacts the size and quantity of observed bursts, we did not notice any difference in relative burstiness when comparing multiple cases.

5.1 Revisiting structural causality

Where does traffic burstiness come from? Prior work [23, 53, 54] shows that the heavy-tailed property of the flow size distribution directly determines link-level traffic self-similarity, a phenomenon that is sometimes referred to as *structural causality*. Heavy-tailed flow size distributions are shown to be the sufficient condition for generating scale-invariant burstiness and the network stack is shown to play a negligible role in self-similarity [23, 53]. For instance, for traffic generated by TCP Reno for a heavy-tailed Pareto file size distribution with the shape parameter α , there exists an almost linear relation between H and α : the estimated H is close to $(3 - \alpha)/2$.⁷ Heavier tailed distributions (i.e., α close to 1) are more strongly self-similar (H closer to 1). The self-similarity of traffic with heavy-tailed flow sizes is in contrast to the lack

⁷The $H = (3 - \alpha)/2$ relation shows the values of H predicted by the a theoretical ON/OFF model in the idealized case corresponding to a fractional Gaussian noise process with independent traffic sources with constant ON/OFF amplitude [54]. This captures an ideal self-similar process.

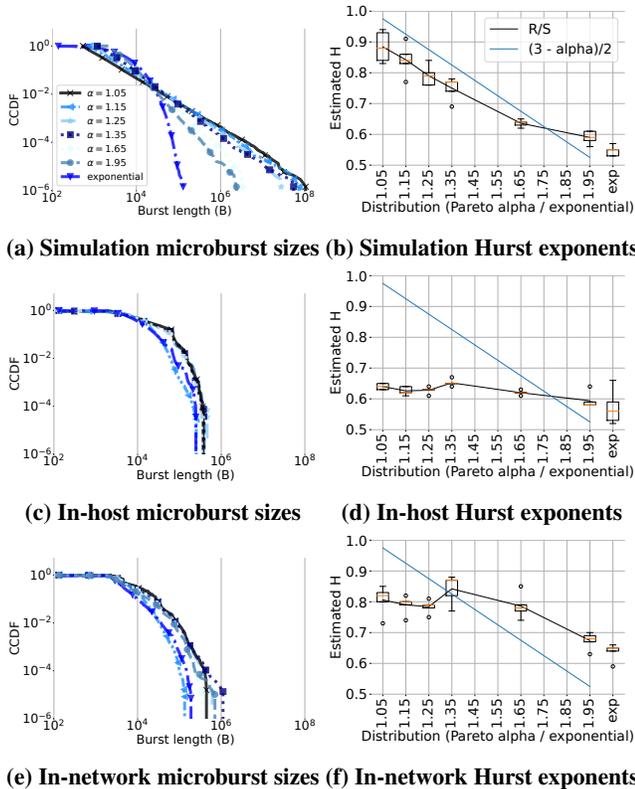

Figure 6: Microburst sizes and Hurst exponents of different synthetic workloads for simulated and testbed experiments. The interference of host networking elements is visible in the difference between the three scenarios.

of correlation structures for short-tailed flow size distributions such as an exponential distribution (H close to 0.5).

We first replicate this result using OMNET [1], an extensively used simulator [8, 14, 47], and observe an almost linear relation between α and H —consistent with the findings of prior work [53], the estimated H values closely track the $(3 - \alpha)/2$ line. In a setup where the two simulated servers are connected via a network switch, we establish 32 long-running TCP connections and use Pareto and exponential flow size distributions (Figure 5a shows the flow size distributions). To achieve a target offered load of 6 Gbps, flows are initiated exponentially with a mean interarrival time of $87\mu\text{s}$. We repeat each experiment five times. In the box and whisker plots, each box depicts the 1st and 3rd quartiles, the whiskers represent the upper and lower extremes, the circles are outlier points, and the orange dashes show the median Hurst estimates. Figure 6b shows that heavy-tailed flow size distributions generate self-similar traffic. Figure 6a shows that these distributions also result in larger microbursts with heavier tails.

Next, we repeat the above scenario in a testbed, using Valinor to analyze burstiness after the software stack and on the wire. Using Valinor-H for in-host analysis, we observe that

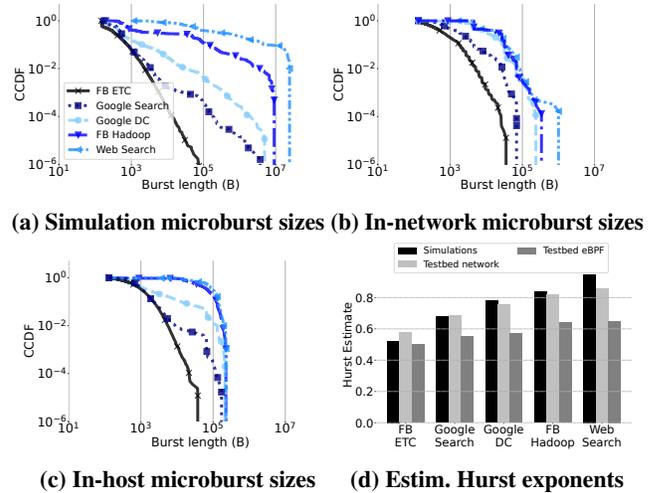

Figure 7: Self-similarity and microburst sizes vary across workloads and between testbed and simulation results. Positioned before the NIC, Valinor-H captures a smoother snapshot of traffic than in-network measurements.

the impact of the heavy-tailed distributions on self-similarity is barely visible at this stage with distributions with varying α parameters behaving similarly and close to a light-tail exponential distribution (Figure 6d), e.g., the software stack greatly diminishes the degree of self-similarity of heavy-tailed Pareto distribution with $\alpha = 1.05$ from $H = 0.88$ in the simulations (Figure 6b) to $H = 0.64$ at the eBPF hook (Figure 6d). We observe a similar effect on the microburst size distributions that are much more similar across different workloads and have shorter tails (Figure 6c).

We next use Valinor-N for analyzing traffic as observed on the wire. The patterns again change in interesting and non-uniform ways. Similar to in-host measurements, the in-network measurements indicate that the influence of flow size on self-similarity is lower than the simulated experiments, e.g., $H = 0.80$ and $H = 0.78$ for $\alpha = 1.05$ and $\alpha = 1.65$, respectively, on the wire in the testbed experiments compared to $H = 0.88$ and $H = 0.63$ for the same workloads in the simulated experiments (Figure 6f). The more amplified long-range burstiness in the network compared to in-host experiments is due to the intervention of driver and NIC functions (such as segmentation offloading scheduling) that reside below Valinor-H. We investigate the roles of these functions in §5.3. Figure 6e shows that the flow size distribution has a relatively subdued impact on the ultimate size of microbursts on the wire once the traffic traverses the host networking stack.

Summary: The shape of the traffic in the testbed experiments (in-network and in-host) is substantially different compared to the simulated experiments with identical setups. This suggests that host networking elements (e.g., qdiscs, process schedulers, and NIC schedulers, not modeled in common simulators) alter burstiness.

5.2 Impact of workloads

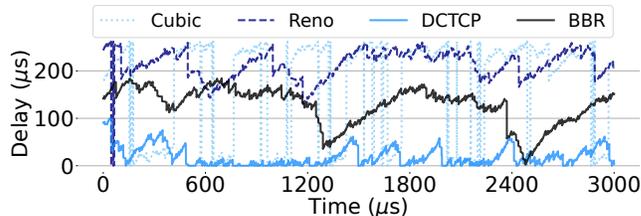

Next, we repeat the above experiments (using both the simulator and the testbed) by replaying the traces of five classes of workloads from [47]: (1) Facebook’s ETC workload, (2) Google search workload, (3) Google’s aggregated internal data center workload, (4) Facebook’s Hadoop workload, (5) DCTCP’s web search workload [9]. Figure 5b shows the flow size distributions of these traces. Similar to the previous experiments, in simulations, there exists a direct correlation between the flow size distributions, self-similarity, and the burst lengths (Figure 7). In the testbed, however, the difference in burst lengths starts to fade away as host networking components come into play. We also observe that the scaling behavior varies substantially across different workloads and between the simulated and testbed experiments. Hurst coefficients are larger for the more heavy-tailed distributions in the network but mostly homogeneous before reaching the driver. For example, the self-similarity estimates for the ETC workload (p_{99}^{th} flow size = 1.8 KB), the Google DC workload (p_{99}^{th} flow size = 31 KB), and the web search workload (p_{99}^{th} flow size = 27 MB) are 0.57, 0.75, and 0.85, respectively for in-network measurements and 0.50, 0.57, and 0.65, respectively for in-host measurements.

5.3 Sources and implications of burstiness

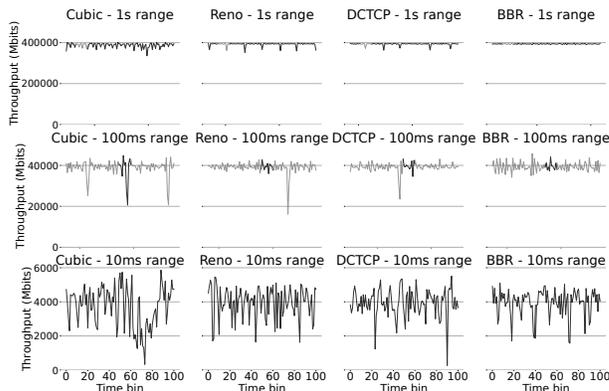

The previous section shows the aggregate impact of host networking elements on bursts. In this section, we measure the impact of each element, starting with the transport layer and moving to the elements that operate *below* the TCP/IP stack (e.g., qdiscs) and *in parallel* to it (e.g., the process scheduler).

5.3.1 Transports and congestion control

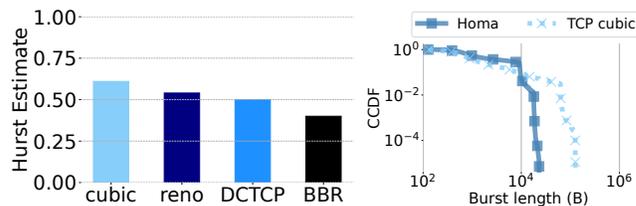

Starting with transports, we evaluate four TCP congestion control variants under a mixture of background traffic and a small-scale incast traffic pattern where two sender machines target one receiver. The background traffic consists of two *iperf* flows each taking 18Gbps of bottleneck link bandwidth. The incast traffic follows the map-reduce workload size distribution. For this experiment only, we run both the workload generators and the applications outside the container environment. Figure 8a shows how TCP Cubic [28], TCP Reno, DCTCP [9], and BBR [17] react to queue buildups in the network. Compared to Reno, TCP Cubic (the default congestion control setting in recent versions of Linux kernels) uses a more aggressive function for increasing its congestion window upon receiving acknowledgments. Therefore, it experiences larger queueing oscillations than Reno. BBR uses round-trip times to adjust its transmission window and varies its pacing rate to keep the in-flight bytes near its estimated bandwidth-delay product. Thus, it experiences a more steady queueing behavior while trying to keep the buffer half full.

(a) Buffer occupancy under Incast

(b) Timeseries of packet arrivals

(c) H estimates for TCP variants (d) Homa vs Cubic bursts

Figure 8: (a) Valinor captures the in-network buffer occupancy for different transport protocols. (b), (c) Timeseries and H coefficients show that burstiness (at both short and long timescales) varies significantly across transport protocols. (d) A receiver-driven transport, Homa, is less bursty than TCP Cubic.

Finally, DCTCP uses explicit congestion notifications from switches to maintain consistently low queuing.

Figure 8b presents the throughput timeseries of the four congestion control variants at different timescales followed by their Hurst exponent estimates in Figure 8c. With the help of pacing and RTT estimations, BBR is able to maintain a steady throughput and a non-bursty traffic shape, reflected by $H = 0.40$. On the other hand, Cubic’s less conservative transmissions incur a self-similarity estimate of 0.60.

Finally, we deploy Homa’s kernel module [47] as a representative implementation of receiver-driven transports in the Linux kernel. In receiver-driven transports, the destination initiates more packets by issuing *grant* control packets for the sending host. In our setup, Homa sends the first 90 KB of each flow unscheduled as an attempt to initiate the communication and retrieve the path’s congestion status. The

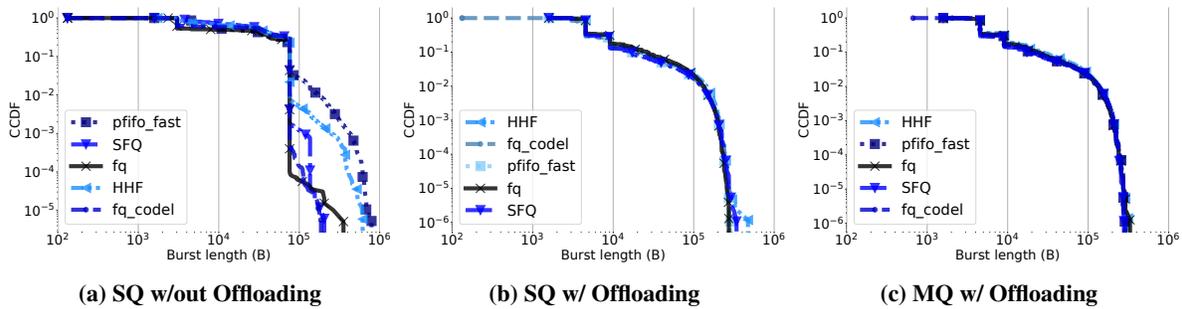

Figure 9: Burst behavior of Linux queueing disciplines in the absence and presence of offloading (Offloading) and NIC scheduling (SQ=single-queue, MQ=multi-queue). Both MQ and TCP segmentation offload compromise the intended shape of software packet scheduling.

following packets are then scheduled using grants. Due to its limited implementation scope, the Homa module is not able to achieve line rate performance. Therefore, we limit our observation to the map-reduce workload tuned down to 6 Gbps offered load. Figure 8d presents the burst lengths for Homa and TCP Cubic as observed by Valinor-H eBPF framework. We observe that the p99 burst length under Homa is $9\times$ lower than Cubic which might reflect two facts. First, unlike Cubic which sends up to 64 KB long data chunks, Homa’s prepared *sk_buff* chunks are mostly as large as its MTU (9 KB in this experiment). This is also due to the fact that Homa kernel module is not making use of TSO because of certain Intel NIC limitations. Secondly, Homa uses pacing to keep the NIC fully saturated in its Linux implementation which further controls the spacing between its transmissions [52]. Combined, these factors result in Homa’s less bursty behavior compared to TCP Cubic, not just at small timescales (Figure 8d) but also at large timescales ($H = 0.54$ for Homa vs. 0.62 for Cubic). However, we suspect a different behavior from Homa on different setups that can make use of NIC offloading.

5.3.2 Software switching

Linux leverages queueing disciplines (*qdiscs*) to enforce scheduling among segments originating from different applications in the system. If generic segmentation offload is not in use, *qdiscs* are the last software components to decide the order of data entities on NIC’s FIFO rings. We study five representative queueing disciplines implemented in Linux:

1) Fair queue (fq) is the default scheduler in recent Linux kernels and is mainly used to enforce pacing on a per-flow (per socket) basis. The appropriate pace among flows is either explicitly enforced via socket options, or is determined by the TCP congestion control (e.g., BBR). By default, *fq* uses deficit round-robin with a default quantum of 3028 bytes to drain flow queues, with an initial quantum equalling TCP’s initial 10-packet window.

2) fq_CoDel. The controlled delay (CoDel) algorithm, combined with fair queue, enforces CoDel on per-flow sub-queues. CoDel, a more recent AQM algorithm, uses packet sojourn

time inside each flow queue to detect slow flows and prevents the queueing delay to exceed a user-specified target by dropping excess traffic.

3) Stochastic Fair Queueing (SFQ) extends flow-queueing with random-early marking/drop semantics with small default queue sizing to control the queueing delay. Similar to *fq*, it uses round-robin scheduling on per-flow sub-queues. SFQ uses a default deficit of one MTU.

4) pfifo_fast is a First-In First-Out priority queue. Higher priority packets are distinguished by their Type of Service (TOS) fields in IP headers which are set by upper layers.

5) Heavy Hitter Filter (HHF) attempts to identify and separate short flows from heavy hitters to prevent head-of-the-line blocking and increased delays for latency-sensitive flows. Such flows are given a higher deficit compared to heavy hitters in each transmission round.

We study *qdiscs* under three scenarios: First, to see the actual contribution of *qdiscs* to the traffic shape, we disable segmentation offload and serialization offload and limit the number of the transmit rings to one (single-queue). Segmentation is the process of breaking large *sk_buffs* into MTU-sized segments and is usually deferred to the last processing stages to reduce CPU utilization and improve flow performance. Segmentation offload can either be performed in the hardware (TCP Segmentation Offload or TSO) or just before passing the data to the hardware (Generic Segmentation Offload or GSO). Additionally, in a multi-queue architecture, the network stack communicates to the NIC via separate ring buffers pinned to each CPU core to reduce inter-core communication overheads and improve throughput. When enabled, a (reportedly, round-robin [65]) packet scheduler in the hardware will decide the order in which packets are drained from ring buffers.

Initially, we run 1000 Iperf instances spread across 200 containers, simulating the map-reduce workload on the single-queue server without offloading. Figure 9a demonstrates how, *in isolation*, per-flow queueing can significantly shorten the size of egress bursts. Techniques such *pfifo_fast*, and HHF use one large buffer containing packets from all egress flows, allowing multiple data segments of one flow to be enqueued simultaneously. On the other hand, per-flow queueing allows

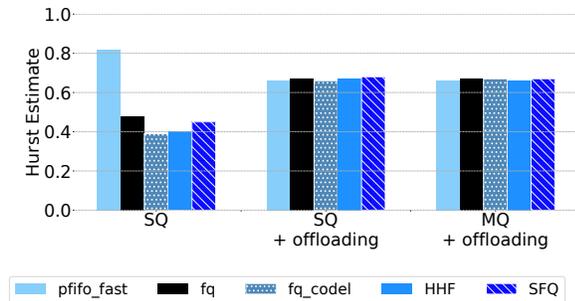

Figure 10: Hurst estimates for different queuing disciplines.

the scheduler to interleave among packets of different flows, primarily to maintain fairness and prevent head-of-the-line blocking [62].

To verify the impact of round-robin scheduling on blunting bursts, we repeat the same experiment with *fq* qdisc, increasing the per-flow deficit from one MTU (1514 bytes) to 16 MTUs, and observe a linear correlation between *fq* deficits and burst lengths. For example, the 90th percentile of burst lengths under a deficit of 16 packets is increased to 25 KB from 13 KB under that of 8 MTUs (92% increase).

While qdisc is the last layer to perform packet scheduling in the software, the traffic ultimately often passes through segmentation offloading and NIC scheduling before reaching the wire. Is the impact of qdiscs on the wire preserved *after the interaction* with these lower layers? To investigate, we enable all the offloading features and perform our measurements again. Figure 9b demonstrates the impact of offloading segmentation and serialization on lengthening the egress bursts. With TSO at work, qdiscs no longer serve packets. Instead, they schedule between dynamically sized *sk_buffs*. Hardware offloading then helps increase the throughput by nearly 50% for all cases while moving the buffering to the hardware where large segments are broken into MTU-sized packets and sent on the wire. This significantly undermines qdisc’s decisions on shaping the traffic. With offloading in action, the median burst sizes for *fq*, *fq_codel*, and *pfifo_fast* are, 132 KB, 127 KB, and 127 KB, respectively. While without offloading, these systems experienced a median burst length of 76 KB, 76 KB, and 172 KB⁸, respectively.

To further ruffle the output of qdiscs, we enable the default multi-ring root qdisc which assigns a separate qdisc instance to each CPU core and enables the NIC scheduler to perform last-level scheduling on transmit rings (multi-queue architecture). Figure 9c presents the outcome. *With NIC scheduling and segmentation offloading at work, the shape of the qdisc’s outgoing traffic is barely preserved on the wire.* That is because, NICs are equipped with internal round-robin schedulers to drain the software rings, further reducing the chances of creating long bursts. Finally, Figure 10 demonstrates the estimated Hurst exponents for the three scenarios. Without

⁸*pfifo_fast* combined with offloading can exacerbate burstiness as both layers are prone to creating large, uncontrolled bursts.

segmentation offloading, the degree of burstiness is considerably reduced ($H < 0.5$) for all but one case. Only *pfifo_fast* which does not offer any form of fair queuing suffers from heavier burstiness ($H = 0.8$) under the single-queue scenario.

Implications of disabling offloading and multi-ring scheduling. Apart from burstiness, both offloading and NIC scheduling have a profound impact on flow performance metrics. Our measurements demonstrate that disabling TCP segmentation offload for a workload consisting of 1000 same-size flows results in 71% decline in median flow throughput, 46% increase in median packet RTTs, and 3× increase in sender CPU utilization. Therefore, disabling offloading, in order to enable software control is not always a viable option. Multi-queue NICs are also considered a quick solution with potential side effects. While enabling multi-queue reduces resource contention, they can increase response times and are usually fixed-function [65].

5.3.3 Software pacing

The above observations raise another important question on host networking design decisions. While many congestion control techniques [7, 17, 37, 47, 57] advocate for pacing in order to achieve accurate control over in-transit data, existing pacing implementation in the Linux kernel is deeply away from the wire, at *fq* qdisc. *Are qdiscs a suitable place for enforcing pacing?* To investigate, we repeat the map-reduce (M/R) workloads on the server with both offloading and NIC scheduling enabled and observe that *for workloads with large flows (intra-rack M/R), pacing doesn’t have a significant impact on burstiness, and for those with short flows (intra-cluster M/R), pacing results in throughput reduction.* Overall, our results highlight the limitations of software pacing for data center workloads.

Concretely, we configure *fq* to pace 200 flows based on their fair share of bandwidth (200 Mbps), and gradually increase the portion of the flows that are counted as heavy hitters from 0% (no flow is paced) up to 100% (all flows are paced). Figure 11 compares the bursts for (a) workload with mostly large flows and (b) workload with a mix of small and large flows. In the former workload, we observe that while the impact of pacing ratio is less evident, pacing allows for better bandwidth allocation and the line rate is preserved for all rows. On the other hand, in the latter workload, the throughput is reduced by 22% under pacing. This is because short flows are not able to make up for the freed bandwidth that pacing creates. We also compare packet RTTs and find that pacing large heavy-hitters helps reduce median RTTs by two orders of magnitude as short flows experience less head-of-the-line blocking. This behavior changes in the intra-cluster workload as we do more pacing, as the increased RTT of paced flows drives the overall median RTT up by 160%. Further details on the theoretical analysis of burstiness under software pacing can be found in Appendix §B.

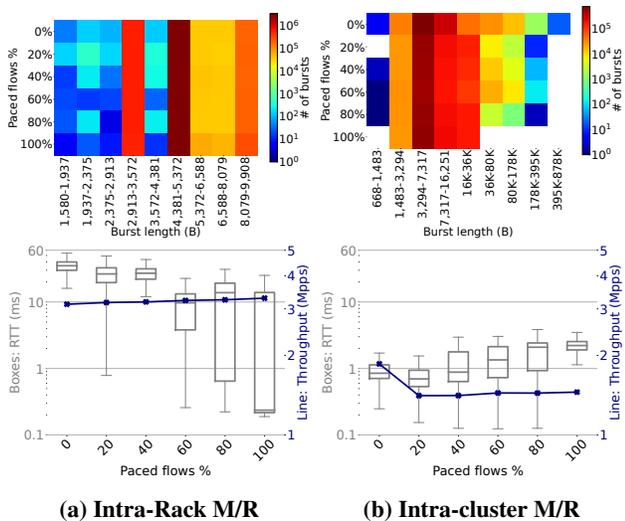

Figure 11: Software pacing is workload dependent. For workloads consisting of large flows, its impact on smoothing bursts is unmade by lower layers. For workloads with both short and long flows, it reduces throughput.

5.3.4 Byte Queue Limits

Linux kernel employs buffers at various stages of network stack processing to streamline the data movement among various components. The NIC driver queue is the last buffering stage before triggering the hardware. A fixed-size driver queue (a.k.a., TX ring) would ensure that the NIC can always find ready-to-send packets without communicating with the OS. However, due to the unpredictable size of packet buffers in the Linux kernel (ranging from 64B up to tens of kilobytes), the queuing time will considerably add to the overall RTT of packets. To prevent that, OS developers propose a dynamic bound on TX rings that adjusts the limit based on NIC’s transmission rate and the availability of data in the TX rings [29]. To that end, after every transmission, BQL uses time intervals to check whether the NIC was starved in previous transmissions. If the NIC was not fully utilized during any interval while data was available at higher layers, the BQL algorithm increases the limit on the TX ring. Otherwise, if the NIC was fully busy, the BQL is decreased to reduce the queuing overheads. Enforcing smaller queue limits also ensures that the main queuing occurs at the qdisc-level where more advanced queuing disciplines can be employed.

Apart from Linux, NIC buffer sizing is also an important consideration for kernel-bypass runtimes that are less inclined to distribute TX processing among multiple ring buffers [36, 51]. Figure 12 demonstrates the impact of driver queue size on performance and burstiness. Intuitively, as we increase the size of the driver’s buffer, we greatly increase the queuing time experienced by egress traffic, therefore, preventing the bursts of packets from arriving at the NIC. On the other hand, a larger driver queue is more prone to creating longer bursts as

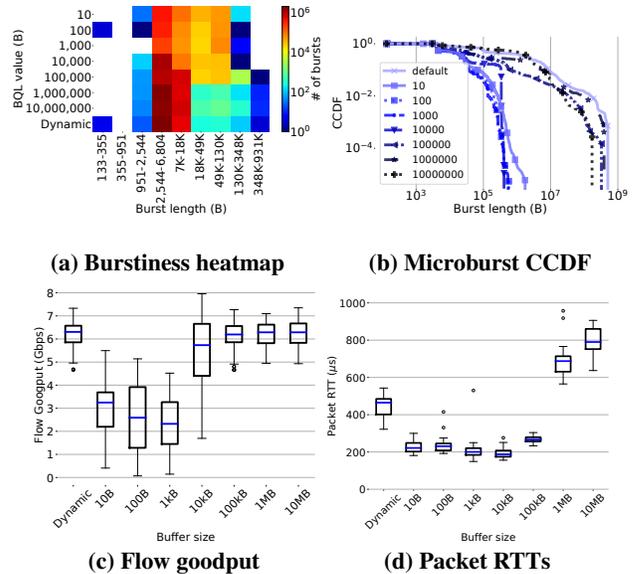

Figure 12: Larger BQL settings produce longer bursts. Also, the dynamic BQL algorithm presents a similar behavior to a large static ring size.

it is more susceptible to triggering segmentation offload (99th percentile burst length for 1 KB buffers and 1 MB buffers are 68 KB and 9 KB, respectively, but 99.99th lengths shift to 68 KB and 86 KB, respectively). The microburst length distributions in Figure 12b further suggest that the default dynamic buffer sizing algorithm tends to maintain larger ring buffers which leads to longer bursts.

5.3.5 Linux process scheduling

Apart from the network stack, the operating system features various internal components that might change the traffic shape. For example, Linux offers a range of process scheduling classes suited for various use cases:

Completely Fair Scheduler (CFS) is the default process scheduling class in Linux which aims at achieving fairness among active processes in the system while maintaining responsiveness for I/O-bound applications. when running a mix of compute-intensive and network-intensive workloads, CFS attempts to proportionally share the CPU among workloads leading to longer response times [39].

Real-time scheduler supports two policies: *Round-robin* and *First-In-First-Out (FIFO)* scheduling. Both policies give strict priority to I/O-bound applications (if configured properly). By default, the round-robin policy preempts high-priority processes every 100ms while the FIFO policy is non-preemptive. We also deploy Microquanta [46] a semi-real-time scheduling class with microsecond time precision.

Valinor’s picture of traffic burstiness is consistently similar when the network application is running alone as Hurst estimates vary between 0.51 and 0.54 for all the schedulers. How-

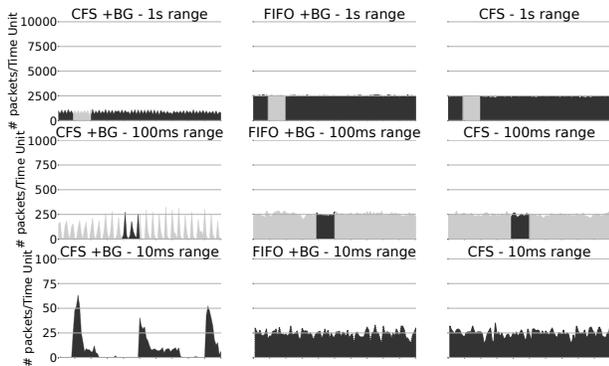

Figure 13: Impact of process scheduling on traffic bursts.

ever, when the background process is introduced, a coarse-grained process scheduler like CFS must enforce fair CPU time sharing, resulting in the leap of its H estimate to 0.74 while other schedulers are able to schedule the network application’s threads in short timescales and result in smooth transmissions. To validate the self-similarity estimates, we plot the time series of CFS (running only the network workload), CFS+BG (running the network workload alongside background threads), and the real-time FIFO scheduler running both applications (FIFO+BG) in Figure 13. The self-similar nature of the CFS+BG scenario is noticeable in the leftmost column as CFS causes the network packets to be sent in larger chunks, causing intermittent but larger bursts at short time spans.

6 Related work

Traffic self-similarity. A large group of studies rely on quantifying bursts by using the notion of self-similarity in the time series [5, 24, 38, 50, 53–55] but overlook the role of host networking on shaping bursts. Valinor leverages the theoretical frameworks developed in these works to uncover *the impact of host networking on bursts*.

Detecting bursts. A growing number of proposals try to identify *what flows* are bursty [18, 19, 40, 48] but they cannot identify *why* those flows are bursty. Crucially, they cannot identify the elements on the traffic path that contribute to or blunt traffic burstiness. Frameworks such as BurstRadar [33] and SynDB [34] rely on buffer congestion or external triggers to capture packet arrivals, which prevents them from capturing long-range dependency patterns in host egress traffic.

Similar to Valinor, a few proposals study the causes of bursts. Some papers pinpoint transport protocol internals such as segmentation, slow start, bulk acknowledgments, and fast re-transmit as potential sources of bursts at the source level [10, 31, 69]. Another category of works study the impact of offloading techniques like segmentation offload on microbursts [35, 72]. Specifically, [35] investigates the impact of application behavior, operating system syscalls, and

NIC offloading features on both sender and receiver hosts on burstiness and further show that burstiness imposed by TCP segmentation offload can marginally be controlled by configuring the kernel’s maximum GSO size. Compared to these studies, Valinor has a broader scope; it studies the impact of various host elements (not just transport protocols), the effects of low-level offloading mechanisms on software scheduling and pacing, and bursts at various timescales (not just microsecond-scale). Finally, [25] introduces Millisampler, a host-centric burst characterization tool to study the impact of service placement on buffer contention and packet loss. Valinor uses its switch framework to detect synchronized flow arrivals at points of interest and unlike Millisampler which operates at *sk_buff* granularity, can attribute bursts at packet resolution. We believe that Valinor and Millisampler combined can assist data center network operators in accurately detecting the sources of bursty traffic at various timescales.

Burst control. A large and growing number of proposals [9, 27, 32, 37, 41, 43, 44, 59, 61, 62, 70] focus on *controlling* bursts, e.g., via rate-limiting at the switch [44], fine-grained pacing [61], and high-precision transport protocols [37, 41]. These studies are orthogonal to Valinor. Understanding the temporal properties of bursts and the causal mechanisms contributing to burstiness will benefit the design of effective burst control mechanisms.

7 Conclusions

We presented the design of Valinor, a burst measurement framework that consists of an in-host eBPF framework and an in-network timestamping module for programmable switches. Valinor can capture burstiness at different scales (ranging from nanoseconds to seconds). We use Valinor to demonstrate how host networking elements affect bursts. We show that the scaling behavior of traffic at long timescales and burstiness at fine timescales vary significantly across different host networking configurations (process schedulers, congestion control algorithms, single vs. multi-queue NICs, etc.) and across different classes of practical workloads. In particular, we show the impact of hardware-resident functions (e.g., NIC schedulers) that are largely overlooked in characterizing burstiness. This variability of burstiness and the implications of bursts on performance underscore the need for measurement systems to perform periodic burst analysis.

A Rescaled-range analysis for estimating H

For a weak stationary stochastic process $X = (X_t : t = 0, 1, 2, \dots, N)$, the mean-adjusted series is defined as $Y, Y_t = X_t - m$ where m is the empirical mean of the process X . Let Z denote the cumulative deviate of Y where $Z_t = \sum_{i=1}^t Y_i$. We also define m_t as the cumulative mean of the series X through time t .

The rescaled range of X is denoted by

$$(R/S)_t = \frac{R_t}{S_t}, t \in \{0, 1, 2, \dots, N\} \quad (3)$$

where the Range series R is defined as

$$R_t = \text{Max}(Z_1, Z_2, \dots, Z_N) - \text{Min}(Z_1, Z_2, \dots, Z_N), \quad t \in \{0, 1, 2, \dots, N\} \quad (4)$$

and the standard deviation series S is defined as

$$S_t = \sqrt{\frac{1}{t} \sum_{i=1}^t (X_i - m_t)^2}, t \in \{0, 1, 2, \dots, N\} \quad (5)$$

According to [30], R/S scales with the power law of t . Therefore, to estimate H , the slope of the least-squares linear regression of R/S over t in a log-log scale is used. The resulting exponent is in the 0-1 range and a value between 0.5 to 1 indicates low to strong long-range dependence (self-similarity), respectively. In other words, an H estimate close to one indicates a strong desire to maintain the previous trend or more burstiness. As the H estimate nears 0.5, the time series becomes indistinguishable from random noise, and a value close to zero signifies the traffic's aim at reverting to its mean value.

B Theoretical analysis of software pacing under different workloads

We presented the size of per-flow bursts for explicit software pacing in §5.3.3. To further verify our findings using the notion of self-similarity, we first plot the time-series of packet arrivals in 1s, 100ms, and 10ms time scales in Figure 14 for both the intra-cluster (Figure 14a) and intra-rack (Figure 14b) workloads. One can notice the gradual decay of burstiness in all time scales as higher degrees of pacing are enforced to the intra-cluster workload. On the other hand, we can observe that the intra-rack traffic follows a non-bursty, steady trend in all time scales regardless of pacing.

Next, we calculate the Hurst exponents for the intra-rack and intra-cluster workloads. According to Figure 14c, self-similarity in the latter workload follows the degree of pacing (i.e., percentage of the paced flows) where 100% pacing results in 31% reduction in the Hurst estimate compared to the no-pacing case. For example, the Hurst estimates are 0.91, 0.73, and 0.63 for 0%, 40%, and 100% pacing ratios, respectively. However, under the intra-rack workload pacing seems

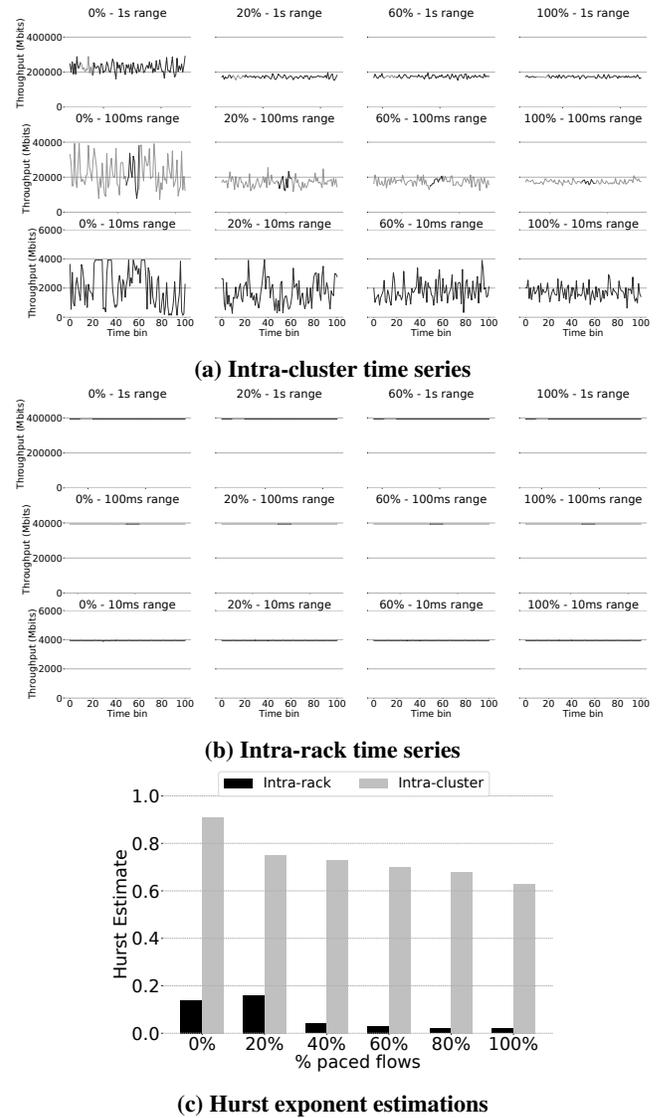

Figure 14: Time-series graphs and Hurst exponents for the software pacing experiments presenting the traffic behavior at three time ranges.

to have little to no effect as the egress traffic follows a mean-reverting behavior during 1-second time ranges ($H < 0.20$ for all the cases).

Finally, Figure 15 presents the corresponding auto-correlation functions (ACFs) for the above time series. While the cycling trend of bars between positive and negative correlations suggests a strong mean-reverting behavior for the intra-rack workload (Figures 15e-15h), the intra-cluster ACF features a slow-decaying, strong positive correlations across time lags, suggesting strong self-similarity (Figures 15a-15d). As we increase the pacing ratio (from 0% gradually to 100%), the correlations start to decline.

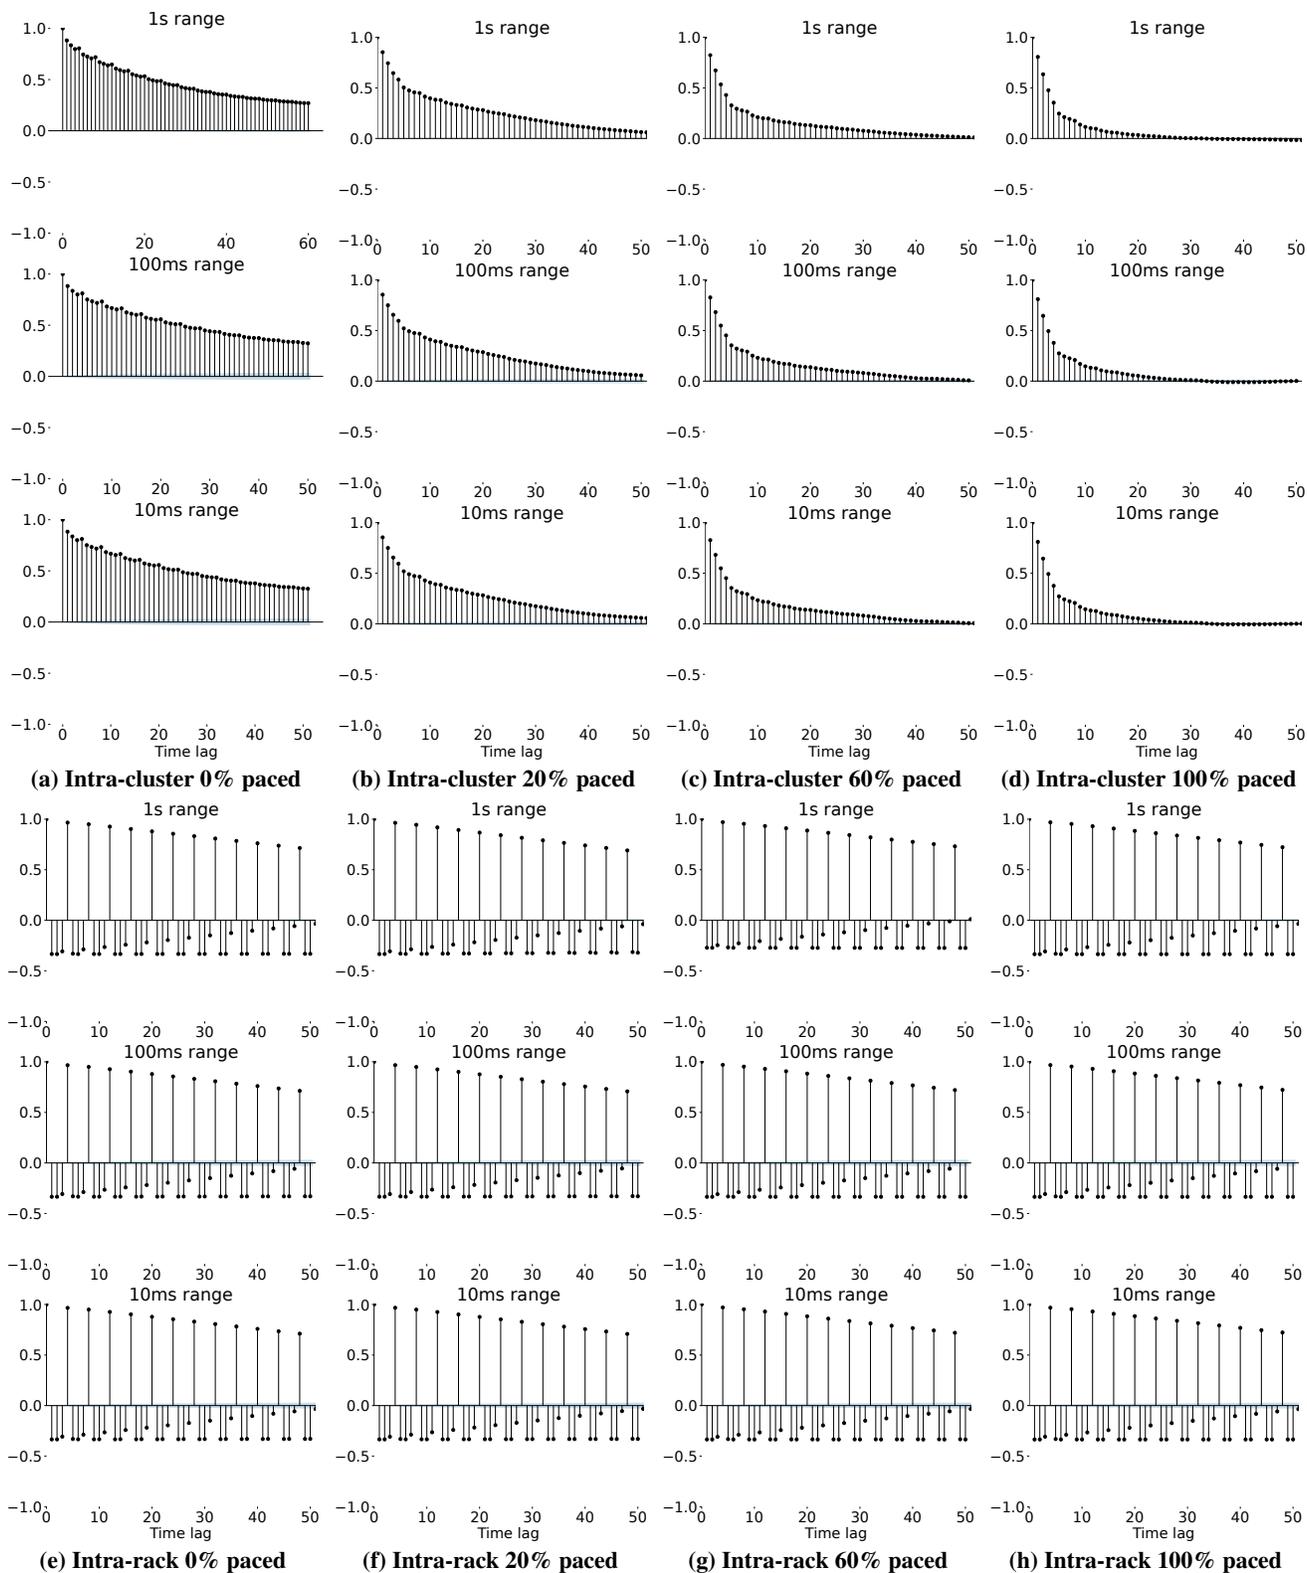

Figure 15: Comparing the auto-correlation functions (ACFs) for two workloads when we increase the ratio of paced flows from 0% to 100%. For the intra-cluster workload, enforcing pacing on flows can significantly reduce the self-similarities. For the intra-rack workload, the correlations between consecutive time lags oscillate between positive and negative numbers, signifying the mean-reverting nature of the workload irrespective of the pacing.

Poseidon: Efficient, Robust, and Practical Datacenter CC via Deployable INT

^{*}Google LLC, [†]Rice University

Abstract

The difficulty in gaining visibility into the fine-timescale hop-level congestion state of networks has been a key challenge faced by congestion control (CC) protocols for decades. However, the emergence of commodity switches supporting in-network telemetry (INT) enables more advanced CC. In this paper, we present *Poseidon*, a novel CC protocol that exploits INT to address blind spots of CC algorithms and realize several fundamentally advantageous properties. First, Poseidon is *efficient*: it achieves low queuing delay, high throughput, and fast convergence. Furthermore, Poseidon decouples bandwidth fairness from the traditional AIMD control law, using a novel adaptive update scheme that converges quickly and smooths out oscillations. Second, Poseidon is *robust*: it realizes CC for the actual *bottleneck hop*, and achieves max-min fairness across traffic patterns, including multi-hop and reverse-path congestion. Third, Poseidon is *practical*: it is amenable to incremental brownfield deployment in networks that mix INT and non-INT switches. We show, via testbed and simulation experiments, that Poseidon provides significant improvements over the state-of-the-art Swift CC algorithm across key metrics – RTT, throughput, fairness, and convergence – resulting in end-to-end application performance gains. Evaluated across several scenarios, Poseidon lowers fabric RTT by up to 50%, reduces time to converge up to 12 \times , and decreases throughput variation across flows by up to 70%. Collectively, these improvements reduce message transfer time by more than 61% on average and 14.5 \times at 99.9p.

1 Introduction

Effective datacenter congestion control (CC) needs to provide high throughput, low latency, fairness, and fast convergence across varied workloads. CC is becoming more and more critical as applications increasingly demand low-latency operations at datacenter scale. Examples of such applications include memory and storage disaggregation [9, 21, 25, 31], which require latencies as low as $O(10\mu s)$ at 1M+ IOPs per server [14], and ML applications that require high network utilization to keep expensive accelerators busy [37, 45]. Large scale incasts with $O(5000)$ flows [35] caused by shuffle operations [1] and partition-aggregate workflows continue to be prevalent and need CC to be fair across flows in order to avoid starvation and control the tail latency, which is critical for the performance of such applications [20]. Simultaneously, CC is becoming more challenging because link

bandwidths are growing faster than buffers at switches [5], and high-packet-rate servers [3, 24] benefit from simple CC algorithms offloaded to NICs to save CPU for applications.

Datacenter CC algorithms in deployment today rely on either end-to-end signals (e.g., delay [35]) or quantized in-network feedback (e.g., ECN [8]), owing to their simplicity. An underlying problem with these signals is that they are aggregated *end-to-end* across all hops on a flow’s path. Thus, these CC algorithms react to collective congestion along the path (for delay) or congestion at *any* hop on the path at different times (for ECN), leading to reducing a flow’s rate before reaching its fair share in the network. This leads to underutilization, slow ramp-up, and/or unfairness in multiple scenarios shown in §2.1 and §5.

However, with the emergence of commodity switches that support in-network telemetry (INT), a new opportunity has emerged. INT-enabled switches can modify or append to packet headers to convey information local to the switch, such as the time the packet spent in the queue. Some state-of-the-art CC algorithms [7, 40], use INT to gather telemetry information for every hop to gain more visibility into the network and control the outstanding packets at each hop. Still, such solutions react to congestion at *any* hop, which leads to the unfairness and ramp-up problems mentioned above.

In the last few decades, several schemes have been introduced that leverage help from network switches for better CC [13, 22, 27, 34, 40] but almost none have been deployed widely in datacenters. Based on the successful deployment of ECN-based solutions [8] and no deployments of XCP [34], RCP [22], and similar AQM solutions, we believe a *deployable* CC scheme using INT should also have the following properties: 1) works seamlessly in heterogeneous brownfield deployments where new switches and old switches co-exist and provides benefit even if a subset of switches support INT. 2) uses a simple, low-overhead, non-intrusive INT scheme that requires minimal coordination among applications, networking stacks, NICs, and switches.

Therefore, in this paper, we ask the question: *How can we harness the power of INT to design a datacenter CC algorithm that is **efficient** (high throughput, low latency, and fast convergence), **robust** (max-min fairness across traffic patterns including multi-hop and reverse-path congestion), and **practical** (simple and deployable)?*

We find that learning the congestion state of every hop of a flow is unnecessary. Instead, an efficient and practical

CC can be realized based on the congestion state of *only the bottleneck hop* of a flow – the hop that limits the rate of the flow as per the max-min fair allocation. It’s worth noting that a *congested hop* is not the *bottleneck hop* for all flows passing through it, but only for flows that send more than their max-min fair-share rate, and thus, CC should ideally decrease the rate of only those flows that send above their fair-share.

Armed with this key insight, we develop a novel INT-based CC protocol called *Poseidon*. Poseidon grounds itself in Swift [35], the state-of-the-art CC that’s deployed in production at scale for TCP [17] and kernel-bypass stacks [41]. But Poseidon advances beyond Swift by leveraging INT instead of purely E2E measurements, and formalizes an adaptive congestion window update function that compares the *max* per-hop delay (obtained via INT) against a *rate-adjusted target* bottleneck hop delay.

This paper makes contributions in two main areas:

First, Poseidon utilizes the power of INT to provide unique properties, like network-wide max-min fairness, monotonic fast convergence, and stable rate under high concurrency.

- By comparing the max per-hop delay against a dynamic target, Poseidon converges to the network-wide max-min fair allocation, where flows only react to congestion on their bottleneck hop. A corollary to this is that flows in Poseidon do not decelerate before reaching their fair-share rate, resulting in fast convergence.
- Poseidon provides a characterization for the spectrum of *cwnd update* and *target max per-hop delay* functions that guarantee both fairness and high utilization. This allows us to explicitly decouple the fairness objective from the rate increase-decrease function (e.g., AIMD); Poseidon leverages this to use an *adaptive* increase-decrease function (without an AI component) that accelerates arriving at the fair-share allocation and smooths oscillations around it in the presence of many flows. Poseidon uses a novel target function, which achieves low queuing delay and high utilization for both sparse workloads (a few fast flows) and high-concurrency workloads (many slow flows).
- Poseidon is amenable to incremental deployment, including seamless coexistence in brownfield scenarios.

Second, Poseidon provides a simple, practical, and deployable design for enabling INT in datacenters for CC.

- We detail an efficient INT mechanism where switches signal the maximum per-hop queuing delay on a packet’s path, using only a small and fixed amount of packet header space, at line rate.
- We analyze requirements for deployable INT for CC and compare proposed formats against those requirements.

We implemented Poseidon in a production networking stack (similar to Pony Express [41]) and a testbed with commodity programmable switches, with no changes to the NIC or applications. Our testbed evaluation shows that Poseidon is robust to reverse-path and multi-hop congestion scenarios explained in §2.1. In addition, we have evaluated Poseidon

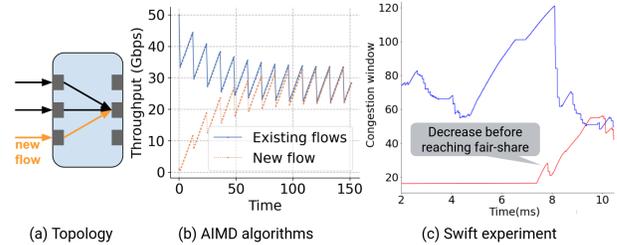

Figure 1: MD on ramping-up flows delays convergence.

extensively in packet-level simulations (§5) and show that, compared to Swift and HPCC [40], it is robust to the above scenarios. Relative to Swift, Poseidon improves application-level message transfer latency by 61% at median and 14.5× at 99.9p. This is achieved by lowering fabric RTT by more than 50%, reducing congestion window ramp-up time up to 12×, and decreasing throughput variation for flows with small windows by up to 70%. In brownfield, Poseidon achieved at least 50% of the op latency gain of full deployment.

2 Motivation

In this section, we first show how congestion control (CC) algorithms are inefficient if they cannot distinguish the bottleneck hop of a flow from a merely congested hop. Then, we motivate the importance of brownfield deployment to support incremental roll-out and highlight why the format of INT is important for deployment.

2.1 CC Challenges in Datacenters

We use several scenarios in datacenter networks to highlight how two classes of issues – reacting to signals from hops other than the bottleneck hop, and increasing with a fixed value – cause unfairness, low link utilization, and slow ramp-up.

2.1.1 Decelerating Before Reaching Fair-share

Traditionally, when a hop is congested, a flow with a lower rate (e.g., a new flow) does not increase its rate monotonically to the fair share; instead, with every congestion signal, its rate decreases. Figure 1(a) draws an example where a new flow competes with two existing flows, Figure 1(b) shows the typical behavior for AIMD algorithms, and Figure 1(c) shows the data from that experiment in production using Swift. This behavior prolongs the time for the lower-rate flow to ramp up and leads to a longer tail flow completion time. The root cause is that in current CC algorithms, all flows must react *the same way* to the congested hop (either increase/decrease) regardless of their rate. This mechanism is designed to achieve fairness and stability given an end-to-end signal (e.g., delay, loss, ECN) without coordination across flows [19]. Poseidon leverages INT to get a richer signal and allows flows to increase their rates monotonically until reaching the fair-share rate.

2.1.2 Multi-hop Congestion

Datacenter networks are usually oversubscribed at ToR and Spine layers [46], thus it is common for a flow to see multiple

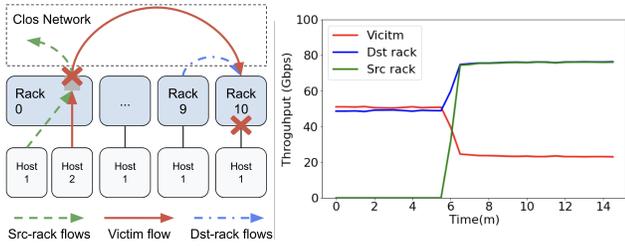

Figure 2: A Swift flow facing congestion at multiple hops (red) cannot compete at congested hops

congested hops in its path, especially in an incast. However, when a flow faces congestion in more than one hop, it gets lower throughput than other competing flows that traverse a single congested hop. The reason is that flows reacting to loss and ECN [8, 28] from multiple hops see more losses or marked packets on average, as the drops or markings happen asynchronously across different congested hops. In Swift, the fabric delay of such flows is higher, since every congested hop introduces more delay to the sum. HPCC [40], even though it uses INT, will also react to congestion at *any* hop with high in-flight bytes even if the flow is not contributing much to it.

Figure 2 shows this scenario in an experiment in production settings using Swift. The red flow (victim), that competes with the blue flow at the destination, gets much lower throughput once the green flow starts at the source ToR. The root cause is that the victim flow reacts to the congestion on Rack 0 uplink or Rack 10 downlink even when it didn’t get the fair-share. This is because Swift looks at the end-to-end fabric delay and the victim’s fabric delay includes both the delay at Rack 0 and Rack 10.¹ We observe the same problem even if the flow reacts to the max hop delay [8, 40] as shown in §5.6. Ideally, the victim flow should always only react to the congestion at the hop where it got more than the fair-share.

2.1.3 Reverse-path Congestion

In Figure 3, as we increase the number of flows on the reverse-path (blue), the forward traffic (red) gets lower throughput and cannot utilize the bandwidth. The root cause is that *the end-to-end delay* used in Swift includes the delay of ACKs in the reverse-path. Thus, Swift decreases the congestion window as if it is competing for the forward *and* reverse path bandwidth. This issue can happen because of congestion on any hop in the reverse-path, and can also cause unfairness if only a subset of flows on a bottleneck see reverse-path congestion, but is special for CC algorithms that use the end-to-end delay. A solution is to use synchronized timestamps at hosts (at μ s level) in order to break fabric delay into forward and backward delays [39], but we show that CC can use INT to separate congestion signals of forward and reverse path and avoid the overhead of maintaining a synchronized clock.

Summary of the above three scenarios: many existing CC

¹Although the victim flow always faces a higher delay than the other two flows, its throughput didn’t reach 0. The reason is that flow-scaling, designed for windows < 10 [35], rises victim’s target delay.

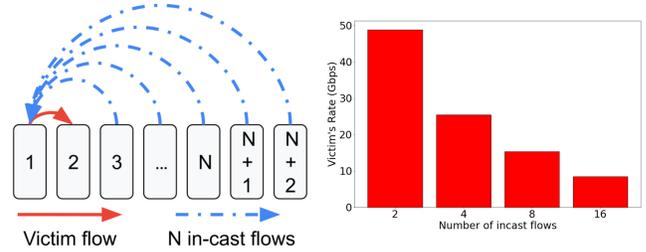

Figure 3: Flows react to reverse-path congestion.

algorithms – when using loss, ECN, delay, or INT signals – react to every congested hop along the path, rather than only the congestion on the bottleneck hop. To put it another way, all flows going through a congested hop react the same way, either increase or decrease their rate, regardless of whether they have achieved their fair share or not. In §3.1, we show how Poseidon solves this problem by reacting to congested hops only for flows that reached their fair share.

2.1.4 Slow Convergence and Throughput Oscillation

An efficient CC algorithm should converge quickly to the right rate when the flow’s rate is far from it and stay near it in a stable fashion. However, because many existing CC algorithms [8, 32, 35, 40] do not know the fair-share rate or how far they are from that rate, they rely on an AIMD, a well-understood algorithm that converges to fairness.

However, AIMD causes slow convergence for large windows and an unstable rate for small windows because AIMD increases the congestion window (*cwnd*) by a *fixed* amount every RTT. On the one hand, as *cwnd* becomes larger, the increase ratio compared to the window size becomes smaller: An increase of 1, takes 5 RTTs to double a window of 5, but 50 RTTs to double a window of 50. Slow *cwnd* growth can be particularly detrimental in workloads that desire high throughput from a few flows per host (e.g., ring topology in ML applications). On the other hand, as we increase the number of flows and get smaller *cwnd*, the effect of the increase amplifies for windows close to the additive factor. (Each one of 500 flows with a window of 1 may double its rate.) This causes oscillating *cwnd* in high-degree incast applications (e.g., shuffle [1]). A CC algorithm may use a combination of a multiplicative factor and additive factor [7, 40] for faster ramp-up, but still, the disproportionate effect of the additive increase component will manifest for a small *cwnd*.

The root cause is that AIMD was designed to provide fairness regardless of the quality of the signal (e.g., a binary loss signal in TCP Reno). Yet, it is used in many modern data-center CC [8, 35], including the ones based on INT [40]. If we knew the fair-share from switches, we could converge faster [22, 34], but such solutions are hard to deploy. Instead, in Poseidon, flows can estimate if they are close or far from the fair-share and adjust the step size accordingly to converge faster and have a more stable throughput around the fair-share rate (§3.3), similar to some previous CC algorithms designed to facilitate large WAN BDPs [18, 28].

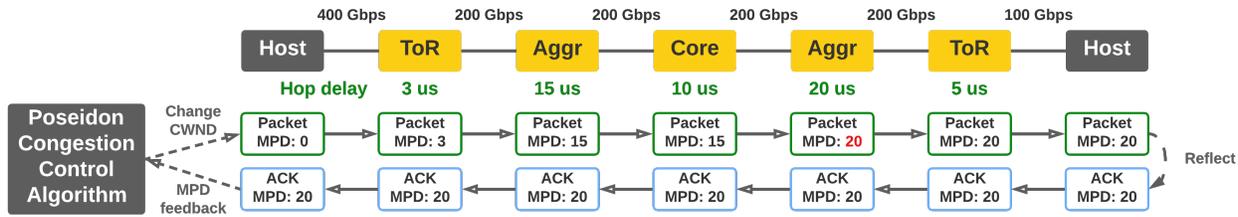

Figure 4: An example of Poseidon MPD signal propagation.

2.2 Deployment

Brownfield deployment. An important requirement for deploying INT in production is to support brownfield deployments. Hardware may be replaced gradually, from the ToR level to higher levels, or from one pod to another [26]. This transition phase can last for years [47]. INT may not be enabled on some switches, and at any point, we may want to roll back to disable INT without coordinating hosts and switches. Therefore, even if we use a separate queue for the new traffic [35], we still have to address the following requirements:

1. Being able to route the traffic regardless of whether a switch has INT enabled or not: While two hosts can coordinate their capabilities during a connection’s initial handshake, we don’t want any coordination between hosts and switches or switches with each other in order to forward packets and use ECMP. This places a tight requirement on the format of INT packets, as discussed in §4.2.
2. Getting some gains on an incremental INT deployment: Even though only a subset of hops supports INT, the CC algorithm should still benefit from that partial information.
3. Fair interaction between flows that have INT support on every hop and those that have it only on a subset of hops.

In §4.1, we explain why adjusting the target helps deploy Poseidon in brownfield. We also present our solution to combine end-to-end delay and max-hop delay to keep fairness while providing some incremental benefit in brownfield.

Low-overhead non-intrusive INT. For easy deployment, we prefer coordinating the least number of components and sustaining minimum overhead. Above, we mentioned that the traffic must go through the brownfield without any coordination between hosts and switches. At the end-host, we also want minimum coordination between applications, networking stack, and NIC. For example, a fixed INT length is preferred as it doesn’t change MTU.

We want INT on all packets, so its overhead regarding bandwidth and packet processing in the hosts, NIC, and switches is important. Small INT length is preferred for low bandwidth overhead and easy deployment in offloaded NICs [10, 11]. Finally, INT information cannot be encrypted, require complex functions, or rely on the per-flow state in the switch.

There are multiple formats for supporting INT, two of which are IFA [36] and P4-INT [2]. These formats differ in multiple aspects. Instead of proposing yet another format, we describe the features required for an INT format to be deployable in a production datacenter for CC. §4.2 covers these requirements and how the formats satisfy them.

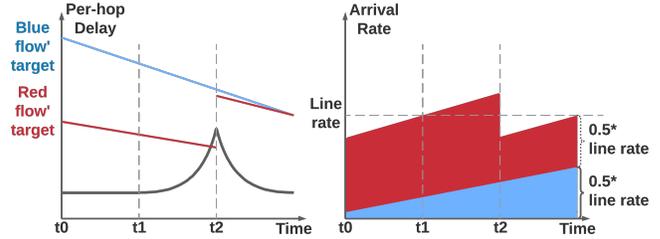

Figure 5: Delay is bounded by the faster flow’s target.

3 Design

Poseidon achieves high link utilization, low queuing delay, network-wide max-min fairness, with fast convergence and stable per-flow throughput. In this section, we describe the design of Poseidon: First, we introduce a key idea that allows Poseidon to only react to the bottleneck hop (§3.1). Next, we demonstrate how Poseidon guarantees fairness on a single hop (§3.2) and how decoupling the fairness from the *fixed* increase in AIMD allows us to introduce an adaptive increase/decrease algorithm that achieves faster convergence and more stable throughput than AIMD (§3.3). Finally, we show that Poseidon achieves network-wide max-min fairness (§3.4).

3.1 Key-idea: Only React to Bottleneck Hop

Poseidon only reacts to the bottleneck hop by decreasing the congestion window only if the flow got the fair-share on congested hops over its path. We explain how to do that without knowing the fair-share. Poseidon compares a delay signal with a target delay to increase or decrease the window. The key idea is in the definition of the delay signal and target:

1. It applies the target to the **maximum per-hop delay (MPD)** to allow flows to react to the most congested hop.
2. It adjusts the **target** based on the **throughput** of the flow to make sure only the flows that get the highest rate on the hop reduce their windows.

Figure 4 illustrates an example of how max per-hop delay is propagated. Each packet carries the MPD and each hop updates it. The ACK packet will reflect MPD back to the source. Note that Poseidon could naturally support heterogeneous link bandwidth in the network.

Now we describe each point in more detail. Every flow tries to maintain the **maximum per-hop delay (MPD)** close to a **maximum per-hop delay target (MPT)**, namely, increasing the congestion window when $MPD \leq MPT$ to keep the link busy and decreasing the window when $MPD > MPT$ to limit the congestion. MPD adds small and fixed overhead to packets and is one of the important designs to find the bottleneck hop:

In the max-min fair state, the hop with maximum latency is the bottleneck hop of the flow for Poseidon; otherwise, the flow has not reached its fair-share along its path (§3.4). The former case must decrease the congestion window, and the latter must ignore the congestion and increase the window. We achieve that by adjusting the target.

Poseidon calculates MPT for each flow based on its rate: **the larger the rate is, the smaller MPT will be** (§3.3 defines the function). This means that flows with higher rates have lower targets, thus decreasing their window earlier and more aggressively². This became possible using INT, as now all flows competing in the same queue tend to observe the same congestion signal (per-hop delay). Figure 5 shows an example: As the arrival rate on the link goes over the line rate at time t_1 , a queue builds up. The hop delay grows over the target of faster flow, red, and forces it to reduce its window at t_2 . However, the slower flow, blue, can still increase its window (solves §2.1.1). Interestingly, this means that given the same congestion signal from the network, some flows increase and some decrease their rate. In the next section, we demonstrate how Poseidon achieves fairness given this flexibility without relying on an additive increase.

Algorithm 1 shows how Poseidon updates the congestion window ($cwnd$). The pacing only happens when the $cwnd$ is less than 1, similar to Swift [35]. Note that the multiplicative-increase (MI) happens per packet, thus Line 5 in Algorithm 1 has to approximate the ratio for each packet, while $cwnd$ decreases happen only once per RTT, thus it is a simple multiplication. The retransmit and recovery functions are included in Appendix A.

3.2 Single-hop Fairness

We show that with the right increase/decrease functions, Poseidon can achieve fairness on a single hop. The AIMD algorithm benefits from the fact that *all* flows either increase rate with the same amount or decrease rate with the same ratio [19]. However, because of Poseidon’s rate-adjusted target delay and delay-based increase/decrease function, Poseidon has a new case, where *faster flows decrease rate* while *slower flows increase rate*. This happens if the queuing delay is higher than the faster flow’s target, but lower than the slower flow’s target.

To prove that Poseidon can achieve fairness, we show that fairness improves in all possible cases:

1. MPD is low, and all flows increase rate.
2. MPD is high, and all flows decrease rate.
3. MPD is high, some faster flows decrease, other slower flows increase their rate.

Assume a queue with two flows A and B with rates a and b where $b > a$. As a result, the target of A is larger than the target of B ($T(a) > T(b)$). In Figure 6, the fairness is graphically defined as the angle between the actual bandwidth share and fair-

²In rare cases, the queuing delay of a port may jump over the target of both fast and slow flows because of synchronized packet arrival. We make sure that faster flows with smaller targets decrease more aggressively (§3.3)

Algorithm 1: Poseidon’s Main Algorithm

Input: mpd : maximum per-hop delay,
 $cwnd$: flow’s congestion window size,
 rtt : round-trip time,
 now : current timestamp
Parameter: min_md : minimum MD ratio,
 max_mi : maximum MI ratio,
 min_cwnd : minimum cwnd,
 max_cwnd : maximum cwnd

```

1 Function ReceiveACK():
2    $mpt \leftarrow T(\frac{cwnd}{rtt})$ 
3    $update\_ratio \leftarrow U(mpt, mpd)$ 
4   if  $mpd \leq mpt$  then
5      $cwnd \leftarrow$ 
6        $cwnd * (1 + \frac{update\_ratio - 1}{cwnd} * num\_acked)$ 
7   else
8     if  $now - t\_last\_decrease > rtt$  then
9        $cwnd \leftarrow cwnd * update\_ratio$ 
10  return  $cwnd$ 
11 Function Poseidon():
12   $cwnd\_prev \leftarrow cwnd$ 
13  if  $is\_ack$  then
14     $cwnd \leftarrow ReceiveACK()$ 
15  else if  $is\_retransmit$  then
16     $cwnd \leftarrow RetransmitTimeout()$ 
17  else if  $is\_fast\_recovery$  then
18     $cwnd \leftarrow FastRecovery()$ 
19   $cwnd \leftarrow clamp(cwnd, min\_cwnd, max\_cwnd)$ 
20  if  $cwnd < cwnd\_prev$  then
21     $t\_last\_decrease \leftarrow now$ 
22   $pacing\_delay \leftarrow 0$ 
23  if  $cwnd < 1$  then
24     $pacing\_delay \leftarrow \frac{rtt}{cwnd}$ 
25  return  $cwnd, pacing\_delay$ 

```

share line. We define the update function $U(T(rate), delay)$ as the multiplicative factor (where $new_cwnd = cwnd \times U()$) with a specific flow rate and network delay. In order to converge to the line rate, it is ≥ 1 if the delay is less than or equal to the target and < 1 if the delay is more than the target³.

$$U(T(rate), delay) = \begin{cases} \geq 1, & delay \leq T(rate) \\ < 1, & delay > T(rate) \end{cases} \quad (1)$$

In all three cases, if we want to guarantee that the fairness improves, the updated rates should stay in the red triangle

³We assumed, in average, if arrival rate $<$ line rate, delay is low, and if arrival rate $>$ line rate, delay increases.

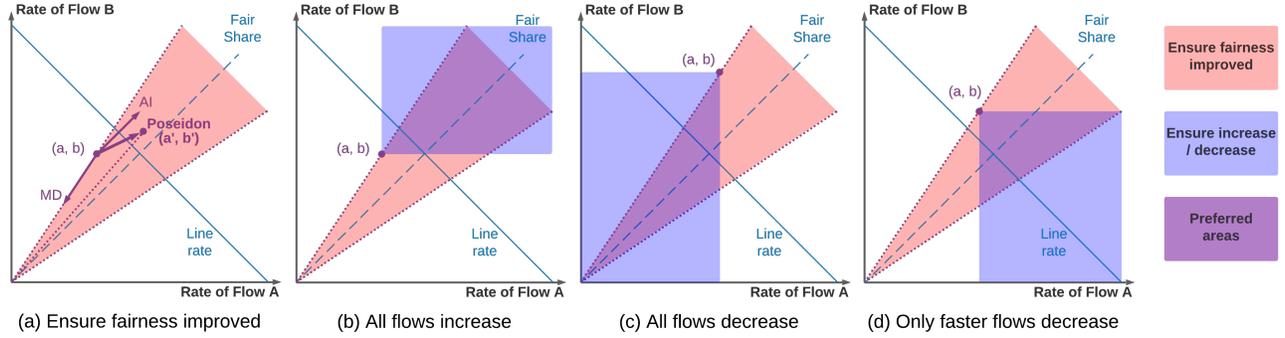

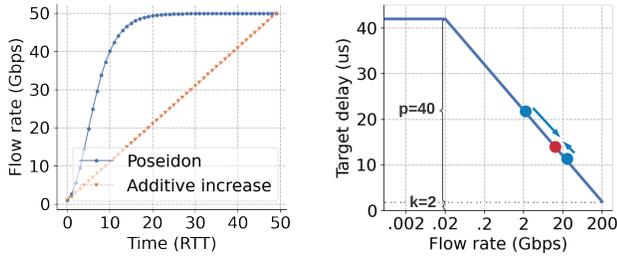

Figure 6: Poseidon updates the rate (in the purple area) such that it increases fairness (red) toward the line rate (blue). b) the queue is under-utilized and both flows increase rates; c) the queue is overloaded, and both flows decrease rates; d) the faster flow decreases, and the slower flow increases its rate.

(a) AI takes 50 RTTs from 1G to 50G, Poseidon takes around 15 RTTs and is stable at the fair-share rate. (b) Poseidon target function has high resolution over all spectrum of rate (min-rate=0.02G, max-rate=200G).

Figure 7: The ramp-up using adaptive step sizes is fast and slows down near the target for stability.

(Figure 6(a)). One side of the triangle is defined by the current ratio of rates, and the other side is symmetric across the fair-share line. If we assume $a < b$ and the delay is D , this requirement can be written as:

$$\frac{a}{b} < \frac{b \cdot U(T(b), D)}{a \cdot U(T(a), D)} < \frac{b}{a}, \forall a < b, \forall D > 0 \quad (2)$$

$$\frac{a^2}{b^2} < \frac{U(T(b), D)}{U(T(a), D)} < 1, \forall a < b, \forall D > 0$$

In summary, Poseidon achieves high link utilization and fairness if the functions $T()$ and $U()$ satisfy Eq. 1 and Eq. 2. Figure 6 illustrates Eq. 1, updates that allow full link utilization, in blue color, and Eq. 2, updates that converge toward fairness, in red. The desirable overlapped area is marked in purple. The additive increase will be in parallel to the fair-share line, and the multiplicative increase/decrease with the same ratio stays on the same edge of the red triangle where the node (a, b) is (Figure 6(a)). For case 1 in Figure 6(b), the red area ensures the fairness is improved, and the blue area ensures all flows increase their rate; for case 2 in Figure 6(c), the blue area ensures all flows decrease their rate; for case 3 in Figure 6(d), the blue area ensures the slower flow increases rate while the faster flow decreases rate. Next, we introduce a target function $T()$ and the update function $U()$ which satisfy the above requirements and have more desirable properties.

3.3 Adaptive Update Steps

Based on §3.2, Poseidon can use any function that satisfies Eq. 1 and Eq. 2. But we designed the following functions to leverage the *distance* between the target and max-hop delay to not only decide whether to increase or decrease, but also adjust the *update ratio adaptively* to reach a better trade-off between stability and fast convergence. Appendix B proves that they satisfy Eq. 1 and Eq. 2:

$$T(\text{rate}) = p \cdot \frac{\ln(\text{max_rate}) - \ln(\text{rate})}{\ln(\text{max_rate}) - \ln(\text{min_rate})} + k \quad (3)$$

$$\text{min_rate} < \text{rate} < \text{max_rate}, p > 0, k > 0$$

$$U(T(\text{rate}), \text{delay}) = \exp \left[\frac{T(\text{rate}) - \text{delay}}{p} \cdot \alpha \cdot m \right] \quad (4)$$

where $\alpha = \ln(\text{max_rate}) - \ln(\text{min_rate})$

rate is $\text{cwnd} * \text{MTU} / \text{RTT}$. k defines the minimum target delay; p tunes the maximum target when the rate is equal to min_rate and decides how far-apart the target of two flows with close rate can be. In practice, the target cannot be lower than a limit without decreasing the throughput because synchronized arrivals can cause premature window decrease. The target cannot be very large too because a) it can cause packet drops in switches when the target delay exceeds the queue capacity; b) as long as we achieve high utilization, we prefer to back-pressure hosts to leverage other mechanisms such as load-balancing and admission control for isolation. We use min_range and max_range to not waste the target range for differentiating rates that only happen rarely [35]. m defines the “step” when updating the rate. The larger m is, the slower the rate of update will be (sensitivity analysis is in §5.6.2).

When $|T(\text{rate}) - \text{delay}| \rightarrow 0$, then $U(\text{rate}, \text{delay}) \rightarrow 1$. This means when the delay is far away from the target, flows increase/decrease more drastically for faster convergence, and when the delay approaches the target delay, the steps will be more gentle to achieve stable flow rates (solves §2.1.4). Figure 7(a) shows how the flow can quickly increase its rate to reach 50 Gbps using the adaptive solution. We explain the intuition behind the update function with an example. Assume

the rate of a flow is x , and the target delay is D . We define the target rate r , such that $T(r) = D$ thus $U(r, D) = 1$. We can rewrite the update function for the flow as follows (calculation is in Eq. 11):

$$U(x, D) = \frac{U(x, D)}{U(r, D)} = \left(\frac{r}{x}\right)^m \quad (5)$$

Thus, the update function is only related to the ratio of r and x ; when x is far-away from r , the change will be larger. Poseidon updates the rate of flow from x to r in one RTT, because $x \cdot U(x, D) = r$ if $m = 1$, and for $m < 1$, it will take more RTTs because $x \cdot U(x, D)^m = r$. In this way, the parameter m controls how fast Poseidon converges to the fair-share rate.

A legitimate alternative for $T(\text{rate})$ is $\frac{\alpha}{\sqrt{\text{rate}}} + \beta$ which is an extension of the Swift flow-scaling (Appendix §C). However, we designed Eq. 3 because it gives a meaningful difference between the target of flows over *all* rates: The target of a flow with rate a and $c \cdot a$ have a fixed difference $T(a) - T(c \cdot a) = \ln(c)/p$, providing uniform resolution across all ranges of rates (Figure 7(b)). This generalizes Swift’s use of $1/\sqrt{\text{cwnd}}$ for target flow scaling (§3.5 of [35]), which only provides high resolution for small windows. Similarly, an option for the update function is to use the ratio of target over delay, similar to Swift. Appendix B.3 shows why distance provides a better result in high concurrency scenarios.

3.4 Network-wide Max-min Fairness

The key designs of Poseidon to achieve network-wide max-min fairness are: 1) only react to the max-hop delay; 2) the target delay of a flow increases when the flow rate decreases. We will start from the definition of max-min fair and then show how the above two designs achieve max-min fairness.

Definition 1 (Max-min Fairness [16, 38]). A feasible allocation of rate \vec{x} is “max-min fair” if and only if an increase of any rate within the domain of feasible allocations must be at the cost of a decrease of some already smaller rate. Formally, for any other feasible allocation \vec{y} , if $y_s > x_s$ (s is a flow), then there must exist another flow s' such that $x_{s'} \leq x_s$ and $y_{s'} < x_{s'}$.

For a certain network and workload, the max-min fair allocation is unique [38]. In the max-min fair allocation, for each flow, there is a unique queue (switch port), which restricts the rate for that flow. We denote this queue as a flow’s **bottleneck**, and the flow’s rate should be the fair-share rate of that queue. (As a special case, a flow’s bottleneck can also be the source or destination host, if either of them restricts the rate of the flow.) Specifically, we can conclude the following Lemma from the above definition (proved in Appendix D):

Lemma 1. *When achieving network-wide max-min fairness, each flow will have the largest rate among all flows on its bottleneck hop and not on any other saturated hop.*

Formally, for the “max-min fair” allocation \vec{x} , for any flow s , denote the flows that traverse s' bottleneck as $\{b_1, b_2, \dots, b_k\}$,

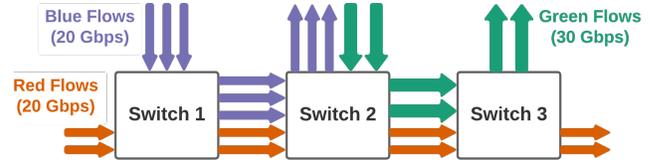

Figure 8: The stable state of max-min fairness among 3 switches with 100 Gbps links.

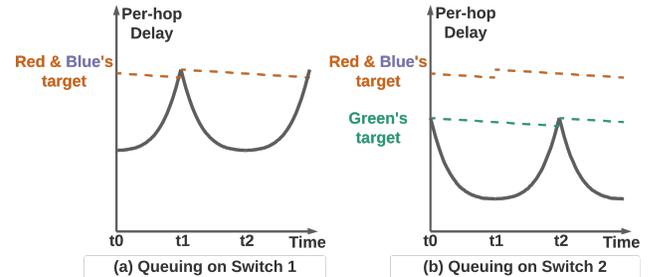

Figure 9: Only the queuing delay on red flows’ bottleneck (switch 1) can reach red flows’ target.

then for any flow b_i , $x_s \geq x_{b_i}$. Denote the flows that traverse one of the saturated non-bottleneck hops of s as $\{c_1, c_2, \dots, c_k\}$, then there must exist some c_j such that $x_{c_j} > x_s$.

With the above definition and Lemma, we first give an *intuition* about why Poseidon could converge to the max-min fair state from any initial state.

With other CC algorithms, the hop with max queuing delay for a flow may not be the bottleneck hop based on the max-min fairness. Thus, using INT naively and reacting to the max delay cannot lead to max-min fairness. However, Poseidon uses a monotonically decreasing target function, which lets faster flows have lower target delay. With this design and Lemma 1, a flow should have the smallest target among all other flows on its bottleneck, and its target is never the smallest on other congested hops. Moreover, the delay on a queue will generally remain close to the minimum target among all flows on that queue. So gradually, the delay may reach a flow’s target on its bottleneck; but on other congested non-bottleneck hops, the delay is not able to reach its target. Thus, **in Poseidon’s final stable state, the max hop delay must come from flow’s bottleneck.** And because each flow only reacts to its bottleneck, it achieves fairness on the bottleneck with other flows that have the same bottleneck (§3.2). Then, the network-wide max-min fairness is achieved by Poseidon.

We provide an example in Figure 8 where green flows have higher rates than red and blue flows in max-min fair state, $r_{green} > r_{red} = r_{blue}$, so green flows also have smaller targets, namely, $T(r_{green}) < T(r_{red}) = T(r_{blue})$. Switch 1 is the bottleneck of red and blue flows, and switch 2 is the bottleneck of green flows. On switch 2, the delay is similar to the target of green flows, $d_{sw2} \approx T(r_{green})$, because the moment the delay passes the target, green flows reduce their rate. Meanwhile, red and blue flows have higher targets than the delay d_{sw2} , as shown in Figure 9(b). This prevents red flows from reacting to the queuing on switch 2, which means every flow only

reacts to its bottleneck and maintains max-min fairness. This property of Poseidon solves the problem mentioned in §2.1.2.

Theorem 1. *Poseidon converges to the max-min fairness.*

To formally prove that the network converges to the max-min fair state, we use induction to prove that each queue achieves max-min fair. Denote the max-min fair rate allocation as \bar{x} , and for each queue, we denote the fastest flow's rate on that queue as R_q^x . Then we sort all the k queues in the network according to R_q^x from smallest to largest: $R_{q_1}^x \leq R_{q_2}^x \leq \dots \leq R_{q_k}^x$. For any other flow rate allocation \bar{y} , with induction: **(1)** we prove that the queue q_1 will converge to the max-min fair allocation; **(2)** assuming the queue q_1 to queue q_m have already converged to the max-min fair allocation \bar{x} , we prove that the queue q_{m+1} will also converge to \bar{x} . A detailed proof is provided in Appendix §E.

4 Deployment

Here, we discuss the design decisions that facilitate the deployment of Poseidon in a large-scale datacenter network. Firstly, Poseidon provides benefits even if only part of the network supports INT (incremental deployment), and bounds the unfairness between flows that see INT vs those that do not. Secondly, Poseidon allows old switches to transparently route INT traffic, adds minimum overhead to packets and switches, and requires no changes in applications or NICs.

4.1 Brownfield Deployment

For a network where a subset of switches can provide hop delay information, Poseidon splits the fabric delay into two parts: the MPD from switches equipped with INT; and the delay from the rest of the path. This is calculated based on the end-to-end delay, using the NIC timestamp similar to Swift [35], minus the max-hop delay (both forward and backward). Then we apply Poseidon based on the maximum of the two. Note that this solution is not robust to reverse-path or multi-hop congestion happening in the hops that do not have INT, but still provides incremental benefits (§5.5).

The fairness issue is only relevant if the bottleneck hop of the two flows is the same. Consider two flows A and B and three switches, X, Y, and Z. A goes through switch X to Z, and B goes through Y to Z. The common switch, Z, is the bottleneck, X supports INT and Y doesn't. If Z has INT, both flows get the right feedback about Z in max-hop delay. Therefore, we get partial benefits. If Z doesn't have INT, the fabric delay of flow A doesn't include the delay of X, but for flow B it will include the delay of Y. Therefore, flow B observes a high delay and may decrease its window sooner. However, we argue that this decrease will be minimal and bounded because of target scaling. As the rate of flow B goes down, its target will go higher. The moment the target increases by the delay at hop Y, the rate of flow B will stabilize.

Interestingly, the above argument suggests that in order to get most of the benefit, we should prioritize deploying INT

in the usual congestion points (ToRs with oversubscribed uplinks or incast in downlinks). We evaluate this in §5.5.

4.2 A Deployable INT Format for CC

In this section, we describe the requirements for deploying INT in datacenters for CC and compare existing INT formats.

4.2.1 Requirements

We consider both the INT metadata that we ask from each hop and how/where we put it inside the packet.

Make INT information available to the sender for CC: INT metadata on the forward path should be reflected in the reverse path ACKs for CC signaling. Ideally, ACKs could reflect opaque information that could be carried in the INT header but not be replaced by switches. Or, similar to ECN, INT could be marked by switches in the forward direction and echoed back to the sender in L4 headers.

Low-overhead INT metadata: For simplicity and precision, we want INT on all packets, thus its bandwidth and processing overhead must be low. Having many metadata fields per packet adds bandwidth overhead [15] and is costly for switches, NICs, and offloaded transports to process [11].

Fixed-sized INT metadata: Per-hop INT metadata makes the number of INT fields not only large but also variable. This is bad for two reasons: a) It is wasteful to reduce MTU for the worst case because link failures may add more hops to packets transiently, so that the number of hops is long-tailed. A smaller MTU means more packets to be processed by hosts and switches. b) Variable-sized INT metadata is more complex to parse at switches, offloaded transports, and middleboxes if they access bytes after the INT header. Therefore, for the CC use case, it is essential for an INT format and its implementation in the switch to use fixed-size INT metadata, and support *aggregation* functions (e.g., max/min/sum) that can overwrite the information from the previous hop.

Implementable in dataplane at line rate: The aggregation function must require minimal state and computation in the switch. This means that it must be simple (e.g., max/min/sum) and not require per-flow state.

Transparent to routing: Many datacenters use a hash-based scheme (ECMP [30], WCMP [48]) to balance the load over multiple ports. Such schemes may use the 5-tuple and/or IPv6 flow label. A brownfield deployment requires a scheme that balances load efficiently for packets with/without INT metadata in switches with/without INT support. For switches without INT support to balance INT traffic, they must be able to find and parse L4 headers. Thus, we either need to a) put INT metadata after L4, b) enable switches to pass over the INT metadata by adding it as a sub-header in headers that support extensions, such as VLAN-tag, MPLS-tag, IP option, GRE shim layer, or VXLAN shim layer. We believe option (a) is easier to deploy as it is transparent to the network, and thus works with different L2/L3 protocols, with virtualized and

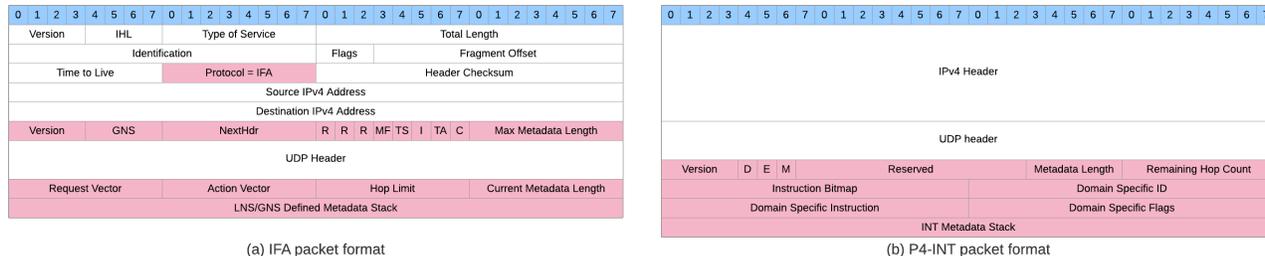

Figure 10: INT packet format in a) In-band Flow Analyzer (IFA) b) P4-INT

non-virtualized traffic, and with other boxes (except special middleboxes, which are usually implemented in extensible software anyway [23, 43], and don't need to parse INT).

Compatible with encrypted packets: Many cloud providers encrypt network traffic inside datacenters [4]. But switches must be able to change INT data. Fortunately, recent NIC encryption modules such as PSP [6] allow passing an offset in the packet descriptor to only encrypt the bytes after. PSP also only authenticates the bytes after its header. For UDP checksum, PSP requires its implementation to support zero values (thus there's no need to rely on switches, even though programmable switches can update that). We also verified that we can change where the NIC expects the PSP header.

4.2.2 INT formats

Figure 10 shows two predominant INT formats in the context of IPv4; the IPv6 format is similar. Poseidon is possible on both formats, but a few improvements help its deployability.

IFA [36] indicates the presence of INT with a special protocol value in the IP header and adds part of the header between the IP and L4 header. P4-INT [2] indicates INT using a DSCP (traffic class) value/bit and puts all metadata after the L4 header. In order to use ECMP on switches without changing their configuration, we prefer to not change the location of L4. Still, IFA can be used on most switches by first changing the expected location of the UDP header for IFA packets (using User Defined Fields, UDF) and then rolling out INT. IFA also supports a format that puts INT metadata at the tail of the packet to avoid changing the location of L4.

Neither of the formats has a place to reflect the forward path INT. But given that the switches in the reverse path don't need to read the forward path INT, the receiver can just reflect the INT metadata in L4 headers, and the sender networking stack will consume it along with the INT metadata.

Neither of the formats defines a max calculation action, however, they allow extending the action vector.

Finally, we believe an overhead of 12B for sending a 2B metadata is excessive for small packets and look forward to working with the community to reduce overhead while maintaining protocol flexibility.

5 Evaluation

First, §5.1 explains our prototype implementation on a testbed with a production networking stack and NIC to highlight the

ease of implementation and show the robustness of Poseidon to multi-hop and reverse-path congestion. Then we use simulations to explain how and why Poseidon is robust in those scenarios (§5.2). §5.3 shows that the adaptive window update enables faster convergence and better stability. Next, we present the aggregate benefit of the above techniques on op latency (flow completion) in multiple scenarios (§5.4). Finally, we wrap up with brownfield results (§5.5) and a parameter sensitivity analysis (§5.6). We use **Swift**, a practical CC deployed at scale, and **HPCC**, the state-of-the-art in INT-based CC, as our main points of comparison.

Simulation setup: We implemented Poseidon along with Swift and HPCC in the OMNeT++ packet simulator and simulated a Clos network of 200 Gbps links, with 245 ns link delay (including 230 ns FEC delay), 600 ns switch delay, 64 MB buffer size, and 4096 Bytes MTU size. For Poseidon, we set the parameters in Eq. 3 and Eq. 4 as $p = 40$, $k = 2$, $m = 0.25$ based on §5.6.2. For Swift, we follow the best parameters in [35] and set the base delay to 25 μ s, the max flow scaling to 100 μ s, and the hop-based scaling to 1 μ s per hop. We verified the fidelity of the simulator by comparing it to the result of the testbed. Note that RTT here is calculated based on NIC timestamp and doesn't include the delay in the networking stack at the host. For HPCC parameters, we use the values from the paper [40]. To be fair in our comparisons, we enable pacing only when $cwnd < 1$, similar to Swift⁴.

5.1 Implementation in Testbed

For the host networking stack, we change Swift implementation in a transport stack similar to Pony Express [41] to 1) at the sender, add a 2-bytes INT header for max-hop-delay right after L4; 2) at the receiver, reflect back the max-hop-delay in another 2-bytes in the payload; 3) at the sender, update the congestion window based on Poseidon algorithm in §3.3.

For network switches, we extract the queuing delay at the egress pipeline and update the max-hop-delay in the INT header. We implemented the P4 program with only 2 lines of P4 code (Listing 1) and 16 lines of parser/deparsed code in a Tofino switch. Moreover, we verified that packets with or without INT headers can both be routed.

Our testbed only has two hosts and one switch (Figure 11(a)). To simulate congestion from multiple hosts, we create 8 virtual interfaces in hosts with 100G links and route the

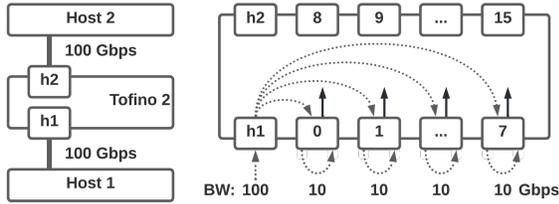

⁴HPCC always paces packets, but that is costly in software and hardware.

```

bit<16> queuing_delay =
    (bit<16>) (eg_intr_md.deq_timedelta >> 8);
hdr.telemetry.max_hop_delay =
    max(hdr.telemetry.max_hop_delay, queuing_delay);

```

Listing 1: Core P4 code for telemetry in Poseidon.

(a) Testbed topology (b) Create virtual hosts
Figure 11: Testbed with 8 virtual sender/receiver ports

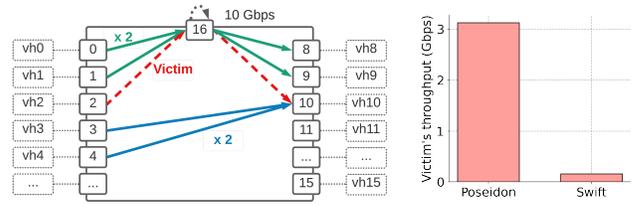

traffic inside the switch based on the virtual IPs into separate loopback ports. Each port, loopback at MAC layer, is configured to 10Gbps and plays the role of a virtual sender/receiver (Figure 11(b)). Ports 0-7 receive traffic from host 1, and ports 8-15 pass the traffic to host 2.

Testbed Results: To create multi-hop and reverse-path congestions from Figure 2 and Figure 3, we route the flows between virtual senders/receivers as Figure 12(a) and Figure 13(a) show. For the multi-hop congestions, Poseidon could fairly share the bandwidth between background flows and the victim flow, while Swift only spares 0.16 Gbps for the victim flow in Figure 12(b). For the reverse-path congestion, Poseidon could achieve line rate for the victim flow, while Swift could only achieve 1.91 Gbps (similar throughput as the flows on the reverse-path) as shown in Figure 13(b).

5.2 Robustness From Max-min Fairness

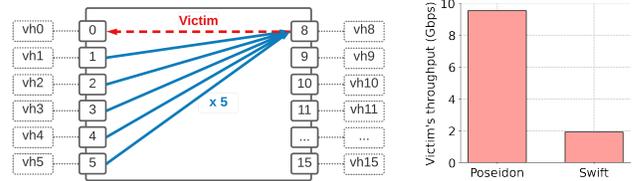

Poseidon achieves fairness in multi-hop congestion. Consider the scenario in Figure 14(a) where we have M green flows at Rack 0 and N blue flows at Rack 10. We add more flows to change M and N to create different multi-hop congestion scenarios. With Swift, the moment we have congestion at multiple hops ($M > 0$ and $N > 0$), the victim flow, red, cannot compete with other flows (Figure 14(b)). The reason is that Swift reacts to the inflated sum of delays (Figure 14(c)). Therefore, the victim reduces its congestion window until its scaled (because of flow-scaling) target delay matches this larger end-to-end delay. HPCC and DCTCP also react to the congestion at *any* hop, thus when $M = N$, the victim does an MD when *either* of the hops gives a congestion signal (ex: ECN) and cannot achieve the fair rate.

Poseidon, however, allows the victim flow to achieve its max-min fair share ($200Gbps/\max(M + 1, N + 1)$) by only reacting to the bottleneck hop where it gets the fair-share. One reflection is that Poseidon’s congestion signal, max-hop delay, and target only changes when the bottleneck hop or its congestion changes. For example, they stay the same when

(a) Victim from virtual host 2 (vh2) contends with 2 flows on port 16 and 2 flows on port 10. (b) Victim achieves fair-share rate in Poseidon.

Figure 12: Multi-hop congestion. (Linerate: 10 Gbps)

(a) 4 flows create a congestion on the victim’s reverse-path. (b) Victim achieves line rate (10 Gbps) in Poseidon.

Figure 13: Reverse-path congestion. (Linerate: 10 Gbps)

M changes from 0 to 2, but change when N increases from 2 to 9 in Figure 14(c) and Figure 14(d). Although the victim flow experiences higher RTT than other flows, Poseidon uses a higher congestion window to achieve the fair rate. Another interesting point happens when both hops have the same fair-share rate ($M = N$). Although the delay of both hops is close to the target (Figure 14(d)), with a rate-adjusted target, the moment the victim reduces its window, Poseidon raises its target and will not react to the max-hop delay until the rate increases again. §5.6 shows that both max-hop latency and scaling the target are necessary to achieve fairness.

Poseidon utilizes forward path regardless of reverse-path congestion. Reproducing the scenario in Figure 3, Figure 15(a) shows that with Swift, as the number of flows on the reverse-path, N , increases, victim’s throughput decreases to the fair-share rate in reverse-path. However, with Poseidon, the victim could maintain 200 Gbps (line rate). The reason is that Poseidon only uses the max-hop delay from the forward path, which is not affected by the reverse traffic (Figure 15(b)). HPCC doesn’t have this problem since it only uses INT information on the forward path.

5.3 Fast Convergence and Stability

Figure 16 shows the rate of flows in Swift and Poseidon as we add competing flows one by one and then remove them. At a *single* hop, not only does Poseidon achieve the fair-share, similar to Swift, but also lower throughput variation, hence better stability. Next, we evaluate Poseidon’s convergence time and throughput stability.

Poseidon converges fast for flows with large windows. Figure 17(a) shows the ramp-up phase of a flow, growing its window to a large value. This flow is competing with another one on a 200G link. First, the ramp-up shows that Poseidon does fewer rate reductions than Swift and HPCC. Second, it shows that Poseidon achieves a super-linear ramp-up at

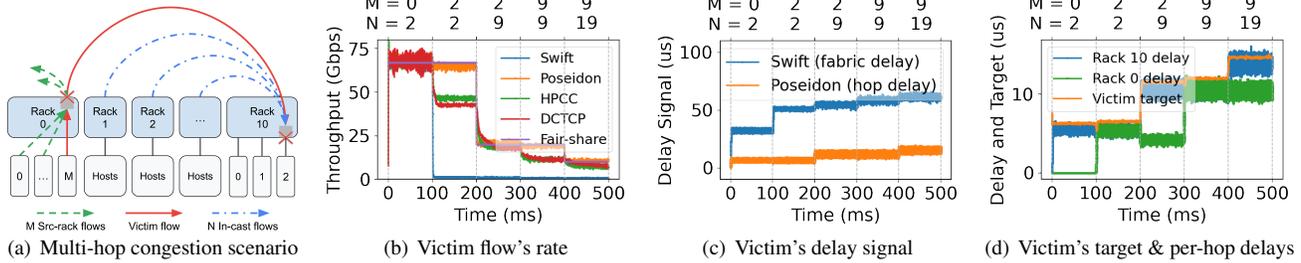

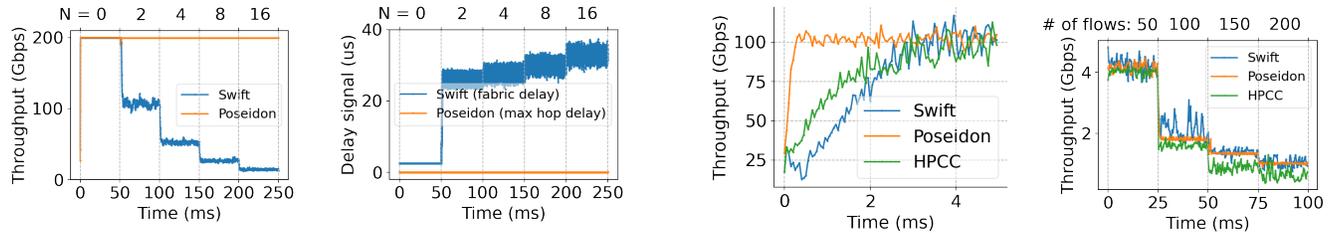

Figure 14: Multi-hop congestion with the same or different fair-share rate on different hops (linerate: 200 Gbps).

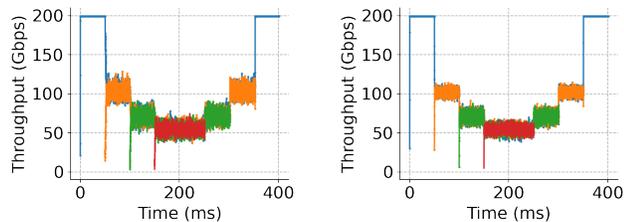

(a) Victim's rate is protected by Poseidon (linerate: 200 Gbps) from the congestion on the reverse-path.

(b) Victim's congestion signal never changes for Poseidon, despite increasing delay on the reverse-path.

(a) Fast convergence for big windows (b) Stability under high concurrency

Figure 17: Poseidon achieves fast convergence for flows with large windows & stable rate for flows with small windows.

Figure 15: Reverse-path congestion: N reverse flows

(a) Single hop fairness in Swift

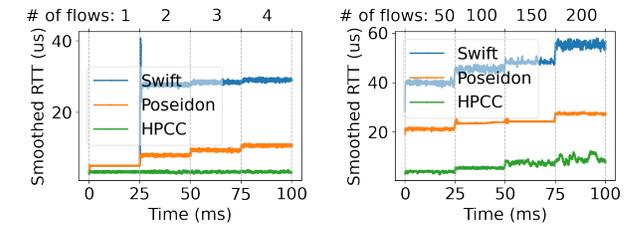

(b) Single hop fairness in Poseidon

Figure 16: Fairness on a single hop with step-in&out flows, throughput is measured every $50 \mu s$.

the beginning, and the rate of growth decreases as it reaches the fair-share rate as expected in Figure 7(a). As a result, Poseidon converges around $12\times$ faster than Swift and HPCC.

Poseidon achieves stable throughput for flows with small windows. Figure 17(b) shows the throughput for a flow competing with $N - 1$ others on a hop. Poseidon reduces the standard deviation of throughput by $24\times$ for $N = 200$ (70% on average over the four cases). As mentioned in §3.3, the reason is that AIMD in Swift and HPCC becomes more aggressive for smaller congestion windows. By contrast, Poseidon uses an adaptive update ratio to adjust the congestion window.

Poseidon keeps link utilization high with low RTT. Poseidon achieves a smaller RTT than Swift for flows across different rates, which means lower latency for small messages. For example, Figure 18 compares the RTT over different numbers of flows in two cases: large window and small window. Swift cannot use a very low target delay because, for high link utilization, it has to accommodate the summation of delays on multiple hops and the variation of delay in a high-degree incast caused by AI (Figure 17(b)). Since the adaptive update ratio can stabilize the rate, Poseidon could afford to use a tighter target and achieve high link utilization and small

(a) Large window: +1 flow per 25ms (b) Small wnd: +50 flows per 25ms

Figure 18: Poseidon achieves lower RTT than Swift by keeping queues short and stable.

queues at the same time. HPCC, however, achieves lower RTT than Poseidon as it targets near-zero in-network queues at the cost of op latency (§5.4).

5.4 Application-level Improvements

A key application-level performance metric is op latency, namely, the time from a message was enqueued for sending to its completion [22]. We create two scenarios on two racks (A and B) with 3:1 oversubscription and compare op latency for 128 KB messages:

1) Uniform Random (UR): Rack A sends 960 Gbps to Rack B (60% uplink load), while Rack B sends 480 Gbps to Rack A (30% uplink load). The source and destination hosts are randomly chosen. Poseidon has a 61% lower median and $14.5\times$ lower 99.9p op latency than Swift (PLB [44] enabled), 44% lower median and $5.49\times$ lower 99.9p op latency than HPCC in Figure 19(a). This mostly comes from robustness to reverse-path and multi-hop congestion.

2) Uniform Random with Rotating Incast (UR+RI): A and B communicate similar to UR scenario, but Rack A also suffers from rotating incast from 100 hosts in other racks (not A or B). The incast traffic has 100 flows with 0.5 Gbps load

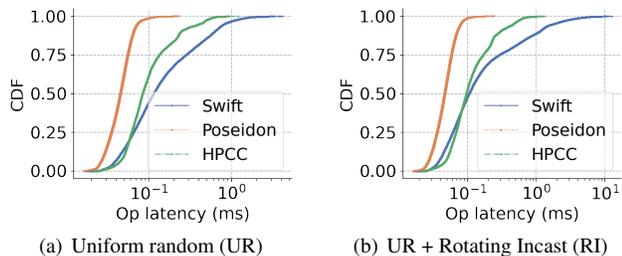

Figure 19: Poseidon improves op latency (FCT)

(50G in aggregate) and changes its target after sending a message from each host. Poseidon achieves 56% faster median and $41\times$ lower 99.9th op latency for UR traffic than Swift (PLB [44] enabled), 51% faster median and $6.25\times$ lower 99.9p op latency than HPCC in Figure 19(b). Besides being robust to reverse-path congestion, Poseidon allows UR flows to ramp up faster than Swift when the rotating incast targets another victim.

5.5 Brownfield Evaluation

With brownfield deployments, Poseidon achieves partial performance gains over Swift. We repeat the UR scenario explained in §5.4 over 4 racks. There are 24 hosts in each rack connected through 6 hops to hosts in other racks. Only ToRs have 3:1 oversubscription. Figure 20(a) compares the op latency of Poseidon with INT at all switches vs. Poseidon in the brownfield where only 2 or 4 ToRs support INT. It shows that Poseidon can achieve most of the gains compared to Swift in the brownfield.

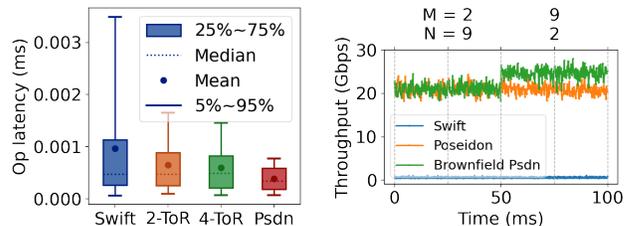

To evaluate the fairness scenarios in §4.1, we use the topology in Figure 14(a) and enable INT only on Rack 10. We make sure all blue flows send to the same host and all green flows send to another to create congestion on multiple hops for them. In Figure 20(b), when $M = 2, N = 9$, the bottleneck of red and blue flows is on Rack 10 that has INT, thus victim and other blue flows reach the fair rate (20 Gbps). When $M = 9, N = 2$, the bottleneck of red and green flows is on Rack 0, which doesn't have INT, and brownfield Poseidon gives a little more bandwidth to the red flow because the green flows have to react to the end-to-end delay. The unfairness is bounded because green flows increase their target until it covers the sum of delay on their congested hops.

5.6 Sensitivity Analysis

5.6.1 Ablation Study

To show the importance of each major aspect of the Poseidon design, we use the same algorithm and parameters as Poseidon, but remove one design aspect each time: 1) **maximum per-hop delay (MPD)** information instead of RTT; 2) **rate-adjust** target for per-hop delay; and 3) **adaptive increase ratio** algorithm instead of AIMD.

Figure 21(a) compares the throughput in the multi-hop scenario (Figure 14(a)). It shows that network-wide fairness is only achieved when using *both* rate-based target scaling

(a) Message op latency shrinks when (b) Unfairness is bounded when the more switches are equipped with INT bottleneck is not on the INT-capable switches.

Figure 20: Partial gains and fairness in brownfield Poseidon and max hop delay. However, removing the adaptive update ratio will not harm the max-min fairness, and Poseidon can achieve fairness even using AIMD. Figure 17 has already shown that AIMD slows down ramp-up and causes wider throughput variations in the presence of many flows.

5.6.2 Robustness of Parameters

Though Poseidon could achieve the design targets with a wide range of functions and parameters, it is worthwhile to understand the trade-off of each parameter. In this section, we vary the three parameters in Eq. 3 and Eq. 4 and show why we choose: $p = 40, k = 2$, and $m = 0.25$.

p controls the range of target scaling, affecting round-trip time and rate variation. Figure 21(b) shows that when we have congestion from hundreds of flows, a higher p allows reacting to rate unfairness faster and reduces rate variations. However, that means enduring larger RTT in the network.

k avoids under-utilizing the link bandwidth. Figure 21(c) shows the utilization % when we have a few flows on the bottleneck (where the rate is close to max_rate thus the target is close to k) vs. the fabric RTT when we have hundreds of flows. For small k values, the fluctuation of the queuing delay may lead to link under-utilization as the target is low and flows reduce the congestion window conservatively. However, if the value of k is too large, the RTT will increase.

m determines the trade-off between the variance of flow rates and the convergence speed. Figure 21(d) compares the convergence time in Figure 17(a) experiment and rate variation in Figure 17(b) for different values of m . Larger m values improve stability as they dampen the effect of the target in Eq. 4 but also slow down convergence.

6 Related Work

Delay-based: Swift [35], the basis of Poseidon, is a state-of-the-art delay-based algorithm that relies on hardware timestamps from NICs. Swift has some elements of Poseidon, although for different purposes. 1) It separates fabric delay from engine delay and tracks a separate congestion window for each. However, this separation was because of fundamental differences in congestion at fabric hops vs. hosts, and doesn't address fabric issues explained in §2.1. 2) Swift uses a larger target delay for flows with smaller congestion windows to address synchronized packet arrival from many flows on a

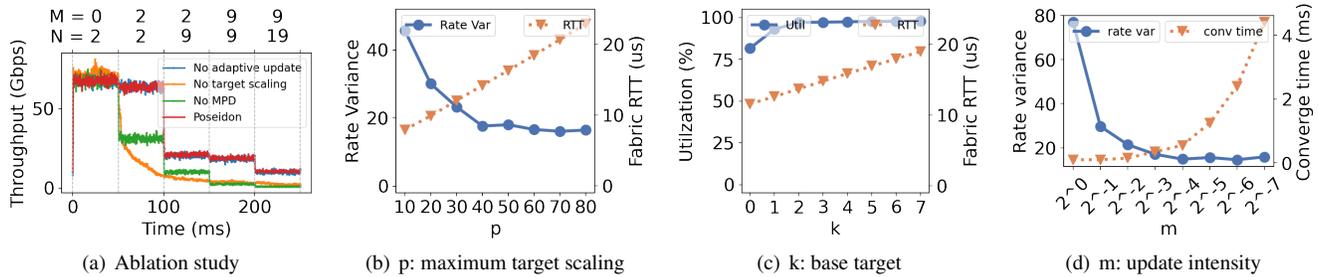

Figure 21: Ablation study in multi-hop congestion scenario and sensitivity analysis over three parameters.

bottleneck link (flow scaling for windows <10), which forces flows to converge to the same window. Appendix §C shows even if we combine flow-scaling with max-hop latency, Swift still faces unfairness. 3) For multiplicative decrease, Swift decrease depending on how far the delay is from the (almost fixed) target, but still uses a fixed step for additive increase. At a higher level, Swift only looks at the end-to-end delay while Poseidon uses max-per hop latency and rate-based target scaling to respond to the bottleneck hop. Copa [12] adjusts the target rate based on *end-to-end delay* to achieve short queues and fair allocation, but Poseidon compares the max-hop delay to a rate-adjust target to reach *network-wide max-min fairness*.

ECN-based: ECN can be seen as a one-bit INT signal from switches that is set based on a configurable threshold inside switches. It is successfully deployed in datacenters and used by end-to-end CC algorithms such as DCTCP [8] because ECN was non-intrusive (two bits in the IP header) and those algorithms were deployable in brownfield environments. Still, ECN-based algorithms do not recognize the bottleneck hop and *all* flows react to any hop in their path that marks packets.

Richer signals from switches: XCP [34] and RCP [22] get help from switches to enable flows to react to congestion and achieve the fair-share allocation. In particular, XCP introduced the idea of decoupling utilization from fairness. However, both proved difficult to deploy in datacenters because of the lack of a brownfield solution and the overhead in high-speed switches. Poseidon achieves fairness using target scaling and introduces adaptive update ratios to reach better stability. It is deployable in brownfield and requires minimal changes in hardware to support max-hop delay in INT.

HPCC [40] uses queue length, timestamp, and tx-bytes of each hop to estimate in-flight bytes on each link and update a congestion window in an AIMD fashion in order to achieve very low queuing in the network. However, HPCC doesn't recognize the bottleneck hop: high utilization on *any* hop along the path should not force a flow that didn't get the link's *fair-share* to reduce rate. In addition, HPCC assumes all flows experience the same base RTT, relies on the additive increase to achieve fairness, doesn't address brownfield deployment, and requires bandwidth and CPU overhead from three INT metadata *per hop*. In contrast, by using a novel target-scaling solution, Poseidon achieves fairness without relying on AIMD, supports brownfield deployment, and only

needs a *single max hop delay per packet*. PowerTCP [7] argues that CC should react to both absolute CC signal and its change rate to avoid slow reaction or overreaction to queue build-up. Poseidon's adaptive update ratio in Figure 7(a) addresses this issue. PowerTCP similar to HPCC still looks at congestion at *any* hop and uses per-hop INT metadata.

Receiver-driven: NDP [29] and HOMA [42] face challenges in oversubscribed networks where may have congestion in the core. However, Poseidon is insensitive to over-subscription, and we expect similar gains on op latency by applying Poseidon's idea to receiver-driven schemes.

Combined with schedulers: HOMA [42] combines a CC algorithm with a scheduling policy that prioritizes the shortest remaining flows to achieve shorter flow completion time. While Poseidon is currently a pure CC algorithm, we believe it has the potential to be integrated with similar scheduling policies and preserve the benefits of fast convergence and robust performance.

7 Conclusion

We proposed *Poseidon*, a congestion control algorithm that reduces op latency through fast convergence and lower latency and is robust in multi-hop and reverse-path congestion by leveraging in-band network telemetry (INT) in a novel way. Poseidon only needs a single max-hop delay per packet from INT, which makes it easily deployable with low overhead. We showed how INT packets can be deployed in brownfield and how Poseidon can still gain from an incremental deployment. In the future, we plan to implement Poseidon in NIC offloading protocols (e.g., RDMA), leverage INT to break down the delay at end-host networking stacks, use INT to hint path changes to avoid hash collisions [33], and apply the target scaling idea to other congestion signals, such as in-flight bytes [40], to achieve lower in-network delay.

This work doesn't raise any ethical issues.

A Poseidon Algorithm

Algorithms 2 shows the *RetransmitTimeout* and *FastRecovery* functions called in Algorithm 1 for completeness.

Algorithm 2: Poseidon's CWND Update Algorithms

```

1 Function RetransmitTimeout():
2   retransmit_count ← retransmit_count + 1
3   if retransmit_count ≥
4     RETX_RESET_THRESHOLD then
5     | cwnd' ← min_cwnd
6   else
7     | if now - t_last_decrease > rtt then
8       | cwnd' ← cwnd * min_md
9   return cwnd'
9 Function FastRecovery():
10  retransmit_count ← 0
11  if now - t_last_decrease > rtt then
12  | cwnd' ← cwnd * min_md
13  return cwnd'

```

B A Valid Cluster of Functions

We prove that the cluster of functions in Eq. 3 and Eq. 4 satisfy Eq. 1 and Eq. 2.

The target functions are:

$$T(x) = p * \frac{\ln(\max_rate) - \ln(x)}{\ln(\max_rate) - \ln(\min_rate)} + k \quad (6)$$

$$\min_rate < x < \max_rate, p > 0, k > 0$$

Then we give a cluster of update functions, which is specifically designed for the above target functions:

$$U(x, D) = \exp\left[\frac{T(x) - D}{p} \cdot \alpha \cdot m\right] \quad (7)$$

where $\alpha = \ln(\max_rate) - \ln(\min_rate)$

B.1 Proof for Target Functions

When delay $D \leq T(x)$:

$$Update(x, D) = \exp\left[\frac{T(x) - D}{p} \cdot \alpha \cdot m\right] \geq 1 \quad (8)$$

When delay $D > T(x)$:

$$Update(x, D) = \exp\left[\frac{T(x) - D}{p} \cdot \alpha \cdot m\right] < 1 \quad (9)$$

Thus, Eq. 3 satisfies Eq. 1.

B.2 Proof for Update Functions

Without loss of generality, assume two flows' rates $a < b$, delay is D .

For the rhs, since $T(a) > T(b)$:

$$\begin{aligned} \frac{U(b, D)}{U(a, D)} &= \frac{\exp\left[\frac{T(b) - D}{p} \cdot \alpha \cdot m\right]}{\exp\left[\frac{T(a) - D}{p} \cdot \alpha \cdot m\right]} \\ &= \exp\left[\frac{T(b) - T(a)}{p} \cdot \alpha \cdot m\right] \\ &< 1 \end{aligned} \quad (10)$$

For the lhs:

$$\begin{aligned} \frac{U(b, D)}{U(a, D)} &= \frac{\exp\left[\frac{T(b) - D}{p} \cdot \alpha \cdot m\right]}{\exp\left[\frac{T(a) - D}{p} \cdot \alpha \cdot m\right]} \\ &= \exp\left[\frac{T(b) - T(a)}{p} \cdot \alpha \cdot m\right] \\ &= \exp\left[p \cdot \frac{\ln(a) - \ln(b)}{\alpha} \cdot \frac{1}{p} \cdot \alpha \cdot m\right] \\ &= \exp[m \cdot (\ln(a) - \ln(b))] \\ &= \exp\left[m \cdot \ln\left(\frac{a}{b}\right)\right] \\ &= \left(\frac{a}{b}\right)^m \end{aligned} \quad (11)$$

So as long as $m < 2$, we can have

$$\frac{U(b, D)}{U(a, D)} = \left(\frac{a}{b}\right)^m > \frac{a^2}{b^2} \quad (12)$$

Thus, Eq. 4 satisfies Eq. 2.

B.3 Updating Based on Ratio vs. Distance

A valid update function with the same target function as in Eq. 3 is to use the ratio of target and max-hop delay. This can be seen as an extension of the Swift's MD function.

$$U(T(rate), delay) = \frac{T(rate) + m}{delay + m}, m \geq 0 \quad (13)$$

A problem with Eq. 13 is that it scales its update ratio depending on the value of delay. As an example, suppose that m is negligible, and we went $1 \mu s$ above the target. If the target is 4, the update ratio will be 0.8, but if the target is 30 (high concurrency scenario), the update ratio will be 0.968.

This means that for high concurrency scenarios where fair-share rate is low, and the target is high, the convergence will be slow. For example, Figure 22 compares the op latency in UR+RI scenario introduced in §5.4 for the update function based on the distance in Eq. 4 vs. the function based on the ratio in Eq. 13. The update function based on the distance clearly has an advantage at the tail.

C Flow Scaling in Swift

Swift uses flow scaling to inflate target delay to compensate for synchronized packet arrivals. The authors in [35] noticed

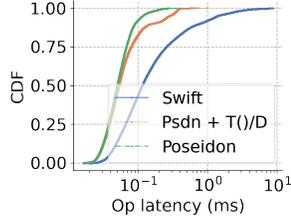

Figure 22: Poseidon can achieve lower op latency using the update function based on the distance of target and max-hop-delay

that the average queue length grows as $O(\sqrt{N})$ where N is the number of flows on a link. Swift adjusts the target in proportional to $1/\sqrt{cwnd}$ because it argues that the $cwnd$ trend is inversely proportional to the number of flows when Swift converged to its fair-share. The flow scaling in Swift also helps fairness as it speeds slow flows with a larger target, and slows fast flows with a smaller target. However, the flow scaling of Swift is not applicable to max-hop delay to find the bottleneck hop because of two reasons: 1) Its effect is nominal for windows > 10 (See Figure 5 in [35]) and more importantly 2) The formulation that reached $1/\sqrt{cwnd}$ assumes, at fair-share, flows see the same RTT (\approx target delay) and pushes them to have the same $cwnd$. However, to solve the scenarios in §2.1 and get the fair-share, we only need to react to the congestion at the bottleneck hop. This means that flows get different RTTs and pushing flows to get the same $cwnd$ cannot achieve the fair share rate ($rate = \frac{cwnd}{RTT}$). For example, in the fair-share allocation of multi-hop congestion scenario, the victim flow will have higher RTT and needs higher $cwnd$ to achieve the fair-share.

We show this shortcoming in the following equations. Suppose that the link capacity is C , and the congestion window and RTT for flow i are $cwnd_i$ and RTT_i . The target delay is calculated as follows, where t_{base} is the base delay in Swift and A is just a constant.

$$t = t_{base} + A \cdot \frac{\sqrt{N}}{C} \quad (14)$$

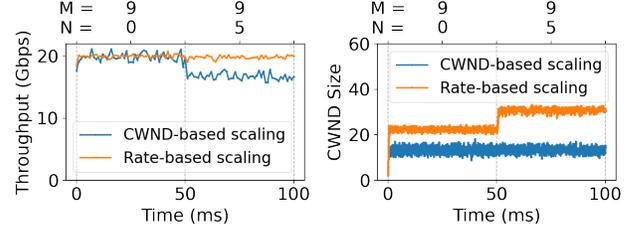

$$\text{Fair share for flow } i = \frac{cwnd_i}{RTT_i} = \frac{C}{N} \quad (15)$$

If we **assume** that at the steady state RTT_i is equal to t (target delay) for all flows and thus $cwnds$ are equal to w in order to get the same throughput, we can estimate \sqrt{N} from Eq. 15 as follows

$$\sqrt{N} = \frac{A + \sqrt{A^2 + 4 \cdot C \cdot w \cdot t_{base}}}{2 \cdot w} \quad (16)$$

Therefore, \sqrt{N} can be estimated by $\frac{\alpha}{\sqrt{w}} + \beta$.

However, as explained above, to achieve fair-share rate, flows get different RTTs thus converging to the same congestion window is not fair. Now, we show that if we follow the

(a) Rate of the victim flow

(b) CWND of the victim flow

Figure 23: Compare scaling the target using the rate or congestion window in Poseidon.

formulation of how Swift reached $1/\sqrt{cwnd}$ for cases that flows have different RTTs at fair share, we end up with a valid Poseidon rate-based scaling. We repeat Eq. 14 here as Eq. 17 after changing t to t_{hop} to emphasize that for Poseidon we have a target for per-hop delay.

$$t_{hop} = t_{hop_base} + A \cdot \frac{\sqrt{N}}{C} \quad (17)$$

If we combine Eq. 17 and Eq. 15 we get

$$t_{hop} = t_{hop_base} + \frac{A}{\sqrt{C}} \cdot \sqrt{\frac{RTT_i}{cwnd_i}} = \frac{\alpha}{\sqrt{\frac{cwnd_i}{RTT_i}}} + \beta \quad (18)$$

$\frac{cwnd_i}{RTT_i}$ in Eq. 18 is the rate of flow i . Therefore, for the flow scaling of Swift to work in a fair-share setting where flows can have different RTTs, the target should increase in reverse relation to rate not just $cwnd$. Figure 23 compares the throughput and congestion window of the victim flow in Poseidon if it uses the above target function using rate vs $cwnd$ in the multi-hop congestion scenario (Figure 14(a)). The victim and $N = 9$ flows start at time 0. Then at 50 ms, $M = 5$ flows start to create congestion at the source rack. Figure 23(b) shows that after 50ms, target scaling based on the rate converged to a higher $cwnd$ to keep the throughput the same for the victim flow.

Eq. 18 is a special case of $T(b) = p \cdot b^q + k$, a valid cluster of functions that satisfy Eq. 1 and Eq. 2 for $-2 \leq q < 0$, with $q = -0.5$. However, we believe Poseidon’s function in Eq. 3 is a better function as explained in §3.3.

D Proof of Lemma 1

We first repeat the Lemma here: When achieving network-wide max-min fairness, each flow will have the largest rate among all flows on its bottleneck hop and not on any other saturated hop. Formally, for the “max-min fair” allocation \bar{x} , for any flow s , denote the flows shared the same bottleneck with s as $\{b_1, b_2, \dots, b_k\}$. For any flow b_i , $x_s \geq x_{b_i}$. Denote the flow’s share on the saturated non-bottleneck hop of s as $\{c_1, c_2, \dots, c_k\}$, then there must exist some c_j such that $x_{c_j} > x_s$.

Proof: Assume there exists a flow s that has reached its fair-share rate r , and there is another flow s' on its bottleneck hop with an even larger rate r' . But this state is not max-min fair

because flow s could get some bandwidth from flow s' and let them have the same rate $\frac{r+r'}{2}$. By contradiction, the flow s has the largest rate on its bottleneck hop.

On the other hand, assume there exists a flow s , which is the fastest flow, with rate r , on one of the non-bottleneck hops. However, given that this link is congested, its fair-share flows with rate r' could obtain bandwidth from flow s and increase their fair-share rate to at least $\frac{r+n \cdot r'}{n+1}$, where n is the number of fair-share flows. By contradiction, the flow s cannot be the largest flow on its non-bottleneck hop.

E Proof of Convergence to Max-min Fairness

Problem description:

For any network topology, any traffic pattern (flows' source and destination, routing), given an initial flow rate allocation, Poseidon converges to the max-min fair allocation.

Notations:

Denote all the link bandwidth as B ;

Denote the target for flow with rate r as $T(r)$;

Denote a flow rate allocation as \vec{y} ;

In allocation \vec{y} , denote the rate of flow f as y_f ;

In allocation \vec{y} , denote the maximum flow rate on a saturated queue q as R_q^y ;

In allocation \vec{y} , denote the delay on a queue q as D_q^y ;

Denote the max-min fair rate allocation as \vec{x} ;

In max-min fair allocation \vec{x} , denote the maximum flow rate on a saturated queue q as R_q^x , which is also the fair-share rate of that port.

Designs of Poseidon and observations:

Design 1: Poseidon reacts to the maximum hop delay along the path.

Design 2: In Poseidon, the target of a flow increases when the flow rate decreases. And Poseidon decreases the flow rate when the delay is higher than the flow's target; increases the rate when the delay is lower than the target.

Observation 1: The queuing delay on a saturated port is no larger than the target of flows with the fastest rate on that port.

Observation 1 holds true because of design 2: if the delay exceeds the target of a flow, that flow will decrease its rate immediately. However, in Poseidon, the decrease operation only happens once per RTT, so the reaction of decreasing rate may happen at most one RTT later. But this will not affect the overall trend of queuing.

Observation 2: the queuing delay on an unsaturated port is always 0.

Observation 2 holds true when senders send packets without bursts. However, the synchronized arrival of many flows may create a transient queue. But the queue will disappear within 1 RTT, because the average data sent within one RTT is less than the line rate.

Proof:

We will use induction to prove any allocation \vec{y} will converge to max-min fair allocation \vec{x} .

In allocation \vec{x} , if we sort the saturated queues based on their maximum flow rate (fair-share rate), we can get:

$$R_{q_1}^x \leq R_{q_2}^x \leq \dots \leq R_{q_k}^x \quad (19)$$

$$T(R_{q_1}^x) \leq T(R_{q_2}^x) \leq \dots \leq T(R_{q_k}^x) \quad (20)$$

(1) prove queue q_1 will converge to the max-min fair allocation:

For any allocation \vec{y} , for queue q_1 , its fastest flow's rate is $R_{q_1}^y$. Note that this q_1 is still the same q_1 sorted by allocation \vec{x} .

Because the queue q_1 is saturated in \vec{y} , it has to satisfy:

$$\sum_{f \in \text{Flows}(q_1)} y_f \geq B \quad (21)$$

And we already know:

$$\sum_{f \in \text{Flows}(q_1)} x_f = B \quad (22)$$

Because in allocation \vec{x} , all the flows on queue q_1 has the same rate, which is $R_{q_1}^x$. Any other allocation \vec{y} 's largest rate cannot be as small as $R_{q_1}^x$ because their rates are not all equal, so we have:

$$R_{q_1}^y \geq R_{q_1}^x \quad (23)$$

$$D_{q_1}^y = T(R_{q_1}^y) \leq T(R_{q_1}^x) = D_{q_1}^x \quad (24)$$

Because of the same reason, we also have:

$$D_{q_i}^y = T(R_{q_i}^y) \leq T(R_{q_i}^x) = D_{q_i}^x, \forall i \in [2, k] \quad (25)$$

So for flows whose rates are smaller than $R_{q_1}^x$, their target is higher than delay on queue q_1 and also delay on any other queue q_i :

$$T(y_f) > T(R_{q_1}^x) \geq R_{q_1}^y, \forall y_f < R_{q_1}^x \quad (26)$$

$$T(y_f) > T(R_{q_1}^x) \geq T(R_{q_i}^x) \geq R_{q_i}^y, \forall y_f < R_{q_1}^x, \forall i \in [2, k] \quad (27)$$

Thus, those flows with smaller rate will keep increasing and flows with larger rate than $R_{q_1}^x$ will decrease because of the delay on queue q_1 or on other queues. Eventually, all of them will converge to the same target:

$$T(y_f) = T(R_{q_1}^x), \forall f \in q_1 \quad (28)$$

So that:

$$T(R_{q_1}^y) = T(R_{q_1}^x) \quad (29)$$

Thus, we show that the queue q_1 will converge to the max-min fair allocation \vec{x} .

(2) Assume queue q_1 to q_m have already converged, prove queue q_{m+1} will converge:

Assume queue q_1 to q_m have already converged to max-min fair allocation \vec{x} , so we have:

$$T(R_{q_i}^y) = T(R_{q_i}^x), \forall i \in [1, m] \quad (30)$$

For queue q_{m+1} , the flows whose bottleneck is q_{m+1} will not travel queue q_1 to q_m . Because if they travel to one of those ports, those ports will have a higher fair-share rate, which contradicts the max-min fair allocation's conclusion.

Thus, with a similar analysis as the proof for step 1, we have:

$$T(y_f) > T(R_{q_{m+1}}^x) \geq R_{q_{m+1}}^y, \forall y_f < R_{q_{m+1}}^x \quad (31)$$

$$T(y_f) > T(R_{q_1}^x) \geq T(R_{q_i}^x) \geq R_{q_i}^y, \forall y_f < R_{q_1}^x, \forall i \in [m+2, k] \quad (32)$$

So that, the flows with smaller rate than $R_{q_{m+1}}^x$ will increase their rate, while flows with larger rate will decrease their rate, until:

$$T(y_f) = T(R_{q_{m+1}}^x), \forall f \in q_1 \quad (33)$$

So that:

$$T(R_{q_{m+1}}^y) = T(R_{q_{m+1}}^x) \quad (34)$$

So we proved that queue q_{m+1} will also converge to max-min fair allocation \vec{x} .

In conclusion, all the ports in allocation \vec{y} will eventually converge to the max-min fair allocation \vec{x} .

Rearchitecting the TCP Stack for I/O-Offloaded Content Delivery

Abstract

The recent advancement of high-bandwidth I/O devices enables scalable delivery of online content. Unfortunately, the traditional programming model for content servers has a tight dependency on the CPU, which severely limits the overall performance. Our experiments reveal that over 70% of CPU cycles are spent on simple tasks such as disk and network I/O operations in online content delivery.

In this work, we present IO-TCP, a split TCP stack design that drastically reduces the burden on CPU for online content delivery. IO-TCP offloads disk I/O and TCP packet transfer to SmartNIC while the rest of the operations are executed on the CPU side. This division of labor realizes the separation of control and data planes of a TCP stack where the CPU side assumes the full control of the stack operation while only the data plane operations are offloaded to SmartNIC for high performance. Our evaluation shows that IO-TCP-ported `lighttpd` with a single CPU core outperforms the Atlas server and `lighttpd` on Linux TCP for TLS file transfer by 1.8x and 2.1x, respectively, even if they use all 10 CPU cores.

1 Introduction

The demand for online content delivery is booming in recent years [1, 5]. Especially, the popularity of high-quality video streaming is growing rapidly [9, 56]. For cost-effective streaming service, it is highly important for online video service providers [3, 4, 11, 19, 26, 44] to optimize their content delivery systems.

However, improving the content delivery performance is increasingly challenging as the growth of CPU capacity stagnates [50]. While modern innovation in I/O devices such as high-bandwidth NICs and NVMe disks has alleviated the I/O bottleneck, the lack of CPU cycles often fail to translate the high I/O performance into content delivery throughput. The root cause lies in the inefficiency of the modern OS abstraction which requires all disk data to be brought to main memory before being delivered to remote clients. For this reason, CPU (or more precisely, the memory subsystem) eas-

ily becomes the performance bottleneck for I/O-intensive applications like video content delivery as over 70% of its entire cycles are spent on simple I/O operations. To effectively harness the recent advancement in the I/O devices, the OS abstraction must reduce the dependency on CPU and its memory system for I/O operations.

Our approach to breaking the CPU dependency is to employ peripheral processors to handle the I/O operations. We observe that the recent programmable I/O devices such as SmartNICs [7, 24, 27, 33] or Computational SSDs [28, 40] may make up for the insufficient compute cycles in CPU. As the PCIe standard allows peer-to-peer DMA (P2PDMA) without the intervention of CPU [35], one can conceive a server system whose NIC offloads disk I/O operations completely from the CPU. In fact, recent works like DCS [46] and DCS-Ctrl [63] have demonstrated that an FPGA-based coordinator can perform all disk I/O operations via P2PDMA for a content delivery server. The main drawback of these systems is that they do not support TCP-based delivery commonly adopted by today's video streaming [3, 11, 26].

However, supporting TCP for an I/O-offloaded server raises an interesting question of function placement – if disk I/Os are offloaded to SmartNIC, where do we run the TCP stack? Running the TCP stack on CPU is impossible as the data for packet payload is unavailable. So, the obvious alternative is to run it on the NIC side. While it is non-trivial to implement a full TCP stack on an FPGA¹, it is possible to run it on SmartNIC. Actually, recent SmartNIC platforms support Arm-based embedded processors that run Linux with a full TCP stack [7, 33]. However, running the full TCP stack on NIC typically requires its application to co-execute on the same platform, with limited resources. In fact, we observe that the throughput of `nginx` on SmartNIC with 8 Arm cores is smaller than that with even a single CPU core.

We tackle this question with I/O Offloading TCP (IO-TCP), a split TCP stack design for I/O-intensive applications. The

¹There are a few TCP/IP stacks on the FPGA [87, 88], but they simplify the key features with assumptions on the data center environment.

key idea of IO-TCP is to run only the "control plane" operations on CPU while delegating all "data plane" operations to SmartNIC that can access disks via P2PDMA. Figure 1 shows the overview of our design. The control plane includes all core functionalities of the TCP protocol – connection management, reliable data transfer, and congestion/flow control. On the other hand, the data plane operations refer to all aspects of data packet creation and transmission including content fetching from disks. This design ensures that the CPU side assumes full responsibility of controlling all operations while actual disk and network I/O operations are offloaded to SmartNIC under the hood. This design enables dedicating CPU cycles to complex control operations while exempting them from simple but repetitive I/O operations. The rationale for the design is that the split stack avoids CPU cache pollution from intensive disk IO [96] that slows down the control path operations, stretches the RTT, and lowers the throughput. In addition, the control path would benefit from advanced hardware features of modern CPU as it is compute-intensive with frequent random accesses and branches. In contrast, the data path depends more on memory bandwidth than computation, and it is easily parallelizable and can be even built into hardware.

While IO-TCP presents a great potential for saving CPU cycles, it brings a few new challenges. First, IO-TCP must handle TCP packet retransmission on SmartNIC without the timeout or packet loss information, which may issue redundant disk I/Os. To avoid the inefficiency, IO-TCP employs an internal ACK protocol to notify the SmartNIC of the data delivery so that it can safely throw it out from memory. Second, the RTT measurement in the host TCP stack could be inaccurate due to disk-induced delay on SmartNIC before transmission. In IO-TCP, actual data packet transfer is delayed until the packet content is fetched from the disk. However, disk I/O could add significant delay to packet transfer even without any congestion in the network path. IO-TCP addresses this challenge by carefully removing the disk-induced delay from RTT measurement. It employs an echo packet that allows the host stack to keep track of the packet departure time accurately. Third, IO-TCP must provide a well-defined API for an application to flexibly construct file or non-file content for data transfer. For this, IO-TCP extends the Berkeley socket API with a few "offload" functions that open a file and send the file content from the NIC. The "offload" functions are implemented as a form of API remoting, and the results are seamlessly delivered to the application on the CPU side.

We implement IO-TCP with the Mellanox BlueField-2 SmartNIC [31] that can directly access NVMe disks with P2PDMA. For the host stack, we extend an existing user-level TCP stack [58] to support I/O offloading while we implement the NIC stack with the DPDK library [12]. It requires 1,793 lines of code modification for the host stack and 1,853 lines of C code for the NIC stack. To evaluate the effectiveness with real-world applications, we also port lighttpd [23] to

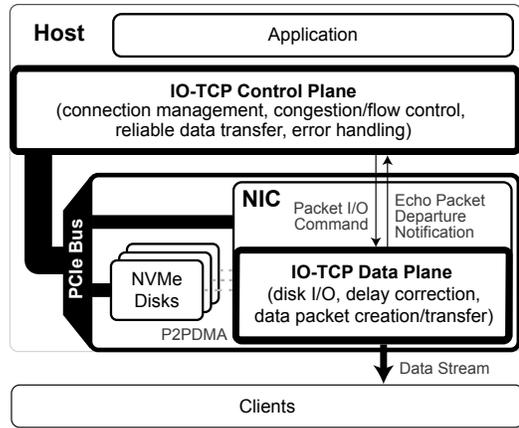

Figure 1: Overview of IO-TCP stacks

using IO-TCP with only about 10 lines of code modification.

Our evaluation demonstrates that IO-TCP-ported lighttpd achieves 77.4 Gbps of TLS video content delivery with a single CPU core, nearly saturating the full bandwidth of four NVMe disks. In contrast, the Atlas server [74] on FreeBSD and lighttpd on Linux reach only 44.2 and 37.4 Gbps, respectively, even with all 10 CPU cores. We observe that the current bottleneck of IO-TCP lies in the low memory bandwidth of the BlueField-2 NIC, but we believe the future version will achieve better performance. The main contributions of this work are summarized as follows. (1) We analyze the impact of CPU usage and cache interference by disk I/O on the performance of modern content delivery systems. (2) We present the design and implementation of IO-TCP, a split TCP stack design that fully leverages recent I/O advances in SmartNICs by separating TCP control and data planes. (3) We demonstrate how IO-TCP can surpass the limitations of the CPU bottleneck to achieve I/O bandwidths far greater than what the CPU could have normally performed.

2 Background & Motivation

We provide a brief background on content delivery systems in terms of recent trends in computing hardware.

2.1 Inefficiencies in Content Delivery System Stacks

Modern content delivery systems [2, 14, 26] consist of a large number of geographically distributed content delivery Web or reverse proxy servers. These systems serve as the basis for many applications such as video streaming and Web page accesses. Among them, the video traffic takes up about 60% of the entire Internet traffic and the overall volume has increased due to the recent pandemic [39, 56]. Average Web object sizes range from 0.01 to 1 MB while average video chunk sizes are between 0.2 to 1.5 MB [89].

For high performance, the server design has traditionally focused on optimizing disk access and CPU utilization because hard disk I/O is many orders of magnitude slower

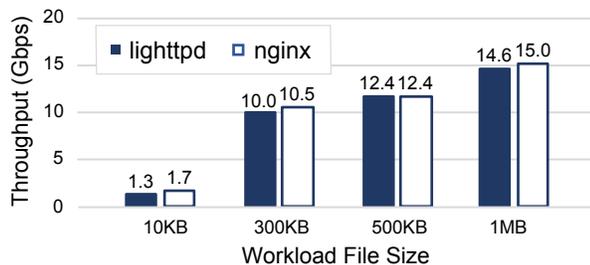

Figure 2: Throughputs of lighttpd and nginx on a single CPU core.

Function	% CPU
Read data from disk to a kernel buffer	33.53%
Memory management	21.93%
Move data to TCP send buffer (no copy)	10.30%
Open files and get stat	6.00%
Control Plane	28.24%
Total	100%

Table 1: CPU usage per data plane function in nginx when serving disk-bound workload with `sendfile()`. The breakdown for lighttpd is also similar.

than modern storage. For fetching small objects such as Web page content, the server is optimized to minimize the disk seeks while maintaining a small memory footprint for indexing [47]. For large-object access like video download, the server exploits sequential disk reads to maximize the disk throughput. Also, it typically employs `sendfile()` to avoid redundant memory copy and context switching between user and kernel spaces. To improve CPU utilization, the server typically takes the event-driven architecture [48, 67, 77, 81].

Traditional disk-based optimizations have become largely obsolete due to the advent of inexpensive large RAM and flash-based disks (e.g., NVMe SSDs) that removed the seek-induced limitations. Since the major disk bottleneck is lifted, the memory subsystem becomes the next bottleneck in today’s server [74]. The problem is exacerbated by multiple memory copies due to disk and network I/O as well as content scanning for encryption and decryption. While a recent work [74] optimizes the disk access layer and exploits Intel Data Direct I/O (DDIO) [21] to arrange all such operations to perform with the data in CPU cache, it does not dissipate the workload from CPU. Also, it may be hard to expect a similar benefit if the workload exceeds the CPU cache size.

To better understand the performance of Web-based content delivery, we run experiments with two popular Web servers, lighttpd (v1.4.32) [23] and nginx (v1.16.1) [29] for disk-bound workload, which simulates a typical setting for HTTP-adaptive video streaming. The server setup is the same as in §5.1, and we use various file sizes that represent Web objects and video chunks of different quality. We configure the servers to use `sendfile()` for good performance.

Figure 2 shows the results with a single CPU core (refer to Figure 7 for performance trend over multiple CPU cores). The performances of both servers are similar, and they generally improve with larger file sizes. As our NVMe disk achieves

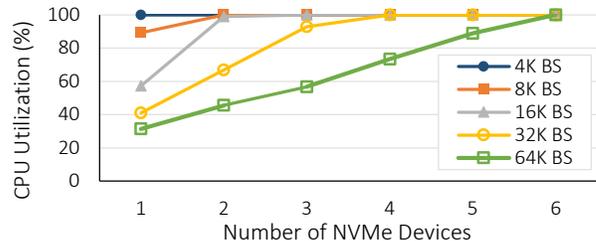

Figure 3: CPU utilization of fio with for varying number of NVMe disks. BS refers to block size.

around 2.5 GB/s (or 20 Gbps) per disk for random file reading, the single CPU core utilizes around half the bandwidth (10 Gbps) of a single NVMe disk for 300KB files. Considering that a server-class machine can carry 8 to 10 NVMe disks per CPU, CPU is a major source of resource bottleneck.

We analyze the CPU overhead in popular Web servers for content delivery. Table 1 shows the CPU cycle breakdown of nginx reported by `perf`[36]. `sendfile()` and `open()` take up the majority of the CPU cycles, which amounts to 71.76% of the consumed cycles. `sendfile()` reads the data on disk to kernel buffers, and serve it to clients without memory copy (33.35%). This clearly shows where the most of CPU cycles are spent in a content delivery server – disk and network I/O. Offloading these operations from the CPU would have a great potential for improving the performance.

2.2 Mismatch between I/O Device Advances and CPU Capacity

The capacity growth with recent I/O devices is impressive. Two decades ago, the fastest hard disk could achieve only about 200 random I/O operations per second (IOPS), but the recent NVMe disk can perform over 1 million IOPS [41, 97], a speedup of almost four orders of magnitude. For the same period, the bandwidth of an Ethernet NIC has improved by 400 times (from 1 Gbps in 1997 to 400 Gbps in 2021) while 800 Gbps / 1.6 Tbps Ethernet is expected to be standardized in a few years [55]. In contrast, CPU capacity improvement has been largely hampered by the end of Moore’s law and breakdown of Dennard scaling² [54]. The first general-purpose multicore CPU appeared in 2005 [6], but the number of cores of Intel CPU has increased by only 28 times for 16 years [22].

Figure 3 shows the utilization of a single CPU core when saturating the NVMe disks with fio [15]. We use Intel Xeon Silver 4210 (2.20GHz) for CPU and Intel Optane 900P for NVMe devices. The figure indicates that it is relatively easy to handle large block sizes but a single core cannot saturate even 2 NVMe disks with a block size of 4KB. For 16KB blocks, it can handle up to 3 NVMe disks in parallel. Even when serving large files, disk I/O could still spend a significant portion of the CPU cycles as metadata access in filesystem would require frequent random accesses for small blocks.

²Dennard scaling dictates that the power density stays constant as the transistors become smaller. It is said to stop in 2006 and CPU capacity could only scale out since then.

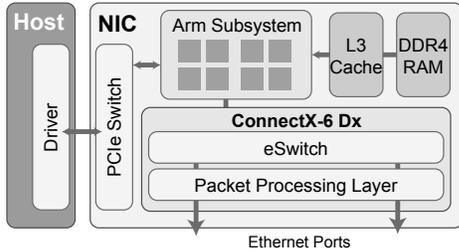

Figure 4: Architecture of the BlueField SmartNIC

In addition to NVMe, the use of persistent memory (PM) sees similar CPU bottlenecks. A recent PM performance study [94] on Intel Optane DC memory shows that 16 cores are required to fully utilize PM read bandwidth even with large I/O sizes like 64KB or 256KB. Due to the CPU bottleneck, many PM-based storage systems fall back to a lightweight storage stack design that misses features [51, 52, 53, 59, 64, 93, 98].

The performance disparity between CPU and I/O devices calls for revisiting the current OS abstraction for I/O operations, especially for serving large files with the growing trend of high-throughput content delivery. Existing OS requires CPU intervention for performing I/O operations such as reading disk content and transferring it via NIC. This is because the programming model on the current OS requires the content of the I/O device to be brought to main memory before performing any operation on the content. This memory-centric execution model wastes CPU cycles for frequent memory access stalls due to memory operations.

2.3 Opportunities with SmartNIC

The key idea of our work is to offload data I/O from CPU to a programmable I/O device while supporting TCP-based content delivery. Any programmable device that can perform direct disk I/O and network packet I/O can meet our goal, but we use SmartNIC as it serves as a convenient place to interact with remote clients. For example, recent SoC-based SmartNICs [7, 33] offer an Arm-based embedded system on top of a NIC data processing unit. These systems support direct access to NVMe disks on the same domain without intervention of CPU or main memory. More specifically, the Mellanox BlueField NIC supports P2PDMA via NVMe over Fabrics (NVMe-oF) target offload [18] through which the Arm processors can read directly from local NVMe disks. These disks are directly mounted on the Linux environment running on the Arm processors, and they run on the same file system as seen by the host OS.

Figure 4 shows the architecture of the Mellanox BlueField-2 NIC (BF-2) [31] that we use for our platform. It is equipped with 8 Armv8 cores and 16 GB of DDR4 memory that runs on Linux³. The Arm subsystem allows running DPDK applications to perform fast packet I/O either with remote machines or with the local host. In addition, applications can

³We run CentOS 7.6, but one can run embedded Linux like Poky [37].

lighttpd setup	Throughput (Gbps)
Linux TCP on BF-2 only	11.98
Linux TCP on BF-2 and 1 CPU core	22.02
IO-TCP-on BF-2 and 1 CPU core	44.13

Table 2: Performance of lighttpd with Linux TCP vs. IO-TCP for serving 300KB files over 1600 connections on BlueField-2 (BF-2) and a single CPU core. We use four Intel Optane 900P in all experiments.

offload TCP/IP checksum calculation as well as TCP segmentation (i.e., TSO) to its ConnectX-6 Dx NIC hardware. The BlueField-2 also supports hardware acceleration for cryptographic operations that we use for supporting TLS.

With the Linux-operated SmartNIC, one might be tempted to use it as an extra server system [90]. However, running a server directly on SmartNIC does not efficiently use the resources. Table 2 compares the performances of lighttpd on only BF-2 (w/ all 8 cores), lighttpd on BF-2 and the host’s single CPU core combined (by evenly dividing the request load), and IO-TCP-ported lighttpd on the same setup. Naïve scaling of processing power with SmartNIC ends up with only half the throughput of our solution (§4).

The experiments clearly show the current limitation with the SmartNIC – the processors and their memory are not so powerful as the host system. In fact, the Arm processors on BF-2 have 2.2x and 4.2x smaller L3 cache and memory bandwidth than those of our host CPU, which limits the overall performance. While this is not an inherent limitation as the next version [32] is reported to have 3.5x larger memory bandwidth, one should carefully design the offload functionality to effectively exploit the architectural difference.

3 Design

In this section, we present the design of IO-TCP that enables content delivery systems to leverage recent SmartNIC I/O advances. The key design choice of IO-TCP is to *separate the control and data planes* of the TCP stack such that the CPU stack takes the full control of every operation (control path) while individual I/O operations (data path) are offloaded to the SmartNIC stack. The core rationale for this is to save the majority of CPU cycles for performing I/O operations while keeping the SmartNIC stack simple to implement. Simplicity is the key to achieve the performance scalability.

There are three design goals for IO-TCP: (1) IO-TCP must conform to the TCP protocol and should be able to support various congestion control implementations. For example, handling disk I/O in the NIC stack should not compromise the congestion control logic in the host stack due to imprecise RTT measurements induced by disk access latency (§3.5). (2) The modification of existing applications should be minimal for migrating to IO-TCP – it should use the same socket API except for offloading file I/O (§3.2). (3) The IO-TCP host stack needs to communicate with the NIC stack for I/O offloading, and its overhead should be made small. In addition, the host stack should be notified of any failures in the NIC stack to

```

int offload_open(const char *filename, int mode) – opens a file in the NIC and returns a unique file ID (fid).
int offload_close(int fid) – closes the file for fid in the NIC.
int offload_fstat(int fid, struct stat* buf) – retrieve the metadata for an opened file, fid.
size_t offload_write(int socket, int fid, off_t offset, size_t length) – sends the data of the given length
starting at the offset value read from the file, fid, and returns the number of bytes virtually copied to the send buffer.

```

Table 3: IO-TCP offload API functions

handle them in time (§3.3 and §3.6).

3.1 Separating TCP control and data planes

To save host CPU cycles, we need to determine which operations would benefit the most from offloading based on the capabilities of SmartNICs and CPU. The embedded processors on either SoC or ASIC-based SmartNIC are better fit for simpler data plane operations while x86 CPUs with advanced features⁴ can handle complex control plane operations faster. To better reflect the architectural difference into the design, we divide the TCP stack into control and data plane operations.

The control plane functions refer to the key TCP protocol features such as connection management, reliable data transfer, congestion/flow control, and error control. These typically require complex state management as the behavior depends on the response from the other end. For example, reliable data delivery on the receiver side requires tracking all received data ranges that are disjoint for proper in-order delivery and ACK generation. It is also tightly coupled with congestion control as loss detection and packet retransmission for reliable delivery in turn re-adjust the send window size. Similarly, flow control needs to run with congestion control as they collectively determine the window size. Error control cannot run alone, either, as it requires tracking detailed flow states to infer any erroneous behavior. Theoretically, each individual operation can be offloaded, but it would be more efficient to offload them together. However, offloading them all could overload the SmartNIC as seen in experiments in §2.3.

The data plane operations refer to all operations that involve data packet preparation and transfer, which supports the implementation of control plane functions. These include managing data buffers, segmenting data into packets, calculating TCP/IP checksums, etc. IO-TCP offloads only the operations in the send path because they are simple, stateless, and easily parallelizable. In addition, IO-TCP offloads the file/disk I/O and combines it into TCP data plane operations. The rationale for offloading is that these operations would interfere with control plane operations on CPU as recent innovation like Intel DDIO would pollute the CPU cache by huge disk data [96]. Offloading them to SmartNIC would allow the control path to execute on CPU much faster, which in turn improves the data path performance. Also, SmartNICs tend to have hardware-based crypto accelerators [24, 27, 31], which enables TLS data encryption at line rate. Section 5.5

⁴Such as larger CPU cache and vectorized instructions like AVX/AVX2.

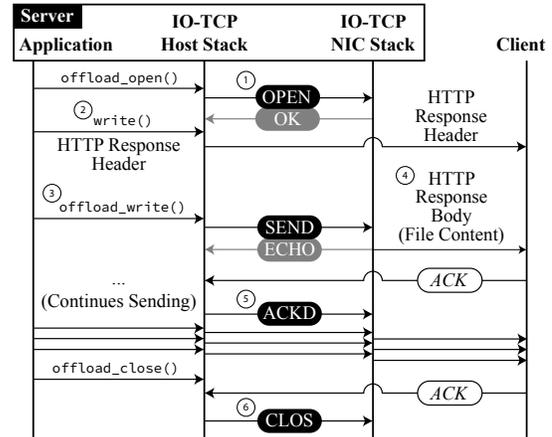

Figure 5: Content delivery from a Web server on IO-TCP

analyzes the source of performance improvement in depth.

3.2 IO-TCP Offload API Functions

Ideally, porting an application to IO-TCP should require little modification of its core logic, yet it should flexibly express the application needs. For example, an IO-TCP application should be able to compose any data to transfer regardless of whether it is file content or not. Towards this goal, we extend the existing socket API by adding only four functions (see Table 3) for offloaded file and network I/O.

`offload_open()` asks the NIC stack to open a file and to report the result (either success or any error). It returns a file ID (instead of a file descriptor) that identifies the opened file in the NIC stack for later operations. `offload_open()` is an asynchronous function whose result should be checked with `epoll()` or subsequent function calls as file opening can fail for various reasons. After all file operations, the application can call `offload_close()` to close the file on the NIC stack. In addition, IO-TCP supports `offload_fstat()` that retrieves the metadata for a file (e.g., file size and permission).

With the opened file ID, the application can call `offload_write()` to send the file content on a TCP connection. Essentially, `offload_write()` carries out the same operation as `sendfile()` in Linux with the file opened at the NIC embedded system. The application can still call an existing socket API like `write()` to send out any custom data (e.g., HTTP response headers), or it can send the content from multiple files opened by the NIC stack. Figure 5 illustrates a subset of these operations with the API functions in the context of an HTTP server.

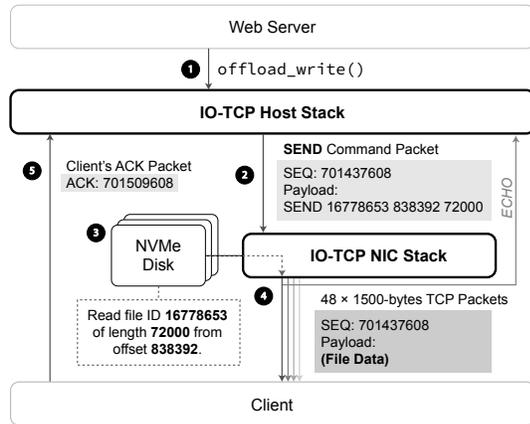

Figure 6: Generation of data packets with `offload_write()`

3.3 IO-TCP Host Stack

The role of IO-TCP host stack is to provide the full TCP functionality to applications while it interacts with the NIC stack to offload the data plane operations. The key challenge in the host stack design is how to create data packets with "missing" file data. Similarly, it should handle TCP packet retransmission without actual file data in the host side.

IO-TCP addresses the challenge by *virtually* performing data plane operations on the host stack. The host stack keeps track of which data in the sequence number space is "virtual" and performs only the bookkeeping operations while it delegates the real I/O operations to the NIC stack. For example, an application can call a mix of `write()` and `offload_write()`, and the host stack writes the immediate content directly into the send buffer while it virtually fills out the buffer range for `offload_write()` by metadata update. `offload_write()` returns immediately with the number of "virtual" bytes that can be written to the send buffer.

Then, the host stack determines the send window size with its congestion and flow control parameters, and posts a "SEND" command to the NIC stack to transfer the virtual data (Refer to ③ and ④ in Figure 5). Note that any data packets with real content (written by `write()`) in the host stack are sent out directly bypassing the NIC stack.⁵ The "SEND" command is carried on a TCP packet destined to the NIC stack (with an internal MAC address of the NIC). The TCP/IP headers of the command packet contain the full connection information (i.e., four connection tuples, sequence and ACK numbers for the next data packet, etc.) while its payload contains the "SEND" command that is eventually replaced by the real content before it is sent out to the client. The "SEND" command specifies a file ID, the start offset to read, and the length of the data. With this information, the NIC stack reads the file content and creates and sends real data packets with the header information. Depending on the file content size, one "SEND" command can be translated into

⁵If real data has to be sent after virtual data, the host stack delays transmission until the arrival of an echo packet (§3.5) to keep the order.

multiple MTU-sized data packets. Figure 6 illustrates how a "SEND" command packet is processed.

The host stack handles packet retransmission in the same manner – sending a "SEND" command with the file content information for retransmission. The rationale for this design is to make the NIC stack as simple as possible. An obvious alternative is to have the NIC stack handle retransmission so that it ensures reliable delivery of whatever data is transmitted due to the "SEND" command. Then, the NIC stack must keep track of all ACKs from the client and run the congestion control logic to determine when to retransmit packets. This would make the NIC stack stateful and more complex, which would be challenging to implement efficiently on some other SmartNIC platforms (e.g., FPGA-based ones).

For all other operations, IO-TCP behaves similarly to the normal TCP stack. All complex operations such as per-connection state and buffer management on the receive path, timer management, reliable data transfer, congestion/flow control, and error control are executed on the host stack. In addition, for the control packets or packets whose data is available on the host stack, the host stack creates and sends them directly to the client bypassing the NIC stack. All incoming packets from the client get delivered directly to the host stack as well. (See ② and client-sent ACKs in Figure 5) This is not only because going through the embedded system on the NIC incurs extra latency, but it also places an unnecessary burden on the NIC stack. This packet steering can be easily enforced in the separated mode of the Mellanox BlueField-2 NIC where an embedded system on NIC has different IP and MAC addresses.

3.4 IO-TCP NIC Stack

The IO-TCP NIC stack is responsible for performing all real data plane operations for the host stack – it handles offloaded file I/O and network I/O for data packet transfer. It operates by handling custom commands from the host stack where each command is carried on a special packet destined to the NIC stack. Currently, four commands are defined: "OPEN", "CLOS", "SEND", and "ACKD". "OPEN" and "CLOS" are for file opening or closing. "SEND" is the main command for sending the file content to the client. "ACKD" is used to efficiently handle retransmission without redundant disk access.

The "SEND" command is the key driver for I/O operations. Conceptually, it extends TCP segmentation offload (TSO) with the metadata that describes how to fill in the packet payload. Given the "SEND" command, the NIC stack checks if the target file is opened, and reads the file content into a fixed-sized memory buffer. The file read offset and its length are aligned to the NVMe disk page boundary (e.g., 4KB), and the actual file I/O is executed asynchronously to prevent blocking of the main thread. When the file content becomes available on the memory buffer, the NIC stack creates a TSO packet with the TCP/IP headers in the "SEND" command packet, and sends it out to the NIC hardware data plane. The NIC

hardware data plane takes care of TCP packet segmentation and TCP/IP checksum calculation.

3.5 Challenges with Integrated I/O

Combining file I/O into the network I/O in the NIC stack brings a few unique challenges in the correctness of the TCP stack operation.

Retransmission timer and RTT measurement. TCP relies on delay measurement for setting up retransmission timers. However, the delays induced by disk I/O could confuse the RTT measurement. Even with fast NVMe disks, the disk access delay for reading a few KBs of data is in the order of microseconds, and it can be up to milliseconds if the I/O requests for the same disk are backlogged. We observe that our early implementation of IO-TCP often retransmits the packets even if the original packets have not been sent out to the client.

To address this problem, we have the NIC stack send back an *echo* packet to the host stack just before transferring data packets for the corresponding “SEND” command. The host stack starts the retransmission timer only when it receives an echo packet for the SEND command. For accuracy, the host stack adds a one-way delay of the echo packet (~3 microseconds on our platform) from the NIC stack to itself to the timeout value. The CPU overhead for the echo packet is small as it is sent per “SEND” command and a typical “SEND” command is translated to tens to even hundreds of MTU-sized packets for large-file delivery.

Also, for precise RTT measurement, the NIC stack reflects the real “packet processing” delay into the TCP timestamp option value, i.e., the delay between the arrival of a “SEND” command to the NIC stack and the departure of the corresponding data packets from the NIC stack. That is, the “SEND” command packet carries the TCP timestamp option filled by the host stack, and the NIC stack updates the value before sending out the packets. As the timestamp option value is in the millisecond granularity [38] and the time feed in the host stack is on the order of microseconds, the host stack sends the extra time information in the microsecond granularity to the NIC stack. Then, the NIC stack can round up the timestamp value if necessary.

Handling retransmission. Since retransmission of I/O-offloaded packets is also implemented with the “SEND” command, a naïve implementation that re-reads the file content would waste the disk and memory bandwidth. To avoid the inefficiency, the NIC stack keeps the original data content in memory until the host stack confirms the delivery to the client. When the host stack sees the ACKs for the I/O-offloaded sequence space range, it periodically informs the NIC stack of the delivered portion with the “ACKD” command packet. Then, the NIC stack can recycle the memory buffers holding the delivered data. To minimize the overhead, the host stack informs the NIC stack whenever it sees

a threshold amount of data (e.g., we use 32KB for now) acknowledged by the client from the last time. Note that this buffer memory essentially serves as the socket send buffer in the normal TCP stack, and the required memory in practice roughly corresponds to the bandwidth-delay product. A 100 Gbps NIC with 30ms of average RTT for the connections would require 375MB of the buffer memory in aggregate.

3.6 Handling Errors

In IO-TCP, the host stack is responsible for handling all TCP-level errors such as handling packet losses, malformed packets, or abrupt connection failures. Since the NIC stack only sends packets on behalf of the host stack and all incoming packets bypass the NIC stack, the host stack can reason about any TCP-level errors as other TCP stacks do.

In contrast, the NIC stack must report errors in file I/O to the host stack. For an “OPEN” command, the NIC stack responds to the host stack whether opening a file was successful or not. Then, the host stack raises an event to the corresponding file ID so that the application learns the result. Since the host stack caches the metadata for an offloaded file (see §4), it can return an error if `offload_write()` is passed wrong parameter values. In case a file read operation itself fails, it is reported to the host stack with an “Error” command packet with the file ID and the error code. Then, `offload_write()` would return `-1` with the error code at `errno` next time the application calls it.

3.7 Support for TLS and QUIC

TLS is widely used in the modern Internet as QUIC [65] and HTTP/2 [20] adopt it by default. IO-TCP can support TLS similarly to kTLS [92] except that it offloads the encryption to the SmartNIC. This is feasible as many SmartNICs (including Bluefield-2) [24, 27, 31] already support AES and SHA in hardware. So, the CPU side runs the TLS handshake and sets up the encryption and hashing keys with the SmartNIC. All data in the receive path should be decrypted by the CPU stack similarly to other receive-path processing in IO-TCP. One complication lies in how to encrypt the non-offloaded data, but one can forward such packets to SmartNIC for encryption or encrypt them with CPU’s AES-NI instructions. Support for TLS is still in progress as we have implemented content encryption with AES-GCM in NIC hardware and plan to support TLS handshake and TLS record structures.

The key idea of IO-TCP can be easily applied to other transport layer protocols like QUIC – Appendix A briefly explains the architecture of IO-QUIC. We plan to elaborate on the detailed design in the follow-up work.

4 Implementation

IO-TCP host stack. We implement the IO-TCP host stack by modifying mTCP [58], a high-performance user-level TCP stack. We choose mTCP as its socket API is similar to the Berkeley socket API and it supports event-driven programming with `epoll`. The host stack extends the mTCP API

functions with four offload functions (as shown in Table 3). Each offload function is implemented by exchanging special command packets with the NIC stack. The NIC stack detects a command packet by checking the special value in the ToS field in the IP packet. The "SEND" command packet has valid TCP/IP headers with the full connection information so that only the payload (as well as checksums) needs to be replaced with the real file content before being sent to the client.

For `offload_open()`, the host stack generates a unique file ID for the file path and returns it to the user. Under the hood, it attaches the file ID to the "OPEN" command to refer to the opened file on the NIC stack. As part of response, the NIC stack provides the metadata of the opened file (e.g., output of `fstat()`) so that the host stack can handle `offload_stat()` locally on its own. This should cut back the round trip to the NIC stack. For file operations, both the host and NIC stacks share the same file system – the host OS mounts the file systems on the NVMe disks as read/writable while the NIC stack mounts them as read-only. One problem is that any update on the host-side file system does not automatically propagate to the NIC stack as they run on a separate operating system. While we currently assume that the files do not change during the content delivery service, one should add support for dynamic synchronization of the two file systems in the future.

IO-TCP NIC stack. The NIC stack is implemented as a DPDK application. It operates by handling command packets from the host stack. Each Arm core runs one main thread and a few disk reading threads that are pinned to the core. The command packets are distributed to the main threads by receive-side scaling (RSS) on the NIC hardware, which ensures in-order packet delivery in the same connection.

For efficient memory buffer management, the NIC stack pre-allocates all buffers for file content at startup. Each main thread owns $1/n$ of them to avoid any lock contention, and a simple user-level memory manager allocates and frees the buffers at low cost. We implement zero-copy DMA of file data and packet header with DPDK (i.e., scatter-gather DMA), which improves the large-file delivery throughput (in the experiments for Figure 8) by 63%.

File reading, even with faster NVMe disks, is slower than memory operations, so each main thread employs a few disk reading threads to prevent blocking of the main thread. Disk reading threads use direct I/O to bypass the inefficiency in the file system cache [74], and communicate with the main thread through shared memory. An alternative is to use a user-level disk I/O library like Intel SPDK [42]. In fact, we observe that SPDK reaches the peak disk read performance with half the Arm processor cycles used by direct I/O, but we stick to a regular file system here (i.e., ext4 on Linux) as SPDK's support for file system is not mature yet.

IO-TCP TLS implementation. We modify the DPDK NIC driver to offload TLS symmetric key encryption with the

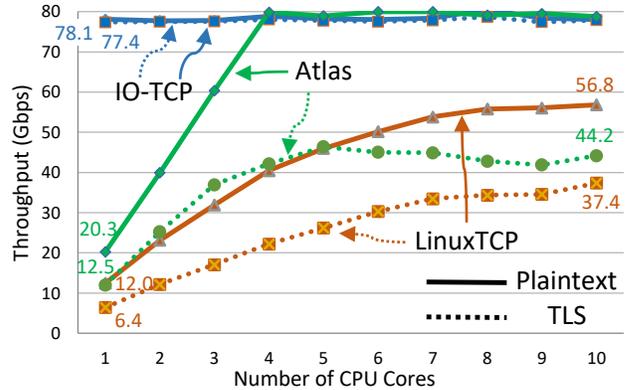

Figure 7: Comparison of throughputs of lighttpd on Linux TCP and IO-TCP, and those of the Atlas server [74] over varying number of CPU cores serving 500KB files. Dotted lines are for TLS traffic.

BlueField-2 NIC. Our TLS module initializes the NIC with TLS offloading feature enabled, and it registers a chosen ciphersuite with the NIC and returns an ID for it. When the TLS module marks the packets with the ID, the packets are encrypted with the corresponding ciphersuite. We implement AES-GCM with 256bit keys with ConnectX-6 Dx, which supports the encryption almost at line rate.

Porting lighttpd to IO-TCP. To evaluate the effectiveness of IO-TCP in the real-world applications, we port lighttpd v1.4.32 to IO-TCP. We obtain the mTCP-ported lighttpd code in Github [16], and have modified it to support offloaded I/O operations. Porting it to IO-TCP was straightforward as we needed to modify only about 10 out of 41,871 lines of the lighttpd code.

5 Evaluation

We evaluate IO-TCP with the following questions in mind: (1) how much performance improvement does IO-TCP bring over Linux or custom TCP stacks for content delivery systems? (2) does it result in significant CPU cycle saving? and (3) do our design choices (Retransmission timer and RTT measurement correction) serve their purposes well? Before running the experiments, we first verified the correctness (integrity of transferred files) of the IO-TCP stack with the IO-TCP-ported lighttpd server even in the case of many packet losses and multiple concurrent connections.

5.1 Experiment Setup

Our experiment setup consists of one server and two client nodes. The server machine has two Intel Xeon Silver 4210 CPU @ 2.20 GHz (20 cores)⁶, with two 100G Mellanox BlueField-2 SmartNICs and four Intel Optane 900P NVMe SSDs. We attach one SmartNIC with two NVMe disks using NVMe-oF target offload so that the NIC can access the two NVMe disks directly. The host CPU runs on Linux 4.14 while the SmartNIC runs on Linux 4.20. The client machines are each equipped with an Intel E5-2683v4 CPU @ 2.10GHz (16

⁶We use only one CPU (i.e., 10 cores) for experiments.

cores) and a 100G Mellanox ConnectX-5 NIC. All clients run on Linux 4.20, and we confirm that the clients are not the bottleneck for the experiments. All NICs are connected to a 100 Gbps Dell EMC Networking Z9100-ON switch.

We populate the NVMe disks with 100KB, 300KB, 500KB and 1MB files, which represent the video chunks of different quality [74, 89]. We make sure that the workload is disk-bound so that the working set size exceeds the main memory size. Each disk has an advertised read throughput of 2500 MB/sec, which would imply that we have a theoretical limit of 80 Gbps when reading from our four disks.

5.2 IO-TCP Throughput

We evaluate the effectiveness of IO-TCP in the large-file content delivery. We compare the throughput of IO-TCP-ported `lighttpd` and that of the stock version with `sendfile()` over varying numbers of CPU cores. We also compare against the Atlas server of Disk|Crypt|Net [74] that runs on FreeBSD 1.10. The Atlas server integrates raw disk reading into large-file transfer over a user-level TCP stack. For Atlas, we use a dual-port Chelsio 100Gbps NIC (T-62100) as FreeBSD 1.10 does not support the `netmap` [86] driver for BF-2. We have added support for TSO to the NIC driver. We note that it is not an apples-to-apples comparison as the current implementation of the Atlas server deviates from the correct operation of a typical Web server – the current version does not support regular file systems, so it simply returns a random content whose HTTP response headers are also hard-coded into NVMe disks. While implementing a proper custom file system should fix the problem, the current version benefits from avoiding the overhead. Nevertheless, comparing with Atlas would give us the rough idea of how well an IO-TCP-ported server fares over the state-of-the-art CPU-based server. Clients run `wrk` [43] to concurrently request on 1600 persistent connections. For testing Atlas, we reduce the number of concurrent connections to 800 for plaintext transfer as its custom TCP stack becomes unstable at high concurrency.

Comparison with Linux TCP and Disk|Crypt|Net. Figure 7 shows the results for serving 500KB files. `lighttpd` on IO-TCP achieves 78.1 Gbps with a single CPU core on the host side for plaintext transfer, which demonstrates that a single CPU core is sufficient to handle the control plane operations for all 1600 clients. IO-TCP saturates the full bandwidth of the four NVMe disks, and each NIC reaches 39 Gbps, indicating that the performance scales to the number of NICs. In contrast, Linux TCP does not go beyond 57 Gbps even with 10 CPU cores. Even when we use both CPUs (i.e., 20 cores), we do not see performance improvement (56.2 Gbps). This shows that the memory bandwidth is inefficiently utilized [74] despite the usage of a zero-copy API like `sendfile()`. When `lighttpd` on each CPU runs with a distinct port and serves a disjoint set of files, the performance goes up slightly (59 Gbps) as it benefits from local memory bandwidth. However, the improvement is limited because the content often has to

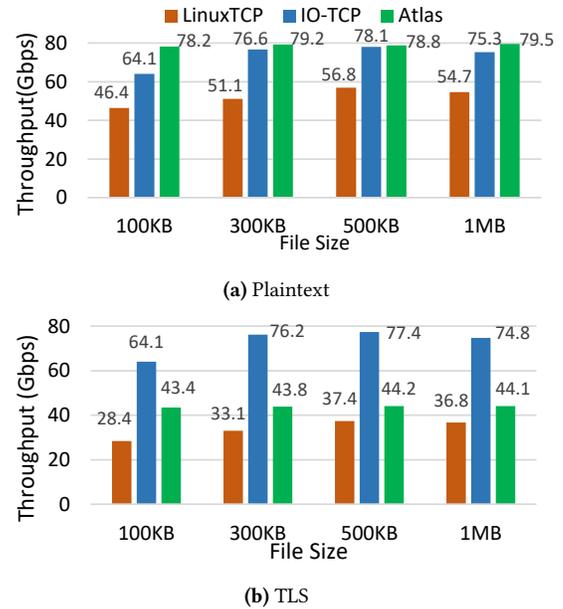

Figure 8: Comparison of maximum performance of `lighttpd` on LinuxTCP, and IO-TCP and Atlas for varying file sizes.

cross the NUMA domain to a NIC and the placement of kernel objects are not NUMA-aware. On the other hand, Atlas performs much better, reaching the same performance of IO-TCP at four CPU cores. When we add more NVMe disks (up to 8) and use two CPUs with both NIC ports, the performance of Atlas peaks at 107 Gbps where the memory bandwidth becomes a bottleneck. The performance of IO-TCP goes up to 95.2 Gbps if IO-TCP serves a random content with raw disk access like in Atlas, but the bottleneck lies in the memory bandwidth of the BF-2 NIC. This shows that efficient use of the host memory bandwidth is highly effective in achieving a very good throughput with only CPU. However, the performance advantage disappears when serving TLS traffic where the memory bandwidth becomes a bottleneck much earlier (discussed in the next paragraph). Figure 8a compares the performances with different file sizes. All performances of Atlas are similar as it avoids calling filesystem APIs. The performance of IO-TCP is comparable to those of Atlas from 300 KB files. IO-TCP outperforms Linux TCP by 38% to 51% and it uses 2x to 10x smaller number of CPU cores to reach the peak performance.

TLS performance. IO-TCP excels at serving TLS traffic. We enable packet encryption with AES-GCM with 256bit keys on the NIC crypto hardware for IO-TCP. For stock `lighttpd`, we use OpenSSL 1.0.2k [34] with TLSv1.2, and use the same algorithm for symmetric key encryption. Both Atlas and the IO-TCP-ported `lighttpd` do not implement the TLS handshake, but the overhead for the handshake with stock `lighttpd` is negligible as we use persistent connections. Figure 7 and Figure 8b show that IO-TCP experiences little performance degradation with TLS due to the dedicated crypto hardware on NIC. In contrast, Atlas achieves only 44.2 Gbps even with

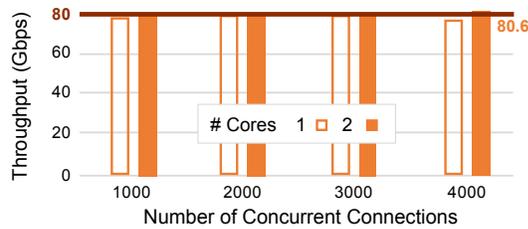

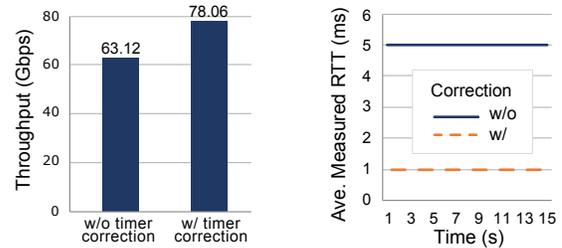

Figure 9: Comparison of TLS performance of IO-TCP over different number of connections using 1 and 2 CPU cores.

10 CPU cores as the main memory bandwidth becomes the bottleneck. The performance goes up to 54.6 Gbps with two CPUs, but overall, the TLS performance is 51% to 56% of the plaintext throughput. The similar trend is seen with Linux TCP - the TLS performance drops by 48% to 63%. We confirm that both Atlas and Linux TCP benefit from the AES-NI instructions of the CPU, but their TLS performances are poor due to content scanning for encryption. We note that the working set size of Atlas exceeds the CPU cache, so their TLS performance is bottlenecked by the memory bandwidth much faster. So, the claim that Disk|Crypt|Net manages the workload within the CPU cache depends on the hardware.

Connection scaling. Figure 9 shows the performance of IO-TCP serving 1000 to 4000 concurrent TLS connections. We observe that the performance is more or less stable over different number of connections. For 4000 connections, IO-TCP loses about 5% of performance with a single CPU core, but it reaches 80 Gbps again with two CPU cores. We check that the plaintext performance exhibits comparable trends. At 4000 connections, each connection would get around 20 Mbps, a comfortable bandwidth to stream 4K videos.

Comparison with user-level TCP stacks. One might be tempted to compare the performance with recent user-level TCP stacks like mTCP [58], IX [49], TAS [62], and F-Stack [13] as they use the CPU cycles efficiently. However, we find that these stacks are not optimized for large-file content delivery as most of them do not implement `sendfile()` nor benefit from TSO. In fact, we measure the performance of TAS, mTCP, and F-Stack on the same platform with all 10 cores, but they show 8, 21.4, and 36 Gbps, respectively, for 500KB file delivery. Even if they implement a zero-copy API, we doubt that it would substantially outperform Linux TCP because the primary goal of the kernel-bypass networking stacks is to avoid the overhead of frequent system calls and kernel data structures for small-message transactions. However, transferring large messages would rarely impose the system call overhead nor suffer from the overhead of kernel structures. Instead, insufficient memory bandwidth (or CPU cycles) is the main cause for poor performance in large-file content delivery, which kernel-bypass TCP stacks do not help.

TCP fairness. We also evaluate if IO-TCP provides bandwidth fairness among the competing connections. Jain’s Fairness Index of IO-TCP ranges from 0.91 to 0.97 for different

(a) Correcting retransmission timers.

(b) Correcting timestamps for more accurate RTT estimates.

Figure 10: Time measurement correction in IO-TCP

numbers of concurrent connections. We see a similar range (0.90 to 0.97) with Linux TCP for the same experiments.

5.3 Evaluation of IO-TCP Design Choices

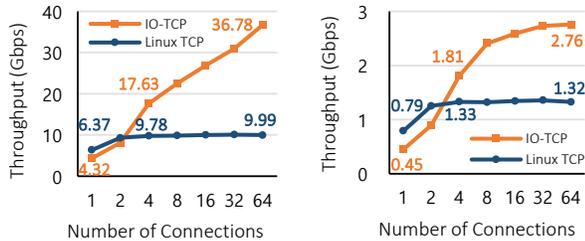

Retransmission timer correction. We evaluate the impact of echo packets that adjust the retransmission timer – when the real data packets are sent out. Figure 10a compares the throughput of lighttpd on IO-TCP with and without timer correction. Without timer correction, the IO-TCP host stack stays at 63.12 Gbps. With timer correction, IO-TCP improves the throughput by 22.6%. This is because IO-TCP without timer correction experiences highly variable RTTs and produces 600x more timeouts than that with timer correction. Such performance drop due to premature timeouts can be more severe in the wide-area-networks (WANs) where the end-to-end RTTs are larger.

RTT measurement correction. We compare the impact of fixing the TCP timestamps on the NIC stack. We measure the average RTT values recorded by the TCP stack every second with 200 concurrent connections. Figure 10b shows that the average RTT is 1 ms with timestamp correction. When we disable the TCP timestamp correction, the average RTT reaches 5 ms, a blowup by a factor of 5. This is because the RTT includes disk access delay that adds a few milliseconds. More accurate latency measurement is critical to trigger the timeout in time when there is a packet loss.

5.4 Overhead Evaluation

The split architecture of IO-TCP may suffer from the communication overhead between host and NIC stacks as well as lower computing capacity of the Arm-based subsystem in the NIC. For this reason, the CPU-only approach on Linux TCP would perform better than IO-TCP for a small number of concurrent connections as CPU can comfortably handle the connections without the overhead. However, this trend will change as the number of connections increases.

Figure 11a shows the throughputs over different numbers of concurrent connections requesting 300KB files. With a single persistent connection, Linux TCP outperforms IO-TCP by over 1.5 times. However, it reaches the peak performance with as few as four connections and the performance stays the same beyond that. In contrast, the throughput of IO-TCP

(a) Throughputs over varying # of connections w/ 300KB files (b) Throughputs over varying # of connections w/ 10KB files

Figure 11: Overhead Evaluation.

slowly increases due to the overhead, but it outperforms the Linux TCP at four connections.

The performance trend continues to hold with smaller file sizes. Figure 11b shows the throughput for serving 10KB files over different numbers of connections. Like in the previous case, Linux TCP and IO-TCP reach the peak performance at 4 and 64 connections, respectively, but their performance is much lower than in Figure 11a due to the increased overhead of file operations. Nevertheless, IO-TCP outperforms Linux TCP at four or more concurrent connections.

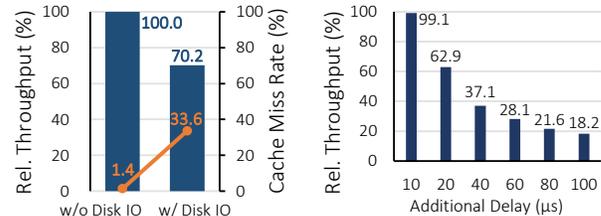

To evaluate the latency overhead, we compare the latency of single-file downloading with IO-TCP vs. Linux TCP. IO-TCP shows 50 to 80us of an extra delay for 10KB files, but the extra overhead goes up to 150 to 200us for 300KB files. This latency overhead at low congestion is inevitable as the host CPU is much faster than the Arm processor in the NIC, but it is negligible for content delivery in wide-area networks.

Memory bandwidth limitation. The performance bottleneck of our current prototype lies in the low memory bandwidth of the BlueField-2 NIC when it accesses more than two NVMe disks. We confirm this by running the same test as in Figure 8a without disk I/O – we observe that the performance reaches 80 Gbps per NIC. Note that disk I/O is the only memory copy for packet payload in our NIC stack as we employ scatter-gather DMA. Nevertheless, we still think our design is promising in the future. First, Arm-based SoC can be designed with much higher memory bandwidth and future SmartNICs would benefit from it. For example, Bluefield-3 [32] is reported to have 3.5x better memory bandwidth (~90 GB/s) than Bluefield-2, and we expect over 100 Gbps per NIC⁷ for the same workload as in Figure 8a. Cavium ThunderX2 [8], an Armv8-based SoC server, has 166 GB/s of peak memory bandwidth, even larger than that of our CPU. Second, improving the memory bandwidth of the SmartNIC is more cost-effective as Arm SoCs are less expensive than server-class x86 CPUs [70] and one can easily scale the overall performance by employing multiple NICs. We note that the current SmartNIC price is very high, but it will go down with wider adoption as evidenced in the GPU prices.

⁷ 40 Gbps (per NIC) × 90 GB/s (BF-3 BW) / 25.6 GB/s (BF-2 BW) = 141 Gbps

Functions	Instr. per cycle	
	Before	After
APP: Parsing HTTP request	0.82	1.57
APP: Writing response header	0.92	1.89
TCP: Check RTO expire	2.65	3.26
TCP: Process ACK	0.13	1.24
Overall IPC	0.93	1.47

Table 4: Comparison of the IPC of lighttpd and control plane functions before and after data plane offloading with IO-TCP.

(a) Relative throughputs and cache miss rates with and without disk IO. (b) Relative throughputs over extra miss rates with and without disk IO delays by the control plane.

Figure 12: Analysis on the source of performance improvement.

5.5 Source of Performance Improvement

We analyze the source of performance improvement with IO-TCP. First, we observe that the control plane functions in the IO-TCP stack run faster after the separation of the data plane. Table 4 indicates that the instructions per cycle (IPC) of the control path in the IO-TCP stack improves by 58% with the division of labor. Especially, ACK processing benefits the most from the split – note that it is the key function that initiates complex operations frequently such as looking up the TCB in the connection table, determining packet loss/duplicate ACKs, computing the new send window size, etc. After the split, the IPC of this function improves by 9.53x. The performance gain mainly comes from reduced cache/memory contention as we find that the cache miss rate of last-level cache (LLC) improves by 27% with the separation. Then, how come the cache miss rate is reduced? This is because DDIO of NVMe disk IO evicts the data in the CPU cache if both planes run together [96]. To confirm this, we measure the TCB lookup performance with and without NVMe disk reading (fio). Figure 12a shows that the cache miss rate of the TCB lookup goes up by a factor of 24 if we co-run disk IO, which in turn reduces the lookup performance by 30%. Finally, we observe that the faster execution of the control plane actually improves the content delivery throughput. To show this, we add redundant code into the ACK processing function so that we can delay its execution by as much as we want. Figure 12b shows that the throughput degrades significantly as the extra delay increases. This implies that the faster control plane reduces the end-to-end RTT and increases the send window size quickly, which ends up improving the overall performance.

6 Related Work

PCIe P2P communications. Enabling PCIe P2P communication between external devices could reduce CPU overhead significantly when transmitting data among them. NVIDIA GPUDirect RDMA [17], GPUDirect Async [45], and AMD DirectGMA [10] techniques, provide a way for other devices to directly access data from GPU by exposing GPU memory directly to PCIe memory space. EXTOLL [79] proposes enabling direct communication between Intel Xeon Phi coprocessors (accelerators) and the NICs, so accelerators can communicate with each other over the network without CPU involvement. Morpheus [91] enables communications between NVMe devices and other PCIe devices. DCS [46] and DCS-ctrl [63] propose a hardware-based framework to enable P2P communication among various types of external PCIe devices. However, all these P2P solutions only consider data communication on hardware, without considering the kernel stacks. As a result, those solutions still suffer from kernel stack overhead when running content delivery applications.

Accelerated networking stacks. There are several existing works that attempt to improve the performance of networking stacks. Some works try to improve the performance of existing kernel stacks. Fastsocket [71] improves the TCP stack performance by achieving table-level connection partitioning, increasing the connection locality, and eliminating the lock contention. StackMap [95] dedicates network interfaces to applications and offer a zero-copy, low-overhead network interface for applications. Megapipe [57] leverages partitioned, lightweight sockets, and batches system calls to improve the performance. Another approach is bypassing the heavyweight kernel stack and running the whole stack in the user level. mTCP [58], IX [49], Sandstorm [73], F-Stack [13], and PonyExpress/Snap [75] leverage user-level packet I/O libraries, and leverage multiple CPU cores to process incoming flows simultaneously, in order to increase the processing throughput and reduce latency from kernel calls. ZygOS [85], Shinjuku [60], and Shenango [80] further improve the tail latency of packet processing by improving the load balancing of the tasks among CPU cores. Arrakis [82] and IO-TCP share the same vision of separation of data and control planes, but Arrakis is focused on bypassing the kernel involvement on the data path while IO-TCP harnesses extra processors for work division of the TCP stack operations. TAS [62] builds a TCP fast path as a separated OS service, which targets to improve the performance of RPC calls in the data center. Disk|Crypt|Net [74] builds a scalable video streaming stack, containing a novel kernel-bypass storage stack and an existing kernel-bypass network stack, which achieves lower latency and higher throughput for video streaming applications. However, all these solutions still require huge CPU involvements in packet processing, which still consumes a lot of CPU power on transmitting data among external devices. A recent work called AccelTCP [78] offloads TCP connection management as well as connection relaying into SmartNIC,

which relieves a part of packet processing computation from host CPU cores. However, it focuses only on improving the throughput for short-lived connections and L7 proxies.

NIC offload. Traditionally, there have been a spectrum of NIC offload schemes. Stateless schemes like TCP/IP checksum offload, TCP segmentation offload (TSO) and large receive offload (LRO) have become ubiquitous in modern NICs while stateful schemes like TCP Engine Offload (TOE) and Microsoft Chimney Offload [25] have largely been deprecated due to security and maintenance concerns coming from its complexity. IO-TCP is essentially TSO with file reading, and we believe it can be easily implemented into commodity NIC hardware due to its simplicity.

More recently, several works have focused on offloading various tasks to SmartNICs to improve the performance for specific applications. KV-Direct [68] leverages FPGA-based SmartNIC to improve the performance of in-memory key-value stores. Floem [83], ClickNP [69], and UNO [66] leverage SmartNICs to accelerate general packet processing for network applications. Metron [61] offloads packet tagging into the NICs to reduce the latency of packet processing for network functions. iPipe [72] builds a general framework for offloading distributed applications into SmartNICs. Lynx [90] uses the SmartNIC as part of an accelerator-centric architecture where the SmartNIC allows direct networking with the accelerators. Gimbal [76] uses SmartNIC as the traffic orchestrator for disk IO, and realizes efficient multi-tenancy using congestion control algorithms and fair scheduling. LeapIO [70] offloads disk IOs to SmartNIC and provides the seamless address space for cloud tenants while [84] handles NVMe-oF on NIC for remote storage access. However, neither supports TCP operations to clients from NIC. To the best of our knowledge, our IO-TCP is the first work that leverages SmartNICs to accelerate disk and packet I/O for content delivery systems.

7 Conclusion

In this paper, we have presented IO-TCP, a split TCP stack design that offloads I/O operations from CPU for scalable content delivery. IO-TCP provides a new abstraction that leverages SmartNIC processors to perform I/O operations, which significantly relieves the pressure on CPU and its main memory system. Also, our proposal maintains the simplicity in the NIC stack design so that it can be easily implemented with low-powered processors on I/O devices.

Our evaluation shows IO-TCP significantly saves CPU cycles while it delivers the benefit even for small-file transfer when it serves enough connections. Along with the benefit, we also discuss the limitations of the current prototype, and we hope that SmartNIC vendors will consider higher memory bandwidth for the embedded system when designing the next version of their SmartNIC. Figure 13: An adaptation of IO-TCP to QUIC.

Appendix

A Support for the QUIC protocol

Unlike TCP/IP headers, the QUIC header is variable-sized, so the host stack should carefully estimate the header size before offloading. Since the data length can exceed an MTU size, the SmartNIC should perform QUIC packet segmentation with generation of QUIC headers as well as UDP/IP headers. In addition to file IO offloading, UDP packet segmentation with large content on SmartNIC could improve the performance further as QUIC on the Linux UDP stack suffers from frequent context switchings for invoking a system call for each UDP packet. For reliable transfer, the host stack should keep track of STREAM frame packet numbers and data offsets that are sent out. Retransmissions can be handled similarly to IO-TCP as the IO-TCP NIC stack manages the file content buffers independently of the particular transport layer protocol. Likewise, the "ACKD" command can free the file content buffers that are confirmed to be delivered to the QUIC client.

We have finished implementing "IO-QUIC" in the plaintext version, and we will add support for TLS in the future. Unlike the IO-TCP implementation, the host stack of our IO-QUIC implementation uses unmodified Linux kernel as it communicates with the NIC stack with a special UDP packet.

B Performance Comparison with Asynchronous `sendfile()` on FreeBSD

Recent FreeBSD supports asynchronous `sendfile()` that does not block on disk reading [30], so we compare the per-

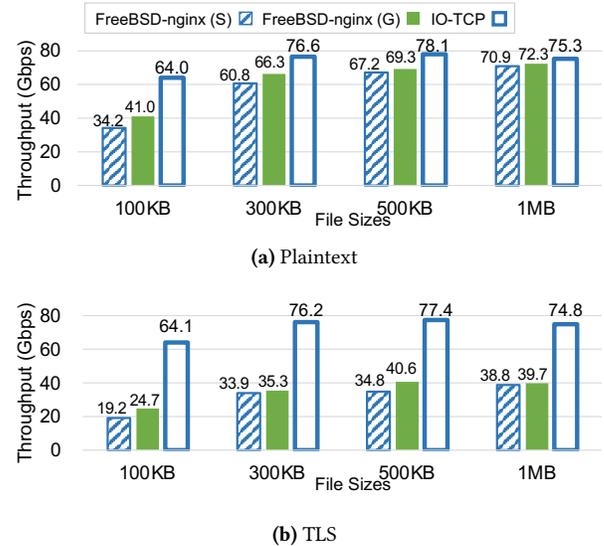

Figure 14: Comparison of maximum performance of nginx that uses asynchronous `sendfile()` on FreeBSD vs. IO-TCP. IO-TCP uses the same number as in Figure 8a and Figure 8b.

formance of nginx (v1.20.1) on FreeBSD (v13.0) that utilizes this feature. Since FreeBSD does not allow disabling individual CPU cores, we use all 20 CPU cores for FreeBSD experiments (FreeBSD-nginx(S)). Also, to gauge the impact of higher-capacity CPU, we employ a different server with two Intel Xeon Gold 6142 CPUs @ 2.60 GHz, a 100G Mellanox ConnectX-5 NIC and 32GB memory of DRAM (FreeBSD-nginx(G)). Again, we use all 32 cores in the two CPUs for the experiments.

Figure 14a shows the results over different file sizes. Overall, FreeBSD achieves better performance than Linux for plaintext transfer, but it does not reach the performance reported in [74] (~70 Gbps with 8 cores). This is because the stock FreeBSD version does not support other features in [74] except asynchronous `sendfile()`. In contrast, IO-TCP outperforms all other setups despite that FreeBSD uses 19 to 31 more CPU cores. In terms of the TLS performance, Figure 14b shows that FreeBSD suffers from the same issue as Linux.

Hydra: Serialization-Free Network Ordering for Strongly Consistent Distributed Applications

Inho Choi¹, Ellis Michael², Yunfan Li¹, Dan R. K. Ports³, and Jialin Li¹

¹National University of Singapore, ²University of Washington, ³Microsoft Research

Abstract

Many distributed systems, e.g., state machine replication and distributed databases, rely on establishing a consistent order of operations on groups of nodes in the system. Traditionally, this ordering has been established by application-level protocols like Paxos or two-phase locking. Recent work has shown significant performance improvements are attainable by making ordering a network service, but current network sequencing implementations require routing all requests through a single sequencer – leading to scalability, fault tolerance, and load balancing limitations.

Our work, Hydra, overcomes these limitations by using a *distributed* set of network sequencers to provide network ordering. Hydra leverages loosely synchronized clocks on network sequencers to establish message ordering across them, per-sequencer sequence numbers to detect message drops, and periodic timestamp messages to enforce progress when some sequencers are idle. To demonstrate the benefit of Hydra, we co-designed a state machine replication protocol and a distributed transactional system using the Hydra network primitive. Compared to serialization-based network ordering systems, Hydra shows equivalent performance improvement over traditional approaches in both applications, but with significantly higher scalability, shorter sequencer failover time, and better network-level load balancing.

1 Introduction

Replication is ubiquitous in data center applications. Consensus protocols like Paxos, Viewstamped Replication, and Raft are used to maintain multiple copies of data, providing the illusion of a single correct service that remains available even as individual replicas fail and recover. However, these protocols impose substantial latency and throughput overhead.

A recent line of work demonstrated that in-network processing can alleviate this cost [42, 43, 56]. This *network sequencing* approach routes requests through a sequencer – implemented in a programmable switch or middlebox – which assigns a monotonically increasing sequence number to each request. By pre-establishing a total order of all requests, they enable lighter weight consensus protocols, ultimately yielding impressive performance gains: Network-Ordered Paxos achieves throughput within 2% and latency within 10% of an unreplicated, non-fault-tolerant system [43].

However, employing this approach in practice is not easy. Fundamentally, the difficulty stems from the fact that *network*

sequencing requires serialization: all traffic for a replicated service must pass through a single sequencer. This poses three major challenges in production networks. First, the single sequencer must process all request traffic, posing a scalability bottleneck. Second, it imposes a new routing requirement for specific application traffic, which network operators are loath to accept. Restricting path diversity interferes with existing policies, carefully engineered for load balancing and fault tolerance. Finally, it introduces an undesirable coupling between network and application-level recovery. Replacing a failed or unreachable sequencer requires coordinating a simultaneous update to the network routes and recovery of the sequencer state (via a consensus protocol). This adds deployment complexity and increases system downtime during the recovery process. All three are serious barriers to adoption, based on our experiences with large-scale production data centers.

This paper asks whether network sequencing can be achieved *without* serialization. We answer that question in the affirmative by presenting the design of Hydra,¹ a new protocol for network sequencing that allows packets to be sequenced by multiple active sequencers. Hydra’s sequencers themselves run a lightweight coordination protocol, in which each sequencer independently assigns sequence numbers to requests that can be merged to establish a total order of operations. Specifically, Hydra leverages a combination of per-sequencer sequence numbers and loosely synchronized physical clocks across sequencers to assign a global ordering while still efficiently detecting dropped messages.

Hydra is a practical protocol; we have built both a software implementation that runs on end hosts and one in P4 [11] that runs on an Intel Tofino programmable switch; the latter uses only a small fraction of switch resources, demonstrating its practicality for modern network devices. Hydra’s sequencing functionality allows it to run the existing NOPaxos [43] and Eris [42] replication and transaction processing protocols with minimal modification, while making them more resilient to sequencer faults with marginal performance cost.

Our evaluation results demonstrate that Hydra achieves a 378% increase in throughput and 42% reduction in latency compared to an atomic multicast baseline, while scaling to high numbers of receivers, multicast groups, and sequencers. Comparing to systems that use a network serialization approach, Hydra significantly improves network-level load bal-

¹Hydra is named after the Lernean Hydra of Greek mythology, a multi-headed serpent that could regrow a new head if one was chopped off [31].

ancing and reduces system downtime by $5\times$. Moreover, Hydra achieves these benefits without sacrificing performance: our Hydra-based state machine replication system gets latency within $5\ \mu\text{s}$ and throughput within 17% of NOPaxos, and our transactional system attains 47% higher throughput than Eris.

2 Background

Establishing a consistent order of operations is fundamental to many distributed systems: state machine replication [43,52,53,61] requires all correct replicas to execute a totally ordered set of client operations; distributed transactional systems [5,14,17,19,26,39] mandate that all shards of the data store process transactions in a serializable order; distributed caches [50,55] require consistent updates to ensure coherence.

Traditionally, guaranteeing strong consistency necessitates running complex application-level distributed protocols which involve coordination among servers. For instance, many state machine replication protocols [52,53,61] designate a single leader to assign an order to operations, and require it to communicate with replicas before returning a result to the client, and existing distributed databases execute concurrency control, atomic commitment, and consensus protocols for each client transaction. This expensive coordination is at odds with the demanding throughput, latency, and scalability requirements of modern data center applications.

2.1 Request Ordering in the Network

The need for these protocols stems from the fundamental assumption of a fully *asynchronous* network which can arbitrarily drop, reorder, or delay messages. A classic line of work in distributed computing proposes stronger communication primitives to simplify distributed applications, including virtual synchrony [8,9], atomic broadcast [10,34], and atomic multicast [28]. These provide broadcast or multicast operations that ensure all correct receivers will deliver the *same set* of messages in the *same order*. Such guarantees can obviate the need for consensus protocols – but implementing them is a problem equivalent to consensus [13], so applications do not enjoy a performance benefit.

Network ordering without reliability guarantees. A recent line of work [42,43,56] proposes a new network model that balances guarantees and implementation efficiency. This new model moves the responsibility of consistent message ordering into the network, but leaves reliable delivery of messages to application-level protocols. By providing ordering guarantees in the network, this network/protocol co-design approach allows faster replication protocols than traditional designs; by *not* enforcing reliability, the network model is simple enough to implement efficiently.

A key mechanism employed by these systems to implement network ordering is *in-network serialization*. For instance, Speculative Paxos [56] routes all client requests first to a designated switch in the network before multicasting to the replica servers. The single switch serves as a serialization

point and ensures that, with high probability, all replicas receive client requests in the same order. NOPaxos [43] extends this serialization approach by using programmable switch ASICs to provide *guarantees* of request ordering. The designated switch stamps a sequence number into each client request. Receivers then ensure consistent ordering by processing requests only in sequence number order. Additionally, sequence numbers allow replicas to identify dropped messages (by detecting gaps in the sequence).

Eris [42] further generalizes the sequencing approach to support requests that are sent to multiple replication groups (e.g., to implement fault-tolerant distributed transactions). The sequencer switch maintains a counter for each group, and on each client request, *atomically* increments the counter value for all destination groups. These counter vectors ensure a consistent ordering of all multi-group operations, while still allowing receivers to independently detect dropped messages.

2.2 Limitations of In-Network Serialization

Prior work [42,43,56] has demonstrated the performance benefits of the network ordering approach and its applicability to several classes of distributed systems. However, the in-network serialization approach employed by existing network ordering solutions has important limitations.

Scalability bottleneck. A key requirement in the serialization approach is that all client requests need to go through a *single sequencer device*. This device can become a performance bottleneck. While in-switch sequencers can sustain a far higher sequencing rate than the server-based replicas that actually execute operations, sequencer capacity can still be a scalability limit for sharded database systems like Eris [42] where one sequencer serves many replica groups. Moreover, if the sequencer is implemented on an end host, as can be more practical for many deployments, poor CPU-based packet processing performance is at odds with the horizontal scaling capability of the system.

Prolonged system downtime. Being a serialization point of all client requests, a failure in the sequencer will result in unavailability of the entire distributed system. Sequencer failover is more complicated than traditional recovery (e.g., changing leaders in a Paxos deployment) because it couples network rerouting with application-level recovery. To resume operation, the network control plane must first detect the failure and carry out network-wide routing changes to redirect client traffic to a new sequencer, and afterwards begin a view change procedure to ensure system state is consistent; only then can replicas process requests from the new sequencer. Rerouting in a large data center network is expensive: previous studies [38,42,43] show that updating forwarding tables in a single switch alone can take more than 200 ms. Before this lengthy rerouting procedure is complete, the system will remain unavailable.

Worsened data center network properties. Data center networks are carefully engineered to provide high reliability, performance, and cost efficiency [2, 27, 49]. By adding redundant paths to the network and using protocols like ECMP, these networks can effectively load balance network traffic, tolerate link and switch failures, and sustain high bisection bandwidth. Serializing traffic through a single switch, however, reduces the number of available paths and can easily nullify these desirable network properties. For example, it can lead to link congestion at the sequencer switch.

Incompatible with multi-pipeline switches. Many switch ASICs scale out processing capacity by using multiple (e.g., 2–8 [18]) separate pipelines, with few or no shared resources. Existing sequencing approaches, however, update and atomically read a single copy of the sequence number. This requirement restricts deploying network sequencing logic to a single switch pipeline [36]. This not only limits the maximum throughput of the network sequencer to a fraction of the switch capacity, it complicates cabling and routing because specific physical ports are bound to each pipeline.

3 Sequencing with Multiple Sequencers

Hydra allows multiple active sequencers to work concurrently, preventing a single sequencer from becoming a scalability bottleneck or a single point of failure. This allows Hydra to support new deployment models for network sequencers.

3.1 Deployment Options

Hydra supports a spectrum of deployment models.

Root switches. Prior work envisioned using programmable switches at the root of a tree topology as sequencers, leveraging their centrality in the data center network. Such switches can handle high request load, making scalability beyond a single switch’s capacity a less urgent concern, but they do so through the use of multiple ASICs and forwarding pipelines which prior sequencer designs do not support. Hydra can also improve availability by decoupling sequencer failover from reroute latency of the underlying network (§7.5). In addition, using multiple Hydra sequencers rather than routing all sequenced traffic through one switch provides path diversity, which allows better link-level load balancing and resilience to link failures (§7.4).

ToR switches. Many existing data center architectures cannot deploy programmable switches at the network core: they use large, multi-ASIC chassis switches at the root layer [15, 27], and programmable switches are not available in this configuration. For example, Tofino-based switches are only available in smaller 32/64-port configurations. For many scenarios, using top-of-rack switches as sequencers is thus a more practical alternative. In such deployments, scalability and fault tolerance are acute concerns: ToR switches fail more commonly [25] and frequently experience congestion on their

uplinks. Hydra can avoid both problems by employing multiple sequencers (§7.4).

Sequencer appliances. In our experience, incrementally deploying new functionality in existing switches, ToR or otherwise, can be a challenge: coordinating updates with existing switch functionality and validating the correctness of a custom data plane are both obstacles. An appealing alternate approach is to employ a cluster of switches as dedicated “sequencer appliances” attached to the network as edge devices rather than being part of the fabric [57], as proposed for other network function accelerators [37, 64]. Again, fault tolerance of individual sequencers and congestion on their network links (which may not exploit the full bandwidth of the switch) are major concerns, which Hydra can alleviate.

End hosts. A final approach eschews specialized hardware in favor of using end hosts as sequencers [43]. This offers obvious deployment benefits and may be the only practical approach for many environments. However, both scalability and fault tolerance are critical here: Eris’s end-host sequencer barely handles the load of a 15-shard database [42], making it an option only for smaller deployments. Hydra’s multiple-sequencer approach allows it to go beyond this limit, providing a practical, scalable approach for environments where specialized hardware is unavailable (§7.1.3).

3.2 Addressing and Routing

Regardless of deployment options, Hydra integrates easily with existing data center routing structures. Each Hydra deployment has a unique IP address. Each sequencer in the deployment advertises its IP address via BGP anycast, allowing routes to be dynamically updated as sequencers join or leave the deployment. Messages are routed to individual sequencers using traditional shortest-path routing and load balancing techniques, e.g., ECMP. Alternatively, in an SDN-oriented design with a centralized controller, the network controller can install appropriate anycast routes for the group of sequencers.

Apart from these routing changes, Hydra does not require any changes to any other elements in the network besides the sequencers themselves. This is a key design constraint, and one that differentiates Hydra from other ordering approaches like IPipe [41], which exchanges timestamps between every switch, as well as complementary techniques like RDMA, which requires complex in-network flow control [29].

4 Hydra: Serialization-Free Network Ordering

4.1 High-Level Abstraction

The core abstraction provided by Hydra is a group communication protocol. A Hydra deployment consists of receiver *groups*, and each group contains one or more *receivers*. Hydra offers a *groupcast* primitive, where a sender specifies one or multiple groups as the destination, and the message is multicast to the receivers in the destination groups. The Hydra groupcast primitive provides the following properties to the

participants:

- **Partial Ordering.** Hydra groupcast messages are partially ordered (the partial order relation is denoted as \prec) – all groupcast messages with overlapping destination groups are comparable. If groupcast message m_1 is ordered before m_2 ($m_1 \prec m_2$) and a receiver receives both m_1 and m_2 , then every receiver delivers m_1 before m_2 .
- **Unreliable Delivery.** Hydra only offers best effort message delivery. A groupcast message is not guaranteed to be delivered to any of its recipients.
- **Drop Detection.** If a groupcast message is not delivered to all its recipients, the primitive will notify the remaining receivers by delivering a DROP-NOTIFICATION. More formally, let R be the set of receiver groups for message m , then either one of the following two conditions holds: **all** receiver groups in R deliver m or a DROP-NOTIFICATION for m , or **none** of the receiver groups in R delivers m or a DROP-NOTIFICATION for m .

These are the same guarantees provided by the network abstractions in NOPaxos and Eris [42, 43]. However, critically, Hydra allows scalability, fast failure recovery, and load balancing across sequencers, where previous designs fell short.

4.2 Prior Approach: Centralized Sequencer

A recent line of work [6, 7, 42, 43, 63] proposed to use dedicated devices in the network – a programmable switch, a network processor, or an end-host server – as a centralized sequencer to establish message ordering. In particular, Eris [42] builds a *multi-sequenced groupcast* primitive that provides the same set of guarantees as we specified in §4.1.

To implement multi-sequenced groupcast, a centralized sequencer maintains a *sequence number* for each group in the system. Senders of a groupcast message encode all recipient groups in a special packet header, and the packet is first routed to the sequencer. Upon receiving a groupcast packet, the sequencer atomically increments the sequence number for each recipient group, and writes a *multi-stamp* into the packet. The multi-stamp contains a set of $\langle \text{group-id}, \text{sequence-num} \rangle$, one for each recipient group. The groupcast packet is then forwarded to each receiver in each receiver group.

Groupcast receivers track the next sequence number they expect from the sequencer. When a receiver receives a groupcast packet, it checks the sequence number that corresponds to its group ID in the multi-stamp. The receiver rejects the packet if the sequence number is lower than the expected value (indicating out-of-order or duplicated messages), and delivers a DROP-NOTIFICATION to the application if the sequence number is higher than expected.

Multi-sequencing provides the three properties of §4.1. By incrementing sequence numbers *atomically*, the sequencer ensures that if two groupcast messages have overlapping groups, all receivers in those groups will deliver the two messages in a consistent order. By maintaining per-group sequence numbers, any packet loss from the sequencer to a receiver

Algorithm 1 SequencerHandlePacket(pkt)

```
id: sequencer ID
N: total number of Hydra groups
clk: switch physical clock
seq[N]: sequence number for each group
1: pkt.id  $\leftarrow$  id
2: pkt.c  $\leftarrow$  clk
3: for grp in pkt.grps do
4:   pkt.seq[grp]  $\leftarrow$  ++seq[grp]
5: end for
6: Forward pkt
```

will result in a gap in the received sequence numbers, and hence a DROP-NOTIFICATION. However, using a centralized sequencer introduces the limitations previously described.

4.3 Consistent Ordering with Multiple Sequencers

Naïvely applying multi-sequenced groupcast to a multi-sequencer deployment violates the guarantees listed in §4.1. Suppose each sequencer independently maintains sequence numbers for each receiver group, and groupcast messages can be forwarded to any of the sequencers. Consider two groupcast messages m_1 and m_2 , both destined to group G_1 , but routed through two sequencers. The two sequencers may write the same sequence number (since they maintain sequence numbers independently) for G_1 into m_1 and m_2 . When receivers in G_1 receive m_1 and m_2 , they cannot consistently order the messages while providing drop detection. Breaking ordering ties with sequencer ID, for example, would be consistent across receivers, but a receiver that only received the “larger” of m_1 and m_2 would have no way of inferring the existence of the “smaller.”

To enforce all the guarantees in §4.1 while scaling to multiple sequencers, we propose a new approach by combining *loosely synchronized clocks* across sequencers and *per-sequencer sequence numbers* to establish consistent ordering and detect drops, and using *periodic flush messages* to ensure receiver progress.

4.3.1 Physical Clocks for Message Ordering

Hydra uses a combination of sequence numbers and physical clocks to order messages. Concretely, each Hydra sequencer possesses a local *physical clock* that is strictly monotonically increasing; each sequencer also maintains a sequence number for each receiver group. Physical clocks are loosely synchronized across sequencers, but this is *not* required for safety; clock skew can only slow progress. Safety of Hydra only depends on physical clocks not drifting *backwards*. This requirement is already common practice: existing clock synchronization protocols such as NTP ensure that clocks can only move forward [51].

Each Hydra groupcast message is routed to one sequencer before being forwarded to all receivers in each destination group. When a sequencer receives a groupcast message, in addition to incrementing the sequence number for each recip-

Algorithm 2 ReceiverHandlePacket(pkt)

M : total number of sequencers

 buf : ordered queue of undelivered messages
 $s[M]$: largest sequence number received (per sequencer)
 $c[M]$: largest clock value received (per sequencer)

```
1: if  $pkt.seq[gid] \leq s[pkt.id]$  then
2:   return
3: end if
4:  $c[pkt.id] \leftarrow \max\{c[pkt.id], pkt.c\}$ 
5: Deliver DROP-NOTIFICATION for
   ( $s[pkt.id] + 1 \dots pkt.seq[gid] - 1$ ) (inclusive)
6:  $s[pkt.id] \leftarrow pkt.seq[gid]$ 
7: if  $pkt$  is not a flush message  $\wedge$   $pkt \notin buf$  then
8:   Add  $pkt$  to  $buf$ 
9: end if
10: for  $p$  in  $buf$  do
11:   if  $p \preceq \min\{c[m], m\} : m \in (1 \dots M)$  then
12:     Dequeue  $p$  from  $buf$  and deliver  $p$ 
13:   else
14:     break
15:   end if
16: end for
```

ient group and inserting a multi-stamp, it writes its current clock value into the packet (Algorithm 1 line 2-5). Note that reading the clock value and incrementing sequence numbers must be done in an atomic block. Strict monotonicity of physical clocks and the above atomicity requirement ensure the following: for any two groupcast messages m_1 and m_2 with an overlapping recipient group g sequenced by the same sequencer, $s_1 \neq s_2 \wedge (s_1 < s_2 \iff c_1 < c_2)$, where s_1 and s_2 are the assigned sequence numbers for g , and c_1 and c_2 are the assigned clock values.

With a clock value inserted into each groupcast message, Hydra defines the partial ordering (\prec) of groupcast messages in the following way: for groupcast messages m_1 and m_2 with overlapping recipient groups and clock values c_1 and c_2 sequenced by sequencers with IDs i and j , $m_1 \prec m_2$ if $c_1 < c_2 \vee (c_1 = c_2 \wedge i < j)$ ². Breaking ties between equal clock values using sequencer IDs is necessary in guaranteeing the partial order property in §4.1.

Hydra groupcast receivers deliver groupcast messages to their users *according to our partial order*. If a receiver receives groupcast messages m_2 before m_1 with $m_1 \prec m_2$, it must either deliver a DROP-NOTIFICATION for m_1 before delivering m_2 or add m_2 to a buffer until it receives m_1 . However, delivery based on physical clocks alone is not strong enough to detect message drops.

4.3.2 Combining Physical Clocks and Multi-Stamps for Drop Detection

Attaching sequence numbers to messages offers the useful property that any dropped message can be detected by observ-

²For ease of exposition, we slightly abuse the \prec notation: it applies to both groupcast messages and (clock value, sequencer ID) tuples.

ing gaps in the number sequence. Unfortunately, this property is lost when using physical clocks to order messages – a receiver seeing a message with a clock value c cannot determine if it missed any message with $c' < c$. To detect message drops, Hydra combines physical clock values and sequence numbers from multiple sequencers. Hydra receivers buffer incoming messages and deliver them in clock value order, but *only* once they have determined – based on sequence numbers – that no message with a lower clock value from another sequencer will be delivered.

Specifically, each Hydra receiver maintains two values for each sequencer i (Algorithm 2): the largest group sequence number $s[i]$ it has received from i , and the largest clock value $c[i]$ among messages it has received from i . Let c_{min} be the minimum value among all $(c[i], i)$ tuples, ordered by \prec . A Hydra receiver delivers messages using the following rules:

- (i) it delivers pending groupcast messages in clock value and sequencer ID order (line 10),
- (ii) it will only deliver a single message or DROP-NOTIFICATION for each sequence number from each sequencer (lines 1 and 6),
- (iii) it only delivers groupcast messages m if $m \preceq c_{min}$ (line 11), and
- (iv) when receiving groupcast message m with sequence number s from sequencer i , if $s > s[i] + 1$, it delivers a DROP-NOTIFICATION for each message from $s[i] + 1$ to $s - 1$ (line 5).

From our discussion in §4.3.1, rules (i) and (ii) ensure the partial ordering property of Hydra groupcast. To show how rules (iii) and (iv) enforce drop detection, we leverage a key invariant: for a receiver r in group g and for any groupcast message m that has g as a recipient group, if $m \preceq c_{min}$, then r has either received m , or has received another groupcast message m' stamped with a higher sequence number from the same sequencer. With this invariant, the drop detection property of Hydra groupcast is guaranteed, since r either delivers m (m is received and rules (i) and (iii)), or delivers a DROP-NOTIFICATION for m (m' is received and rule (iv)). As an optimization, Hydra receivers can delay the delivery of DROP-NOTIFICATIONS until a message is needed to advance c_{min} . Because Hydra is robust to message reordering, this does not affect the correctness of the receiver protocol.

4.3.3 Ensuring Progress with Flush Messages

Our groupcast design so far ensures all the properties listed in §4.1, but has one remaining issue. In order for a receiver to make progress in delivering messages, it needs to receive groupcast messages from *all* sequencers to advance c_{min} . For instance, if a receiver has received message $m \succ c_{min}$, to deliver m , the receiver needs to receive messages from other sequencers to advance c_{min} . Consequently, any single sequencer that stays idle for an extended period of time would impede the progress of all groupcast receivers in the system.

To ensure progress in message delivery, each sequencer

Message Legend

$$M_1 = \langle G, 1, \{(1,1), (2,1)\}, 42 \rangle \quad M_2 = \langle G, 2, \{(1,1)\}, 42 \rangle \quad F_1 = \langle F, 1, \{(1,3), (2,2)\}, 80 \rangle$$

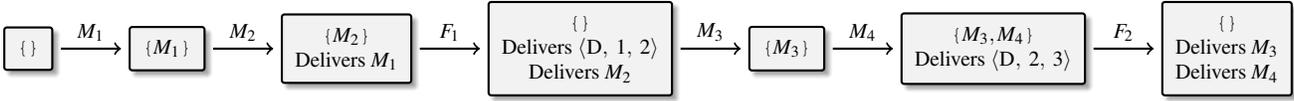

$$M_3 = \langle G, 2, \{(1,2)\}, 85 \rangle \quad M_4 = \langle G, 2, \{(1,4)\}, 90 \rangle \quad F_2 = \langle F, 1, \{(1,3), (2,4)\}, 98 \rangle$$

Figure 1: An example execution of the Hydra message delivery protocol. At every step, the state of the Hydra buffer is displayed along with any messages delivered to the application. Hydra groupcasts are written $\langle G, \text{sequencer}, \text{multi-stamp}, \text{timestamp} \rangle$, while flush messages are written $\langle F, \text{sequencer}, \text{multi-stamp}, \text{timestamp} \rangle$, and DROP-NOTIFICATIONS are written $\langle D, \text{sequencer}, \text{sequence_num} \rangle$. A multi-stamp is a set of $(\text{group}, \text{sequence_num})$ tuples. This execution follows a receiver in group 1 receiving messages from two sequencers, 1 and 2. Transitions between states of the receiver show the message being received.

periodically sends a *flush* message to all groupcast receivers containing its current clock value and the latest sequence number that the sequencer has sent to each receiver group (without incrementing). When a receiver receives a flush message from sequencer i , it follows the same procedure (§4.3.2) to advance $c[i]$, c_{min} , and $s[i]$. Applications are unaware of flush messages. Receivers, however, still use the sequence number in flush messages to deliver DROP-NOTIFICATIONS, following rule (iv) (Algorithm 2 line 5). Again, Hydra receivers can delay the delivery of DROP-NOTIFICATIONS until they are needed as an optimization.

The above protocol guarantees that, in the absence of failures (we discuss failure handling below), all received groupcast messages on every receiver will eventually be delivered. Clock divergence on different sequencers can delay message delivery (up to the clock skew), since c_{min} on each receiver depends on the sequencer with the slowest clock value, but cannot violate any of the safety properties.

Figure 1 shows an example execution of Hydra from the point of view of a single receiver receiving groupcast and flush messages from two sequencers. At every step of the execution, the receiver accepts an incoming message and delivers groupcasts and DROP-NOTIFICATIONS and retains pending groupcasts in its local buffer according to the rules defined in §4.3.2.

4.4 Handling Sequencer Failures

If a sequencer fails or link failures occur between a sequencer and some of the groups, some (or all) groupcast receivers will stop delivering messages, since they no longer receive messages from the failed sequencer and are unable to advance c_{min} . We use a reconfiguration protocol to address this issue.

Concretely, each Hydra deployment uses a centralized, fault-tolerant configuration service to manage a sequence of configurations. Each configuration specifies the set of sequencers and groupcast receivers (here we only discuss changes to sequencers across configurations). Groupcast receivers also store the current configuration locally. When a receiver suspects that sequencer j in the current configuration n has failed, e.g., when it has not received messages from

sequencer j in a timeout period, it notifies the configuration service. The configuration service creates a new configuration $n + 1$ with sequencer j removed, and sends the configuration to all groupcast receivers.

When groupcast receivers receive the new configuration, they run an agreement protocol to agree on the last sequence number each receiver group should deliver from the failed sequencer. To do so, each Hydra receiver additionally stores, for each sequencer, the largest sequence number it has seen in a multi-stamp for each receiver group (not just its own). To continue the sequencer removal process, each receiver sends a message with the largest sequence numbers (for all groups) it has received from the failed sequencer to the configuration service and stops processing messages with higher sequence numbers from that sequencer. Once the configuration service receives a quorum of these messages from each receiver group, it aggregates them to derive the highest sequence number each receiver group has or should have received from the failed sequencer. The configuration service sends a removal message to each group. A groupcast receiver delivers all necessary DROP-NOTIFICATIONS based on this removal message and continues to deliver messages following the rules in §4.3.2; the removal message serves as a final flush from the failed sequencer (with an infinitely large timestamp). Once all pending messages from the failed sequencer have been delivered, the receiver can safely transition to the new configuration. To avoid inconsistencies caused by different configurations, a receiver always attaches its current configuration number when delivering messages to the application.

Discussion. How does Hydra’s recovery protocol compare, in terms of availability, to single-sequencer systems like those originally used by NOPaxos and Eris? Like these systems, Hydra experiences an interruption in message delivery caused by the failure of a sequencer. However, Hydra receivers can resume delivering messages from the other sequencers once they run the above protocol, which requires coordination only between the receivers, not the network layer. Thus, its unavailability period depends only on failure detection time and the agreement protocol latency, which can be orders-of-

magnitude shorter than the duration of network rerouting. It can also support more aggressive sequencer removal with shorter timeouts. Even though deploying more sequencers increases sequencer failure probability, by avoiding network rerouting on the critical path, Hydra still achieves overall improvement in system availability.

Adding new sequencers. To add a sequencer k to the system, the configuration service similarly creates a new configuration $n + 1$ with sequencer k added, and sends the configuration to all receivers. Once a receiver receives the new configuration, it stops delivering groupcast messages to the application, and waits until it receives a flush message from the new sequencer k that has a higher timestamp than its latest delivered message. It then sends that flush message to the configuration service. When the configuration service receives a quorum of flush messages from each receiver group, it picks the flush message with the highest timestamp, denoted as t_k , and broadcasts that flush to all receivers; t_k effectively serves as the starting time of the new configuration. A receiver then resumes delivering messages for the previous configuration, until the next-to-be-delivered message has timestamp bigger than t_k . At that point, the receiver transitions to the next configuration, sets $s[k]$ to the sequence number in the flush message it receives from the configuration service, and starts delivering messages from the new sequencer. Note that if an old sequencer (removed previously) rejoins in a new configuration, the sequencer’s ID is reassigned to a value unique from all other IDs, and its sequence numbers are all reset.

4.5 Correctness

We provide a detailed discussion of the safety of the Hydra protocol in [Appendix B](#). In addition, a TLA⁺ specification [40] of the Hydra groupcast and sequencer addition/removal protocols ([Appendix C](#)) has been model checked against Hydra’s safety guarantees.

The liveness of the Hydra protocol is straightforward: as long as (1) receivers continue to receive groupcasts or flush messages from non-failed sequencers, and (2) the configuration service remains available and can communicate with a quorum of each receiver group to remove failed sequencers and complete the addition of new sequencers, Hydra groupcasts will be delivered.

4.6 Optimizations

Flush messages facilitate progress of Hydra receivers. However, generating flush messages at an overly aggressive rate will adversely affect a receiver’s performance, as these flush messages consume network, CPU, and I/O resources. To strike a balance between message delivery latency and throughput, we propose two optimizations: receiver-side flush message solicitation and in-network flush message aggregation.

4.6.1 Receiver-Side Flush Message Solicitation

In our basic protocol described in §4.3.3, sequencers periodically send flush messages to all receivers. We can manually tune the flush message generating interval \mathbb{T} on sequencers to adjust the latency/throughput trade-off: a smaller \mathbb{T} improves message delivery latency but increases the load on the receivers, while a larger \mathbb{T} has the opposite effect. However, since flush messages are broadcast to all receivers, this one-value-for-all policy cannot account for the different processing capacities and load levels on different receivers. Moreover, blindly sending flush messages every \mathbb{T} time unit, particularly when \mathbb{T} is small, can result in significant amount of unnecessary traffic. To see why this is the case, consider a receiver that currently has no message to deliver. Any flush message sent to this receiver, before the next Hydra message (with a higher clock value) arrives, will have no effect on the receiver’s delivery progress and thus are strictly unnecessary.

Our key observation is that *receivers*, not sequencers, have perfect knowledge of when flush messages are required: receivers only need flush messages to make progress *when they possess undelivered messages*. We therefore propose a receiver-centric optimization, in which sequencers do not actively generate flush messages; instead, receivers explicitly request flush messages when needed. This optimization also enables various solicitation policies on the receivers. To optimize for latency, a receiver can immediately request flush messages when it receives groupcast messages that cannot be delivered. To optimize for throughput, it can delay requesting flush messages, equivalent to a batching approach. It can also apply a more sophisticated approach where it determines the solicitation delay based on the current load of the receiver, adaptively optimizing for both latency and throughput.

4.6.2 In-Network Flush Message Aggregation

Our message delivery rules (§4.3.2) require that a receiver delivers a groupcast message if and only if it has received messages with higher clock values from **all** other sequencers. The implication of this rule is that, the number of flush messages required to deliver a groupcast message increases *linearly* with the number of sequencers. To further reduce the processing overhead caused by excessive flush messages, we propose an advanced optimization technique inspired by recent in-network aggregation work. Concretely, we leverage ToR programmable switches connected to Hydra receivers to track each sequencer’s clock value and sequence numbers. These numbers are updated when a ToR switch receives a flush message, but it does not immediately forward the flush message to the receiver. Only when the minimum stored clock value becomes large enough, the switch sends a single aggregated flush message containing all the clock values and sequence numbers to the receiver. To accurately determine this threshold, receivers attach the largest clock value among all undelivered messages in its flush message solicitation request. The ToR switch uses this value as the clock threshold,

which guarantees that the aggregated flush message would allow the receiver to deliver all undelivered messages in the buffer (those when the solicitation request was made). By applying our in-network aggregation optimization, the number of flush messages a receiver processes remains constant regardless of the number of sequencers.

5 Hydra Implementation

A Hydra deployment contains a dynamic set of groupcast senders, receivers, and sequencers, managed by a configuration service. We use a centrally-controlled SDN approach for managing groupcast routing: a POX [58]-based SDN controller installs rules that route groupcast messages to a randomly-selected reachable sequencer. When using end-host sequencers, we use a source routing approach: the configuration service tracks addresses of sequencers, which are cached on Hydra senders. When sending groupcast messages, senders randomly pick one of the sequencers and send to it via unicast. No special network routing is required.

Hydra sequencers each maintain minimal state: a unique sequencer ID, a sequence number for each receiver group, and a physical clock that is monotonically increasing. One of our key design principles is *simplicity*. It enables us to implement a Hydra sequencer *efficiently* on different hardware platforms.

In-network sequencing using programmable switches. Implementing Hydra sequencers in the data plane of network switches offer the highest sequencing performance, as current programmable switches can process billions of packets per second, with switching latency consistently under a few hundred nanoseconds. Hydra groupcast is implemented as an application-level protocol atop UDP. We reserve a special UDP port for Hydra groupcast, and append a customized Hydra header after the UDP header. The Hydra header includes a bitmap to specify the destination groups, a vector of sequence numbers (one for each destination group), and a single clock value. The switch implementation uses one switch register array element for each receiver group to store its current sequence number. The switch checks each bit of the bitmap, and for each enabled bit, increments the corresponding sequence number register and writes the sequence number into the Hydra header. Since there is no dependency across groups when processing a groupcast message, bit checking and sequence number updating for all destination groups can be done in parallel. This enables us to significantly reduce the required pipeline stages, allowing us to scale to higher number of groups. Subsequently, the switch stamps the hardware clock time into the header, and uses the replication engine to multicast the packet to receivers.

End-host Sequencers. Implementing Hydra sequencers on end-host servers offers better flexibility and portability, particularly attractive for deployments that cannot deploy specialized hardware. The downside is comparatively lower packet processing performance. Our Hydra protocol, however, en-

ables scaling sequencing performance by adding additional sequencers. As we will show in our evaluation (§7.1.3), throughput of Hydra scales linearly with the number of sequencers.

Sender and receiver libraries. Hydra provides user-space libraries for sending and receiving groupcast messages. In addition to coordinating with the configuration service to track active sequencers and groups, this library also implements receiver-side buffering to deliver messages in the right order, and the flush message solicitation policies of §4.6.1. We have implemented two I/O stacks for the libraries. First, a polling-based DPDK [23] stack for efficient, kernel-bypassed packet processing. Second, a Linux-based transport using sockets and libevent [45] for better compatibility. Our evaluation in §7 uses the DPDK stack.

6 Building Distributed Systems using Hydra

Our Hydra groupcast primitive has a unique set of trade-offs between its guarantees and efficiency of the implementation. Compared to best effort primitives such as unicast and IP multicast, Hydra offers strong message ordering guarantees; compared to atomic broadcast and atomic multicast primitives, Hydra does not guarantee reliable message delivery, but can be implemented efficiently using a single phase protocol. In order to show the benefits of its design, we applied Hydra to two recent distributed systems – NOPaxos and Eris [42, 43] – and built a state machine replication called HydraPaxos and a distributed transaction processing system called HydraTxn.

Hydra’s groupcast provides the same guarantees as the network protocols used in NOPaxos and Eris (Ordered Unreliable Multicast and Multi-sequenced Groupcast). Therefore, Hydra is readily composed with these existing protocols. HydraPaxos and HydraTxn use the NOPaxos and Eris protocols to tolerate server faults and handle DROP-NOTIFICATION, while use Hydra to provides message ordering guarantees and allows the adding and removing of sequencers. The only necessary modifications to NOPaxos and Eris are the disabling of their sequencer failure handling protocols, as this is handled by Hydra itself. Both HydraPaxos and HydraTxn can commit operations in a *single round trip* in the normal case.

HydraPaxos. HydraPaxos is a state machine replication system based on NOPaxos that tolerates crash failures of less than half of the replicas (or equivalently, with $2f + 1$ replicas, HydraPaxos tolerates f crash failures). It guarantees linearizability [30] as long as the application state machine is deterministic. Each HydraPaxos deployment registers a unique Hydra groupcast address. HydraPaxos clients send state machine operations as a groupcast message with a single destination group. Each replica in a HydraPaxos deployment acts as a single Hydra receiver of the group. HydraPaxos operations are handled in a single round trip in the normal case. Once Hydra delivers an operation to the replicas, the replicas use the NOPaxos protocol to ensure operations are committed durably. Briefly, each replica adds the operation to

its log, and the *leader* replica executes the operation against the current state. Clients wait for consistent replies from a majority of replicas (including the leader) before considering a reply committed. When a DROP-NOTIFICATION is delivered to a replica, replicas need to reach consensus on the fate of the message – either to process or to permanently ignore – to ensure linearizability. The replica first attempts to recover the missing message by contacting other replicas in the group. If replicas fail to recover the dropped message, they coordinate (driven by the leader) to commit the message as a NO-OP.

HydraTxn. HydraTxn, is a fault-tolerant, distributed transaction processing system. HydraTxn partitions the entire data store into multiple shards with each shard replicated on multiple servers. Clients wrap data reads and writes into transactions. HydraTxn guarantees atomic, strict serializable execution of the transactions, and tolerates failures of less than half of the replicas in each shard. Similar to HydraPaxos, each HydraTxn deployment uses a unique Hydra groupcast address. Each shard of the deployment is assigned a unique group, and each replica in the shard registers a Hydra group receiver, delivering Hydra messages and DROP-NOTIFICATIONS. For transactions that qualify as independent transactions – stored procedures that has no dependency across shards and requires no client interactions – clients send the transaction in a single Hydra groupcast message destined to all the involved shards. HydraTxn also supports more general transactions by dividing them into multiple independent transactions and using two-phase locking on the servers to ensure isolation. As in HydraPaxos, independent transactions are handled in a single round trip in the normal case. Replicas in each shard involved in the transaction log the transaction and reply to the client, with the leader of each shard additionally executing the transaction. Clients wait for majority quorums from each shard to reply before considering a transaction committed. Since a transaction groupcast may involve multiple shards, DROP-NOTIFICATION requires all involved shards, not just the local group, to reach consensus on the reception/dropping decision. Similar to Eris [42], we use a logically separate, fault-tolerant failure coordinator service to manage this agreement protocol.

7 Evaluation

Our Hydra implementation includes Hydra host libraries, switch data and control planes, end-host sequencers, and Hydra co-designed replication (HydraPaxos) and transactional (HydraTxn) protocol implementations. The switch data plane is implemented in 1040 lines of P4 [11] code, and the switch control plane is written in 493 lines of Python code. We implemented the end-host sequencer, Hydra host libraries, the HydraPaxos protocol, and the HydraTxn protocol in approximately 8000 lines of C++ code.

Our evaluation testbed consists of 10 nodes connected to an APS BF6064X-T (Barefoot Tofino-based) programmable switch. We ran servers/replicas on nodes with dual 2.90GHz Intel Xeon Gold 6226R processors (32 total cores), 256 GB

RAM. We used the remaining nodes to run clients and end-host sequencers. Clients use 2.10GHz Intel Xeon Gold 6230 processors (20 total cores) and 96 GB RAM. All nodes ran Ubuntu Linux 20.04 and use Mellanox ConnectX-5 100 GbE NICs. We statically partitioned resources on the programmable switch to implement multiple switch sequencers.

7.1 Hydra Groupcast Microbenchmarks

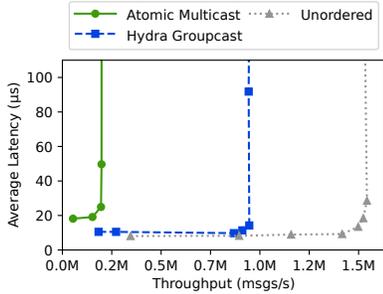

We first used microbenchmarks to evaluate the performance of our Hydra groupcast primitive. We ran closed-loop clients, each sending groupcast messages to a set of receiver groups. When a Hydra receiver *delivers* a groupcast message, it immediately replies to the client. Clients send the next groupcast message when they receive replies from each receiver in all destination groups (we assume no receivers fail).

We compared Hydra to two other groupcast implementations. First, we implemented a version of genuine atomic multicast [28]. To atomic multicast a message, a client first sends the message to all the receivers in each destination group. Receivers in each group run a consensus round to agree on a message timestamp and send the group timestamp to the client. The client picks the highest timestamp as the final message number, and forwards the message number to all involved group receivers. Receivers deliver messages in message number order. Second, we implement an unordered multicast – receivers immediately deliver client messages without any ordering guarantee – as a baseline.

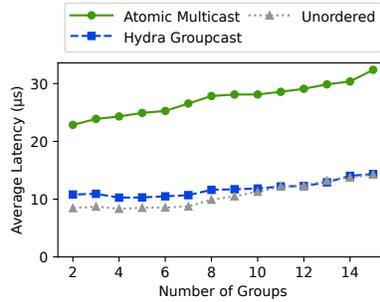

7.1.1 Latency and Throughput

In the first experiment, we used a single group with three receivers to evaluate the base case performance. Two switch sequencers were deployed when evaluating Hydra, and we applied the receiver-side solicitation optimization (§4.6.1). We gradually increased the offered client load, and measured both the latency and the throughput of each system. As shown in Figure 2a, Hydra achieves a 378% increase in throughput and 42% reduction in latency compared to atomic multicast. Running consensus among group receivers for each message adds substantial throughput and latency overheads to atomic multicast. On the contrary, Hydra receivers require no coordination among each other to deliver messages in consistent order. In the worst case, they wait for a half RTT (receiver → switch → receiver) to receive flush messages in order to deliver a groupcast. This overhead is reflected in Hydra’s small latency penalty (3 μ s) compared to the baseline. As Hydra receivers can deliver messages without explicit flush messages when sequencers receive enough traffic, Hydra is able to attain throughput within 39% of the baseline.

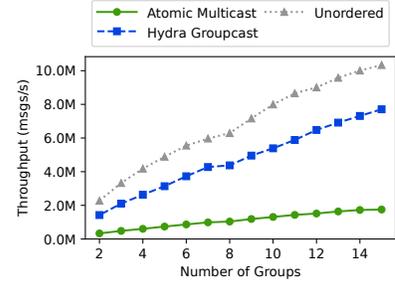

Increasing group size. Next, we added more receivers to the group. When we increased the group size threefold (from three to nine), throughput of Hydra dropped only by 8%, and its latency remained the same. Hydra scales well to larger group sizes because receivers can independently determine the correct order of messages with no coordination. Perfor-

(a) Latency and throughput for a single group of three receivers

(b) Latency with increasing number of groups

(c) Maximum throughput with increasing number of groups

Figure 2: Latency and throughput of running a micro multicast benchmark. We use two switch sequencers for Hydra, and compare its performance to an atomic multicast and an unordered multicast protocol. For (b) and (c), we use a group size of three.

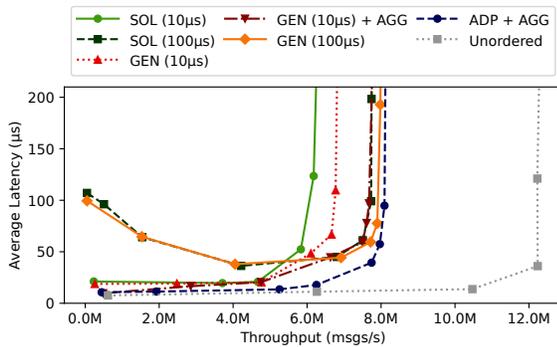

Figure 3: Impact of different flush message policies and parameters on performance of Hydra. The policies are: the receiver solicitation strategy (SOL), sequencer generation strategy (GEN), adaptive solicitation strategy (ADP), ToR switch aggregation (AGG).

mance of atomic multicast, however, degrades proportionally to the number of receivers as the cost of consensus increases. At group size of nine, Hydra outperforms atomic multicast by 567% in throughput and 56% in latency.

Scaling to more groups. To test how well Hydra scales to larger number of groups, we fixed the group size to three receivers, and increased the total number of groups. We used a workload where 80% of the groupcast messages were destined to a single group, and the remaining 20% had two destination groups. Clients chose destination groups following a uniform distribution. As shown in Figure 2b and Figure 2c, Hydra’s throughput and latency continue to closely match the baseline. At 15 groups, throughput of Hydra is within 25% of the baseline, and 340% higher than atomic multicast.

7.1.2 Impact of Flush Messages

As we discussed in §4.6, policies for generating and handling flush messages can affect Hydra performance. To evaluate their effectiveness, we ran 15 groups each with three receivers, deployed four switch sequencers, and measured the latency and throughput of Hydra with increasing client load. We apply three flush message policies and show their impact in Figure 3: (1) sequencers periodically generate flush messages (GEN),

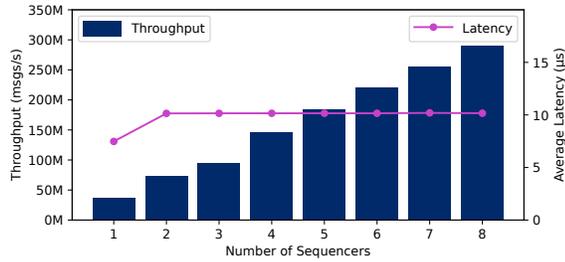

(2) receivers solicit flush messages from sequencers after a delay (SOL), (3) receivers adaptively solicit flush messages based on current load (ADP). We also examine the impact of having ToR switches aggregate flush messages from sequencers (AGG).

When we use a higher delay for generating or soliciting flush messages, receivers on average need to wait longer to deliver messages. This effect is validated by the higher average latency experienced by GEN and SOL when their delay is at 100 μ s. By decreasing the delay, both policies enjoy better message delivery latency. Unfortunately, it also degrades maximum throughput, as receivers use more CPU cycles to process flush messages – up to 14% lower throughput for GEN. ToR switch aggregation reduces the impact of frequent flush messages: AGG improves the throughput of GEN by 14%. Finally, by using an adaptive solicitation strategy, ADP achieves both low latency – it immediately requests flush messages when it has spare CPU cycles – and high throughput – it does not receive excessive flush messages at high utilization. As shown in Figure 3, it attains latency within 3 μ s and throughput within 33% that of the baseline result.

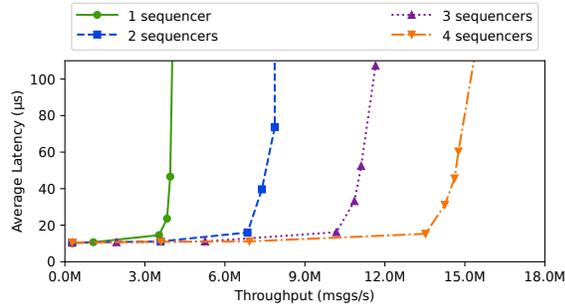

7.1.3 Sequencer Scalability

To evaluate the sequencer scalability of Hydra, we emulated an increasing number of switch sequencers (up to eight) on the same physical switch. For each emulated sequencer, we allocated a dedicated queue in the switch traffic manager that rate limits to 10 Gbps. Due to the limited number of physical servers, we only deployed 15 real Hydra groups, each with three receivers. To saturate the sequencers’ capacity, we deployed additional virtual groups, whose request traffic were simply dropped at the switch egress ports. Figure 4a shows that throughput of the system increases linearly with more deployed switch sequencers. With eight sequencers, Hydra can process more than 250 million groupcast per second. The additional switch sequencers also have minimum impact on groupcast latency.

For clusters without programmable switches, sequencers can be deployed on end-host servers, offering an immediately

(a) Latency and sustainable throughput of Hydra with increasing number of switch sequencers

(b) Latency and throughput of Hydra with increasing number of end-host Hydra sequencers

Figure 4: Scalability of Hydra with increasing number of sequencers. We use 15 groups, three receivers per group, and deploy sequencers on switches and end-host servers. We also generate additional group-cast traffic to virtual Hydra groups to saturate the sequencers.

deployable solution. End-host sequencers, however, have limited processing capacity compared to an in-switch implementation. Figure 4b shows that Hydra can avoid this dilemma by adding more end-host sequencers, with near-linear scaling. With enough Hydra traffic, request load were evenly distributed among all sequencers. Since receivers need to wait for at least one message from each sequencer for message delivery, latency of Hydra increases slightly with more sequencers.

7.2 HydraPaxos Evaluations

Next, we evaluate the performance benefits of co-designing state machine replication (SMR) systems with Hydra. We compared our HydraPaxos to three other SMR protocols: Paxos (with the Multi-Paxos optimization), Fast Paxos, and NOPaxos. We also ran an unreplicated system with no fault tolerance as a baseline. All protocols were implemented in the same codebase for a fair comparison. We deployed each SMR system on three replica servers, ran an echo-RPC application, and measured the end-to-end latency and throughput of each system with increasing client load. We used two switch sequencers for HydraPaxos, and one switch sequencer for NOPaxos. Figure 5 shows HydraPaxos achieves significantly higher throughput than Paxos (204%) and Fast Paxos (180%), by avoiding replica coordination in the common case. Figure 5 also shows that our design can attain performance comparable to a network serialization approach: HydraPaxos achieves

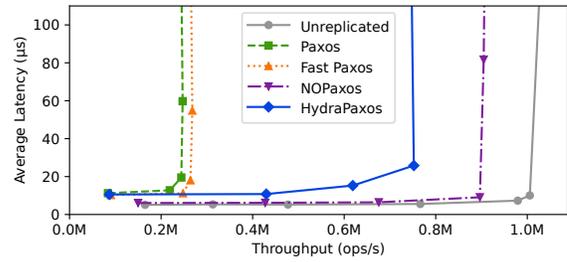

Figure 5: State machine replication system comparison. We measure the latency and throughput of HydraPaxos and other SMR protocols with three replicas. HydraPaxos uses two switch sequencers.

latency within 5 μ s and throughput within 17% of NOPaxos. Like NOPaxos, HydraPaxos can sustain its throughput even with a moderate rate of packet drops ($\leq 0.1\%$), because drop recovery uses a lightweight protocol; a full evaluation appears in Appendix A.

7.3 HydraTxn Evaluations

The second distributed application we evaluated was a fault-tolerant, distributed transactional system. We compared HydraTxn with three other systems: Granola [19], Eris [42], and a standard distributed transactional system [17] called Lock-Store that uses two-phase commit, two-phase locking, and Paxos. All systems are implemented in the same code base. We deployed each system on 15 database shards, each replicated on three servers. HydraTxn uses two switch sequencers, while Eris uses only one. Similar to our experiment in §7.1.3, we rate limit each sequencer’s bandwidth in the switch traffic manager and generate traffic to virtual Hydra groups.

We use the YCSB+T [16] benchmark that wraps read and write operations into stored-procedure style transactions. The workload we used consists of single-shard transactions with a read/write ratio of 1:1. Keys are selected using a uniform distribution. As shown in Figure 6, HydraTxn avoids server coordination overhead when processing transactions, leading to a $3.1\times$ and $1.9\times$ throughput, and a 49% and 13% latency reduction compared to Lock-Store and Granola. Performance of Eris is bottlenecked by the single switch sequencer. Excessive client load can even cause sequenced packets to be dropped in the network, leading to throughput collapse due to more frequent drop agreement protocol [42]. Hydra enables HydraTxn to scale beyond the central sequencer bottleneck, achieving a 47% throughput improvement over Eris.

We also tested HydraTxn’s resilience to network anomalies by injecting simulated packet drops. As in the SMR experiment, small to moderate levels of packet drops have minimal impact on HydraTxn’s performance (Appendix A).

7.4 Network-Level Load Balancing

To evaluate the impact of our approach on network properties, we simulated a data center network with a three-layer FatTree topology in NS3. The network consisted of 2560 servers and 112 switches. All servers generate background traffic follow-

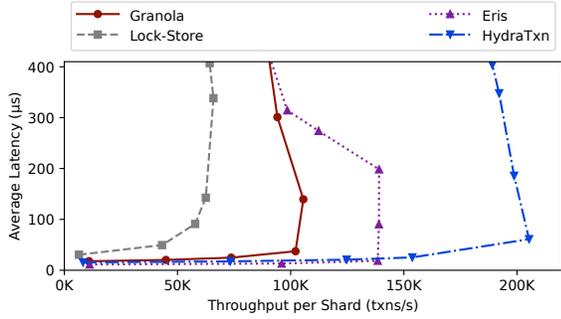

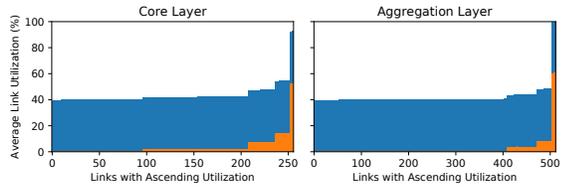

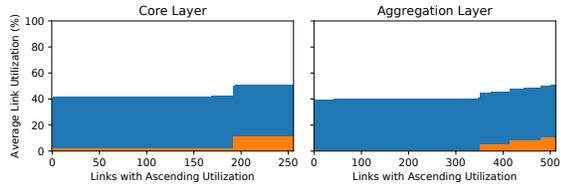

Figure 6: Distributed transactional system comparison. We measure the latency and per-shard throughput of HydraTxn and other transactional systems when running on 15 shards each replicated on three servers. HydraTxn uses two sequencers, while Eris uses one sequencer.

(a) Network link utilization when multicast messages traverse a single ToR switch sequencer

(b) Network link utilization when multicast messages are randomly routed to one of the eight ToR switch sequencers

Figure 7: Average link utilization of a simulated data center network. We simulate a three-layer FatTree topology with 2560 servers and 112 switches. Links between servers and ToR switches are 1 Gbps, and all other links are 10 Gbps.

ing a Poisson distribution. We set up 16 multicast receiver groups in the network, each with three receivers. We selected a few servers across the data center to generate periodic multicast messages, each message destined to a randomly selected group. We compared two approaches: a network serialization approach where all multicast messages are routed through a single ToR switch, and the Hydra approach where eight ToR switches are deployed as sequencers. Figure 7 shows the link utilization of each aggregation and core layer link for each approach. In the network serialization deployment, several aggregation layer links were fully saturated due to concentrated multicast traffic. By distributing multicast traffic across multiple sequencer switches, utilization of all core and aggregation links stayed below 50% in the Hydra deployment, demonstrating the load balancing benefit of our approach.

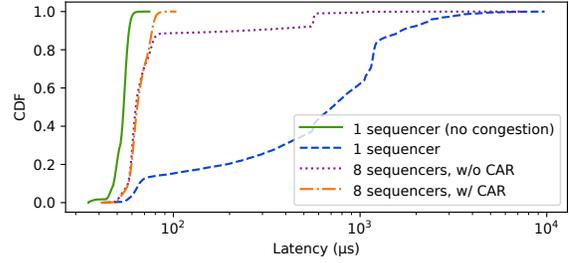

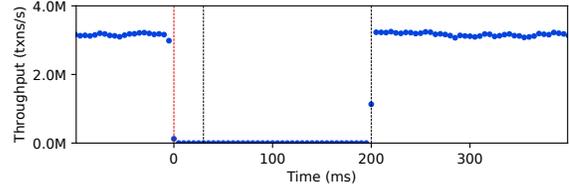

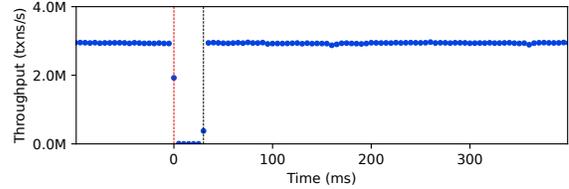

Figure 8: Latency distribution of multicast in the same simulated data center network as Figure 7. We generate bursty traffic to a single sequencer switch that causes congestion.

(a) Throughput of Eris during a sequencer failover

(b) Throughput of HydraTxn during a sequencer failover

Figure 9: Throughput of Eris and HydraTxn during a sequencer failover. For both, we injected a sequencer failure at time 0.

We then studied the impact of network congestion by generating bursty background traffic to one of the sequencer switches. Figure 8 shows that in a network serialization deployment, congestion at the sequencer switch caused median multicast latency to degrade by more than 13 \times . By distributing multicast traffic to multiple sequencer switches, Hydra reduces the impact of local congestion and improves the median latency by 11 \times . We also simulated congestion-aware routing (CAR) [3] for Hydra. By preferentially routing to non-congested sequencers, Hydra further improves multicast tail latency.

7.5 Sequencer Failover

Lastly, we evaluated the effectiveness of Hydra in handling sequencer failures and compared it to the network serialization approach. To do so, we used the same transactional system setup in §7.3, triggered a sequencer failure during the run, and measured the sustained throughput over time. As shown in Figure 9b, after the Hydra receivers detected the failure of one of the sequencers (we used a 30 ms timeout value), they immediately ran a reconfiguration protocol to remove the failed sequencer. The protocol only took a few hundred microseconds. HydraTxn was able to resume normal operation

and returned to its maximum throughput afterwards, using the remaining sequencers. By contrast, Eris (Figure 9a) relies on the network control plane needed to perform rerouting once a failure is detected, to forward client requests to a new sequencer switch. We simulated a 100 ms rerouting delay which matches results in the literature [38]. Unlike HydraTxn, Eris remained unavailable during network rerouting, demonstrating the benefit of our redundant sequencer approach.

8 Related Work

Ordered group communication primitives such as atomic multicast [28] have a long history, dating back to virtual synchrony [8], and have been implemented and used widely [4, 9, 32, 34, 62]. The classic atomic broadcast model is equivalent to consensus [13]. Our work explicitly adopts the *ordered but unreliable* communication model introduced by NOPaxos [43] and Eris [42], which enables network-accelerated sequencing.

Other distributed systems also use sequencers. CORFU [63] combines an unreliable sequencer with replicated storage on flash to build a shared log that can be used to build distributed data structures [7]. vCorfu [63] extends it to a multi-log abstraction analogous to multi-sequencing. Scalog [22] addresses the blocking reconfiguration and sequencer scalability issues of previous shared log designs by distributing log data to replicated data shards and periodically order log entries using an Paxos-based ordering layer. Hydra does not guarantee message persistence, so it avoids the overhead of intra-shard replication. Hydra also eliminates coordination among the sequencers on the critical path, which reduces message delivery latency and avoids potential bottlenecks of a centralized ordering service. Percolator [54] uses a sequencer for transaction processing, and deterministic databases like Calvin [60], SLOG [60], and Aria [47] combine sequencers with transaction schedulers for concurrency control.

Hydra builds on work on improving the scalability of consensus protocols. Its use of multiple active sequencers and flush messages is analogous to Mencius’s rotating leader [48]. Hydra uses loosely synchronized clocks [46] to establish a total order, an idea used in concurrency control protocols like CLOCC [1], Spanner [17], and TAPIR [66]. Protocols like PTP [59] make clock synchronization widely available in data centers, and recent work like Sundial [44] and DPTP [35] demonstrates the precision available. Hydra’s approach of using timestamps to order operations is similar to that of TEMPO [24]. However, TEMPO requires at least one and a half RTTs to commit a timestamp. Hydra, using network sequencers, can commit timestamps in half of an RTT even in the presence of concurrent requests. Similar to TEMPO, Hydra also waits for higher timestamps from other sequencers to ensure a timestamp is stable.

Hydra is designed to support programmable devices as sequencers, including PISA/RMT switch ASICs [12]. Recent work shows that these switches can implement complex pro-

ocols including consensus [20, 21] and chain replication [33]. Like NOPaxos and Eris, Hydra intentionally implements a limited set of sequencing functionality on the switch, leaving most of the protocol complexity at the end hosts. Red-Plane [37] and SwiSh [64, 65] provide abstractions for replicating switch data plane state for reliability and scalability, respectively; sequencing, which requires strong consistency and frequent updates, represents a worst-case performance scenario for both, necessitating a different approach.

A concurrent effort, IPipe [41] uses programmable switches in a data center to implement causally and totally ordered communication. Senders in IPipe attach local timestamps to messages, and receivers deliver messages strictly in timestamp order. To determine when a timestamp is safe to deliver, switches in IPipe track barrier information from all ingress links and write the aggregated barrier timestamp into each packet. Hosts and switches periodically send beacon messages on idle links to ensure progress.

Hydra similarly uses timestamps to order messages. A key difference is that IPipe uses sender-generated timestamps, while in Hydra timestamps are generated by the sequencers. Consequently, IPipe requires synchronized clocks on *all* nodes in the network and in-network computation at *each* switch, a deployment challenge in heterogeneous networks where not all switches are programmable [57]; Hydra accommodates more practical deployments by only running logic on the sequencers and replicas, and only synchronizing clocks across sequencers. Moreover, in a IPipe deployment, any node, link, or switch failure in the network would stall the progress of all receivers; in Hydra, only failures local to the sequencers may impact progress.

9 Conclusion

The deployment of network sequencing approaches has been hindered because they require serializing messages through a single sequencer. Hydra addresses this with a new protocol that allows the concurrent use of multiple sequencers. A Hydra deployment serves as a drop-in replacement for sequencers in systems like NOPaxos and Eris, making their benefits more widely accessible. In particular, it scales beyond the performance of a single sequencer, which allows commodity servers rather than programmable switches; reduces system downtime during sequencer failures; and improves network load balancing by avoiding serialization.

A Additional Evaluation

A.1 Clock Skew

Clock skew among sequencers does not affect Hydra correctness, but can delay message delivery progress. To evaluate the impact of clock skews, we deployed eight switch sequencers, 15 groups (no virtual groups), and three receivers in each group. We injected artificial clock skews to different sequencers, and measured both the latency and throughput of Hydra. As shown in Figure 10, clock skew does not impact Hydra throughput. Messages stamped by sequencers with faster clocks are buffered temporarily on the receivers, but the rate of delivering messages remains the same. At small to medium clock skews (1 to 10 μs), Hydra experiences marginal latency penalties (0 to 5 μs). Such clock skews are realistic: modern clock synchronization protocols [59] can maintain clock skews in the sub-microsecond range, and recent work has demonstrated synchronization error under 50 ns between programmable switches [35]. Even a 200 μs clock skew only resulted in less than 100 μs of added latency.

A.2 Message Loss for HydraPaxos and HydraTxn

Handling message drops. When Hydra messages are dropped in the network, HydraPaxos replicas need to coordinate to handle DROP-NOTIFICATIONS. To evaluate HydraPaxos’s resilience to network anomalies, we measured its maximum throughput when an increasing percentage of packets were artificially dropped in the network. Figure 11 shows that HydraPaxos is able to sustain its high throughput even with a moderate rate of packet drops ($\leq 0.1\%$). HydraPaxos uses a lightweight protocol to recover from DROP-NOTIFICATIONS, as long as the message is not dropped on *all* replicas. At higher drop rates, throughput of HydraPaxos starts to decline due to more frequent coordination. We observe a similar level of throughput reduction for NOPaxos at these high drop rates.

We conduct the same experiment for HydraTxn. As in the SMR experiment, small to moderate levels of packet drops have minimal impact on HydraTxn’s performance (Figure 12): its peak throughput decreased only by 11% even when the network dropped 1% of packets, and remained higher than that of Eris.

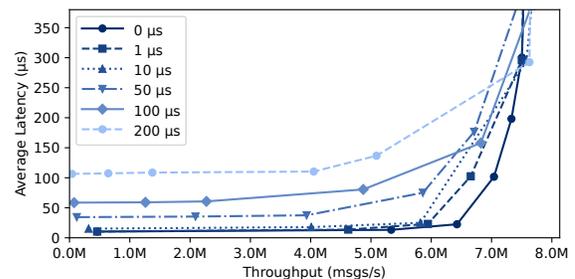

Figure 10: Latency and throughput of Hydra with increasing clock skew among sequencers. We use 15 groups, three receivers per group, and eight switch sequencers. Clock skew shows the maximum skew between any two sequencers.

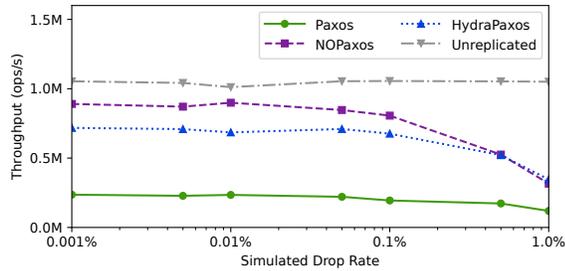

Figure 11: Maximum throughput of SMR systems with increasing packet drop rate. All systems run on three replicas. HydraPaxos uses two switch sequencers.

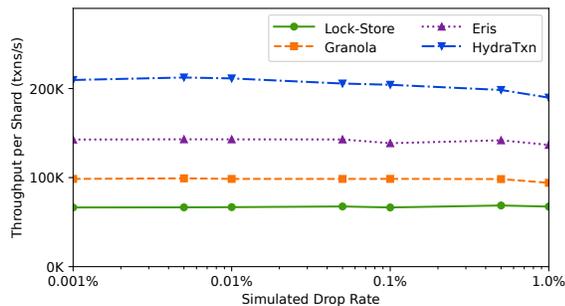

Figure 12: Maximum throughput of transactional systems with increasing packet drop rate. All systems run on 15 shards each replicated three-way. HydraTxn uses two switch sequencers.

B Proof of Safety

As specified in §3.1 Hydra provides the following guarantees to receivers of groupcast messages:

- **Partial Ordering.** All groupcast messages are partially ordered (the partial order relation is denoted as \prec) – all groupcast messages with overlapping destination groups are comparable. If groupcast message m_1 is ordered before m_2 ($m_1 \prec m_2$) and a receiver receives both m_1 and m_2 , then every receiver delivers m_1 before m_2 .
- **Unreliable Delivery.** Hydra only offers best effort message delivery. A groupcast message is not guaranteed to be delivered to any of its recipients.
- **Drop Detection.** If a groupcast message is not delivered to all its recipients, the primitive will notify the remaining receivers by delivering a DROP-NOTIFICATION. More formally, let R be the set of receiver groups for message m , then either one of the following two conditions holds: **all** receiver groups in R deliver m or a DROP-NOTIFICATION for m , or **none** of the receiver groups in R delivers m or a DROP-NOTIFICATION for m .

It is important to note that Hydra receiver groups, like NOPaxos and Eris receiver groups, use quorum-based protocols to decide which messages are delivered to the group and which are permanently dropped. In order to tolerate the failure of some receivers in a receiver group, the drop detection requirement only considers each receiver group as a whole. Here, a receiver group delivers a message m or DROP-

NOTIFICATION for m if every receiver in some quorum delivers m or a DROP-NOTIFICATION for m . Individual receivers in a group can diverge from the quorum when a sequencer is added or removed, and the receiver groups themselves must be able to handle this divergence. (NOPaxos and Eris do handle this case.) If an application using Hydra requires that the drop detection property apply uniformly to all receivers, then the quorum size for each receiver group is the size of the entire group.

Also important to note is that in the drop detection requirement, when we say a receiver delivers a DROP-NOTIFICATION for message m , what we mean is that the receiver delivers a DROP-NOTIFICATION for m before delivering any message ordered after m in the partial order. In this way, the drop detection requirement is indeed a safety requirement and not a liveness guarantee.

In the absence of sequencer failures, the correctness of Hydra’s groupcast delivery is straightforward. Receivers deliver groupcast messages only when the message’s clock value is less than or equal to c_{\min} , the minimum among the latest timestamps received from each of the sequencers. In fact, they only deliver messages whose timestamp is exactly c_{\min} , as ties in clock value are broken by sequencer ID. Because receivers only deliver messages in sequence number order, once message m is delivered by a receiver, no message with smaller sequence number or clock value from m ’s sequencer will be delivered by the receiver. Therefore, messages are always delivered in (timestamp, sequencer ID) order, which is a total order; the partial ordering guarantee is satisfied *a fortiori*. Furthermore, because receivers always deliver DROP-NOTIFICATION for smaller undelivered sequence numbers before delivering a message when there would be gaps in the sequence numbers delivered for that sequencer, the drop detection guarantee is satisfied.

In order to show that the sequencer removal process is correct, we first note that it is consistent with the Hydra safety guarantees for a receiver to at any time deliver a DROP-NOTIFICATION for the next sequence number yet to be delivered for some sequencer. The sequencer removal process is functionally equivalent to each receiver delivering infinitely many DROP-NOTIFICATIONS for all non-delivered sequence numbers for that sequencer. The agreement round is only necessary to determine exactly how many DROP-NOTIFICATIONS each receiver must explicitly deliver based on the results from each quorum. If a message m or a DROP-NOTIFICATION for m is delivered by a quorum from group g , and the sequencer that sequenced m is removed, then the configuration service is guaranteed to receive a multi-stamp with a sequence number for g at least as high as m ’s. Before transitioning to the new configuration (or delivering any message with a timestamp larger than m ’s), all other receiver groups that m was sent to must deliver a DROP-NOTIFICATION for m . Similarly, if no quorum from any receiver group received m or a message with sequence number larger than m ’s before agreeing to

stop processing messages from the removed sequencer, then m will never be delivered by any receiver group (nor will an explicit DROP-NOTIFICATION for m be delivered by any receiver group). Therefore, for every groupcast sequenced by the removed sequencer, either all groups deliver the message or a DROP-NOTIFICATION for it or none do, satisfying the drop detection requirement.

When a sequencer is added, the flush message with timestamp t_k constructed by the configuration service when adding sequencer k is sent to all receiver groups. t_k is necessarily larger than the clock value of any message delivered by a quorum of receivers by construction. No message from sequencer k with clock value less than or equal to t_k will be delivered, nor will any DROP-NOTIFICATION for a message from sequencer k with clock value less than or equal to t_k . t_k was derived from a flush message that included sequence numbers for all groups, and upon entering the new configuration, a receiver immediately sets its sequence number for the added sequencer to the one included in this flush message. Conversely, once the new configuration starts, receivers in the new configuration will deliver messages or DROP-NOTIFICATIONS from the new sequencer with timestamp greater than t_k following the normal protocol for message delivery. Therefore, for any groupcast sequenced by the added sequencer, either all groups deliver the message or a DROP-NOTIFICATION for it or none do, satisfying the drop detection requirement.

C Hydra TLA⁺ Specification

MODULE *Hydra*

Specifies the *Hydra* protocol.

Receiver groups in this model are treated as single entities. This is done to increase model checking performance and avoid making assumptions about the protocol being run by the receiver groups. This specification focuses on the Hydra protocol and avoids the details of the quorum-based protocol being run by the receivers.

The Benefit of Hindsight: Tracing Edge-Cases in Distributed Systems

Abstract

Today’s distributed tracing frameworks are ill-equipped to troubleshoot rare edge-case requests. The crux of the problem is a trade-off between specificity and overhead. On the one hand, frameworks can indiscriminately select requests to trace when they enter the system (head sampling), but this is unlikely to capture a relevant edge-case trace because the framework cannot know which requests will be problematic until after-the-fact. On the other hand, frameworks can trace everything and later keep only the interesting edge-case traces (tail sampling), but this has high overheads on the traced application and enormous data ingestion costs.

In this paper we circumvent this trade-off for any edge-case with symptoms that can be programmatically detected, such as high tail latency, errors, and bottlenecked queues. We propose a lightweight and always-on distributed tracing system, Hindsight, which implements a *retroactive sampling* abstraction: instead of eagerly ingesting and processing traces, Hindsight lazily retrieves trace data only *after* symptoms of a problem are detected. Hindsight is analogous to a car dash-cam that, upon detecting a sudden jolt in momentum, persists the last hour of footage. Developers using Hindsight receive the exact edge-case traces they desire without undue overhead or dependence on luck. Our evaluation shows that Hindsight scales to millions of requests per second, adds nanosecond-level overhead to generate trace data, handles GB/s of data per node, transparently integrates with existing distributed tracing systems, and successfully persists full, detailed traces in real-world use cases when edge-case problems are detected.

1 Introduction

Troubleshooting failures and performance problems in large-scale distributed systems is crucial. On one side, tiny performance misbehavior in a production system could be costly [1, 2, 19]. On the other side, exacerbated by growing system complexity, diagnosing problems takes onerous effort from system developers and requires significant engineering resources. Distributed tracing was invented as the solution of troubleshooting distributed systems by recording detailed, end-to-end traces of request executions, and have been proved helpful for a wide range of use cases [59, 62].

Prior distributed tracing works have demonstrated a wide range of use cases. Common-case analysis focuses on aggregated system behaviors, such as monitoring resource usage [46, 59, 60, 62, 70]. In contrast, edge-case troubleshooting (§2.1), the topic of this paper, focuses on rare and outlier system behavior, such as tail latency [18, 38, 48, 69, 74].

Since an edge case is rare by definition, tracing edge cases requires trace coverage of all requests. In typical production environments, tracing *every* request—including transmitting, processing, and storing comprehensive telemetry—requires enormous backend infrastructure and storage that is unacceptable to infrastructure operators. State-of-the-art tracing frameworks manage this overhead by collecting a small sample (0.001%) of traces [9, 34, 37, 64]. Though previous works practically reduce tracing overhead through head sampling [34, 64] and tail sampling [36, 37] techniques, they cannot trace edge cases at scale (§2.3).

In this paper, we resolve the problem of tracing edge-case requests in production environments. To achieve this, we focus our attention on *symptomatic* edge cases, where the performance effects of the problem manifest shortly after its causes and where the impacts can be observed programmatically. We propose **retroactive sampling** to collect telemetry data *back in time* from the present moment of detection from all machines that serviced the request. The key idea is to generate all trace data but only collect useful data through a retrieval mechanism.

To implement retroactive sampling, we built Hindsight—an always-on, lightweight distributed tracing system that is compatible with existing tracing APIs—as a practical tool for edge-case analysis. Under retroactive sampling, all trace data is recorded locally but only reported when a symptom is detected, allowing applications to generate copious trace data in case they are needed without encumbering the tracing system’s backend collection infrastructure. Retroactive sampling ultimately reports the same volume of trace data as other sampling methods, but ensures that edge-case traces are not missed. To provide efficient and coherent retroactive sampling, Hindsight’s design separates its dataplane, *e.g.* generating trace data into fast local memory, from control logic, *e.g.* for indexing metadata, coordinating among machines, and triggering collection for symptomatic requests on demand.

As demonstration, we apply Hindsight on three use cases corresponding to our running examples. We run experiments on the DeathStar Microservices Benchmark [24], the Hadoop Distributed File System [63], an Alibaba benchmark derived from production traces [42], and on several micro-benchmarks. We have integrated Hindsight with OpenTelemetry [52] and as a replacement collection component for X-Trace [23]. Our experimental results show that Hindsight imposes nanosecond-scale overhead when generating trace data, can scale to 55 GB/s of data per node, rapidly reconstructs traces when triggered, and coherently captures problematic traces (>99%), as well as related lateral traces, within 100 ms of identifying a symptom.

In summary, our paper makes the following contributions.

- We describe the retroactive sampling abstraction for capturing traces of symptomatic edge-cases.
- We present the design of Hindsight, a distributed tracing system that implements retroactive sampling. Hindsight is compatible with existing tracing APIs and can be transparently integrated with existing applications.
- We apply Hindsight on real-world use cases and show that efficiently collecting edge-case requests is practical.
- We evaluate Hindsight on multiple benchmarks and real systems, showing that it can achieve nanosecond-level overhead on trace data generation and handle GB/s data per node while collecting coherent traces.
- We illustrate that Hindsight is compatible and performs better than state-of-the-art tracing systems (X-Trace and Jaeger) with more efficient trace-data generation and lower overhead, while providing edge-case tracing.

2 Motivation

2.1 Edge-Case Troubleshooting

Consider the following three examples of real-world use cases UC1–UC3 of edge-case troubleshooting from prior work.

Error diagnosis (UC1). Hardware failures, component errors, exceptions, and programming mistakes abound in large production systems [73]. Application developers often play the role of detective, to identify root causes of errors. An error might only arise due to a specific, rare combination of factors and code paths exercised; the symptoms of a problem often manifest far from the root causes [22, 41, 45], and the potential root causes are manifold, perhaps combined software or hardware problems on many nodes or network links [35].

Tail-latency troubleshooting (UC2). Distributed systems track a wide range of high-level health metrics, such as API distributions, latency percentiles, resource utilization, and many others [33, 34]. An operator may observe an unusual metric jump, say the 99th percentile latency has spiked for some important API. However, knowing about the spike is not enough; the application developer must identify the specific service, code paths, or conditions that contribute to the peak to address any underlying problems [18, 38, 48].

Temporal provenance (UC3). Many modern distributed systems respond to requests through an architecture of loosely coupled microservices [62]. Application developers need tools for tracking queuing issues when the number of components in a distributed system is large [3–6, 8], since a request R exhibiting symptoms (*e.g.* prolonged queueing time) may not be the true culprit for the backlogged queue. Rather, the developer wants to follow the *temporal provenance* of R to determine *lateral traces* of other related requests with which R interacted through shared components and queues [72].

2.2 Distributed Tracing

Distributed tracing frameworks are in widespread use in both open-source [31, 52, 78] and major internet companies [34, 58, 64] to chronicle *end-to-end requests*. A trace is a recording of one request, and each trace contains spans, events, and annotations, along with timing and ordering, generated from every machine visited by the request. Compared to traditional logs and metrics, the key distinction of distributed tracing is that a trace captures the full end-to-end structural flow of request execution across all components visited.

Advantages. Distributed tracing is thus particularly useful for troubleshooting cross-component problems in large systems, since the request traces explicitly tie together the individual slices of work performed across different machines, enabling an operator to observe how the work done by one machine influences, and is influenced by, work done on others [23, 58, 64, 68]. Prior research on distributed tracing demonstrates a range of use cases, including common-case analyses centered on aggregate system behavior, distributions over data, and relationships between system components [34, 59, 60, 62].

Limitations. Since edge-case troubleshooting concerns rare and outlier system behavior, the symptoms and evidence of a problem might only manifest in a very small fraction of requests. Unfortunately for the operator, this sparsity may yield exceptionally few exemplar traces of edge-case behaviors and symptoms, owing to the design of modern distributed tracing frameworks. Let us look closer at how traces are captured before returning to this problem.

Current designs. Fig. 1 depicts a typical distributed tracing framework [34, 52, 58]. When a new request arrives at the application, the tracing framework assigns it a unique traceId (①). Every request is assigned a traceId, but not every request is actually traced; the framework sets a per-request sampled flag to indicate as such. From this starting point, the application then propagates the traceId and sampled flag alongside the request at the application level and includes them with all inter-process communication (②).

Any component that handles the request can generate trace data (*e.g.* spans, events) using the tracing framework’s client library (*e.g.* OpenTelemetry [52])—trace data is only generated if sampled is set. Trace data gets explicitly annotated with the traceId, thereby associating the data with the request (③).

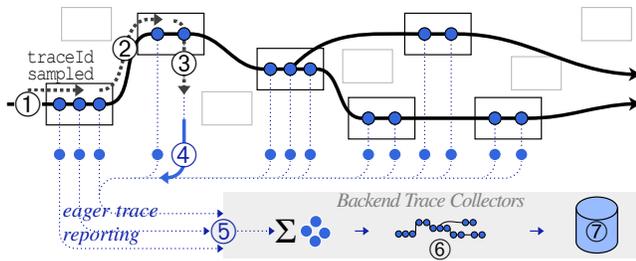

Fig. 1: Distributed tracing (§2.2). A request (solid black line) traverses system processes, depositing trace data that is eagerly ingested into the trace collector backends. End-to-end trace objects are constructed from trace data, processed, and stored in a database.

Ultimately there may be many components and machines that handled the request and contribute trace data. At the same time, many requests may execute concurrently (*e.g.* in different server handler threads), generating temporally-interleaved data with different traceIds.

The framework’s client library eagerly enqueues, serializes, and transmits trace data (4) to its centralized backend collection infrastructure, or *backend* for short (5). The backend is distinct from the traced applications and is responsible for continually receiving, processing (6), and storing (7) trace data generated across all of the application’s components. The backend uses the traceId to *join* data that was dispersed across many machines but belongs to same request into a single coherent trace object. The backend finally persists that trace object in a database if it decides to retain the trace.

Overhead vs. incompleteness. Traces can be detailed and produced at high volume, risking overheads. Traces at Google, for instance, are typically more detailed than debug-level logging [64]; each traced request at Facebook, similarly, generates several MBs of tracing data and approximately 1 billion traces are captured per day [34]. At high rates, tracing frameworks may encounter several potential bottlenecks: when generating data within the traced application (3); when transmitting trace data over the network (4); and in backend processing and storage (5–7).

To reduce overheads, the de facto practice is to capture fewer traces. Here, operating at the granularity of an entire trace maintains *trace coherence*: if a request is sampled, then the whole trace is kept including all data across all machines; otherwise nothing is kept. Coherent traces are essential for distributed tracing – a partial or fragmented trace has limited value in diagnosis [23, 29, 30, 64] because it loses the end-to-end visibility that makes the trace useful in the first place [58, 59, 68]. There are two main approaches for foregoing traces coherently: the system may decide to omit a request at 1 before tracing and ingestion (*head sampling*) or the traces may be filtered after collection at 6 (*tail sampling*).

Head sampling reduces overheads by simply tracing fewer requests in the first place, *i.e.* by setting the sampled flag for only a small fraction of requests (1). By leaving sampled unset for the majority of requests, trace data will not be recorded

for most requests, thus avoiding application overheads to generate data, ingestion overheads to transmit and process data, and storage overheads (3–7). Head sampling is widely used in practice; it is enabled by default in Jaeger [31] with a 0.1% sampling probability, and some production systems sample as few as 0.001% [34, 64].

Tail sampling is used to drop traces at the trace backends (6). Unlike head sampling, the application will still trace all requests and will incur all expenses of generating and ingesting the trace data (3–5). Tail-based sampling primarily allows backends to lower the trace storage costs by selectively dropping traces after combining them into trace objects but before committing them to storage [36, 37, 53].

2.3 Edge-Case Troubleshooting Troubles

Recall that edge-case problem symptoms only manifest in a small fraction of requests, which are undetermined until the problem takes place. We argue that current approaches are ineffectual at getting traces of edge-cases.

Head sampling sacrifices edge-cases. Indiscriminate sampling decisions made at the *beginning* of a request (1), while useful for curbing overhead, *cannot* know a priori whether a request will encounter a rare edge-case problem and should be traced. For edge-case troubleshooting this presents an obstacle: a low head-sampling probability (*e.g.* 0.1%) means a trace of the problem will exist with low probability (*i.e.* 0.1%). The developer may thus have reports that errors took place (UC1) yet the corresponding ‘rare’ requests were not sampled when those requests began—they lack the detailed cross-machine data necessary for finding the error’s root cause. Likewise, the application’s high-level metric monitoring may indicate a spike in end-to-end tail-latency (UC2); the developer is thus aware that these high-latency outliers exist, yet without a trace, they cannot localize the problem to a particular component or request class. The situation is even more problematic when investigating bottlenecked queues via temporal provenance (UC3): since each request was sampled independently, the tracing system will have only a vanishing probability that traces of *all* relevant requests in the queue were captured.

Tail sampling sacrifices overheads and scalability. Practitioners have long pointed out a discord between what traces are interesting and what traces get head-sampled [7, 9, 11, 54, 55]. Fortunately, many common edge-case symptoms, including error codes (UC1) and high end-to-end response time (UC2), can be recorded directly within the trace data itself. This enables tail-samplers to explicitly seek out edge-case traces, because at this point (6) they can directly inspect the constructed trace object. Today’s tail-samplers support filtering traces based on span attributes or metrics, thereby targeting a range of outlier symptoms such as high tail latency, unexpected error codes, uncommon attributes, rare code paths, and undesirable behavior such as RPC retries [7, 10, 32, 40, 49, 53, 58, 67].

Tail-sampling entails enormous costs, however: they must

trace all requests and ingest all trace data in order to make informed decisions. Application latency and throughput can suffer if tracing libraries lack optimization (*e.g.* $2\times$ throughput reduction using OpenTelemetry tail-sampling (§6.4)). Ingesting all traces consumes substantial network bandwidth between applications and collectors, interfering with latency-sensitive application traffic (*e.g.* up to 200 MB/s per node (§6.4)). Tail-sampling demands large backend infrastructure investment, deploying enough collectors to receive and process all incoming traces (*e.g.* even one chatty RPC server can overwhelm an OpenTelemetry collector (§6.4)). Even assuming perfect horizontal scaling, tail-sampling requires *e.g.* $100\times$ the collector capacity of 1% head-sampling. Lastly, tracing frameworks are also not robust to bottlenecks mid-way through ingestion (*e.g.* network backpressure) and quickly lose trace coherence when overloaded.

Practitioners sacrifice edge-cases. The justified pragmatism of avoiding large overheads means that head sampling reigns supreme in real-world distributed tracing deployments [21, 26, 30, 34, 64]. Even tail-sampling features of commercial products have low thresholds on data ingestion (*e.g.* <350 kB/s per host [65], <34 spans/s per host [50], <6 MB/s per collector [39]) after which vendors will automatically enable head-sampling or incoherently drop spans. Ultimately, the operator who wishes to troubleshoot edge cases is left unfulfilled.

3 Approach

Hindsight aims to overcome today’s trade-off between overheads and edge cases. Our goal is to enable practitioners to target edge-case traces with the flexible criteria of tail sampling, while retaining overheads similar to that of head-sampling, *i.e.* without high application overheads or substantial additional backend infrastructure. We now describe several insights that lead us to Hindsight’s *retroactive sampling* approach.

It is not expensive to generate trace data. We don’t know a priori whether a request will be an interesting edge-case; only after symptoms manifest. Paradoxically, once we observe symptoms, it is too late to just enable tracing from that point on, as we have already missed the events that led to the anomaly. The only sure-fire way of obtaining coherent traces for any edge-case is to record trace data from the very beginning of the request, for every request.

Tail-sampling does just that—with high overheads and steep infrastructure costs. However, these costs are primarily because today’s tracing frameworks tightly couple trace generation with trace ingestion. Ingesting data is expensive, incurring network and backend infrastructure costs. Generating data into local memory is not—outside of distributed tracing, *e.g.*, we observe new technology like Intel PT can generate 100–200 MB/s of processor telemetry per core at 5–15% runtime overhead [28]; likewise method-tracing techniques for Android applications exhaustively record all function entries and exits with <1 ns per tracepoint and $<3\%$ runtime

overhead [43]. We believe that comparable overheads should be possible for distributed tracing. With careful client library design, applications should be able to generate detailed trace data locally into memory, in anticipation of that data being useful if a problem occurs.

Retroactive sampling: nodes generate, but do not ingest, all trace data.

Symptoms are locally observable. Although root causes are many, varied, and difficult to predict, the same is not true of *symptoms* of problems. For example, error codes, tail latency, and exceptions are easily-observed indicators of potential problems. Many symptoms are localized, programmatically detectable, and manifest quickly at some point during or shortly after a request was served [27, 53, 58]. For example, tail sampling techniques, by definition, require that some span in the trace was explicitly annotated with the symptom of an anomaly, and typically wait only 10 seconds to accumulate trace data [51, 53]. For these common cases it is not necessary to ingest and construct full trace objects when the symptom is so readily detectable at the source. Moreover, since symptoms can be detected independent of traces in the first place, we do not need the expensive indirection of writing symptoms into trace data only to later extract and filter them. We believe that the key to capturing edge-cases is to decouple detection of symptoms from collection of traces.

Retroactive sampling: applications embed **triggers** that programmatically observe symptoms and signal after-the-fact that a trace is an edge-case.

Triggers are local but trace data is distributed. Prior distributed tracing frameworks ingest traces eagerly. We instead believe that traces should be lazily ingested, only in response to a trigger fired at some point during or soon after a request. However, triggers are local – only one machine might detect a symptom, yet the trace data for the request will be dispersed across memory of all machines that serviced it. To splice together a coherent end-to-end trace, all of these other machines need to learn of the trigger and send their slice of the trace to the backend collectors. To identify and notify all relevant machines of a trigger, we thus need the ability to *back-track* the end-to-end path of a request.

Retroactive sampling: requests propagate and deposit **breadcrumbs** so triggers can be shared with all relevant machines.

Trace data will eventually expire. Applications generate trace data into local memory where it incurs no further processing. We only send trace data to collector backends if a trigger fires. However, we cannot predict *when* a trigger might fire – even if a request has finished executing locally, we cannot easily know that the request isn’t still executing on some other machine(s) or that a trigger won’t fire remotely. Thus, trace data must remain in memory on each machine indefinitely. Over time this will fill memory and eventually we will need to free up space. The intuitive choice is thus

to expire trace data for the least-recently-seen request. We call the implicit time duration between generating data and overwriting it the *event horizon*. We believe that retroactive sampling should not require a large event horizon – as low as tens of seconds is reasonable – because triggers are automatic and shared quickly. In the majority of cases a machine should learn of a trigger within a matter of seconds or milliseconds. Thus retroactive sampling should be feasible even with large and detailed traces or constrained memory.

Retroactive sampling: triggers are best effort; we assume we will see triggers quickly if at all.

4 Design

Overview. Hindsight is a distributed tracing framework that implements retroactive sampling. Whereas typical distributed tracing frameworks eagerly ingest trace data, Hindsight lazily ingests data only after a trigger, thus allowing retroactive sampling of edge-case traces without paying the overhead costs of ingesting all trace data. Hindsight remains compatible with existing head-sampling and tail-sampling policies. Hindsight trivially implements head-sampling policies by firing an immediate trigger upon a positive head-sampling decision (or if the sampled flag is set). Hindsight is opaque to backend trace collectors and tail-sampling policies, and existing ingestion pipelines require no changes. Likewise, Hindsight is transparently compatible with existing OpenTelemetry APIs and instrumentation [52], and piggybacks breadcrumbs with OpenTelemetry’s context propagation.

Walkthrough. Fig. 2 shows a high-level diagram of Hindsight’s main components.

- ① On request arrival (solid black line) Hindsight generates a unique traceId and thereafter propagates it alongside the request, as done by existing frameworks (§2.2).
- ② Applications record trace data (e.g. events, spans) using Hindsight’s tracepoint client API. This leaves the request’s trace data scattered across the machines it visited.
- ③ A Hindsight *agent* runs on each machine to manage trace data. Hindsight agents do not inspect, process, or eagerly report trace data to backends – instead, agents index metadata by traceId and await further instruction. For most traces nothing further happens, the trace is not reported, and agents eventually evict old trace data.
- ④ If an application node observes an outlier symptom (e.g. erroneous response, high latency, or a bottlenecked queue) it invokes Hindsight’s trigger API and passes the request’s traceId.
- ⑤ The local Hindsight agent receives the triggered traceId. The full trace remains dispersed across many Hindsight agents, so the local agent informs Hindsight’s logically centralized *coordinator* service of the traceId. Hindsight’s coordinator recursively contacts the set of machines that serviced this request, soliciting breadcrumbs deposited by the request at each machine; a breadcrumb is

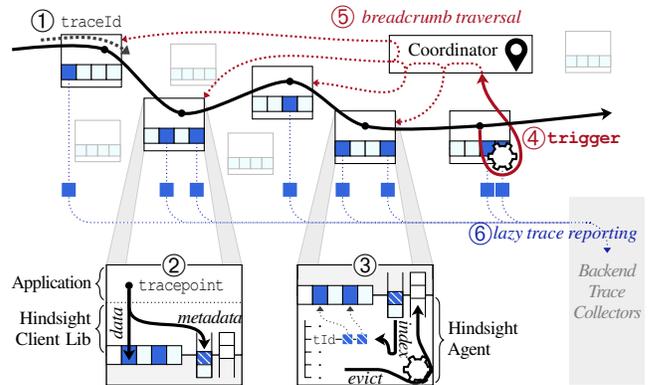

Fig. 2: The end-to-end lifecycle of a trace in Hindsight (§4).

a pointer to another machine involved in the request (e.g. to the RPC caller or callee).

- ⑥ Each agent contacted will set aside its slice of data belonging to the traceId, and asynchronously send it to the backend collector.

Design decisions. Hindsight is most shaped by three key design choices. First, to prioritize trace coherence as a primary objective throughout the architecture. Second, to maintain an efficient data and control plane split to enable tracing 100% of requests. Finally, to support lightweight programmatic trigger mechanisms.

4.1 Trace Coherence

Coherence is a top-level requirement for distributed tracing (§2.2). As soon as any machine drops data for a trace, the trace is incoherent and effectively useless for troubleshooting. Hindsight’s design avoids incoherence in several places.

At ③, agents continually evict old trace data to free up space for new data. Agents do this atomically at the granularity of a trace; there is no point in only dropping part of a trace. However, for a single trace, its data is non-contiguous and fragmented in memory. Agents carefully organize and index metadata about where each trace’s data resides and do not simply evict old data in a LIFO manner.

At ⑤, the coordinator must contact all agents that handled a request before those agents overwrite their slice of trace data. Breadcrumbs are a lightweight and scalable solution – the coordinator recursively follows breadcrumbs and only contacts the specific agents known to have serviced the request. This approach takes only a few milliseconds in our evaluation. Breadcrumb traversal is independent of reporting the trace data; agents set aside and asynchronously send trace data to the collector backends after learning of a trigger.

At ⑥, agents can potentially experience network congestion or backpressure from the collector backends, such as in response to a trigger-happy application that fires too many triggers and causes a backlog of unreported trace data on many, or all, agents. Eventually even triggered data must be dropped. Hindsight agents do not drop data arbitrarily (e.g.,

skipping a full queue) because different agents would then tarnish different victim traces—it only takes one agent dropping its slice of a trace to render the remaining data on other agents practically worthless due to incoherence. Instead, in several places agents use priority queues, with priority determined by consistent hashing of traceIds. A given traceId will enjoy the same priority across all agents and queues, and the same traces will be dropped by all agents in the face of a bottleneck.

Finally, at ④, applications may fire multiple different triggers for a diverse range of symptoms, using a developer-provided triggerId to distinguish different trigger types. Hindsight will prevent a profuse trigger from stifling trace collection of other, low-frequency triggers: agents implement weighted fair sharing for reporting and evicting trace data, with user-defined weights and rate-limits for each triggerId.

4.2 Efficient Data Management

Lazy ingestion significantly reduces the volume of trace data sent from agents to the backend trace collection infrastructure. However, within an individual machine, retroactive sampling requires the application generate trace data into local memory for *all* requests (③). The most sensitive performance bottleneck for Hindsight is thus between client applications generating data (tracepoint) and the local Hindsight agent that manages trace metadata. Our design establishes a clear split between *control* and *data* activities, which congregates general-purpose data and efficiency in the data plane, and embeds all logic in the control plane.

Data plane. Hindsight’s data plane is concerned with efficiently writing trace data from client applications. Using tracepoint, applications write trace data to a large shared memory pool subdivided into *buffers*. Different threads write to different buffers; each buffer may only belong to one traceId at a time, and threads acquire new buffers when full or when the active traceId changes. Consequently, the buffer pool is not consumed sequentially and a single trace may be fragmented across several non-contiguous buffers.

Control plane. Hindsight’s agent process encapsulates control plane activities, continually circulating *metadata* about buffers to the application, via two shared memory queues. Applications poll for available buffers and push full buffers; agents poll for full buffers, index metadata of full buffers grouped by traceId, and push evicted buffers back to the application. Agents receive triggers and communicate with Hindsight’s coordinator, manage breadcrumbs linking the trace data that is strewn across many agents, extract triggered trace data, and report data asynchronously to the backend trace collection infrastructure. Hindsight’s control and data distinction yields an efficient agent implementation because agents only touch metadata.

4.3 Triggers

Applications initiate retroactive sampling via Hindsight’s trigger API (⑤). In the common case, symptoms are easy to detect

and localize: top-level error codes; high latency; increased queue time. Such symptoms can be readily recognized and cheaply computed without the trigger mechanism needing the trace data itself. For example, this may entail adding a trigger call within a service’s exception handler, or after checking for outlier latency upon a request’s completion. Hindsight provides a library of automatic triggers based on metric percentiles, categorical features, and exceptions. All of our use cases (UC1–UC3) can be implemented using Hindsight’s autotriggers. Likewise all existing tail-sampling policies can be implemented using autotriggers, as span-local attribute and metric filters directly translate to metric and categorical autotriggers.

By separating triggers from traces, developers can also implement custom symptom detectors to explicitly decide the conditions for triggering. This further leads to a straightforward integration of triggers into existing metric-monitoring and outlier-detection systems regardless of their architecture.

Lateral traces. Outlier behavior may not map directly to a single request; instead there may be several other related *lateral* requests. For example, to diagnose a bottlenecked queue (UC3), a trigger needs to capture traces for the previous N requests to understand what led to queue buildup [72]; to diagnose a write-ahead log, we desire all requests blocking on a log sync [4, 8]; to diagnose resource contention we require all requests contending for a slow disk or network [3, 5, 6]. By separating triggers from traces, we enable more comprehensive trigger conditions based on factors beyond just a single trace, and triggers that can capture multiple related traces simultaneously. Hindsight enables an application to atomically trigger a group of related lateral traceIds; internally Hindsight will ensure that the group as a whole is coherently collected. By comparison, tail sampling cannot easily express cross-trace triggers or sample lateral traces, because traceId-based sharding in collector backends is fundamentally at odds with sharing state between traces.

5 Implementation

We have implemented Hindsight’s client library in ≈ 4 KLOC of C and Hindsight’s agent and coordinator in ≈ 5.5 KLOC of Go. We chose C for dataplane efficiency and Go for its ease of use for the more complex control plane logic.

5.1 Data Plane Buffer Pool

Each Hindsight agent pre-allocates a fixed-size *buffer pool* in shared memory for applications to directly write trace data. Hindsight logically subdivides the buffer pool into fixed-size buffers (default 32 kB). Client applications write trace data to buffers via Hindsight’s client API. The agent process does not touch data in the buffer pool except when reporting triggered traces. At each point in time, a buffer can only contain trace data of a single request; no two different requests will write trace data to the same buffer at the same time. A single trace will thereby comprise (1) multiple non-contiguous buffers on

<code>begin(traceId)</code>	Request begins in the current thread.
<code>tracepoint((payload))</code>	Record data for the current trace; payload is of arbitrary size in bytes.
<code>breadcrumb(address)</code>	Adds a breadcrumb to the current trace, pointing to some other node address.
<code>serialize()</code>	Obtain the current traceId and a breadcrumb to the current node.
<code>end()</code>	Request ends processing in current thread; flush and remove buffers.
<code>trigger(traceId, triggerId lateralTraceIds...)</code>	Instruct Hindsight to collect traceId and zero or more lateralTraceIds

Table 1: Hindsight client API. Applications can invoke the API directly, or indirectly using Hindsight’s OpenTelemetry [52] tracer.

each agent and (2) many buffers scattered across numerous agents. Buffers are the granularity of data management within Hindsight. Within clients and agents, a buffer is addressable by its `bufferId`—its offset into the buffer pool.

5.2 Client Library

Table 1 outlines Hindsight’s client API. Applications can interact with this API directly, or use Hindsight’s OpenTelemetry tracer which acts as a wrapper.

Writing trace data. When a request begins executing in a thread, it must call `begin`; subsequently it may call `tracepoint` an arbitrary number of times; and finally when it completes executing in a thread, it must call `end`. This usage pattern is typical of distributed tracing frameworks. The `tracepoint` function accepts an arbitrary byte payload if called directly; conversely Hindsight’s OpenTelemetry tracer serializes trace events as payload. Hindsight internally maintains thread-local state including the current `traceId` and a pointer to a buffer. `tracepoint` writes directly to the thread-local buffer without synchronization. Synchronization is only required when acquiring or returning buffers; these operations touch shared-memory queues but are infrequent. A buffer is acquired during `begin`, returned during `end`, and replaced when filled.

Communicating with agents. The client library acquires `bufferIds` by polling a shared-memory *available queue*; if the queue is empty clients immediately return and instead write trace data to a special ‘null buffer’ that is simply discarded. When the client fills a buffer, it writes its `traceId` and the `bufferId` to a shared-memory *complete queue*. The agent continually drains the complete queue, and likewise continually returns fresh buffers to the available queue. Shared memory queues are lock-free and support batch operations; using batch operations, agents are robust to queue contention from multiple client writer threads.

This paired channel design forms a natural separator between control and data with two desirable properties: (1) queues only communicate metadata—a single integer `bufferId` represents, by default, a 32 kB buffer; (2) communication is infrequent, occurring only when buffers are filled or a thread switches over to execute a different request, thereby minimizing synchronization. From the client library’s per-

<code>PercentileTrigger(p)</code>	Clients call <code>addSample(traceID, measurement)</code> . Trigger fires for measurements > percentile p . (e.g. high latency or resource consumption)
<code>CategoryTrigger(f)</code>	Clients call <code>addSample(traceID, label)</code> . Trigger on categorical data that is less frequent than threshold f (e.g. rare API calls or attributes)
<code>ExceptionTrigger</code>	Trigger on an exception or error code
<code>TriggerSet(T, N)</code>	Tracks the most recent N traceIds and includes as lateralTraceIds when T fires.

Table 2: Hindsight autotrigger API can automatically trigger traces based on certain conditions.

spective, it cheaply and blindly writes trace data into shared memory and forwards only the control metadata to agents; conversely agents are agnostic to buffer contents—they do not inspect data in the shared memory pool and use only the metadata communicated via the complete queue.

Depositing breadcrumbs. A breadcrumb is an address of a Hindsight agent. When a request arrives at a node, it carries the breadcrumb of the previous node. During trace context deserialization, the `traceId` and breadcrumb is written to a shared memory breadcrumb queue. Agents poll this queue and index breadcrumbs alongside buffer metadata. Agents do not forward or act upon breadcrumbs until a trace is explicitly collected with a trigger. When a request departs a node, it takes that node’s breadcrumb. Clients can additionally establish forward-breadcrumbs to a named destination node prior to communication. By following breadcrumbs, we can reconstruct the full request graph starting from any node, including for requests with arbitrary concurrency and fan-out.

Triggering trace collection. Applications initiate trace collection by invoking `trigger`, which writes the `traceId`, `triggerId` and zero or more `lateralTraceIds` to a shared-memory trigger queue. In addition, Hindsight will propagate the fired trigger with the request similar to the sampled flag (cf. Fig. 1) so that later nodes immediately learn of the trigger.

A developer can implement custom outlier detection and invoke `trigger` directly, or they can make use of Hindsight’s autotrigger library (Table 2), a separate collection of triggers that track simple conditions over time and automatically invoke trigger when a condition is met. `TriggerSet` is noteworthy as a building block for lateral tracing; it includes N most recent traces whenever T fires.

5.3 Agent

Trace index. The trace index is a map of metadata, keyed by `traceId`. The metadata for a `traceId` includes a list of `bufferIds` and a list of breadcrumbs. Agents also maintain metadata of the triggers that have fired. Agents continually update the trace index with recently-written buffers, by polling `traceIds` and `bufferIds` from the complete queue. The agent will evict traces when the index exceeds a threshold of buffer pool capacity (default 80%) by removing the least-recently used untriggered `traceId` and returning all of its `bufferIds` to the available queue.

Local triggers. Agents poll the local trigger queue and immediately forward triggers to the coordinator. Agents include the breadcrumbs of the triggered traceId, enabling the coordinator to begin recursively disseminating the trigger to other agents. Meanwhile the agent schedules the trigger to be reported. In the case of a spammy local trigger, if the trigger exceeds a per-triggerId rate-limit, the agent will immediately discard the trigger instead of forwarding and scheduling it.

Remote triggers. Agents receive remote triggers fired by other agents via the coordinator. To facilitate rapid trigger dissemination, the agent immediately responds to a remote trigger by providing any breadcrumbs it has for the traceId and lateralTraceIds. Unlike local triggers, agents do not rate-limit remote triggers—they are all scheduled for reporting.

Reporting traces. When a trigger is scheduled for reporting, its traceId and lateral traceIds can no longer be evicted by the regular buffer eviction cycle. The trigger is inserted into a per-triggerId reporting queue. In the normal case when an agent is not backlogged, the reporting queue will be empty. The agent asynchronously pulls triggers from the queues; reads buffers of the traceId and lateralTraceIds from the buffer pool; sends the buffer contents to the backend collectors; and finally returns the bufferIds to the available queue. A trace remains triggered even after reporting its data, in case the request is still generating trace data locally.

Ignoring triggers during overload. If the network or backend collectors are overloaded, reporting queues in an agent can fill up. During overload, the agent continues to report traces as described above for the normal case. The agent implements weighted fair queueing over the reporting queues and supports global and per-triggerId reporting rate limits. From a reporting queue, the agent dequeues the *highest-priority trigger*, by using consistent hashing of traceId, and reports its data as described above for the normal case.

Simultaneously, past a configured threshold, the agent must begin abandoning triggers to free up buffers. Abandoning a trigger entails removing it from its reporting queue and returning buffers to the available queue. Agents coherently select the *lowest-priority trigger* to abandon, by using the same consistent hashing of traceId. In the case of multiple reporting queues, agents will ensure that a well-behaved triggerId is not impacted by a spammy triggerId: agents implement weighted max-min fair-sharing across reporting queues to choose a queue from which to drop triggers.

Trigger priority ensures coherence during overload. Reporting queues are priority queues that use consistent hashing of traceId to determine priority. Across all agents, a given traceId will enjoy the same priority relative to other traceIds. Thus if multiple agents experience overload, they will coherently bias towards reporting the same high-priority traceIds and abandoning the same low-priority traceIds.

6 Evaluation

We now evaluate how effectively Hindsight overcomes the fundamental problem of head-based tracing methods in examples (UC1)–(UC3) and meets the goals of retroactive sampling to provide lightweight and effective request tracing.

Systems. We evaluate Hindsight on three distributed systems. To validate our motivating use cases (UC1–UC3), we integrate Hindsight with the Hadoop Distributed File System (HDFS) [63] (with a ≈ 300 LOC JNI-based Java client library) and the DeathStar Social Network Microservices Benchmark (DSB) [24]. To assess Hindsight at greater scale and load, we develop a flexible, configurable RPC benchmark called **MicroBricks**.

MicroBricks is a microservice benchmark written in ≈ 3 KLOC C++ using gRPC’s high-performance async library. A MicroBricks deployment comprises a topology of RPC services such that each client request will traverse multiple services. A call to a service will execute for some amount of time, then concurrently call zero or more other RPC services with some probability. Each service is independently configured with its own set of APIs, each with their own execution times, child dependencies, and child call probabilities. We evaluate using several different topologies. In particular, we use Alibaba’s microservice trace dataset [42] to derive realistic topologies by calculating per-service execution time distributions, service dependencies, child call probabilities, and client workloads.

Baselines. We configure OpenTelemetry [52] with Jaeger [31] under head-sampling (1% unless indicated) and tail-sampling.

Instrumentation. We instrument MicroBricks with OpenTelemetry to create spans and events for RPC calls and child calls. We use DSB’s existing OpenTracing instrumentation and add support for Hindsight. We use Hadoop’s existing X-Trace instrumentation [23] and update X-Trace to write its trace data to Hindsight.

Summary. Our experiments demonstrate the following:

- Hindsight effectively addresses the overhead vs. edge-cases trade-off faced by existing tracing frameworks.
- Hindsight captures relevant edge-case traces across real use-cases (UC1–UC3).
- Hindsight is lightweight and not a bottleneck for client applications, unlike OpenTelemetry [52] and Jaeger [31]. Hindsight’s trace API imposes nanosecond overheads; Hindsight’s impact on end-to-end application latency and throughput is $< 3.5\%$ when tracing 100% of requests and generating > 200 MB/s of trace data per node.
- Hindsight’s control/data split provides up to 55 GB/s write throughput.

6.1 Overhead vs. Edge-Cases

In this experiment, we evaluate Hindsight in a large-scale setting with a realistic microservice topology derived from

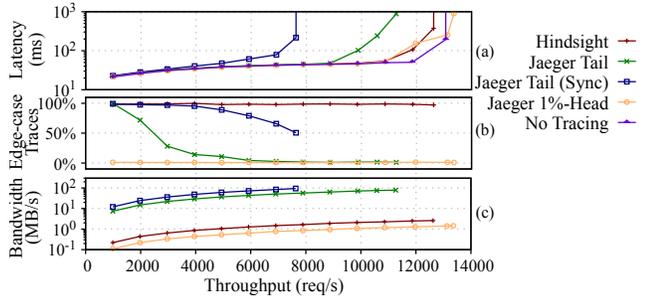

Fig. 3: Overhead vs. edge-cases on a 93-service Alibaba MicroBricks topology with 1% edge-cases (§6.1). For different tracing configurations we show: (a) application end-to-end latency-throughput curves; (b) the rate of coherent edge-trace cases captured; and (c) network bandwidth.

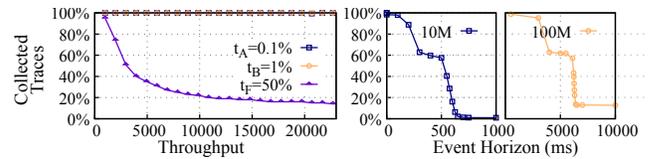

Alibaba request traces [42]. We show that Hindsight overcomes the limitations of head-sampling and tail-sampling.

We deploy MicroBricks with a 93-service Alibaba topology in a 544-core private cluster (comprising 10×Dell R920 48-core 1.5 TB machines and 4×Dell M620 16-core 256 GB machines). We deploy each service in a separate container. We use separate machines to (i) generate workload and (ii) run the OpenTelemetry collector/Hindsight coordinator+collector.

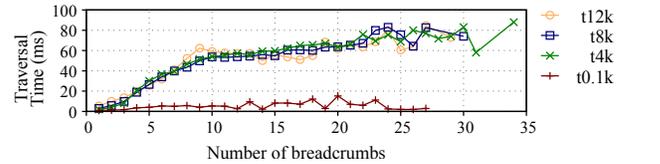

To directly control the number of edge-case traces, we randomly decide with low probability (1%) to designate a request an edge-case when it completes (later experiments consider autotriggers). We annotate the root span of edge-cases with an additional attribute so that tail-sampling can filter traces on this attribute. Hindsight directly fires a trigger for edge-cases from within MicroBricks. We repeat the experiment multiple times, analyzing results under four tracing configurations:

Head sampling (Jaeger 1%-Head). Fig. 3a shows the average request latency and throughput as we vary the offered load from 0 to 14,000 requests/sec (r/s). Jaeger 1%-Head has comparable peak throughput and latency as No Tracing, since it traces only 1% of requests, thus amortizing the tracing overhead. Fig. 3b plots the percentage of coherent edge-case traces captured per second. Since head-sampling cannot discriminate, it only captures $\approx 1\%$ of all edge-case traces, peaking at 1.64 per second. Fig. 3c shows the network bandwidth consumption between application nodes and the OpenTelemetry collector. With few requests being traced, Head-sampling only consumes a maximum of 1.4 MB/s of network bandwidth.

Tail sampling (Jaeger Tail). Tail-sampling imposes more burden on the traced application than head-sampling, attaining 14% lower peak throughput (Fig. 3a). At low load (1,000 r/s), tail-sampling successfully captures $\approx 100\%$ of edge-case traces, at 9.9 per second (Fig. 3b). However, a load of just 2,000 r/s is sufficient for clients to encounter backpressure from the network and the OpenTelemetry collector, and they begin incoherently dropping spans: at 2,000 r/s only 71% coherent edge-cases are captured; at 3,000 r/s only 28%; and so on. Tail-sampling rapidly deteriorates and at peak load captures *fewer* coherent edge-case traces than head-sampling

(a) Coherent traces captured when (b) Event horizon for constrained overloaded with a spammy trigger t_F . bufferpools (10MB and 100MB).

(c) Breadcrumb traversal time as trace size varies, triggering 0.1% (t0.1k) or 50% (t4k, t8k, t12k) traces on different workloads.

Fig. 4: Scalability and overload.

(1.44 edge-cases/s), because 98.8% of captured traces are incoherent. Tail-sampling consumes up to 78 MB/s of network bandwidth (Fig. 3c).

Tail sampling (Jaeger Tail Sync). Jaeger clients asynchronously send spans to OpenTelemetry collectors, and as we just observed, drop spans when client-side queues fill up. We repeat the experiment with a synchronous variant, whereby clients send spans to OpenTelemetry synchronously. Backpressure then manifests as additional critical-path request latency. This approach inevitably increases request latency and reduces peak throughput by 42% (Fig. 3a). However, we can observe the collector ultimately captures more edge-case traces, peaking at 47 edge-cases per second at 6,000 r/s (Fig. 3b) and 72.2 MB/s of network. Beyond this, the OpenTelemetry collector is saturated and cannot process a higher rate of traces; it begins indiscriminately dropping incoming spans, reducing the fraction of coherent edge-case traces.

Hindsight. Hindsight achieves comparable peak throughput to No Tracing ($<3.5\%$), and minimal impact on request latency below peak load (Fig. 3a). Hindsight captures 99–100% of edge-case traces at all throughputs (Fig. 3b). Hindsight consumes a maximum of 2.6 MB/s of network bandwidth since only edge-case traces are being collected (Fig. 3c).

6.2 Scalability and Overload

We now focus on two aspects of Hindsight’s scalability: its breadcrumb traversal mechanism and its ability to rate-limit spammy triggers. We deploy the 93-service Alibaba topology as described in §6.1. To reach a higher request and trace throughput, we scale down the computation performed at each service and increase offered load up to 28,000 r/s. We install three triggers with probabilities $t_A=0.1\%$, $t_B=1\%$, and $t_F=50\%$. t_F represents a faulty trigger—it fires for 50% of requests and thereby adds substantial load to Hindsight’s breadcrumb traversal mechanism. We rate-limit Hindsight’s collector bandwidth to 1 MB/s per agent to backlog the agents and inhibit Hindsight’s ability to collect traces; thus t_F triggers far more traces than Hindsight can collect.

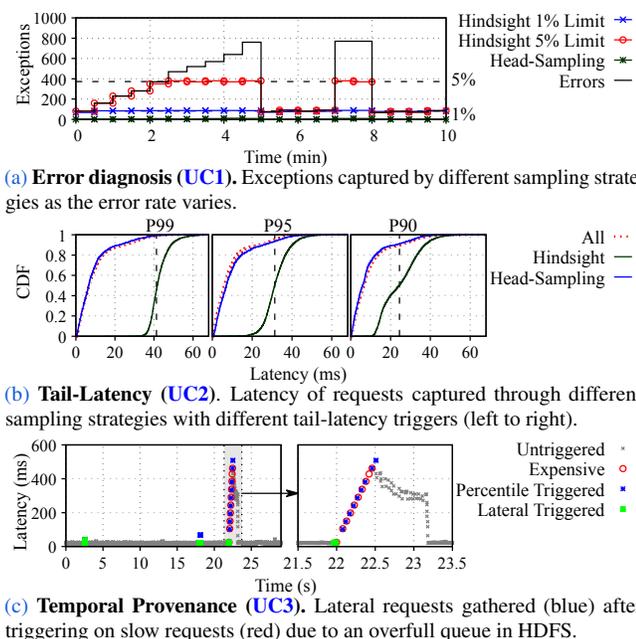

Fig. 5: Hindsight applied on use cases UC1–UC3 (see §2.1).

Coherent rate-limiting. Fig. 4a plots the percentage of coherent traces captured for t_A, t_B and t_F as the offered load increases. Throughout the experiment, Hindsight captures approximately 100% of traces triggered by t_A and t_B , since they fire infrequently. By contrast, t_F triggers far more traces than can be collected. In absolute terms, Hindsight collects $\approx 2,000$ coherent traces per second throughout the experiment, with t_F using capacity not used by t_A and t_B . Thus, higher request rates result in more traces dropped for t_F in both relative and absolute terms.

Breadcrumb traversal. Fig. 4c plots the average breadcrumb traversal time based on the trace size – *i.e.* the number of Hindsight agents that were recursively contacted. We show results for four experiment iterations and label them based on their approximate trigger rates: t_{12k} , t_{8k} , and t_{4k} correspond to triggering 50% traces on 24k, 16k and 8k r/s workloads ($\approx 12k$, 8k, and 4k triggers/second respectively). To compare to a non-overloaded setting we also include $t_{0.1k}$, a 12k r/s workload from §6.1 ($\approx 0.1k$ triggers per second). Traversal time is elevated for t_{12k} , t_{8k} and t_{4k} (up to 86 ms) since spammy triggers substantially increase the load on Hindsight’s coordinator. Conversely, traversal time for $t_{0.1k}$ is < 13 ms since triggers are relatively infrequent. For each experiment, traversal time increases with trace size, but sub-linearly since breadcrumbs can be gathered concurrently from different branches in requests that have fan-out. However, even under the extremely overloaded circumstance, the longest traversal time, which is less than 100 ms, is far smaller than the event horizon as described in the following section and thus is still manageable.

Event horizon. We lastly measure Hindsight’s event hori-

zon. Here, we introduce a delay when an agent receives a local trigger. We vary the delay added to triggers and measure how many coherent traces are ultimately collected. At a certain point, triggers will have too much delay and trace data will have been evicted before the trigger even fires. Fig. 4b plots the percentage of coherent traces captured for t_B as we vary the trigger delay. We repeat this experiment with small buffer pools (100 MB and 10 MB per agent) to exacerbate the event horizon effect. Even a 10 MB buffer pool can capture nearly 100% coherent traces in the absence of added delays, but a 500 ms delay drops coherence to 58% and at 600 ms, coherence is $< 20\%$. A larger buffer pool improves the tolerance to delays: with a 100 MB buffer pool, coherence surpasses 90% with up to 3s delay, but drops to $< 20\%$ by 6.4 s. In practice, we believe our default 1 GB pool is a reasonable choice, bringing an event horizon around 1 minute.

6.3 Case Studies

We now turn our attention to the case studies introduced in §2.1, and demonstrate how Hindsight’s local triggers are able to support these use cases.

Error diagnosis (UC1). We deploy DSB Social Network, a microservice system with 12 microservices and 17 backends [24], on 13 CloudLab c6320 nodes [20]. We add an `ExceptionTrigger` from Hindsight’s autotrigger library to the `ComposePostService`, and run DSB’s default workload with 300 r/s¹. We randomly inject exceptions in the `ComposePostService` module, with exception rates ranging from 1% to 10%. We repeat the experiment twice and rate-limit Hindsight’s collector to approximately 1% and 5% of the total trace data generated by the experiment. Fig. 5a plots the exception rate, and the number of coherent exceptional traces captured, for each 30 s time window. When there are few exceptions, Hindsight captures all traces; when the exception rate exceeds collector bandwidth, Hindsight coherently captures as many traces as possible within this limit.

Tail-latency (UC2). We add a `PercentileTrigger` from Hindsight’s autotrigger library to the `ComposePostService` module in the same setting as above, invoking `addSample` at the end of each `ComposePost` RPC call and providing the measured RPC duration. We set p to 99, 95, and 90, as different thresholds for tail latency. We inject 10% requests at random with 20–30 ms latency. Fig. 5b plots the latency distribution of requests captured by different strategies; the vertical dotted lines mark the tail-latency percentile threshold. Hindsight is able to specifically target traces with high-percentile latency. By contrast, head-sampling is random and thus its captured latency distribution resembles that of all requests – useful for aggregate analysis but not for edge-case troubleshooting. We note that Hindsight does not sacrifice this aggregate analysis use-case; it supports both simultaneously (cf. §6.1).

Temporal provenance (UC3). We add a `QueueTrigger`

¹We measure a maximum attainable DSB throughput of ≈ 350 r/s.

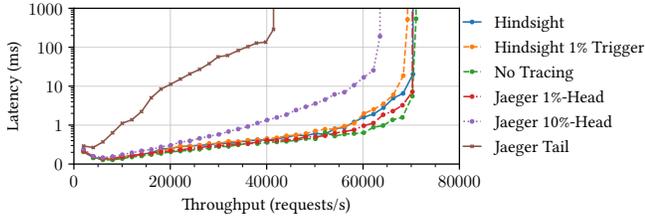

Fig. 6: End-to-end latency and throughput for a 2-service MicroBricks topology configured with various tracers, showing minimal application impact for Hindsight despite tracing 100% of requests.

from Hindsight’s autotrigger library to the HDFS NameNode queue — the QueueTrigger combines a TriggerSet with a PercentileTrigger, parameterized to capture $N = 10$ most recently dequeued lateral requests when 99.99th percentile queuing latency is observed. We deploy HDFS on 10 machines (8 DataNodes, 1 NameNode, and 1 client) and run a Hindsight agent on each machine. We run a closed-loop workload of random 8 kB reads with 10 concurrent requests.

Fig. 5c (left) shows NameNode queue latency over time. We inject a burst of 10 expensive createfile requests 21 seconds into the trace that briefly saturate the queue—Fig. 5c (right) zooms in on this time window. The figure shows high-latency requests (•), requests that fire the autotrigger (X), and the additional lateral requests that were triggered to Hindsight (X). The first expensive request occurred at 22 seconds, followed by a pause while it was executed. Upon dequeuing the subsequent read8k request, QueueTrigger fired due to high queue latency, and Hindsight retroactively sampled the 10 prior traces leading up to the trigger. The sample included the culprit expensive request. Overall, all 10 expensive requests were sampled, 8 unrelated requests prior to the first expensive request, and 9 additional read8k requests. Moreover, several intermittent latency spikes occurred unrelated to the experiment (Fig. 5c, left), which Hindsight also captured; upon investigation, these were due to garbage collection.

Unlike UC1 and UC2, temporal provenance is unsupported in existing tail-samplers. Moreover, temporal provenance is fundamentally difficult to support with tail-sampling due to scalability issues. Temporal provenance requires knowledge of lateral traces (e.g. the 10 previous traces); by implication those traces must all route to the same collector instance. However in practice, tail-sampling necessarily uses traceId for routing decisions – thus related traces may arrive at different, oblivious collectors.

6.4 Hindsight Performance

End-to-end application overheads. Hindsight generates trace data for all requests; thus low overheads are a key goal of Hindsight’s design. In this experiment, we measure the impact of Hindsight on end-to-end application latency and throughput. We deploy a two-service MicroBricks topology with a 100% call probability from the first service to the second. To highlight tracing overheads, neither service performs additional compute. We vary the offered load and measure

API Call	T=1	T=4	T=8	API Call	T=1	T=4	T=8
begin	72.7	194.8	237.9	tracepoint	7.9	8.4	8.6
end	70.7	205.8	216.6				
Category(.01)	45.8	44.9	46.7	tracepoint 8B	3.9	4.0	4.8
Percentile(99)	275.3	293.5	306.9	tracepoint 128B	11.5	13.5	13.0
Percentile(99.9)	407.1	441.9	512.2	tracepoint 512B	37.7	43.1	40.9
Percentile(99.99)	629.4	875.8	1134.0	tracepoint 2kB	160.2	192.9	174.7
TriggerSet(10)	6.57	44.1	52.2				

Table 3: Latency measurements (nanoseconds) for Hindsight client API and autotriggers for a microbenchmark application configured with 1, 4, and 8 Threads (§6.4). Default tracepoint writes a 32 kB trace event; we also measure 8–2048 B tracepoint payloads.

end-to-end request latency and throughput (§A.1).

Fig. 6 plots latency-throughput curves under several different tracing configurations. The lowest latency and highest throughput is achieved with No Tracing, peaking at an average 71.0 k requests/s. Similar throughput is achieved by Jaeger when configured with 1% Head-sampling, at 70.2 k r/s. Hindsight peaks at 70.4 k r/s – a decrease of only 0.9% compared to no tracing. Hindsight generates on average 330 MB/s of trace data at peak request throughput, with an event horizon of 5.2 s, and consumes a combined 0.3 CPU cores across agents, coordinator, and collector. By comparison, Jaeger configured with Tail-sampling peaks at only 41.4 k r/s, an overhead of 41.7%; moreover, the workload over-saturates the OpenTelemetry collector, resulting in 94% of trace data being dropped while consuming 4.5 CPU cores.

Client API and autotrigger microbenchmarks. We run a benchmark application that generates traces and measures the overhead of calls to Hindsight’s client API and autotrigger library. The benchmark writes traces by calling begin to start the trace, writing a total of 16 kB per trace by repeatedly calling tracepoint, then calling end to finish the trace. Each tracepoint call writes a 32-byte event struct (3 metadata fields and a timestamp) using Hindsight’s OpenTelemetry library. Following each trace, the benchmark invokes five different autotriggers. The benchmark runs a custom number of threads to generate traces; each thread independently runs a continuous loop generating traces, and every thread writes a different trace. We configure Hindsight to use 32 kB buffers and a 1 GB buffer pool, and run a Hindsight agent. We run 1 minute per experiment (≈ 10 –50 million traces).

As shown in Table 3, autotrigger overheads vary. CategoryTrigger is relatively cheap (<47 ns) and TriggerSet adds relatively little overhead to the wrapped trigger (6–53 ns). By contrast, PercentileTrigger overheads grow proportional to the percentile: up to 307, 512, and 1,134 ns respectively for tracking 99th, 99.9th, and 99.99th percentile latency due to larger internal data structures for tracking order statistics.

Table 3 also shows API latency for 1, 4, and 8 threads. Overall, Hindsight achieves nanosecond-scale API latency, and by design the expensive API calls (begin, end, and autotriggers) are limited to once per trace. begin and end vary from 70–230 ns, proportional to the number of threads due to contending on shared-memory queues to acquire and re-

turn buffers. By contrast, tracepoint call latency is mostly independent of the number of threads, between 7.9–8.5 ns (reduced to ≈ 4 ns when omitting timestamps). We also measure tracepoint latency for larger payloads up to 2 kB; latency increases only up to 175 ns per tracepoint since tracepoint is primarily a memory copy into the thread-local buffer established by `begin`.

7 Discussion

We next discuss items peripheral to Hindsight’s core design.

7.1 Triggers

Mitigating spammy triggers. Hindsight’s design currently isolates triggers based on a trigger ID, whereby different symptom detectors would use different trigger IDs, ensuring that a symptom detector that fires infrequently is not affected by one that fires too often.

Lateral trace IDs. All of Hindsight’s autotrigger are lightweight symptom detectors that run within the application itself. In principle, the logic to decide when to trigger, and which trace IDs to trigger, is arbitrary. Hindsight’s autotriggers are classes which the application can instantiate that track state over time. For a `PercentileTrigger` that tracks latency, for example, the application must instantiate the autotrigger within the request handler, and add the new latency sample at the end of each request’s execution. A `TriggerSet` can wrap any trigger; internally it maintains a sliding window of the N most recently-seen trace IDs that tested the wrapped trigger. When we applied the `TriggerSet` in the `UC3` experiment (Fig. 5c), for example, we measured queueing latency and the `TriggerSet` internally held the N most recent trace IDs that were dequeued. When the wrapped autotrigger finally calls `trigger`, it will include all N of the trace IDs in the trigger call.

7.2 Consistent Hashing

Hindsight agents have several forms of queuing and scheduling internally, primarily to decide which traces to evict and which to report to avoid any unbounded queue. Simple queuing (e.g. used by `OpenTelemetry`) indiscriminately drops data when the queue is full. When multiple agents have full queues, each independently dropping arbitrary data seriously compromises trace coherence. Instead, when Hindsight agents are at capacity, they bias towards dropping data from the same victim traces by preferentially discarding items from lowest priority traces. Thus even though Hindsight agents are operating independently, they seek to retain the same high-priority trace IDs when under load.

7.3 The Event Horizon

Parameters. Several factors influence Hindsight’s event horizon: (i) the buffer pool size of each agent; (ii) the rate of new trace data being generated; (iii) the time between a request completing and a trigger firing. Inevitably, if there is too much trace data, or if triggers are too slow, Hindsight may

be unable to keep the trace before its data is overwritten. For some use cases this means Hindsight cannot use retroactive sampling. However, head-sampling or tail-sampling would still be viable options, equivalent to existing distributed tracing frameworks.

Extending the event horizon. The solution is either to increase the memory available to Hindsight or to scale down the percentage of traced requests using Hindsight’s optional *trace percentage*. Trace percentage is a separate configuration knob (defaulting to 100%) that controls the percentage of requests that generate trace data in the first place. The starting premise for Hindsight is that 100% tracing is acceptable, so we used 100% as the default and described Hindsight as such throughout this paper. However, if an application has overhead constraints or limited memory for a buffer pool, the percentage of requests that are traced in the first place can be scaled back. Hindsight enforces scale-back coherently across agents through consistent trace ID hashing: e.g. 50% trace percentage will halve the trace data throughput and double the event horizon.

Mismatched and dynamic event horizons. The global event horizon of an application is dictated by the shortest event horizon among the constituent processes, since the whole trace becomes incoherent the moment the first agent evicts any of its data. This fundamental property of Hindsight can be addressed by enlarging the buffer pool memory on higher throughput nodes. Moreover, the buffer pool needs not be of fixed size. We considered implementing a dynamically-sized buffer pool, e.g. that can be configured with a target event horizon, but ultimately chose a fixed-size buffer pool to better bound memory overheads – a desirable property for telemetry systems [71].

Shared buffer pools. In our current design, we deploy one Hindsight agent per traced application process. If multiple containers share a machine, as in our experiments, several agents may run on the same machine. There is no reason why applications could not share a single machine-wide buffer pool, enabling processes to stock their buffer pool capacities and average out the differences between their event horizons.

7.4 Comparison with Tail Sampling

Event horizons. Hindsight’s event horizon has an analogue in tail sampling. Since trace collectors cannot immediately perform tail sampling the instant trace data arrives, and must wait for all of the slices of a trace to arrive from all of the machines the request visited. Today, this is done with a timeout (e.g. 30s by default in `OpenTelemetry` [52]), after which the trace objects are constructed and tail samplers can be evaluated. If the application generates a high volume of trace data, then the trace collector can potentially run out of memory while awaiting data for to do tail sampling.

Tail sampling expressivity. Today’s tail samplers focus on filters and outliers applied to span attributes and metrics. Yet a

tail sampling decision for one trace cannot influence the sampling decision of other traces. By contrast, Hindsight’s lateral traces enable a trigger to specify other, related traces, in addition to the one exhibiting a symptom, allowing it to support use cases like temporal provenance (UC3). Tail samplers do not support such use cases, and they would be challenging to introduce due to the way trace data for different traces route to different collectors based on their traceId.

7.5 Robustness

Application failures. If the application process crashes (*e.g.* SEGV/NPE-type crashes), then Hindsight preserves problematic traces since Hindsight’s agent continues to run and the trace data is preserved in memory in the shared buffer pool. The agent will also be able to continue responding to breadcrumbs. This is a secondary benefit of externalizing trace data on the critical path of requests, and is currently supported by Hindsight. By contrast, existing distributed tracing frameworks buffer trace data in application memory and would lose unreported data upon an application crash.

Agent failures. If Hindsight’s agent crashes (irrespective of whether the application process crashes), then the buffer pool will still exist in-memory on the machine and could be later retrieved to inspect the state just prior to the crash. Hindsight does not currently implement such a recovery process. In addition, if an agent crashes, it will by default prevent Hindsight’s coordinator from following breadcrumbs through this crashed agent. This can be overcome by extending Hindsight to propagate breadcrumbs for the last N visited nodes instead of just one; this would both avoid $(N - 1)$ -hop failures and also speed up Hindsight’s collection process.

Kernel and hardware failures. In the case of kernel crashes or hardware failure, application-level traces are only useful if it was the application’s behavior that triggered the crash. In this case, Hindsight’s data would be lost.

8 Related Work

Distributed tracing. Numerous prior works identify end-to-end requests as a useful granularity for slicing telemetry data and troubleshooting distributed systems. Example use cases include detecting anomalous request structures [37, 64, 72], diagnosing changes in the steady-state [16, 57, 61], modeling workloads [46, 70], and identifying resource and queue contention [25, 44, 72]. Distributed tracing systems have been presented in industry [34, 64], as open-source tools [31, 52, 56, 78], and in academia [23, 45]. Edge-case troubleshooting stands in tension with overheads in distributed tracing, and head-sampling and tail-sampling offer alternative points in this space (§2.2).

Logging frameworks. Distributed tracing is the cousin of log ingestion frameworks that collect and store application-level log data [13, 66]. Log ingestion frameworks are agnostic to concepts like requests, do not record or group log data by re-

quests, and cannot control head-sampling decisions coherently for requests – instead applications generate simple sequential streams of log data all at the same level of logging detail. Consequently, logs are typically far less detailed than distributed tracing and log ingestion frameworks handle a lower volume of data. For example, Chukwa reports on average 10kB/s per node [13]; Splunk limits to 330 kB/s per node [66]; Amazon CloudWatch limits to 5MB/s per log stream [12]. Early distributed tracing works rejected the idea of building distributed tracing atop logging, citing coherence challenges from brittle data, enormous post-processing costs, and fundamental scalability bottlenecks [17, 34, 64]. In practice, trace detail is typically far greater than even non-production debug-level logging [64], and it is easy to see why: head-sampling gives operators leeway to instrument their applications at fine detail, because they can amortize the high cost of a single trace by scaling down the number of collected traces. By comparison, log ingestion frameworks have no such opportunity.

Network provenance. Hindsight is similar in spirit to network packet provenance systems that chronicle the history of network state, enabling use cases such as tracking the origin or path traversed by a packet across the network. Earlier systems, like ExSPAN [77] and SNP [75], adopt this abstraction; more recent works like SyNDB [35] and SPP [14] apply network provenance for packet-level root-cause analysis on Internet scale. Packet provenance systems primarily trace only packet metadata, which is well-structured and can be summarized in-band; these systems tackle additional trust challenges outside of Hindsight’s purview. By contrast, handling metadata to reconstruct the path of a trace is but one concern for Hindsight; Hindsight is focused on handling arbitrary payloads (*i.e.* trace data), and the resulting performance, coherence, and fairness challenges. Hindsight also draws inspiration from works focused on temporal provenance [76] and packet reputation [15] in distributed systems, although Hindsight’s tracing abstractions operate entirely at the application level.

9 Conclusion

Hindsight circumvents the false dilemma between overhead and usefulness for diagnosing symptomatic edge cases by providing developers detailed traces from the recent past when they encounter symptoms of failures. We believe the retroactive sampling abstraction, and our Hindsight implementation of it, can shift the conversation around tracing away from mechanism (how to collect traces) to a question of policy (what traces should be collected), and allow distributed tracing systems to support edge-cases analysis: a key use case for which they were originally conceived.

A Supplemental Experiment Results

A.1 End-to-end Application Overheads

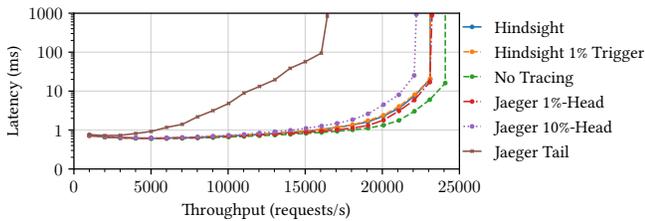

Fig. 7: End-to-end latency and throughput for a 2-service MicroBricks topology configured with various tracers, demonstrating minimal application impact for Hindsight despite tracing 100% of requests.

Fig. 7 shows a variant of the experiment described in §6.4. In the original experiment the services are configured to perform no additional compute. We additionally repeat the experiment with services configured to perform approximately 100 microseconds of matrix-multiply compute per service. We observe similar trends to those discussed in §6.4; in particular Hindsight has a comparable latency and throughput profile to Jaeger configured with 1% head-sampling.

A.2 Head-Sampling and Tail-Sampling Overheads.

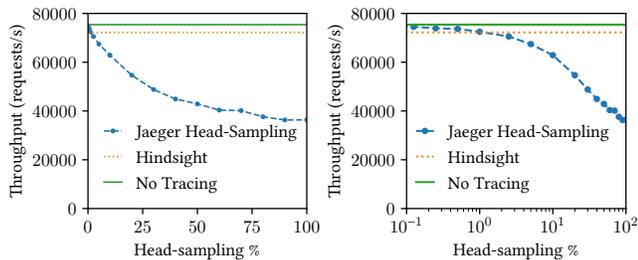

Fig. 8: Head-sampling impact on end-to-end throughput of a 2-service MicroBricks topology under a closed-loop workload. We vary the head-sampling percentage configured for OpenTelemetry Jaeger. The right figure plots the same data with a log-scale x-axis to highlight overheads at low head-sampling percentages. Tail-sampling is equivalent to 100% Head-sampling

We further measure the application-level impact of different head-sampling regimes. We run the application described in Fig. 8 and submit a closed-loop workload to saturate the system. We measure the application-level throughput achieved with by OpenTelemetry and Jaeger configured with different head-sampling percentages. We compare the throughput to that of Hindsight and with No Tracing. The results illustrate that the OpenTelemetry Jaeger overheads at typical low sampling percentages (<1%) is negligible, but the client library performance deteriorates at higher tracing percentages. 100% head-sampling is equivalent to tail-sampling.

A.3 Client throughput

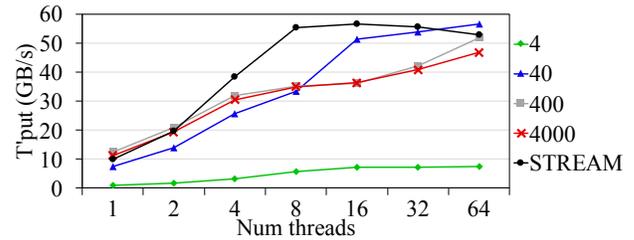

Fig. 9: Client Throughput achieved by a microbenchmark that varies the number of threads and the size of payload to tracepoint calls. Even modest payloads (40 bytes) can saturate memory bandwidth.

The purpose of this experiment is to evaluate the tracepoint write throughput that client applications can achieve, based on the payload size to tracepoint calls. The experiment demonstrates the peak attainable data ingestion throughput for different numbers of threads and different payload sizes. Larger payloads can attain higher throughput, but even with small payloads (40 bytes), we can saturate memory bandwidth.

This experiment configures Hindsight to use 32 kB buffers and a 1 GB buffer pool. We run a client application comprising between 1 and 64 threads. Each thread continually writes traces in a loop to Hindsight. Writing a trace entails calling begin, 100 tracepoints, then end. We repeat the experiment for different numbers of threads and varying the size of tracepoint calls from 4 bytes to 4000 bytes, resulting in traces between 400 and 400,000 bytes in size.

Fig. 9 plots the throughput achieved in GB/s. Small payloads of 4 bytes fail to fully saturate memory bandwidth, achieving only 887 MB/s with one thread and peaking at 7.55 GB/s with 64 threads. By contrast, even a modest increase in payload size to 40 bytes is enough to nearly saturate memory bandwidth; with 400 byte payloads, we achieve throughput of 12.5 GB/s on a single core. We include in Fig. 9 measurements of peak memory bandwidth from the STREAM benchmark [47].

Hindsight achieves high throughput, despite each trace acquiring and writing a new buffer at an arbitrary non-sequential offset in the buffer pool. This occurs because Hindsight’s client library coordinates buffers only during begin and end (at the start and end of each trace respectively) and stores the buffer pointer thread-local in the interim. Calls to tracepoint are then little more than a memory copy to the thread-local buffer acquired by begin.

A.4 Control-Data Trade-offs

Hindsight’s design emphasizes a control-data split, to enable applications to write trace data at large volume while reducing the amount of indexing work agents must perform. The main factor influencing this trade-off is Hindsight’s buffer size. With large buffers, agents index fewer buffers and thus

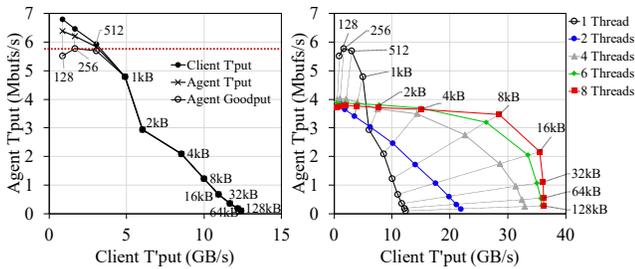

Fig. 10: Buffer size trade-off. Each data point is annotated with the Hindsight buffer size. Small buffers require more indexing work from agents, while large buffers are less memory efficient by exacerbating internal fragmentation.

perform less work; however it may exacerbate internal fragmentation when traces only partially fill buffers. Conversely, small buffers are more space-efficient, but require more indexing work from agents. We evaluate this trade-off by measuring client-side and agent-side throughputs, while varying Hindsight’s internal buffer size from very small (128 B) to very large buffers (128 kB).

We run the benchmark application with one thread, 100 kB traces, and a payload of 1 kB per tracepoint call (Hindsight fragments payloads across multiple buffers when necessary). Fig. 10 (left) plots the client-side throughput of generating data (x-axis) and the agent-side throughput of indexing buffers (y-axis). We annotate data points with the corresponding buffer size used. Large buffer sizes (128 kB) can support peak client data throughput (12.1 GB/s) while requiring little of the agent. Conversely, tiny buffer sizes (128 B) stress the agent buffer throughput since we more frequently cycle buffers through the queues. Fig. 10 (left) plots three lines and indicates two important phenomena. The client throughput line plots the rate at which the client writes buffers, whereas the agent throughput line plots the rate at which the agent cycles buffers; the delta in-between are ‘null buffers’, written by the client because the available queue is empty, *i.e.* the agent cannot keep up. Writing to null buffers means lost trace data; the third line, agent goodput, only counts buffers of coherent traces, *i.e.* excluding all buffers for traces that lost data. We observe that the goodput with 128 B buffers is lower than with 256 B buffers due to greater loss. In general, with ≥ 1 kB buffers, the agent is able to consistently keep up without losing data.

Fig. 10 repeats this experiment with varying numbers of threads, and plots client-side data throughput and agent-side buffer goodput. Buffer sizes of 16 kB and higher are sufficient for reaching peak write throughput while remaining comfortably within agent throughput limits; by default, we select 32 kB for Hindsight.

DiSh: Dynamic Shell-Script Distribution

Tammam Mustafa
MIT

Konstantinos Kallas
University of Pennsylvania

Pratyush Das
Purdue University

Nikos Vasilakis
Brown University

Abstract

Shell scripting remains prevalent for automation and data-processing tasks, partly due to its dynamic features—*e.g.*, expansion, substitution—and language agnosticism—*i.e.*, the ability to combine third-party commands implemented in any programming language. Unfortunately, these characteristics hinder automated shell-script distribution, often necessary for dealing with large datasets that do not fit on a single computer. This paper introduces DiSh, a system that distributes the execution of dynamic shell scripts operating on distributed filesystems. DiSh is designed as a shim that applies program analyses and transformations to leverage distributed computing, while delegating all execution to the underlying shell available on each computing node. As a result, DiSh does not require modifications to shell scripts and maintains compatibility with existing shells and legacy functionality. We evaluate DiSh against several options available to users today: (i) Bash, a single-node shell-interpreter baseline, (ii) PASH, a state-of-the-art automated-parallelization system, and (iii) Hadoop Streaming, a MapReduce system that supports language-agnostic third-party components. Combined, our results demonstrate that DiSh offers significant performance gains, requires no developer effort, and handles arbitrary dynamic behaviors pervasive in real-world shell scripts.

1 Introduction

Unix and Linux shell scripting remains prevalent—8th most popular language on GitHub in 2022 [20]—for data processing, system orchestration, and other automation tasks. Part of this prevalence can be attributed to a unique combination of features: (1) powerful and language-agnostic primitives for composing components available in any programming language; (2) dynamic features such as command substitution, variable expansion, and state reflection on the file system; and (3) a wide range of useful components called commands, available in the broader environment and tailored to specific tasks. These features enable the composition of succinct and powerful programs on a single computer (§2).

Tab. 1: Available options for scaling out shell programs. Compatibility: support unmodified shell scripts. Granularity: support fine-grained distribution. Expressiveness: support arbitrary dynamic behaviors. Agnosticism: support components in any programming language. Equivalence: behavior equivalence with existing shells.

Approach	Compatibility	Granularity	Expressiveness	Agnosticism	Equivalence	Examples

Other languages	☐	■	■	☐	☐	[16, 60, 66]
DiSh	■	■	■	■	■	

Unfortunately, these features also hinder automated shell-script scale-out to multiple computers. Such scale-out is often necessary not only to accelerate computations, but also to compute over data that either do not fit on a single computer or are naturally distributed across multiple computers.

State of the art: Shell users dealing with large datasets that do not fit on a single computer are left with only a few options (Tab. 1). One option is to use a distributed shell [14, 18, 63]. Distributed shells require rewriting scripts manually and only support a small subset of UNIX features—often with limited, if any, dynamic features and varying support for composition constructs. A recent distributed shell named POSH [49] can handle a subset of shell scripts without rewriting—although that subset is limited to dataflow-only computations and also does not include arbitrary dynamic shell behaviors. In addition, since POSH is a shell reimplement, it is not behaviorally equivalent with existing shells and thus risks breaking ported scripts. A second option is to rewrite (parts of) the script in a cluster-computing framework [11, 44, 68, 71].

These only support pure computations (*e.g.*, batch, stream), require manual rewriting, and only rarely [25, 30] support language-agnostic components. Another option is job scheduling tools [19, 29, 58, 69], but these operate at a coarse granularity and do not leverage parallelism available in individual commands. Yet another option is to rewrite scripts in languages that support distribution [3, 40, 42, 66], foregoing the shell’s succinctness and language agnosticism. To summarize, these options operate on a subset of the shell, require significant manual effort, risk breaking correctness, or—most often—suffer from a combination of these limitations (see §8 for more details).

Dynamic shell-script distribution: This paper presents DiSH, a system designed to scale out shell scripts operating on distributed filesystems while maintaining full POSIX compatibility. DiSH satisfies all requirements in Table 1: it operates on existing shell scripts; it distributes scripts at the granularity of individual commands; it handles arbitrary dynamic shell features such as substitution and expansion; it allows the use of commands and utilities of any language; and, most importantly, it is behaviorally equivalent to Bash.

DiSH first instruments the execution of a script to identify regions that may benefit from distribution. At runtime, it compiles these regions to an intermediate representation which it then optimizes to introduce appropriate parallelism, buffering, communication, and coordination. DiSH then executes each compiled region in a distributed fashion using the same shell interpreter, components, and data as the original script.

Implementation and results: DiSH is implemented as a shim layer (rather than a shell) that wraps and orchestrates the (completely unmodified) user shell, delegating all execution to the underlying shell available on each computing node. This design hides distribution from the user and avoids modifying the underlying shell interpreter: the user thinks that their original script is being executed (but faster); each underlying shell is given a part of the distributed script to execute. As a result, DiSH achieves a new milestone in automated shell-script distribution: it offers significant performance benefits, it avoids modifications to shell scripts, and it maintains full POSIX compatibility. Additionally, this modular design allows further research and improvements without modifications in the underlying shell.

We characterize DiSH’s performance on a 4-node on-premise cluster and a 20-node cloud deployment using 76 scripts—including ones not trivially expressible in modern distributed computing frameworks, such as scripts with `for` loops, side-effects, and complex third-party components. DiSH surpasses the speedups achieved by production-grade systems on existing benchmarks and extends speedups to new ones: it achieves significant speedups over (1) Bash (avg: 13.6×; max: 136.3×), a single-node shell-interpreter baseline; (2) PASH (avg: 8.9×; max: 108.8×), a shell-script parallelization system; and (3) Hadoop Streaming (avg: 7.2×;

max: 32.3×), a cluster computing framework that supports language-agnostic components and shell scripts. Moreover, whereas Hadoop Streaming does not support 27/76 scripts and requires rewriting 7/76 scripts, DiSH runs all scripts without any modifications; in fact, DiSH is able to execute the entire POSIX shell test suite, only diverging in one error code out of thousands of assertions.

Paper outline and contributions: The paper begins with an example and overview (§2) of DiSH’s use and techniques. Sections 3–6 present DiSH’s key components:

- Dynamic orchestration (§3): DiSH parses, pre-processes, expands, and orchestrates its input script to enable dynamic distribution at runtime.
- Compilation (§4): During script execution, DiSH compiles certain regions to an intermediate representation and applies a series of optimizations.
- Distribution (§5): DiSH distributes each region to a set of workers in a way that promotes co-location of processing primitives and the data blocks these operate on.
- Runtime support (§6): DiSH bundles additional runtime primitives supporting correct and efficient communication in the context of distributed shell script execution.

The paper then presents DiSH’s evaluation (§7) and related work (§8), before concluding (§9).

DiSH limitations: DiSH currently does not tolerate failures such as worker aborts or network partitions. In such occasions, users are expected to rerun their scripts similar to how they do in non-distributed executions: due to the shell’s dynamic features and its support for third-party components, users often re-run failing scripts from the start. The current DiSH prototype does not implement support for security features such as encryption and containment.

Availability: All the work described in this paper has been implemented and incorporated into PASH—an MIT-licensed project—and is available by the Linux Foundation at <https://github.com/binpash/dish>.

2 Background, Example, and Overview

DiSH allows everyday shell scripts to reap the benefits of distributed computing: execute on data that do not fit on a single machine, often also speeding up expensive computations.

Intended use: DiSH is designed to support a variety of use cases, depending on the details of the distributed environment on which the system is executing. The most common case is one where input data are downloaded and stored in a distributed file system such as HDFS¹ and then processed using

¹The choice of HDFS is not binding. DiSH could work on top of any distributed file system (*e.g.*, NFS or Alluxio [35]) that exposes the locations of file blocks. To achieve performance benefits due to co-location, there also needs to be available compute on the nodes that host that file system.

various analyses. This is useful for datasets that do not fit on a single computer, that are naturally distributed across multiple computers, or that can be processed faster in a data-parallel fashion. DiSH will distribute the computation appropriately, often running data-parallel instances on multiple machines and multiple processors per machine. DiSH also supports hybrid operation where data resides on both distributed and local file systems; this is useful for computations that contain CPU-intensive stages over datasets that do not necessarily reside on distributed file systems.

Example script: Fig. 1 shows a shell script that calculates maximum and average temperatures across the US, on datasets hosted on the National Oceanic and Atmospheric Administration (NOAA). The script is split into three parts: (p. 1) an 11-stage pre-processing pipeline to download data from NOAA and store them on HDFS, with the data range controlled upon invocation via dynamic arguments `$1` and `$2`; (p. 2, 3) two 5-stage pipelines calculating and storing maximum and average temperatures to the local file system.

HDFS is a distributed file system for handling large data sets on commodity hardware. Scripts like the one in Fig. 1 that process files stored in distributed file systems spend most of their execution time moving files across the network. On a 4-node cluster (§7) and 3.6GB of input, running just `hdfs dfs -cat` takes 346s; computing pipeline 2 (maximum temperature) only adds 6s. This phenomenon is due to pipeline parallelism: the execution time of all concurrently executing commands is mostly shadowed by `hdfs dfs -cat`.

Opportunities for scale-out: There are ample opportunities for improving the performance of this script. Since all parts contain stages that operate on large datasets, we should be able to execute (at least some of) their stages in a data-parallel fashion. For example, we should parallelize commands that process their input independently, such as `cut` and `grep`, by having them operate in parallel over partial inputs.

Additionally, carefully colocating computation and data should also improve performance. For example, we should schedule the data-parallel execution of the aforementioned `cut` and `grep` instances on machines that store the respective data segments. Directly operating on distributed file segments, rather than gathering and processing data on a subset of the machines, eliminates most data-movement overheads.

Finally, the execution of program fragments that do not depend on each other could become concurrent: since parts 2 and 3 are independent on each other, we should be able to overlap their execution in a task-parallel fashion.

Key challenges: Unfortunately, exploiting these opportunities to scale out execution automatically is particularly challenging in the context of the shell. First, exposing opportunities at the level of individual commands such as `cut` and `grep` is challenging—and this is why prior systems often focused on coarser, script-level or job-level granularity [19, 69].

Second, pervasive dynamic features, file-system introspec-

tion, and other side-effects impede traditional distribution approaches based on static transformation—this is why prior shell-script distribution work [25, 49] focuses on side-effect-free dataflow subsets. These challenges are compounded by the presence of more elaborate control flow such as `for` loops, `break`, and `trap` statements present in ordinary shell scripts.

Third, behavioral equivalence with existing shells is practically unattainable, especially with shell reimplementations—after all, even production-grade shells such as Bash and zsh diverge subtly in their POSIX behavior [23]. A new distributed shell [14, 49] has little hope of *not* breaking some scripts.

DiSH overview: To overcome these challenges DiSH (1) extracts details about the behavior of commands through command annotations, (2) deals with dynamic features and side-effects by analyzing scripts at runtime using dynamic orchestration, and (3) achieves behavioral equivalence with Bash by only performing script transformations and delegating execution to the underlying interpreter. DiSH is designed to dynamically orchestrate, compile, schedule, and support the execution of shell scripts (Fig. 2). DiSH’s orchestration (§3) kicks in when a potentially distributable script region is identified, saves a snapshot of the user’s shell environment (variables, configuration) and invokes the DiSH compiler with the candidate region (Fig. 2a). The compiler analyzes this region and if possible, translates it to a dataflow graph—which it then optimizes to introduce parallelism, buffering, *etc.* (§4), finally passing it off to the scheduler (Fig. 2b); or aborts compilation (Fig. 2d) because it cannot guarantee that the region is pure,

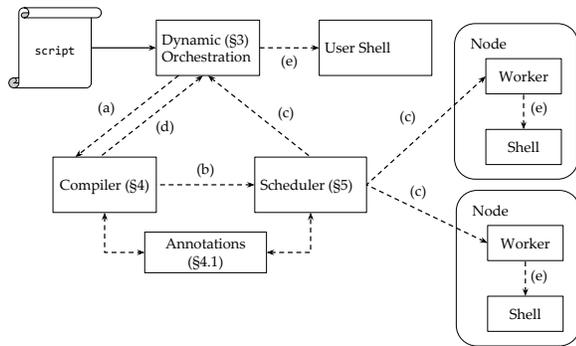

Fig. 2: DiSH architecture overview. Steps: (a) compile script region; (b) schedule compiled dataflow; (c) send dataflow subgraphs to workers; (d) compilation failed, fall back to original region; and (e) execute script region (compiled or original).

i.e., side-effect-free. The scheduler (§5) divides the compiled dataflow graph into different subgraphs which it sends to available cluster workers (Fig. 2c). In response to these execution requests, workers apply a second pass of optimizations to better utilize available resources, translate the dataflow graph back to a shell script (Fig. 2e), load the snapshot of the shell environment stored by the orchestrator, and execute the script using the local, unmodified shell interpreter (§6).

Applying DiSH: DiSH preprocesses the script in Fig. 1 to identify script regions that could benefit from distribution—in this case, all three pipelines. It then replaces each of these regions with calls to the dynamic orchestrator and attempts to distribute them at runtime. During execution, the orchestrator queries the DiSH compiler to determine whether a region is pure and thus distributable: if the compiler succeeds, it translates the region to a dataflow graph. Since regions contain arbitrary black-box commands, DiSH cannot analyze them directly. Instead, it employs a command specification framework that contains partial specifications of command invocations such as their inputs and outputs. For example, DiSH’s compiler uses these specifications to determine that `hdfs dfs -cat /noaa/temps.txt` reads from the HDFS file `/noaa/temps.txt` and writes to `stdout`. Once a region is in dataflow form, DiSH applies transformations to distribute it.

Fig. 3 shows the distribution stages for pipeline 2 (maximum temperature). DiSH first detects operations on HDFS files (*i.e.*, HDFS `cat`) and expands each distributed file to its segments (datablocks), often stored on different physical machines. Informed by command annotations, DiSH applies parallelization transformations: commands like `cut` and `grep` are parallelizable directly and can be executed on the machine with the raw input datablock. The scheduler then splits the compiled graph into subgraphs and maps them to workers in a data-aware fashion. Finally, each worker translates the graph back to a shell script, adds additional runtime primitives (commands), and executes it locally.

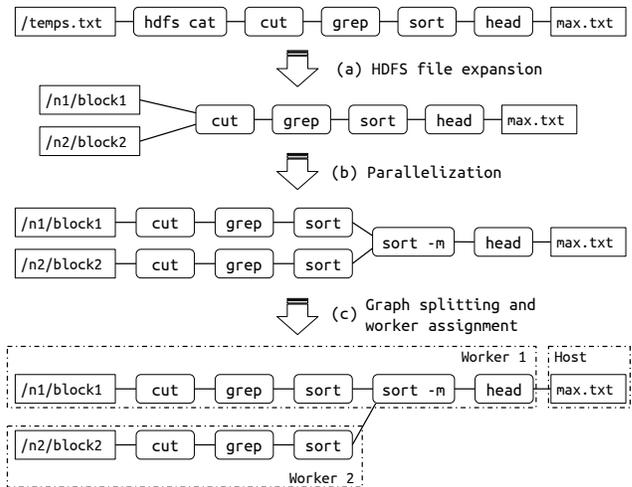

Fig. 3: DiSH dataflow graph stages. (a) HDFS files are expanded to sequences of blocks. (b) the graph is parallelized based on the command specifications. (c) the scheduler splits the graph and assigns subgraphs to workers.

The result? DiSH drops the execution of pipeline 2 from 352s to 6s while maintaining full behavioral equivalence and requiring no modifications to the user shell.

3 Dynamic Shell Orchestrator

To facilitate adoption, an important desideratum in the design of DiSH is to achieve behavioral equivalence with the underlying shell interpreter. To achieve this, DiSH is not designed to operate as another shell, but rather wraps the user’s existing shell interpreter and the shell interpreters on the worker machines. As a result, DiSH hides parallelization and distribution from both the user and the underlying shells: the user thinks that their original script is being executed—just faster—and each underlying shell simply executes a standard non-distributed shell script. This allows DiSH to achieve exceedingly high compatibility with the underlying shell implementation (§7.3), while also minimizing maintenance costs since updates and modifications on the underlying shell are reflected in DiSH without any change.

Fig. 4 shows an overview of the structure of DiSH’s dynamic orchestration. To achieve dynamic shell script orchestration without any shell-interpreter modification, DiSH opts for a light-weight script instrumentation pre-processing step: it instruments *potentially* distributable regions with invocations to the orchestration engine. It chooses regions with the goal of maximizing distribution benefits: intuitively, it focuses on commands and pipelines rather than control-flow statements and variable assignments. However, the choice of these region boundaries is not binding—the preprocessor just needs to be precise enough to determine potential regions, but DiSH will eventually decide whether or not (and if yes, how) to distribute

a candidate region at runtime. The preprocessor first parses the original script, it then replaces the relevant program regions with orchestration prefixes, and then un-parses (emits) it back as an instrumented script that is given for execution to the user’s shell interpreter.

The instrumented script then makes calls to the orchestration engine. The orchestration engine is itself a shell script coordinating with the compiler and worker manager and attempting to distribute the upcoming region (see §4 and 5 for details). If it succeeds, it runs the distributed version of the region. If it aborts, it just falls back to the original region, executing it normally. Reasons for aborting include the region being side-effectful, *e.g.*, modifying some environment variable, or lacking relevant command annotations.

Preprocessor: The preprocessor searches for maximal potentially distributable regions by processing the AST bottom-up, combining distributable subtrees when they are composed using constructs that do not introduce scheduling constraints (*e.g.*, `&`, `|`). When a region cannot outgrow a certain subtree, DiSH replaces it with a call to the orchestration engine. If the region is successfully compiled (at runtime), DiSH translates it to a dataflow representation—a convenient and well-studied model amenable to transformation-based optimizations [26]. At a later point, DiSH running on each node translates the instrumented AST resulting from the compilation back to shell code and passes it to the underlying shell for execution.

Parsing library: DiSH invokes parsing and unparsing routines frequently, and therefore needs them to be very efficient. To that end, it uses an internal Python implementation [32] of POSIX-shell-script parsing and unparsing based on `libdash` [22, 23]. The DiSH parser contains several optimizations such as caching, inlining, and careful array appending to achieve improved performance.

Orchestration engine: DiSH’s orchestration engine is designed to maintain the original script behavior and minimize runtime overhead—as it is invoked multiple times per script. The engine is a reflective shell script: it coordinates transparently with the compiler to determine whether or not to parallelize a script by inspecting the state of the shell and that of the broader system. DiSH constantly switches between two execution modes when executing scripts: (1) conventional shell mode, where scripts execute in the original shell context, and (2) DiSH mode, where the runtime reflects on shell state and invokes the compiler to determine whether to execute the original or an optimized version of the target region. To switch from shell mode to DiSH mode, the engine saves the state of the user’s shell; to switch back, it restores the state of the user’s shell. The state of a shell is quite complex: apart from saving and restoring variables, DiSH must account for various shell flags along with other internal shell state (*e.g.*, the previous exit status, working directory). During an invocation, the engine first switches to DiSH mode, communicates with the compiler and scheduler to determine whether a region can

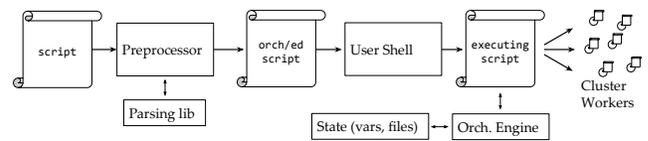

Fig. 4: Dynamic orchestration overview. DiSH instruments scripts with calls to the orchestration engine, which passes program fragments to the worker manager at run-time.

be safely distributed, and it then switches back to shell mode to execute the original or distributed version of the script.

Environment sharing: The distributed version of the script region might execute on a different shell (or even machine). Therefore, a challenge that DiSH needs to address is to make sure that all regions execute in the correct environment—including access to the latest variable values and function definitions. To achieve that the engine takes a snapshot of the environment right before execution. It then transfers the snapshot to the distributed workers, which they load before executing the incoming script fragment. This is safe to do since successful distribution of a region implies that it is pure (and therefore does not affect the environment), and thus the snapshot will be valid until the region finishes execution.

String expansion: To correctly determine if a script region is safe to distribute, the compiler needs to expand all strings in that region. Since DiSH performs compilation and distribution of each script region at runtime, right before execution, it has access to all the latest variables and system state to fully expand all strings in the region. DiSH only implements a common and safe subset of all available expansions, and avoids implementing side-effectful expansions that have the risk of affecting the environment (*e.g.*, `${x=foo}`: set `x` to `foo` if `x` is unset). Note that DiSH keeps expansion local: it does not expand regions succeeding the target region, as these might depend on the execution of the target region.

4 Compiler

This section describes the compiler of DiSH, which builds on the PASH parallelizing compiler [64]. The compiler is given the AST of an input script fragment and information about the commands in that fragment (§4.1). It then attempts to transform it to a dataflow graph (§4.2), an intermediate representation amenable to parallelization transformations. If the compiler succeeds in transforming a script region to a parallel dataflow graph, that graph is then passed to the scheduler which then decides how to map subgraph components to the available worker nodes. As the compiler operates at runtime in a just-in-time fashion, it exploits ample opportunities for parallelization even across subgraphs (§4.3).

4.1 Command Annotations

DISH needs to support analyses and transformations over third-party commands, without access to their source code. To achieve this, DISH uses annotations à la PASH [64] and POSH [49], capturing information about a command invocation’s parallelizability class, inputs, and outputs. Command annotations act as an intermediate layer that provides restricted but sufficient information about the behavior of a command to analysis and transformation systems like DISH. They also enable reuse, as they are not tied to a particular analysis and can thus be reused by different tools. For this work, DISH reuses the set of annotations developed by the authors of PASH [64] extended annotations for commands that appear in the evaluation of DISH (§7).

A command annotation in DISH encodes information at the level of individual command invocations, *i.e.*, precise instantiations of a command’s flags, options, and arguments. Among other information, annotations determine how a command invocation affects its environment, and specifically whether it is pure, *i.e.*, whether it only affects its environment by writing and reading to and from a well-defined set of files—information which DISH uses when translating commands to and from dataflow nodes (§4.2). For example, the annotation for `grep` can be used to extract that the script fragment `grep -f dict.txt src.txt > out.txt` contains two input files `dict.txt` and `src.txt` and one output file `out.txt`. This knowledge of input and output files is used by DISH to enable location-aware distribution, by scheduling the computation on nodes that contain relevant data blocks. Additionally, annotations describe parallelization opportunities—*e.g.*, that `grep "pattern" src.txt` processes each line of `src.txt` independently and thus can be parallelized at a line boundary.

4.2 Dataflow Model

The core of DISH’s compiler is an order-aware dataflow model that captures pure shell script regions that read from a well-defined set of input files and write to a well-defined set of output files—*i.e.*, they do not modify their environment in any other way. This model is expressive enough to capture a shell subset used pervasively in data processing scripts [26].

In this model, nodes represent commands and edges represent files, pipes, named FIFOs, and file descriptors. The model is order-aware in the sense that it keeps information about the order in which nodes read from their inputs, which is important for the script’s semantics. For example, `grep "pattern" in1.txt - in2.txt` first reads from `in1.txt`, then from its standard input, and then from `in2.txt`. This order awareness allows DISH to perform transformations that optimize execution of a script—*e.g.*, by exposing parallelism—but preserve its original behavior.

Translation workflow: Given an AST representation of an input script region, the compiler uses annotations to deduce

whether commands are pure *i.e.*, they only affect their environment through a well-defined set of output files, and attempts to transform them to dataflow nodes. If all commands in the region are pure the compiler transforms the region to a dataflow graph. It then applies transformations (described below), optimizing the graph to expose parallelism and improve the script’s performance. Finally, it serializes the graph back to a (now optimized) shell script, by translating every node back to a command and connecting them all together with appropriate channels (*e.g.*, FIFOs, RFIFOs, redirections).

Transformations: DISH’s transformations enable data-parallel execution by replicating nodes in the graph and adding appropriate split and merge nodes around them. They apply a pass over the graph to remove pairs of inverse nodes—*i.e.*, pairs of nodes whose semantic effects cancel out but whose performance effects are additive—for example, a concatenation-style merge followed by a linear split. For commutative commands, *i.e.*, commands that produce the same output regardless of their input-line order, DISH applies transformations that pack and unpack metadata across the graph—achieving better performance by avoiding unnecessary blocking and buffering. Finally, to improve the flow of data across the graph, DISH applies additional transformations that inject hybrid memory-disk buffer nodes in points in the graph that are likely to become bottlenecks.

Remote file resources and HDFS files: To support scripts that perform data analysis on a combination of HDFS and local files, DISH extends the dataflow model with remote-file resources (RFRs) that encode file blocks in different nodes. RFRs usually represent blocks of files that are partitioned and replicated in HDFS, and contain information about the location of the data in the distributed environment. This information could contain multiple locations to support replication, and is used by the scheduler to assign script fragments to different workers. When the DISH compiler comes across an HDFS file path, it queries HDFS to determine the locations of its file blocks and then expands that file to a sequence of RFRs, each of which represents a block.

4.3 Dynamic Dependency Untangling (DDU)

Scripts often contain regions that are independent, *i.e.*, they have different (file) working sets. Independent regions could potentially run in parallel, better utilizing computational resources and improving the execution times of the scripts in which they belong. However, inferring independence statically and ahead of time is challenging as shell scripts make extensive use of dynamic features. Figure 5 shows an example script that contains independent fragments but also features dynamic behavior. This script iterates over all files in an HDFS directory, compresses them using `gzip`, and finally stores them as independent files.

Determining independence statically in this script would

```

for item in $(hdfs dfs -ls -C ${IN});
do
    output_name=$(basename $item).zip
    hdfs dfs -cat $item |
        gzip -c > $OUT/$output_name
done

```

Fig. 5: Example of independent regions. This shell script compresses all files in a directory—but each iteration results in an independent body region that can be executed in parallel.

require inferring values of environment variables (like `IN` and `OUT`) and the state of the file system, *e.g.*, `hdfs dfs -ls`. DiSH’s dynamic orchestration (§3) circumvents this challenge by making distribution decisions during the execution of the script when environment variables and the file system state are known. DiSH further exploits this by discovering independent dataflow regions at runtime and executing them in parallel—even if they were not parallel in the original script.

When DiSH successfully compiles a dataflow region (at runtime), it knows that the region is pure and therefore can determine the region’s inputs and outputs—and it does so for free, without additional analysis or inference stages. DiSH then uses this information to check for read-write or write-write dependency conflicts with regions that are running concurrently. If none is found, DiSH passes the region to the scheduler, which orchestrates distributed execution, and then immediately continues the execution of the script until it reaches the next dataflow region. Whenever the compilation of a dataflow region fails, DiSH cannot safely detect the input and output information of this region—and thus it needs to wait until every previous region is done executing to ensure that no dependency will be violated.

Since DDU is done at runtime it is both sound, *i.e.*, it does not execute dependent fragments concurrently, and precise, *i.e.*, it offers significant benefits due to improved parallelism and resource utilization—especially for scripts that do not contain highly data-parallelizable commands, such as the commands in the aforementioned compression script (Fig. 5). Compared to analyses over static languages, DDU cannot identify global optimizations such as reordering the final command in the script to run first. This lack of optimality is not specific to DDU, but applies to any shell script analysis; in fact, as far as we know there is no sound and precise static analysis for shell scripts.

5 Distributed Scheduling

This section describes how DiSH’s scheduler distributes a compiled script to a set of workers. The scheduler is given a dataflow graph that is already parallelized and has HDFS files expanded to sequences of remote file resources (RFRs) representing their blocks. The task of the scheduler is then to distribute this graph with the goal of optimizing performance

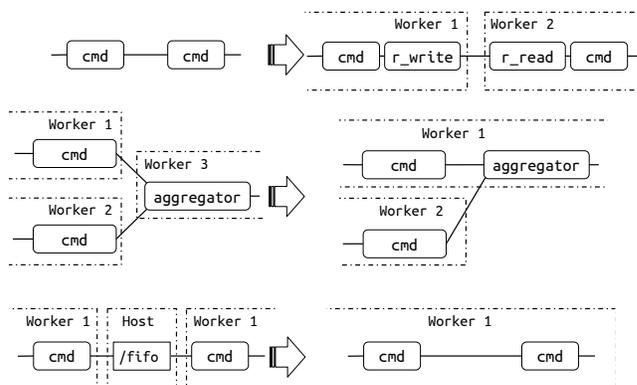

Fig. 6: (Top) Remote writes and reads added during distributed scheduling. **(Mid)** Worker-first aggregation. **(Bot)** Named FIFO teleportation.

by both utilizing available resources and moving computation close to the data. Currently the scheduler knows about the workers in the cluster ahead of time using a configuration file.

The scheduler makes a decision on how to split the graph based on a policy that optimizes performance through collocation of data blocks and the commands that execution over them. The scheduler processes the top-level dataflow graph to generate a set of subgraphs, one for each worker and one for the host machine executing the script. It then replaces edges corresponding to communication channels (*e.g.*, FIFOs, pipes) at the boundaries of each subgraph with remote channels—adding a remote write node on the sender side and a remote read node on the receiver side (see Fig. 6, Top). It also inserts remote reads for subgraph nodes that access files stored on remote workers. The final generated subgraph represents the script fragment that is passed for execution to the user shell running on each worker: the compiled script handles all the redirection to and from local files and the standard input, output, and error streams to and from the worker.

Data-aware scheduling policy: The highest performance overhead when executing distributed shell scripts is networked data movement across workers. DiSH addresses this overhead by introducing a greedy scheduling policy that allocates subgraphs in a way that attempts to minimize data movement across workers. If a data file (or block) is available on a worker, then DiSH maps the maximal dataflow subgraph that starts from that file to that worker—*i.e.*, scheduling as much of the processing as possible on the worker. The scheduler also tracks the amount of work that each worker currently has scheduled, which can vary due to dynamic dependency untangling (§4.3): if a data file is replicated across multiple workers, DiSH chooses the worker with the least amount of pending work to execute that subgraph.

Worker-first aggregation: The distributed dataflow graphs that DiSH executes often contain aggregation (*i.e.*, merge)

nodes, similarly to the reduce stages in Hadoop Streaming. Regardless of the worker on which the aggregation is performed, data from different workers will need to be combined onto a single worker and thus these dataflow nodes will necessarily result in data movement. DiSH prioritizes performing aggregation on one of the participating workers, because workers already contain a subset of the data used in the aggregation (see Fig. 6, Mid). This optimization is particularly beneficial for scripts that filter and aggregate data, often containing commands such as `grep` and `uniq`, because any filtering stages prior to aggregation result in reduced data transfer.

It is worth noting that, absent additional information about commands [49], the location of aggregators involves challenging trade-offs not addressable with a single optimization policy. For scripts that include aggregators that do not reduce data sizes, DiSH's worker-first aggregation optimization risks transferring more data. As DiSH's evaluation confirms (§7), however, worker-first aggregation results in performance benefits for most scripts.

Delegated script concretization: DiSH's scheduler sends workers dataflow subgraphs, encoded in DiSH's intermediate representation, instead of concrete shell scripts ready for execution. Each dataflow subgraph contains holes that workers are expected to fill in, based on the specifics of their local environment. This choice simplifies DiSH's distributed execution, as the scheduler does not need to have up-to-date information about several worker details such as the temporary directories they use. Additionally, this choice enables better resource utilization in a heterogeneous environments with different worker capabilities: a worker can apply another optimization pass to the dataflow subgraph it receives to better manage and utilize its resources.

Named FIFO teleportation: Scripts often use named FIFOs to share data between concurrently executing processes. Named FIFOs introduce a performance challenge, because they are local files that reside on the host machine where the script was executed. Therefore, by default, all data that would normally go through named FIFOs in the original execution would now have to go back and forth between workers and the machine for which the script was developed. DiSH addresses this challenge by observing that named FIFOs are ephemeral, *i.e.*, they maintain no data after the execution of a dataflow region. Based on this observation, DiSH migrates named FIFOs to workers closer to the data, eventually deleting the migrated versions after the dataflow region has finished executing (see Fig. 6, Bot). This transformation, termed FIFO teleportation, improves performance by avoiding unnecessary data movement in scripts that use FIFOs.

6 Runtime Support

DiSH has to address several runtime challenges: communication among workers, identification of HDFS data block lo-

cations, and correctness in view of HDFS blocks split independently of newlines—an assumption necessary for several dataflow transformations. This section describes several components of DiSH's runtime that address the above challenges.

Remote FIFO channel: As described earlier (§5), connections between dataflow nodes are instantiated using UNIX FIFOs in a single-machine setting. Unfortunately, FIFOs do not support networked operation and thus cannot cross worker boundaries. To address this challenge, DiSH introduces a remote FIFO primitive (RFIFO) that is implemented in Go and uses socket-based communication. RFIFOs are intended to operate identically to FIFOs, *i.e.*, implement the semantics of dataflow graph edges, but with support for operation over the network. They have a unique identifier and two ends—a read end and a write end.

Since shell streams are lazy, *i.e.*, a producer blocks until its consumer requests input, the network link is often not fully utilized, lowering throughput and risking introducing significant latency. To avoid these throughput and latency challenges, DiSH adds two buffer nodes to the dataflow graph: one before the write end of the RFIFO, to allow uninterrupted access to data, and one after the read end of the RFIFO, to force the read to request data. This lazy-to-strict optimization maintains correctness and improves performance in most cases; in rare cases, it may lead to unnecessary data transfer between nodes—*e.g.*, when there is a `head` command right after the read end of an RFIFO.

Port discovery service: As transformations and optimizations are applied during the execution of a script—contrary to most other distributed environments—DiSH's scheduler cannot statically predict which ports will be available at runtime for RFIFOs at each worker: different scripts and script fragments running concurrently during a single execution may collide on port usage. To address that, each DiSH worker implements a port discovery service (PDS) that can be accessed by remote FIFOs to (1) advertise their port, and (2) discover the port that their other end uses. The discovery service is implemented in Go with gRPC [61] and supports a few remote procedure calls (RPCs), central among which are a `put` call for advertisement and a `get` call for discovering the port of a remote end. RFIFOs are extended with gRPC clients to advertise ports among local PDS or identify the ports corresponding to their other end by querying the PDS of the respective worker. By deferring port selection until runtime execution, DiSH's port discovery service facilitates loose subgraph coupling and simplifies remote subgraph execution on multiple workers.

HDFS data retrieval: During transformations, the DiSH compiler (§4) needs to retrieve information about HDFS paths to expand them into block sequences. This expansion happens on a critical runtime path and thus needs to be efficient. A prior implementation of DiSH invoked this expansion on every HDFS path using a shell command—by wrapping `fsck`, a command offered by HDFS API for querying the health of

the disk in the cluster, returning information about a file and its partitioning into blocks. This implementation ended up incurring significant latency (> 1s), and thus DiSH switched to the web API reducing expansion to sub-10ms latency.

Enforcing logical block boundaries: A key challenge when processing separate file blocks in HDFS is the mismatch between compiler assumptions about the block shape and how blocks are actually stored in HDFS: HDFS blocks might not be split on newline boundaries, but the parallelizing transformations performed by the DiSH compiler (§4) assume that all blocks are logically separated by newlines. This assumption is crucial and depends on the way commands process their input, *e.g.*, `sort` processes its input line by line, and therefore would require a significantly more complex parallelization transformation if its input could be split at arbitrary points. Developing complex custom parallelization transformations for each command would be infeasible in practice due to the sheer number of available commands and would not allow DiSH to reuse the parallelization transformations developed for PASH [64].

Instead of relaxing the compiler assumption, DiSH addresses the mismatch by ensuring it holds during script execution using additional runtime support. DiSH implements a distributed file reader (DFR) primitive that runs as a service on every worker. The DFR service ensures that parallel dataflow nodes only process batches that are split in newline boundaries, independent of how the actual physical blocks are split—providing the illusion of a logical block that ends at a newline to its consumer. Given a distributed file path, DFR reads the local file or block from the worker’s disk going beyond the first newline character in its block. If the block is not terminated with a new line, then the DFR communicates with the reader of the next block (and potentially any readers after that), returning a complete logical block to its consumer. When a compiled dataflow graph is translated back to a script, DiSH prefixes file paths with a command invoking a DFR client that communicates with the relevant DFR service to retrieve the relevant logical block. Both service and client are implemented in Go, communicating using gRPC and protobufs [21].

7 Evaluation

We are interested in evaluating two aspects of DiSH: (1) its performance, and (2) its compatibility with Bash.

Experiments: We perform four experiments using several real-world shell scripts taken from a variety of sources (Tab. 2). The first two experiments focus on the performance gains (§7.1) achieved by DiSH’s distribution on (1) a 4-node on-premise cluster, and (2) a 20-node cloud deployment—both over a variety of benchmarks and workloads. We compare DiSH’s performance against (1) GNU Bash [50], the *de facto* sequential shell-script execution environment; (2)

Tab. 2: Benchmark summary. Summary of all the benchmarks used to evaluate DiSH, and their characteristics.

Benchmark	Scripts	Pure HS	LOC	Input	Source
1 Classics	10	7/10	123	3G	[5, 6, 31, 39, 59]
2 Unix50	34	30/34	142	21G	[7, 34]
3 COVID-mts	4	4/4	79	3.4G	[62]
4 NLP	21	-	306	120 books	[9]
5 AvgTemp	1	1/1	31	3.6G	[68]
6 MediaConv	2	-	35	0.8 & 0.4G	[49, 56]
7 LogAnalysis	2	-	63	0.7 & 1.3G	[49, 56]
8 FileEnc	2	-	44	1.3G	[41]

Apache Hadoop Streaming [25] (AHS), a production-grade distributed data-processing framework that supports language-agnostic executables; and (3) in the case of the 4-node setup, PASH [32, 64], a shell-script parallelization system from the Linux Foundation. PASH’s parallelism benefits make it a likely alternative to DiSH for smaller clusters, where DiSH’s anticipated benefits of distribution might be smaller, but this likelihood diminishes as the size of the cluster grows.

The last two experiments evaluate DiSH’s dynamic dependency untangling (§7.2) and DiSH’s correctness (§7.3), *i.e.*, its compatibility with respect to Bash across all scripts and the POSIX shell test suite.

Benchmarks: We use 8 sets of real-world benchmarks, totaling 76 shell scripts and 823 LoC. Classics and Unix50 contain classic and recent (c. 2019) scripts that make heavy use of UNIX and Linux built-in commands. COVID-mts contains four scripts used to analyze real telemetry data from mass-transit schedules during a large metropolitan area’s COVID-19 response. NLP contains several scripts from UNIX-for-poets, a tutorial for developing programs for natural-language processing out of UNIX and Linux utilities. AvgTemp contains a large script downloading and processing multi-year temperature data across the US. MediaConv contains two scripts that process, transform, and compress video and audio files. LogAnalysis contains two scripts that apply typical system-administration and network-traffic analyses over log files. Finally, FileEnc contains aliases that encrypt and compress files.

Baselines and implementations: Bash, PASH, and DiSH executed every shell script completely unmodified. Apache Hadoop Streaming (AHS) posed significant expressiveness limitations. Only 42 scripts in Classics, Unix50, COVID-mts, and AvgTemp out of 76 scripts can be implemented natively (Tab. 2, col. Pure HS). Another 7 scripts required manual porting by splitting them into mappers, reducers, and additional components: These components were not available natively by AHS—for example, components for reading from two pipelines for `diff.sh` and for sorting after the reducer for `bigrams.sh` (both in Classics). During porting, we put significant care to avoid limiting AHS’s parallelism: we modified 3 AHS scripts in Classics to help HS introduce additional

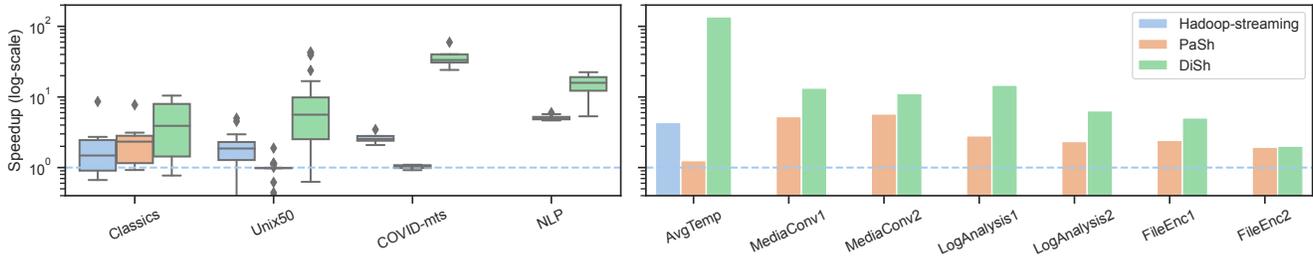

Fig. 7: DiSH performance on a 4-node cluster. DiSH speedup (vs. PASH and Hadoop Streaming whenever possible) over Bash for Tab. 2 rows 1–4 (left, box) and 5–8 (right, bar) (Cf. §7.1). (Log y-axis; higher is better.)

parallelism—for example, we manually expanded `tr -cs` into `tr -c | grep -v` (both stateless). None of the scripts in NLP, MediaConv, or LogAnalysis can be implemented in AHS as they perform processing in loops, the iterations of which depend on the files in a statically indeterminable directory (see Fig. 5) and are therefore not expressible in AHS. We attempted to replace the body of the loop with an AHS invocation but the startup overhead ended up dwarfing the execution time by a factor of ten on average.

Hardware & software setup: The 4-node cluster consists of four 6-core Intel(R) Core(TM) i7-10710U CPU nodes each with 64GBs of RAM, located in the same room and connected with an average bandwidth of 90.8 Mbits/sec. The 20-node deployment consists of x1170 Cloudlab [15] nodes, each equipped with 10 × Intel Core E5-2640 2.4 GHz CPUs and 8GB of memory. Single-machine shells (Bash & PASH) were evaluated on a machine with 20 × 2.80GHz Intel(R) Core(TM) i9-10900 CPUs and 32GB of memory.

For ease of deployment and reproducibility, we used Docker swarm to deploy (1) HDFS, and (2) the DiSH runtime. The containers were created using the standard Ubuntu 18.04 image. We use Bash v.5.0.3, PASH v.6e2ecba, and HDFS/Hadoop streaming version 3.2.2. We explicitly disabled checksum verification from HDFS in all configurations, scripts, and measurements. All scripts were executed completely unmodified, using environment variables, loops, and other shell constructs. To minimize statistical non-determinism we repeated the experiments several times noticing imperceptible variance.

The DiSH implementation comprises 6784 lines of Python (preprocessor, compilation server, expansion, compiler, and parser), 1011 lines of shell code (JIT engine and various utilities), and 1174 lines of C (commutativity primitives, and other runtime components). All counts include only semantically meaningful lines of code.

7.1 Performance

How does DiSH’s distributed perform on small on-premise clusters and multi-node cloud deployments, and how does it compare to state-of-the-art systems?

Tab. 3: DiSH performance in 20-node cloud deployment. DiSH speedup over Hadoop Streaming for scripts that AHS supports.

DiSH speedup over AHS						
Benchmark	Avg	Min	25th	50th	75th	Max
Classics	2.74×	0.92×	2.41×	2.60×	2.85×	6.55×
Unix50	6.64×	0.91×	2.85×	5.38×	10.4×	16.9×
COVID-mts	10.4×	6.64×	8.91×	9.27×	-	16.8×
AvgTemp	7.85×	-	-	-	-	-

Results: Fig. 7 (note the log y-axis) shows the performance of DiSH, PASH, and AHS on a 4-node on-premise cluster across all benchmarks of Tab. 2. Box plots (left) show result quartiles for multi-benchmark suites (Tab. 2, rows 1–4) and bars (right) show results for individual scripts (Tab. 2, rows 5–8). Across all benchmarks, DiSH achieves an average speedup of 13.6× (vs. 2.55× for PASH and 2.1× for AHS) and a maximum speedup of 136.3× (vs. 7.8× for PASH and 8.6× for Hadoop Streaming). The average execution time of all scripts on Bash is 299s, ranging from 1s for `34.sh` in Unix50 to 2840s for `nfa-regex.sh` in Classics. DiSH is only slower than Bash (737s vs 568s) in the case of `diff.sh` from Classics, for which AHS is even slower (766s). DiSH achieves a performance comparable to Bash (1-2s) in `4.sh` and `34.sh` from Unix50, because both perform a short-running head.

Tab. 3 shows the speedup of DiSH over AHS on a 20-node Cloudlab deployment across all scripts implementable with AHS (Classics, Unix50, COVID-mts, AvgTemp). Across all benchmarks, DiSH achieves an average speedup of 6.17× and a maximum speedup of 16.95× over AHS. DiSH is slower than AHS only for three scripts: `nfa-regex.sh` from Classics (0.92×), `29.sh` and `30.sh` from Unix50 (0.91× and 0.94×).

Across all scripts in both deployments, DiSH’s overheads (startup cost, dynamic orchestration, preprocessing, compilation, scheduling) take less than 1 second.

Discussion: DiSH is faster than Bash, PASH, and AHS across Tab. 2’s suites (rows 1–4) with respect to average, and across all of Tab. 2 individual benchmarks (rows 5–8)—often by a significant margin (e.g., 134× for AvgTemp against PASH).

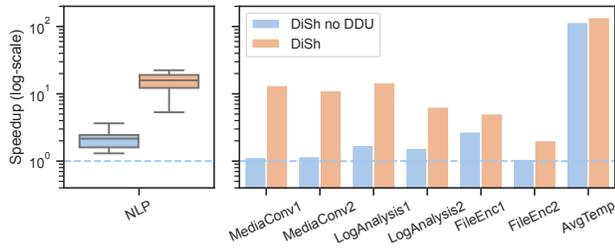

Fig. 8: Dynamic dependency untangling. DiSH speedup over Bash when toggling DDU (higher is better).

DiSH’s (and PASH’s) speedup over Bash is due to parallelism. DiSH’s speedup over PASH is due to DiSH’s co-location of data and computation: PASH cannot offload computation and thus first gathers all data onto a single machine—a time-consuming stage—and then starts processing in parallel. DiSH is slower than Bash only for `diff.sh`, because (1) it is not highly parallelizable and (2) it performs no filtering, *i.e.*, its output is the same size as its input. In contrast to Bash, which simply fetches all data and processes it locally, DiSH tries to allocate most commands on the workers, but this leads to increased data movement since moving data between workers does not avoid sending the whole output to the client.

DiSH’s speedup over AHS is due to a few different reasons. One reason is the increased expressiveness of DiSH’s dataflow model: DiSH accepts and parallelizes complete scripts, discovering more opportunities for parallelism. Many of the AHS scripts are broken into multiple map and reduce stages, often leaving pipeline parallelism and data parallelism unexploited. Another reason is DiSH’s dynamic independence discovery, which allows for additional parallelism and better utilization of resources—in ways that AHS does not support; we zoom into these benefits below (§7.2). In the Cloudlab deployment, DiSH is (marginally) slower than AHS in only two cases: (1) a script that is embarrassingly parallel and thus implementable in AHS using only a single mapper (`nfa-regex.sh`), and (2) two scripts in Unix50 that see slightly more benefits from our manual, hand-optimized AHS rewrite than they do from DiSH’s automated distribution.

We found porting scripts to AHS a serious challenge. Many scripts required significant manual effort, resulted in multiple error-and-fix cycles, and led to script size increases. To overcome AHS’s expressiveness limitations, we had to modify a few scripts in unintuitive ways—often combining plain Bash scripts with AHS mappers and reducers. These modifications made scripts significantly more complex and compounded the effort to test and maintain them. Instead, DiSH distributed scripts successfully without any such challenges.

7.2 Dynamic Dependency Untangling

What is the speedup due to dynamic dependency untangling?

Results: Figure 8 shows DiSH’s speedup over Bash with and without dynamic dependency untangling (DDU, § 4.3). It excludes scripts that contain a single dataflow, for which DDU is not applicable. DiSH’s average speedup over DiSH-w/o-DDU is 6.9×, ranging between 1.2–13.9×.

Discussion: Enabling DDU improves performance significantly across all relevant scripts, by running independent dataflow regions in parallel. This allows DiSH to expose parallelism not just within data pipelines but across them, improving utilization. DDU also improves the distributed execution of scripts that operate on many files, many or most of which are small enough to fit on a single HDFS block.

DDU is the main reason why DiSH gets an edge over Bash on scripts that (1) have implicit independences that are not highly parallelizable, and (2) operate on small data that incur imperceptible data-movement costs. Examples of such scripts include `MediaConv1` and `FileEnc2`.

7.3 Correctness

What is DiSH’s output compatibility with respect to Bash?

Results: To check the correctness of DiSH across all benchmarks, we check that its stdout and exit status are equivalent to the ones produced by Bash. Across all benchmarks, totaling over 650 millions lines (18GB) of output, DiSH produces the same output and exit status as Bash.

We additionally execute the complete POSIX shell-test suite to evaluate DiSH’s compatibility with Bash. Out of all relevant tests, DiSH diverges from Bash in two cases and only with respect to the exit status it returns: both exit with an error, but Bash returns 1 whereas DiSH returns 127, which is outside of the POSIX mandated exit status range between 1–125. The reason is that DiSH always invokes the underlying Bash interpreter using the `-c` flag to set the `$0` variable, and Bash (contrary to most other shells, *e.g.*, `dash`, `ksh`, `mksh`, `sash`, `Smooch`, `yash`, `zsh`) exits with 127 in particular failing cases when called with `-c`.

Discussion: All benchmarks in Tab. 2 were executed with DiSH repeatedly. After hundreds of runs over several weeks, we observed dozens of different execution orders. Comparing the output on every run provides significant confidence about the correctness of the resulting distributed execution. The POSIX test suite mostly evaluates the correctness of dynamic orchestration (§3), as it does not feature many opportunities for parallelization and features no opportunities for distribution.

8 Related Work

DiSH is related to a large body of prior work.

Distributed data processing: Several environments assist in the development of distributed software systems: distributed computing frameworks [11, 44, 45, 57, 71] and domain-specific

languages [3, 8, 13, 40, 42] simplify the development of distributed systems that fall under certain computational classes such as batch processing, stream processing, *etc.* These systems deal with many of the challenges of distribution, but require developers to (re)write their computations manually in models that differ significantly from UNIX shell programming.

Hadoop Streaming and Dryad Nebula are abstractions that allow using third-party language-agnostic components similar to the UNIX shell, atop cluster-computing engines (Hadoop and Dryad, respectively). Both require their users to understand and rewrite their shell scripts using the abstractions provided by each framework. DiSH can operate on arbitrary shell scripts automatically, without requiring any manual effort from its users.

Distributed shells and tools: Several packages expose commands for specifying parallelism and distribution on modern UNIXes—*e.g.*, `qsub` [19], SLURM [69], calls to GNU `parallel` [58]. Different from DiSH, their effectiveness is predicated upon explicit and careful invocation and is limited to embarrassingly parallel (and short) programs. Often, these commands provide options to support an array of special sub-cases—a stark contradiction to the celebrated UNIX philosophy. For example, `parallel` contains flags such as `--skip-first-line`, `-trim`, and `--xargs`, that a UNIX user can achieve using `head`, `sed`, and `xargs`; it also includes other programs with complex semantics, such as the ability transfer files between computers, separate text files, and parse CSV. DiSH embraces the UNIX philosophy, attempting to rewrite shell programs to leverage distributed infrastructure.

Several shells [14, 38, 56] add primitives for non-linear pipe topologies—some of which target distribution. Here too, however, developers are expected to manually rewrite scripts to exploit these new primitives.

POSH [49] is a recent shell for scripts operating on NFS-stored data. It brings pipeline components closer to the data on which they operate, but operates only on shell pipelines that are fully expanded—*i.e.*, ones that do not use dynamic features. DiSH operates on shell scripts that use (1) any POSIX composition primitive, and (2) the full set of dynamic features present in the UNIX shell.

Distributed operating systems: There is a long history of networked and distributed operating systems [4, 12, 43, 46, 48, 51–53, 67]. These systems offer abstractions that (1) are similar, but not identical, to the ones offered by UNIX, (2) operate at a lower level of abstraction (*e.g.*, that of system calls, rather than shell primitives), and (3) often aim at simply hiding the network rather than offering scalability benefits. Instead of implementing full-fledged distributed operating system, DiSH shows that a thin but sophisticated rewriting-based shim can operate on completely unmodified programs, avoid requiring any user input, and achieve significant speedups by executing fragments in parallel across nodes.

Annotation-based transformations: Recent systems [47,

65, 70] lower the developer effort of scaling out program components by performing program transformations based on user-provided annotations. These systems operate in single-language environments, offering declarative DSLs for tuning the semantics of the resulting distributed program. DiSH uses a similar approach, leveraging command annotations from prior projects [49, 64], but operates on-the-fly—within an environment that makes extensive use of dynamic features and that allows combining components from multiple languages.

PASH-JIT [32] parallelizes scripts by dynamically interposing between a shell script and the underlying shell interpreter. This kind of interposition offers significant performance benefits without jeopardizing correctness, *i.e.*, maintains compatibility with the underlying shell interpreter. DiSH uses similar insights and interposition architecture, but operates on a distributed multi-node setting and addresses challenges that are specific to this setting—such as integration with a distributed file system and distributed environment passing.

Cloud build systems: Several cloud build systems [1, 2, 17, 27] distribute and parallelize the execution of large builds by constructing dependency graphs using dependency information explicitly specified by their users. Contrary to these systems, DiSH operates on general shell programs without exploiting domain-specific information—*e.g.*, build dependencies—and by taking a just-in-time approach that resolves dependencies during the execution of the script.

Correct distribution of dataflow graphs: The DFG is a prevalent model in several areas of data processing, including batch- and stream-processing. Systems implementing DFGs often perform optimizations that are correct given subtle assumptions on the dataflow nodes that do not always hold, introducing erroneous behaviors. Recent work [28, 33, 37, 54] attempts to address this issue by performing optimizations only in cases where correctness is preserved, or by testing that applied optimizations preserve the original behavior. DiSH uses its dynamic orchestration to achieve compatibility with the underlying shell and then achieves correct distribution on a per-region level by building on prior work on provably correct transformations for order-aware dataflow graphs [26]. Similarly to other automated shell script transformation works [49, 64], DiSH’s correctness is predicated upon the correctness of the annotations describing commands.

Resurgence of shell research: Recent shell research [10, 23, 24, 32, 36, 41, 49, 55, 56, 64] highlights renewed interest in shell scripting both as a vehicle for impactful research and as a target worthy of scientific attention. We see DiSH as a natural continuation of the insights and research behind recent systems [24, 26, 32, 49, 64], allowing other researchers to leverage DiSH’s POSIX-compliant high-performance dynamic distribution in their future work.

9 Discussion

Programmability: An important consideration with any automated system is how it affects programmability, and specifically the ability to debug a misbehaving program or to test a program for correctness. DiSH does not negatively affect the developer experience compared to a shell: a developer can use a combination of the many existing tools and commands—*e.g.*, `head` and `grep`—as they would normally do to inspect their script’s output and determine what is wrong. When it comes to shell scripts intended for distributed environments, DiSH in fact improves developer experience: a developer may use the same set of commands for local or distributed interactions—*e.g.*, to inspect and project parts of a file, regardless of whether that file is stored in HDFS or the local system. Furthermore, developers using DiSH can reap the scalability benefits of distribution in analyzing or testing scripts by automatically scaling out load to multiple computers.

Command annotations: DiSH’s transformations depend on the existence of command annotations. To maintain soundness, DiSH will avoid compiling and distributing a script region if some command lacks annotations. To increase the distributability of their scripts, DiSH users could opt for more constrained commands—*e.g.*, `cut` instead of `awk` for data projection—and thus enjoy tighter annotations and more applicable optimization transformations. The correctness of applying DiSH’s transformations depends on the correctness of these annotations, and thus annotations are currently expected to be authored by command developers or other experts (but not script developers). Developing automation for testing or synthesizing correct annotations is an interesting avenue for future research that would benefit several systems that use them—*e.g.*, DiSH, PASH [64], and POSH [49].

Fault tolerance: DiSH does not tolerate failures such as worker aborts or network partitions (§1). In such cases users are expected to rerun their scripts as shell users normally do in the non-distributed case. Achieving fault tolerance in the context of general shell scripts is in fact particularly challenging due to the prevalence of black-box components that may perform arbitrary side-effects. A fault-tolerant version of DiSH should be able to track all these side-effects and re-execute them appropriately when a script fails. This is in contrast to constrained cluster computing frameworks such as MapReduce and Spark that have precise information about the inputs and outputs of purely functional program components enabling simplified re-execution of dependency graphs (lineage) in the presence of failures. DiSH’s design however combined with incremental script execution [10] creates an opportunity for addressing this challenge with a hybrid approach: employ conventional fault tolerance approaches for script fragments with annotation information, and instrument the rest of the script to capture and replay its side-effects appropriately in cases of failure.

Conclusion: DiSH is the first system able to distribute unmodified shell scripts that use (1) any POSIX composition primitive, (2) the full set of dynamic features present in the UNIX shell, and (3) distributed file systems such as HDFS. DiSH uses a dynamic orchestration approach that instruments a given script and dynamically distributes it at runtime to then execute it using the underlying shell interpreter. As a result, DiSH avoids modifications to shell scripts and maintains compatibility with existing shells and legacy functionality. Evaluated against several alternatives available to users today, DiSH offers significant speedups, requires no developer effort, and handles arbitrary dynamic behaviors pervasive in shell scripts. DiSH is open-source software, available by the Linux Foundation.

Waverunner: An Elegant Approach to Hardware Acceleration of State Machine Replication

Mohammadreza Alimadadi, Hieu Mai, Shenghsun Cho*, Michael Ferdman, Peter Milder, Shuai Mu
*Stony Brook University, *Microsoft*

Abstract. State machine replication (SMR) is a core mechanism for building highly available and consistent systems. In this paper, we propose Waverunner, a new approach to accelerate SMR using FPGA-based SmartNICs. Our approach does not implement the entire SMR system in hardware; instead, it is a hybrid software/hardware system. We make the observation that, despite the complexity of SMR, the most common routine—the data replication—is actually simple. The complex parts (leader election, failure recovery, etc.) are rarely used in modern datacenters where failures are only occasional. These complex routines are not performance critical; their software implementations are fast enough and do not need acceleration. Therefore, our system uses FPGA assistance to accelerate data replication, and leaves the rest to the traditional software implementation of SMR.

Our Waverunner approach is beneficial in both the common and the rare case situations. In the common case, the system runs at the speed of the network, with a 99th percentile latency of 1.8 μ s achieved without batching on minimum-size packets at network line rate (85.5 Gbps in our evaluation). In rare cases, to handle uncommon situations such as leader failure and failure recovery, the system uses traditional software to guarantee correctness, which is much easier to develop and maintain than hardware-based implementations. Overall, our experience confirms Waverunner as an effective and practical solution for hardware accelerated SMR—achieving most of the benefits of hardware acceleration with minimum added complexity and implementation effort.

1 Introduction

Variants of State Machine Replication (SMR) are responsible for all reliable, consistent, and highly available online services. SMR is at the core of massive-scale systems such as cloud infrastructure coordination services [6, 26], large-scale distributed databases [13, 25, 63, 69], and many other systems that require high availability and consistency [2, 14]. Due to their central nature in critical infrastructure, SMR implementations must be extremely robust and resilient. At the same time, the performance characteristics of the SMR dictate the performance of the overall service. As a result, mechanisms for reducing SMR operation latency and increasing throughput have received significant research attention.

A fundamental requirement of SMR implementations is that networked hosts must exchange multiple messages to

agree on the shared state. While implementations that use traditional NICs and process all packets through the OS network stack are the most straight-forward, their performance is bounded by the large amount of CPU time spent on packet processing [8, 22, 28, 46, 57, 58, 68], limiting the throughput and drastically impacting the operation latency due to many traversals of the software network stack.

To overcome the CPU bottleneck, researchers have begun exploring hardware acceleration of network processing. For example, a recent work demonstrated the ZooKeeper broadcast protocol implemented entirely in reconfigurable hardware on an FPGA (Field-Programmable Gate Array). This implementation is able to approach line-rate throughput with operation latencies that are only marginally higher than the on-the-wire latency of the messages [30].

Unfortunately, although it is an impressive demonstration of hardware-acceleration capabilities, the hardware-only approach is too complex and brittle for practical deployment. Despite the improvements in the ease-of-use of hardware development toolchains, the ZooKeeper FPGA implementation required significant expertise, including a hardware version of the TCP/IP stack and all of the protocol details such as leader election and failure recovery. Implementing and debugging distributed protocols in hardware is significantly more difficult than user-level software implementations. Moreover, consensus algorithms—the core of SMR—are well known for being complex and error-prone in design and implementation. Properly capturing all corner-case behaviors in a hardware implementation is challenging and difficult to verify.

We observe that the complexity of SMR is actually in the uncommon routines. Indeed, the most common operation, the one that limits throughput and dictates operation latency, is extremely simple: a leader node receives requests and broadcasts them to the follower nodes, locally committing requests only after receiving acknowledgements from the followers. Other SMR routines, such as leader election and failure recovery, are indeed considerably more complex. However, these complex operations are used only in special circumstances, such as system bootstrap or replica failures. These operations are rare, not performance critical, and their traditional software implementations are fast enough for all practical purposes.

We propose a new approach to accelerate SMR by creating a hybrid hardware/software organization that implements only a small, simple, but performance-critical portion of the protocol in hardware and leaves the vast majority of the imple-

mentation in traditional user-level software. We showcase Waverunner, our approach for hardware acceleration of Raft [52], a well-known consensus protocol, where the entirety of the robust software implementation remains intact, adding only an extra high-performance hardware-accelerated path for the common-case operation. The Waverunner approach permits a clean separation of the complex operations from simple ones in the Raft application software, and reduces the complexity of transport protocol handling. Waverunner uses UDP for the common routines, but leaves all complex cases, such as error handling and view changes, to the traditional TCP-based software. Moreover, by restricting the Waverunner hardware to only the common case, we are able to leverage FPGA HLS (high-level synthesis) tools to automatically generate the hardware from its C++ description, significantly reducing implementation and adoption effort. Although our prototype system is based on Raft, the Waverunner technique is generic and can be easily adapted for other distributed protocols.

Waverunner is notable for its performance and simplicity. We achieve line-rate operation of Raft (85.5 Gbps after accounting for Ethernet frame overheads on a 100 Gbps network), with the vast majority of the SMR broadcast requests handled in three wire-delay latencies (median latency is 1.8 μ s). At the same time, we retain the robustness, flexibility, and completeness of a software implementation—Waverunner includes a fully operational implementation of Raft without hardware acceleration and can smoothly transition between hardware-accelerated and software-only modes. In a failure test, Waverunner can recover from a leader crash within 1 second. While the implementation of Raft is by no means simple, leaving it in software is appealing for debugging, upgrades, and maintainability. Moreover, the 220-line HLS-based C++ implementation of the hardware, made possible by limiting the hardware only to a simple core routine, greatly simplifies modification and maintainability of the hardware components compared to a full-hardware implementation.

2 Background & Motivation

In this section, we briefly introduce the concepts of state machine replication and FPGAs, as well as the key idea and motivation of our Waverunner approach.

2.1 State Machine Replication

State machine replication (SMR) is the standard approach to build highly consistent and available systems [6, 13, 26]. It aims to provide a consistent view among replicas while tolerating replica failures in a practical environment where messages can be arbitrarily delayed and there are no perfect failure detectors. In the most common model, SMR replicates a sequence of log entries that contain the operations to be executed by each replica. The application is modeled as a

deterministic state machine so that all replicas will have identical states after executing the same sequence of operations.

At the center of an SMR system is a consensus protocol, which is known to be complex and delicate. Most consensus protocols share a common leader-follower model, from early academic ones (e.g., Viewstamped Replication [51] and Paxos [40]) to more recent ones that are widely adopted in industry (e.g., Zookeeper Atomic Broadcast [26], and Raft [52]). Despite their differences, these protocols largely follow a two-stage structure: a leader election and recovery stage when the system elects a new leader and synchronize all replicas after possible failures, and a data replication stage when the leader replicates log entries to the followers as new requests arrive.¹

2.2 Programmable NIC with FPGA

The last three decades have witnessed the emergence of a great mismatch between network speed and CPU performance. The bottleneck of a networked system has gradually moved from the network (NIC and switch) to the CPU and the OS software stack. To mitigate this problem, the use of programmable NICs with Field Programmable Gate Arrays (FPGAs) has emerged. Equipped with on-chip processing units and memory, FPGA-based NICs can process packets at line rate (e.g., 100 Gbps), with stable nanosecond-range latency. In comparison, the traditional software approach can process only several gigabits per second on a CPU core, with latencies measured in milliseconds.

Although capable of high throughput and low latency, FPGA hardware is notoriously difficult to program. Programming FPGAs is particularly challenging because it requires hardware development skills and knowledge of hardware description languages. Although high-level synthesis (HLS) tools make the FPGA programming process more accessible by translating functions from C++ to hardware, these tools are difficult to use effectively when the logic being implemented is complex. As a result, one of our goals in the design of Waverunner is to make sure that all functions that we implement in FPGA hardware are straightforward and simple, so they can be easily implemented with HLS.

2.3 Motivation

As the critical building block of large-scale systems, the performance of SMR has been a focus in many recent studies. High-performance SMR implementations use a wide range of advanced hardware, including programmable NICs with FPGAs [30], RDMA [2], and programmable switches [16, 32, 42]. In this work, we propose a unique hybrid approach to accelerating SMR with FPGAs: only accelerating the data plane and leaving the control plane, including election and recovery, to

¹(Multi-)Paxos does not have a universally agreed algorithm, whether to implement it as a two-stage structure depends on the implementation [2, 10].

Table 1: Raft Implementation Analysis

be processed by software. Our approach leverages the observation that the data plane dominates the system performance when the system is stable (most of the time), while the recovery part is only used in rare cases and is usually fast (seconds or less), so there is no need to accelerate it.

Table 1a and 1b show a CPU cycle analysis of various Raft implementations, including our own implementation in C++. In our experiments, we set the failure rate to once a year, and observe that the data plane consumes the majority of the CPU cycles while the control plane consumes almost none. Moreover, the majority of data plane usage is on common utilities such as networking, data serialization, memory allocation, etc. (Table 1c). Implementing the data plane in FPGA can avoid these costs. Implementing the control plane with software can minimize the programming effort needed in the hardware; it also allows us to rapidly iterate on the software implementation, as required when developing complex modules.

In this paper, we choose Raft as our acceleration target. This is another advantage of our approach: we can accelerate existing protocols and systems rather than develop entirely new ones. The hardware acceleration in deployment can then be optional. That is, the system can run either with or without the programmable NIC. This approach adds great flexibility in practice. Though we use Raft for our prototype, we believe our approach similarly applies to other common consensus protocols, as they have similar structure [64, 67].

3 Waverunner System Overview

Waverunner takes the standard state machine replication model: it replicates a sequence of operation log entries (messages) identically onto each replica. The target of replication is referred to as the application (e.g., a key-value store or a

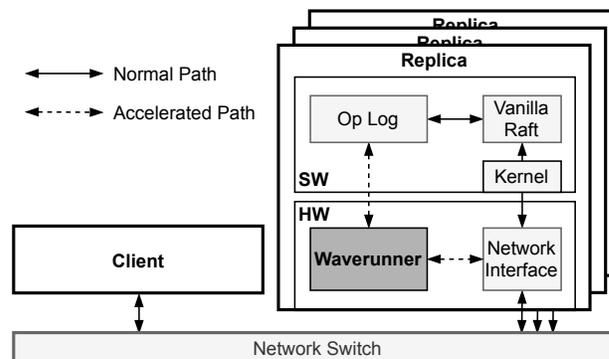

Figure 1: System Design Overview. The solid black lines represent the normal path when Waverunner is disabled, where network packets travel between the application (Vanilla Raft) and NIC via the POSIX interface and Kernel device driver; the dashed lines represent the accelerated path, where the NIC diverts incoming packets to Waverunner, which can send messages into the network via the NIC and/or deliver them directly into a buffer allocated by the application.

lock service). The application must be deterministic; after all replicas process the messages in the order they are recorded in the log, the replicas will all reach the same state. A client for SMR can be either the replicated application itself or an independent client that sends requests to the application. A replica server is either a leader or a follower. Only the leader accepts client requests and replicates these requests to the followers. Followers reject client requests, causing the clients to resend requests to the leader.

System Architecture. The system architecture, including its hardware and software components, is shown in Figure 1. The software includes a complete vanilla Raft implementation that uses conventional TCP sockets provided by the Linux kernel. Additionally, the software can access hardware configuration registers to control the Waverunner hardware. The software can disable Waverunner hardware acceleration, causing all received network packets to be delivered via the conventional network stack. However, if the software enables hardware acceleration, the network interface examines all received packets to identify those carrying Raft messages, and directs packets containing the most common Raft messages (client requests and data replication messages) to the Waverunner hardware protocol handler instead of the kernel network stack. To communicate with the software, the Waverunner hardware writes messages into a pre-allocated user-space log buffer, bypassing the kernel. Uncommon Raft messages and all other network traffic (e.g., ARP requests and ssh connections) are handled by the kernel like with a conventional NIC, regardless of whether Waverunner hardware acceleration is enabled or not.

Typical Waverunner Workflow. Waverunner takes advantage of the Raft leader election protocol to coordinate enabling and disabling hardware acceleration (Figure 2). When the system is first initialized, hardware acceleration is disabled by

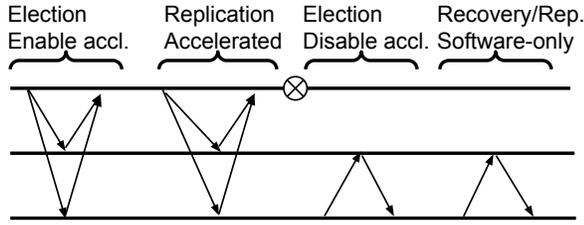

Figure 2: Waverunner Workflow

default. The Raft software triggers a leader election, selecting one of the replicas as the leader, and enables hardware acceleration. The system then replicates data with the assistance of hardware acceleration. The hardware takes care of the data replication operations and deposits the committed log messages into the user-space log buffer for the software application to handle. If a leader failure occurs, the system disables acceleration, conducts another leader election, and performs the requisite Raft protocol actions to resolve the problem before re-enabling acceleration. Other uncommon and complex operations are handled in a similar way. For example, after a series of failure events, the replicas may have diverged log sequences. The leader software will synchronize replicas by re-sending the missing log entries and potentially overwriting existing entries in the followers if necessary. After the complex conditions are addressed and all replicas are in the same state, the system can conduct another leader election and re-enable hardware acceleration.

The safety and consistency properties of SMR guarantee that 1) all replicas will commit the same log entry at the same position in the buffer, and 2) if an operation starts after another one commits, then the two operations will appear in the same order in the logs of all replicas.

4 Waverunner Hardware

In this section, we describe the Waverunner hardware (§ 4.1), explain its hardware data replication operation (§ 4.2), and detail the design of the communication mechanism necessary for Waverunner to achieve high performance (§ 4.3).

4.1 Hardware Architecture

Our Waverunner prototype is based on a traditional PCIe NIC architecture, where a NIC DMA engine, controlled by the host kernel network stack, streams data between the network interface and the host using the PCIe bus. When receiving packets from the network interface, the NIC transfers the packet contents into host memory and raises an interrupt to alert the CPU that the transfer is completed. To transmit packets, the NIC uses the PCIe bus to traverse a queue of packet contents populated in host memory by the software, transferring packets to the network interface.

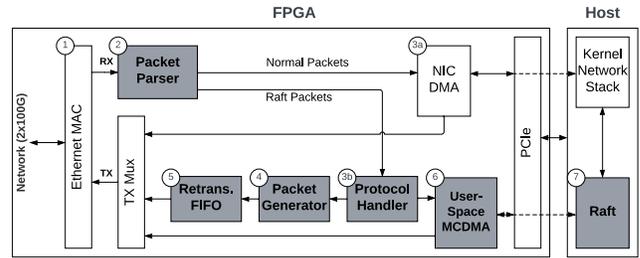

Figure 3: Waverunner Hardware Overview

Waverunner uses a bump-in-the-wire organization to extend the traditional NIC functionality with SMR hardware acceleration, as shown in Figure 3.

When packets arrive over the network ①, they are first streamed through a packet parser ② module to identify packets containing SMR protocol messages. Packets that do not contain SMR messages are streamed to the NIC DMA engine ③a) and are handled by the host kernel. If hardware acceleration is enabled and the packet parser detects a supported Raft message, the message is streamed to the Waverunner hardware protocol handler ③b) instead of the NIC DMA. The protocol handler performs internal bookkeeping on the protocol state, tracking Raft messages forwarded to the followers and their acknowledgements. If the received messages require one or more packets to be sent out (e.g., client requests must be replicated to the follower nodes), the protocol handler streams the messages to a packet generator module ④, which generates the packets and transmits them into the network. Outgoing packets are buffered in a circular buffer ⑤ that includes retransmission logic; when packet loss or reordering is detected, the protocol handler can signal the buffer to retransmit its contents. Notably, in this case, Raft packets are received and transmitted with minimum latency, entirely without host CPU involvement. Finally, the protocol handler determines if the received message must also be sent via User-Space MCDMA ⑥ to the Raft software for further processing ⑦. For each data replication Raft message, Waverunner will write two operation messages into the user-space log buffer in the host memory: 1) when the client request is received and forwarded to the follower replicas, the request is also written into the log buffer, and 2) when a sufficient number of acknowledgements are received from the followers, a commit operation is written into the log buffer. Application software then processes the log in order and performs the committed operations.

Messages to be delivered to the software are streamed to a descriptor-based, high-performance Multi-Channel DMA (MCDMA) engine that transfers the message contents directly to the user-space Raft software, bypassing the kernel network stack in a similar way to DPDK [21]. Each channel of MCDMA has a ring buffer of descriptors. Each descriptor consists of metadata such as the size and address of the data buffer, complete bit, and the pointer to the next descriptor.

Once the MCDMA completes a transaction, it updates the metadata, allowing the CPU software to consume the data. In the case that Raft traffic arrives too fast to transfer to the host and the MCDMA ring buffer becomes full, the Waverunner hardware will drop the packets before the packet parser, preventing the scenario where a message is processed by the Raft protocol handler but not transferred to the software.

To facilitate coordination between the host software and the hardware acceleration modules, the Waverunner hardware exposes a set of control and status registers (CSRs) accessible from the host software. Some registers, such as follower MAC and IP address, are used to configure the Waverunner system before the operation. An ACC_ENABLE register can be used to enable or disable the accelerated packet processing. Finally, the Waverunner hardware and software use several CSRs to maintain the Raft protocol state. After disabling hardware acceleration, the software can read the latest values of these registers from the hardware. The complete set of Raft protocol registers is listed in Appendix (§ C).

4.2 Raft Leader and Follower Operation

Although Raft is complex, Waverunner implements only the most common operations in hardware (pseudocode shown in Figure 4) and relies on the software to handle uncommon and complex interactions. Uncommon hardware-generated messages such as AppendEntryReject are sent to the software via the user-space log without additional processing, while complex messages such as leader election are not identified by the packet parser at all, allowing these messages to be delivered via the traditional NIC DMA (also passing through the OS network stack, and therefore allowing these messages to naturally leverage features such as reliable TCP transport).

When configured to act in a leader role, the hardware accelerator includes protocol handling logic for only two message types: client requests and follower acknowledgements. Upon receiving a client request (Figure 4, lines 2-12), the accelerator updates the Raft protocol state (e.g., lastLogIndex, lastLogTerm), streams the message contents to the packet generator (to transmit AppendEntry messages to the followers), and also sends the message to software. Upon receiving a follower acknowledgement (Figure 4, lines 33-43), the accelerator updates the protocol state and, if the operation is ready for commit (half of the followers have acknowledged), the acknowledgement message is sent to the user-space log. Only one acknowledgement is delivered to the software, subsequent acknowledgements for the same request are ignored. All other protocol messages identified by the packet parser are delivered to the software without updating protocol state and without response packet generation by the accelerator.

The follower role is even simpler, as it handles only AppendEntry messages. Upon receiving a message (Figure 4, lines 15-30), the follower first conducts several safety checks, including the is_leader check, checking if the previous log

```

1 // FPGA receives client request
2 function FPGA-AppendEntry(fs, op):
3   if fs.isLeader
4     prevLogIndex = fs.lastLogIndex
5     prevLogTerm = fs.lastLogTerm
6     logEntry = makePair(op, fs.currentTerm)
7     push(fs.host.log, logEntry)
8     fs.lastLogIndex++
9     fs.lastLogTerm = fs.currentTerm
10    send <'FPGA-append', op, prevLogIndex,
        prevLogTerm, fs.currentTerm, fs.commitIndex>
        to all except self
11  else
12    reject
13
14 // FPGA receives <'FPGA-append', op,
        prevLogIndex, prevLogTerm, term,
        commitIndex>
15 function FPGA-ReceiveAppend(fs, op, prevLogIndex,
        prevLogTerm, term, commitIndex):
16  if not fs.isLeader
17    and fs.currentTerm == term
18    and fs.lastLogTerm == prevLogTerm
19    if prevLogIndex > fs.lastLogIndex
20      reply with retransmission request
21    else if prevLogIndex < fs.lastLogIndex
22      ignore and return
23    fs.host.commitIndex = commitIndex
24    logEntry = makePair(op, fs.currentTerm)
25    push(fs.host.log, logEntry)
26    fs.lastLogIndex++
27    fs.lastLogTerm = fs.currentTerm
28    reply <'FPGA-appendOK', term, fs.id, fs.
        lastLogIndex>
29  else
30    reply <'FPGA-appendReject', fs.id>
31
32 // FPGA receives <'FPGA-appendOK', term, id,
        lastLogIndex>
33 function FPGA-ReceiveAppendAck(fs, term, id,
        lastLogIndex):
34  if fs.isLeader and fs.currentTerm == term
35    and fs.matchIndex[id] < lastLogIndex
36    fs.matchIndex[id] = lastLogIndex
37    if fs.commitIndex < lastLogIndex
38      if a (majority-1) elements in matchIndex
39        >= lastLogIndex
40        fs.commitIndex = lastLogIndex
41        fs.host.commitIndex = fs.commitIndex
42        if the request does not read the
43          system state (e.g., a blind write
44            in a key-value store)
45          notify the client of commit and skip
46            the reply from the host
47          software (in ApplyLog)
48  else
49    halt and notify host to handle failures

```

Figure 4: Pseudocode of the hardware accelerator.

index and term match (ruling out the case of lost or duplicated packets), and confirming that the message `term` value matches the `currentTerm` variable. Then the follower updates the protocol state, streams the message into the packet generator to produce an acknowledgement (`AppendEntryAck`) or rejection (`AppendEntryReject`) message, and updates its local `commitIndex` according to the message `commitIndex`.

It is worth noting that the protocol-specific Waverunner hardware accelerator actions and logic are intentionally primitive. For an FPGA implementation, the logic of these operations is automatically translated from their C++ description.

4.3 User-Space Log Considerations

The behavior of communication between the hardware and software is critical for high Waverunner performance. Raft messages must be delivered by MCDMA (shown in Figure 3) to the log accessible in user-space software without being a bottleneck in the system. We describe three critical aspects of the design of the User-Space MCDMA block.

First, the MCDMA component requires *fast write response*. In our platform, MCDMA is connected to the PCIe bridge using AXI Memory Mapped (AXI-MM) interfaces, where the MCDMA's AXI master interface writes data to the PCIe bridge's AXI slave interface to transfer data to the user-space buffer. Under the AXI-MM protocol, MCDMA first issues the write address to the PCIe bridge, followed by the write data. After the data transfer is complete, the PCIe bridge sends a write acknowledgement response to the MCDMA. In our experiments, we observed a very high latency (300 to 400 cycles) for the PCIe bridge to send the write acknowledgement response after the data transfer. During this period, MCDMA stops processing descriptors and accepting packets from the protocol handler, negatively affecting the system performance. To solve this problem, we insert a small custom FIFO between the MCDMA and the PCIe bridge. The custom functionality of this FIFO is to send write acknowledgement responses immediately after the write operations are completed on the MCDMA side, thereby hiding the high acknowledgement latency introduced by the PCIe bridge and allowing MCDMA to process descriptors for the other channels.

Second, we introduce *batched MCDMA operation* in the hardware. For each MCDMA operation, in addition to the data transfer, there are also descriptor read and write operations across PCIe. The descriptor reads and writes are overheads, which significantly reduce the effective bandwidth for the actual PCIe data transfers. To minimize the descriptor overhead, we designed a hardware module to batch multiple consecutive message writes into a single transfer to amortize the descriptor overheads, solving the performance bottleneck and improving throughput over PCIe. The batching hardware collects messages until one of two conditions is met: either a pre-configured batch size is reached or a pre-configured timeout is reached without new messages arriving on the given chan-

nel. With the second condition, the latency increase caused by batching is negligible.

Finally, although Waverunner hardware acceleration significantly reduces the work that must be done by the CPU of the leader replica, the application code that executes committed operations still consumes CPU resources and can become the bottleneck in the system. One design option is to use a software dispatcher to handle incoming log messages from the hardware and coordinate spreading the handling of the log messages across software threads running on different cores. However, at our target throughput, a software dispatcher would itself become the system bottleneck. Instead, Waverunner shards log messages in hardware, using separate DMA channels to write log messages destined for processing by different application software instances. The leader replica runs multiple application processes, one per core, with each process having its own user-space log buffer into which the hardware deposits Raft messages belonging to the corresponding shard. This approach mirrors the operation of high-performance NICs that allow the software (e.g., DPDK) to install rules into the NIC hardware to steer incoming packets to different descriptor rings or queues to be handled by different cores.

4.4 Transmission with UDP

Our implementation uses UDP to transmit packets between FPGAs. UDP is unreliable for transmission and suffers from packet loss, duplication, and reordering with traditional hardware and software stacks. However, using UDP in the Waverunner hardware greatly reduces the hardware complexity compared to a TCP implementation. To handle the cases of UDP packet loss and reordering, our hardware implements a small retransmission buffer. The buffer, placed between our packet generator and the TX Mux (shown in Figure 3), holds all recently sent packets. In the event of packet loss or reordering being detected in `AppendEntry`, the protocol handler requests the packet generator to create a retransmission request packet (Figure 4, lines 19-20). When a retransmission request arrives at the retransmission buffer, instead of writing it into the buffer, the control logic triggers a retransmission of all packets currently in the buffer. The retransmission is finished when all the packets in the buffer have been transmitted. During the retransmission, incoming packets continue to be written to the tail of the buffer. The buffer is 256 KB, ensuring that in the worst-case scenario in our system (192 byte packets at 26 Mpps) packets will remain in the buffer, eligible for retransmission, for 52 μ s. This time is sufficient to tolerate 28 consecutive retransmission requests in our testbed, and is well beyond the round-trip latency of modern datacenter networks. Notably, the retransmission buffer does not affect system correctness; it simply avoids triggering software failure recovery in case of UDP packet loss or reordering in the network. In the extremely unlikely case that persistent retrans-

missions repeat until a lost packet is no longer present in the retransmission buffer, the hardware triggers a conventional Raft failure recovery in software.

5 Waverunner Control Plane

In this section, we describe our software components. The software is primarily in charge of the uncommon routines of the system, such as bootstrapping and recovering from an abnormal system state. This functionality includes electing a new leader, synchronizing data between a new leader and the replicas, and controlling hardware acceleration. We begin with a vanilla Raft software implementation and add support for interaction with the accelerator hardware. For completeness, we include a discussion of the full Raft implementation, and we explicitly highlight the Waverunner-specific design decisions and additions for software-hardware interaction.

5.1 Switching to Software via Leader Election

Leader failures are handled by re-electing a new leader. Leader election can be initiated by any replica. Each replica keeps a timer in software, starting an election if a timeout is triggered due to a lack of new messages received from the leader. Each replica uses a randomized timeout value, thereby reducing the probability of competition. When the system is idle, a timed loop in the leader's software sends empty requests to the hardware to avoid unnecessary elections. This does not cause extra overhead compared to a software-only Raft implementation, as it would have a similar timed loop to send empty `AppendEntry` heartbeats.

When a follower triggers an election and requests to become leader (referred to as a candidate), its software will first disable the hardware acceleration and wait for the hardware to complete processing of the packets in the hardware accelerator pipeline and MCDMA batch queues.

The candidate software will increment its own `term` and stop responding to replication requests with lower terms, and send a `RequestVote` message to the other replicas. Even if the replicas that receive the message are using hardware acceleration, the message will pass through the hardware transparently and be directly handled by the software. Each replica will confirm that its `term` is smaller than that of the candidate, and then disable hardware acceleration and check if the candidate has a more up-to-date log by comparing the `lastLogIndex` and `lastLogTerm` of the candidate with its own. If the candidate is more up-to-date (or the same), the receiver grants the vote and sets the leader `id` to the candidate. If the candidate receives enough votes (including itself for a majority), it transitions into the leader role.

When the new leader software takes over, the system is a fully capable software Raft. It can perform any traditional system maintenance operations, such as view change. The

software handles all Raft routines not implemented in hardware, such as synchronizing logs on the replicas.

5.2 Synchronizing Missing Logs

When a leader crashes or communication with it fails, the replicas may be left unsynchronized, such that some replicas may have longer logs. In more complex cases, such as election competition or consecutive leader crashes, replicas may even have different *uncommitted* logs at the same log position. Raft's (or any consensus protocol's) logic for handling these situations is complex. To ensure a simple hardware implementation, Waverunner keeps the implementation of replica log synchronization entirely in software.

After a new leader is elected, it initiates synchronization of the replica logs by sending an `AppendEntry` message containing a special `noop` operation to all replicas. If a follower has fallen behind or has non-matching logs, it will reply with an `AppendEntryReject` message, indicating a log mismatch. The leader will then send earlier log entries until the follower acknowledges accepting these logs, ensuring that the follower is synchronized with the leader. The `noop` commit entry is necessitated by the Raft protocol, as simply counting existing log entries in all replicas may fail due to a corner case in the Raft algorithm. (This is a documented idiosyncrasy of the Raft protocol (§5.4.2) [52].)

Note that there is a limit on the maximum number of entries that a replica can hold in its in-memory log. If a replica is down for an extensive amount of time, or a new replica is added to the system, that replica cannot catch up via the aforementioned approach because the leader will have discarded its older logs from memory. In this case, the leader should send a snapshot of the application dataset to the failed replica. The snapshot will contain the system state up to a particular log position which is still in the leader memory, allowing the leader to catch up the replica by sending it the entries starting from the snapshot log position. Similar to the original Raft work [52] and other recent works on speedy SMR [2, 49], the creation of the snapshot is application-specific and is orthogonal to the scope of this paper. For example, a standard approach is available in [65].

5.3 Enabling Hardware Acceleration

After the logs of all reachable replicas are synchronized, the leader will increment the `term` and send out `RequestVoteFPGA` messages to the synchronized followers. This message is identical to a normal leader election, with the additional side-effect of causing the followers to enable hardware acceleration. Once the leader receives acknowledgements from half of the followers (reaching a majority when including itself), the leader enables its own hardware acceleration. All future log entries are replicated by the hardware, without involving the CPU.

Separating hardware and software into different terms provides several benefits. First, it keeps the Raft algorithm intact, eliminating the need to prove correctness of our changes. Second, this approach is easy to implement, debug, and maintain, because the term of a log entry indicates whether it was initially replicated by software or hardware.

If a replica does not receive `RequestVoteFPGA`, but later receives an `AppendEntry` (e.g., a crashed replica rejoins), it will see a higher term in the message. Whenever a replica sees a higher term in `AppendEntry` than its `currentTerm`, or if it cannot find an entry at `prevLogIndex` in its log, it will disable hardware acceleration (if it is enabled) and reply with `AppendEntryReject`. When the leader receives an `AppendEntryReject`, it will disable hardware acceleration, trigger an election to go into a new term, and synchronize with the stragglng replica using software. Afterwards, the system will transition back to running with hardware acceleration using the previously described steps. To summarize, Waverunner uses a unified approach to address all possible cases that deviate from the normal replication routines, including the possible loss of messages, message delays, temporary server anomalies, etc.

6 Evaluation and Results

We evaluate Waverunner with real-world applications and off-the-shelf hardware. The major questions we answer are:

- What is Waverunner’s replication performance?
- Can Waverunner efficiently recover from a failure?
- How well does the Waverunner approach perform with real-world applications?
- How does Waverunner compare to other hardware-accelerated SMR approaches?

6.1 Setup

We conduct our evaluation on a 3-replica Waverunner cluster, with several additional client machines to issue requests in an open-loop manner. Each replica has two Intel E5-2695v4 CPUs, 1TB DDR4 memory, and a Xilinx U280 FPGA connected via PCIe gen 3 x16. Each FPGA has two 100 Gbps QSFP28 ports. Our replicas are connected to one switch and clients to another, and there is a 100 Gbps fiber connecting the two switches. On the FPGAs, we implemented the Waverunner hardware accelerator using Vivado HLS. For the control plane, we modified our C++ Raft implementation to coordinate with the Waverunner FPGA hardware.

In addition to Waverunner, we also evaluate the replication performance of two SMR systems for comparison:

- Mu [2]: An RDMA-based SMR implementation, which aims to provide microsecond level latency for application replication. It has a custom leader-follower consensus protocol. In the Mu implementation, all requests originate from

the leader. This gives it an advantage over Waverunner, where requests are sent over the network from clients.

- DPDK-Raft: An in-house DPDK-based Raft implementation. We built our own DPDK-Raft implementation because the state of the art Raft implementation (in eRPC [34]) is equipped to perform latency tests and we are interested in both latency and throughput experiments. Our DPDK-Raft achieves similar latency as eRPC Raft.

Both Mu and DPDK-Raft use a 100 Gbps Mellanox ConnectX-4 NIC included in the replicas with the same connection specifications as the FPGA (i.e., PCIe gen 3 x16 and 100 Gbps QSFP28).

6.2 Methodology

We present two key metrics: throughput and latency. We report throughput in millions of request packets per second (Mpps) and total network bandwidth used (Gbps). For latency, we report the time in microseconds (μ s) and present the median (50th percentile) and tail (90th and 99th percentile) measurements. To improve accuracy, whenever possible, we collect the results using internal hardware performance counters on the FPGAs, NICs, and switches.

We implement our client using DPDK to achieve high performance and accurate measurement. Precise control of the offered load at the client is difficult to achieve, so we set approximate targets and plot all results by using the actual measured request rates. As a result, experiments that vary the request rate may not have results with round throughput values (e.g., our plots may show 4.1 and 5.2 Mpps, rather than precisely 5 Mpps). For measuring end-to-end latency from the client and to avoid subjecting latency measurements to client-side queueing, we use a sampling approach by concurrently running two DPDK client configurations: one to apply the target load and a second lightly-loaded client (using a separate NIC) to precisely measure the latency.

6.3 Replication Performance Results

We first focus on evaluating the SMR replication performance without a specific application (where the “application” simply discards committed operations) to better understand the capability of Waverunner in a clean environment. The clients send requests to the replica cluster using small random packets (50 bytes for Waverunner and DPDK-Raft, 64 bytes for Mu due to its implementation restriction). We sweep the request rate in steps of approximately 1 Mpps and measure the replication throughput and latency at each step. We described Waverunner’s MCDMA batching with timeout mechanism in Section 4.3. An adaptive batching strategy can minimize latency under all load scenarios, however, we found that for our evaluation, a constant batch size was sufficient to limit PCIe transfer overheads.

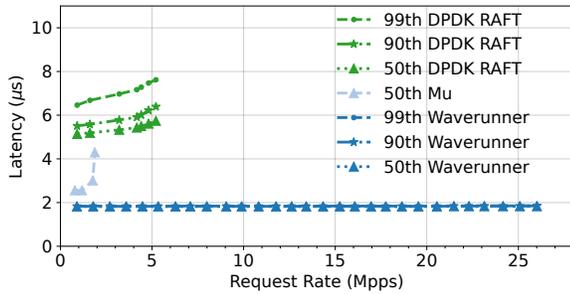

Figure 5: Performance of Packet Replication

Throughput. Figure 5 shows that the maximum request rate Waverunner can achieve is 26 Mpps, which is bounded by the leader’s network receive bandwidth. Under this request rate, the bandwidth utilization of the leader FPGA approaches 85.5 Gbps, the maximum theoretical bandwidth achievable by the network transceivers and switch.²

Beyond this throughput, the FPGA transmit FIFOs experience back pressure from the MAC, which cascades to the Waverunner protocol handler and causes packet loss of incoming client requests and follower acknowledgements. This result indicates that Waverunner can fully utilize the available network bandwidth and achieve the maximum request rate.

On the contrary, Mu and DPK-Raft cannot saturate the network bandwidth with one request per packet, resulting in only ~ 2 Mpps and ~ 5 Mpps peak request rate, respectively. Mu has to rely on client-side batching (aggregating multiple requests into one packet) to increase the request rate and utilize the available network bandwidth. However, doing so also drastically increases the latency. For DPK-Raft, the throughput is bottlenecked by descriptor ring handling via PCIe. At peak throughput, DPK-Raft starts to drop packets because the CPU cannot process and release RX descriptors at the same rate as the incoming packet stream, a situation we overcome in Waverunner by transferring multiple requests using each descriptor (§ 4.3).

Latency. Figure 5 also shows the replication latency for Waverunner, Mu, and DPK-Raft at various request rates. Replication latency is measured from when the leader receives a client request, until the leader receives the corresponding acknowledgements from half of the followers.

The Waverunner replication latency is effectively constant at $1.8 \mu\text{s}$, only marginally higher than the RTT of a minimum-sized packet in our network ($1.68 \mu\text{s}$). There are two characteristics of Waverunner’s latency that are notable: the median, 90th-, and 99th-percentile latencies are all nearly identical, and as the request rate increases, the latency does not increase, all the way until network bandwidth is exhausted. These la-

²Each Ethernet frame includes a 7-byte preamble, a 1-byte start of line delimiter, and a 12-byte inter-packet gap, which together account for the approximately 14.5 Gbps gap to the advertised 100 Gbps line rate.

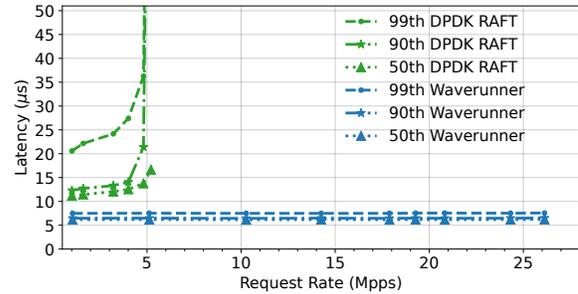

Figure 6: End-to-end Latency

tency characteristics are a unique advantage of an FPGA implementation [30], as most of the components in the FPGA hardware have low and constant latency that is immune to queuing effects, allowing the replication latency to remain stable. In contrast, both Mu and DPK-Raft exhibit substantially higher 90th- and 99th-percentile latency compared to the median latency, and the latency grows as the request rate increases and the CPUs become busier, amplifying interference and system queuing effects. As a result, the replication latency of Waverunner is significantly lower than Mu and DPK-Raft. The worst Waverunner 99th-percentile tail latency is approximately 1/3 (36%) of the best median latency of DPK-Raft ($5 \mu\text{s}$) and 40–80% of Mu ($2.5\text{--}4.3 \mu\text{s}$).

For completeness, we also measure the end-to-end latency on the client for Waverunner and DPK-Raft, as shown in Figure 6. The end-to-end latency on the client includes the replication latency, the RTT between the client and the leader (with 1 switch placed between the two), and the time for the client to process the packets. For Waverunner, this adds another $4\text{--}6 \mu\text{s}$ for the median and tail latencies. For DPK-Raft, the additional time is much larger because DPK-Raft relies on batching and buffering to achieve maximum throughput, which add extra cost to overall latency.

Performance with Different Packet Sizes. In addition to minimum sized packets, we investigate the effect of larger requests on Waverunner, shown in Figure 7. We maintained a constant throughput of 1 Mpps and varied the payload size accordingly. For minimum-sized packets, the replication latency is $1.79 \mu\text{s}$. As the payload grows, the latency increases slowly to a maximum of $2.13 \mu\text{s}$. Importantly, the 99th-percentile latency remains approximately the same as the median.

CPU Utilization. Compared to the RDMA and DPK approaches, Waverunner has an important advantage, especially at high request rates: it places far less pressure on the host CPU cores. For example, to achieve peak performance in our tests, DPK-Raft saturates 18 CPU cores. In contrast, Waverunner consumes negligible host CPU resources because it only needs to manage the MCDMA descriptors for the operation log. This leaves CPU resources almost entirely free, allowing them to be used by the target application.

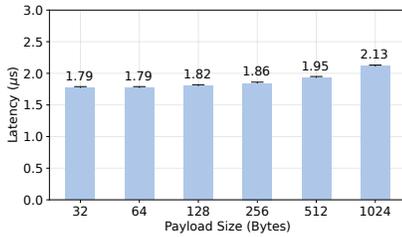

Figure 7: Latency across payload sizes. Bars show 99th percentile.

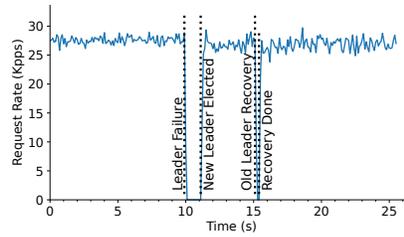

Figure 8: Request rate during failure recovery.

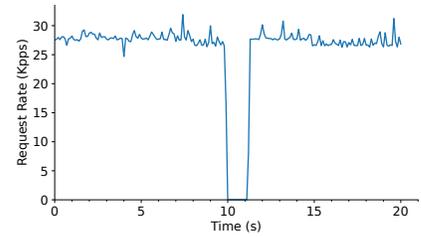

Figure 9: Request rate during view change.

6.4 Fault Tolerance and View Change

We evaluate Waverunner fault tolerance by injecting a leader failure on a healthy cluster. As expected, the leader failure triggers a leader election. At a later point, we resume the old leader, allowing it to rejoin the SMR cluster. Figure 8 presents the behavior by showing the request rate measured at the client as these failure-related events take place.

In this experiment, the system first runs normally for ten seconds, then we halt the leader to simulate a failure. At this point, requests from the clients fail to proceed because the system has no available working leader, and the throughput of the system drops to 0.

We configured the followers with a one second timeout. After timeout, a new leader election begins. This can be seen on the graph slightly more than one second after the failure, where the system resumes processing requests after the clients discover the new leader and resume sending requests.

At 15 seconds, we resume the old leader; this is recognized by the new leader when the old leader rejects the replication requests that it receives from the new leader. Because the old leader is missing log entries from its down time, the new leader starts recovery by catching up the old leader’s replica. After approximately 200 ms, the log recovery completes and the system re-enables hardware acceleration, showing that the hybrid architecture of Waverunner can correctly and efficiently recover from failure.

Similar to the failover test, we performed a view change test; results are shown in Figure 9. Initially, the system runs with three replicas. After ten seconds, we send a view change command to the leader to reconfigure the system down to two replicas (removing one follower). The leader disables hardware acceleration, initiates a leader election to advance to a new term, completes the view change, and then re-enables hardware acceleration.

6.5 Real-world Applications

To understand how Waverunner performs with real-world applications, we evaluate three key-value stores: an in-memory hash table, Memcached, and Redis. We modified the applications to receive requests from Waverunner instead of the

conventional network sockets. This enables low latency and high throughput operation as Waverunner bypasses the kernel to send and receive packets. Scalability across cores is achieved through sharding; the number of replication groups is the same as the number of threads. Unless otherwise indicated, we use 8-byte keys and values, which makes the packets (including network header) 135 bytes for the hash table, 150 bytes for Memcached, and 156 bytes for Redis. We use open-loop clients that perform operations on uniformly distributed keys. Although the applications were not originally designed with SMR in mind, using them with Waverunner transforms them into consistent high-availability systems.

Throughput. To evaluate applications throughput, our client can send a mixture of PUT and GET requests. Both PUT and GET requests are replicated in Waverunner, but are processed differently. For PUT requests, Waverunner responds to the client when the request is committed in Raft (acknowledged by the majority of replicas), allowing the application to handle the request log in the background, eventually updating the key-value store. For GET requests, Waverunner does not generate a client response, instead relying on the application to execute the operation from the log by retrieving the relevant data and sending them to the client. Figure 10 shows the peak sustained throughput we observed. The peak throughput of the original Memcached and Redis implementations is 1.5 Mpps, while the Waverunner implementations reach 20.7 Mpps and 19.9 Mpps, respectively. Redis has a lower throughput because it dynamically increases the size of its hash table and needs to rehash every entry. However, Memcached has a constant-size hash table that is initialized at the start.

We also examined the effect of different GET/PUT ratios on Memcached, shown in Figure 11. We observed that Memcached needs more CPU cycles for PUT requests than GET requests because, in addition to fetching the query in the key-value store (like a GET does), it also locks the region containing the key to update. As a result, higher GET ratios observe higher throughput. For Redis, we observed that changing the GET/PUT ratio does not affect the throughput.

Latency. We measured the end-to-end latency of GET and PUT operations in a 50% GET/PUT test for Memcached and Redis, as shown in Figure 12. To show the effect of different

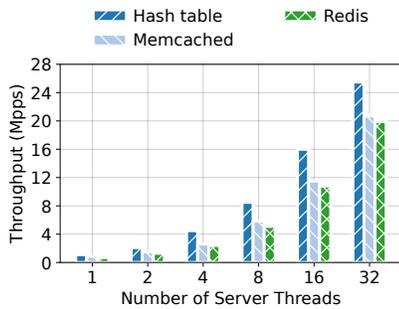

Figure 10: Peak application throughput.

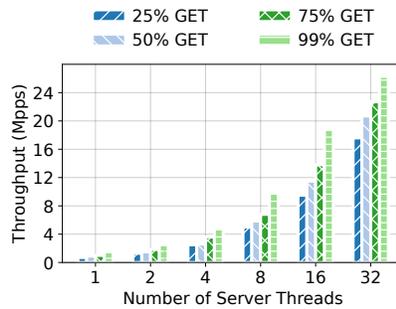

Figure 11: Memcached throughput across request ratios.

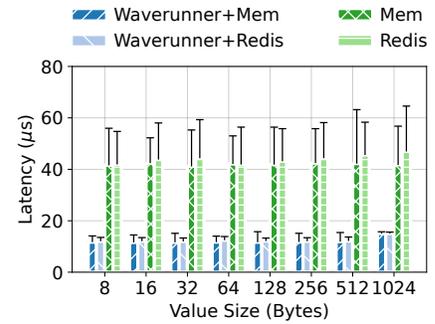

Figure 12: End-to-end latency. The bars indicate 99th percentile latency.

packet sizes, we varied the size of the value from 8 to 1024 bytes. Without Waverunner, Memcached and Redis exhibit a stable end-to-end latency of 41–44 μ s, which is much lower than reported in the prior work [2, 17]. We attribute the lower latency to our high-end Mellanox NICs, both in client and server. When run on commodity NICs, the results (not shown) are much higher and closer to the previously published work.

Waverunner has a lower latency of 11.69 μ s and 12.07 μ s for Memcached and Redis respectively in most cases. With Waverunner, the leader FPGA generates responses for PUT requests without any CPU involvement, resulting in significantly lower end-to-end latency. For incoming GET requests, Waverunner delivers them to the application and transmits the responses to the network without involving the kernel. In summary, applications using our Waverunner framework can achieve performance comparable to kernel bypassing techniques (e.g., DPDK) for processing GET requests, and better performance for PUT requests.

6.6 Comparison to Prior Work

In this section, we discuss a comparison of Waverunner with Consensus in a Box [30] (referred to as ZABFpga below), a recent implementation of the ZooKeeper SMR protocol on an FPGA. We did not find the exact code release corresponding to ZABFpga online, which complicated our ability to study its operation in our environment. Although we did locate a project that appears to include ZABFpga’s code [1], we found it challenging to port to our platform and extract from it just the ZABFpga components. A ground-up re-implementation of ZABFpga would constitute a major development effort. Such difficulties highlight the challenges in the development, portability, and maintenance of FPGA-based systems, stressing the benefits of the Waverunner approach in leaving the majority of the SMR protocol in software and implementing the hardware components using relatively portable HLS.

Based on what we can infer from the description of ZABFpga, the system has excellent performance, and would likely exhibit throughput and latency on par with Waverunner if

ported to our environment, which has 100 Gbps NICs compared to 10 Gbps in the original paper. However, the ZABFpga system clearly required a drastically more complex development effort and would incur massively higher maintenance and troubleshooting cost. This is because ZABFpga implemented the ZooKeeper protocol completely, including the leader election and failure recovery, in custom FPGA hardware. This approach also required implementing the application (a key-value store) on the FPGA, including the ability to store the replication log in DRAM connected to the FPGA. Based on the description in the paper, the replication latency is 3 μ s while Waverunner has 1.8 μ s. It would be unfair to compare two designs on the throughput as the ZABFpga uses 10Gbps NICs to communicate with other nodes.

7 Related Work

Hardware Accelerated Networking. Early works on hardware acceleration in NICs offered a range of features, from simple ones such as checksum calculation and receive-side-scaling (RSS), to complex ones such as RDMA and TCP offloading engines [48]. Although earlier network hardware accelerators hard-wired the acceleration functionality, the trend has shifted toward programmability, with modern *SmartNIC* devices comprising programmable CPU cores [47] or programmable FPGA fabrics [50]. Modern advanced accelerators include functionality such as in-line handling of protocol encapsulation, VLAN processing, and encryption and decryption of data streams [18, 43]. Waverunner is a SmartNIC that accelerates replication routines of the Raft protocol. Like other SmartNICs, we utilized a bump-in-the-wire architecture to accelerate the replication routines in the FPGA. AccelNet [20] accelerates network services for virtual machines on SmartNICs in data centers. However, the acceleration is only loosely coupled with the application, such that whenever AccelNet does not have a rule for a packet, it consults the application to install the missing rule. On the other hand, Waverunner is more specialized, as it identifies Raft packets

and does not need software support to handle other protocols. P4 [4] is a high-level language for network functions with implementations on FPGAs [3, 7, 9, 27, 45, 66]. hXDP [5], an FPGA-based NIC, uses soft cores to execute eBPF, another high-level language to describe network functions. These systems target system-wide packet processing, whereas Waverunner is specialized and optimized for processing only the Raft replication routines.

Caribou [29] implements a hardware accelerator for high-performance databases computations, including the full functionality of a fault-tolerant key value store inside an FPGA. KV-Direct [41], CliqueMap [61], Xenic [59], and RedN [55] extend RDMA primitives to enable remote key value operations to main memory. Waverunner takes a similar approach which puts requests in the follower's memory through PCIe. This is unlike Caribou, which does not use the host and relies on the FPGA to execute the database application. Floem [53], NICA [19], iPipe [44], FlexTOE [60], and FairNIC [23] provide a framework that can offload network applications such as Memcached on programmable SmartNICs. Although its goals of low latency and high throughput are similar to Floem and NICA, Waverunner targets the Raft distributed protocol, using hardware acceleration for the communication among multiple nodes rather than for the application logic.

State Machine Replication. State machine replication achieves fault tolerant, highly available services by leveraging consensus protocols [26, 40, 52]. From among the popular consensus protocols, Waverunner implements the Raft protocol [52], offloading the replication routines to a hardware accelerator. Several prior studies proposed ways to increase the performance of SMRs. eRPC [34], FaSST [35], and Breakwater [12] use an RPC library on top of the NIC API and RDMA, respectively, to provide low latency communication for applications. PigPaxos [11] relays messages by subgrouping followers. These works optimize the network IO bottleneck, increasing the performance considerably, but they still suffer from the CPU bottleneck for implementing all parts of the protocol. Increasing parallelism of SMR [14, 24, 36, 56, 62] can further improve the performance, which Waverunner can benefit from for the application design. HovercRaft [39] moves SMR from the application layer to the transport layer and optimizes Raft to avoid the CPU and network IO bottleneck. Similarly, Waverunner addresses the same bottlenecks by offloading the network communication and replication to the hardware accelerator. Some SMR systems leverage high performance programmable switches [15, 32, 33, 42]. Rather than changing the network infrastructure, Waverunner employs a hardware accelerator in the NIC of each replica to accelerate the replication communication and operations.

There are several studies on low latency SMR through RDMA [17, 31, 37, 38, 54, 65], some of which are based on

variants of Paxos. Although these works offer low latency, they are still bounded by the CPU bottleneck, as all of them cannot send packet at line rate with minimum size packets, and have high replication latency. Mu [2] introduces a microsecond latency SMR in which the leader writes requests in the log of each replica in only one round of RDMA transfers, without involvement from the CPUs on the follower nodes. Comparably, Waverunner achieves constant microsecond latency using FPGAs without changing core routines of the Raft protocol, while achieving high throughput on minimum size packets. ZABFpga [30] accelerates the Zookeeper consensus protocol using an FPGA and shows the benefits of hardware accelerator for SMRs in terms of latency and throughput. Waverunner achieves similar performance, but presents a design for the replication routines of Raft protocol while leaving all complex functionality of the Raft protocol (such as leader election and failure recovery) and the application (a key-value store) in traditional software.

8 Conclusions

We presented Waverunner, a hardware-software hybrid approach for implementing state machine replication. Our approach relies on the observation that, despite the complexity of SMR, the most frequently used routines can be easily implemented in hardware, while leaving the complex protocol and application logic in traditional software. Using this approach, we attain the best characteristics of the prior work, achieving the performance of full-hardware implementations while retaining the flexibility of software implementations with hardware-assist mechanisms such as DPDK and RDMA.

Waverunner is a practical realization of our approach. It is elegant and simple, leveraging a complete software implementation of the Raft protocol at its core and demonstrating how the most-frequently used functionality can be offloaded to hardware using only 220 lines of C++ HLS code. Waverunner achieves network line-rate throughput, nearly constant mean and tail (99th percentile) replication latency regardless of throughput, and leaves the majority of the CPU processing power available for the target application.

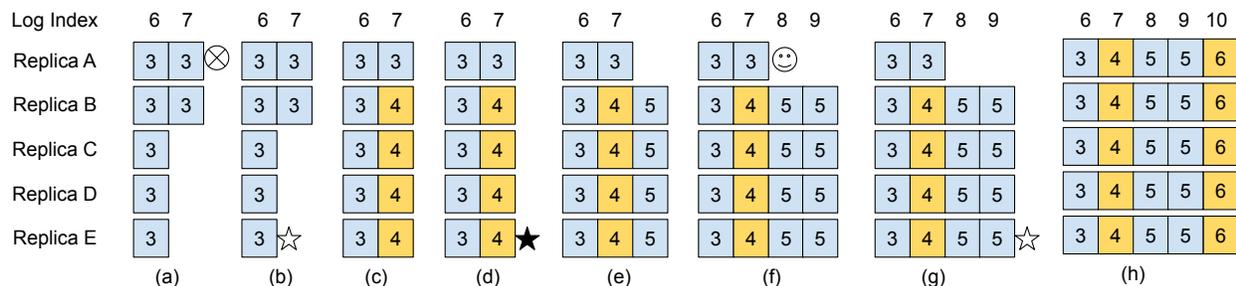

Figure 13: Waverunner Operation. ☆ represents an election that disables hardware acceleration; ★ represents an election that enables the hardware acceleration; ⊗ represents a fail stop and ☺ a recovery. The numbers inside the boxes refer to the term numbers in each log entry. The blue boxes refer to regular log entries; the yellow boxes refer to empty noop log entries.

A Correctness

Here we discuss the correctness of our approach. One reason we choose to implement Raft instead of inventing a consensus protocol is that Raft is widely used and proved correct.³ Using Raft can help us avoid having any errors in inventing a new protocol, which is known to be an error-prone process.

We show that with or without the hardware acceleration, including the transition, the system follows Raft protocol.

Fact 1. When the hardware acceleration is off at a replica, the replica follows the Raft protocol.

Therefore, if hardware acceleration at all replicas is off, the system design is a standard Raft and it is correct.

Lemma 2. When the hardware acceleration is on (and during the process it is switched on) at a replica, the replica follows the Raft protocol.

This is the principle throughout the system design. The hardware part is designed to switch back to software whenever it sees a message that it is not expecting. Not responding to that particular message is not a behavior that violates Raft’s safety because Raft’s original assumption is that the network is asynchronous and messages could be lost. Therefore, the replica as a whole (both hardware and software) is still following the Raft protocol, except that it requests an election. In Raft (and other consensus protocols), doing an election is always safe.

As a replica follows the Raft protocol regardless of whether the hardware acceleration is on or off (or during transition), the system is a Raft and thus correct.

³By “correct” we mean the system has both safety and liveness. Because Raft has already proved on these, we will use “correct” to refer to our system is either a standard Raft or is equivalent to it.

B An Example of Waverunner Operations

Figure 13 walks through an example of Waverunner failure recovery with five replicas A, B, C, D, and E. The numbers in the boxes refer to the term numbers in each log entry.

- (a) Replica A is the leader, using hardware acceleration to replicate log entries to followers until it stops.
- (b) Replica E is first to detect a lack of new messages from leader A. E disables hardware acceleration and triggers a leader election, which it wins (becoming the new leader) after receiving votes from C and D.
- (c) Replica E commits a noop, indicated in yellow, to all replicas except A (which remains unavailable). Note that a log entry in replica B is overwritten because it was ahead of the new leader. This operation is safe because the log entry was not committed.
- (d) Replica E starts a round of RequestVote2FPGA, enabling hardware acceleration on all replicas.
- (e) Replica E operates as the leader, replicating log entries using the hardware accelerator.
- (f) Replica A recovers, immediately observing new AppendEntry messages arriving from leader E. Replica A reports a mismatch with its existing logs by rejecting the new entries.
- (g) Having learned of the mismatch on replica A from the rejection message, replica E disables hardware acceleration with another leader election.
- (h) Replica E then commits another noop and sends the missing log entries to replica A. In this process, the mismatched logs on replica A are also overwritten.

Variables shared by hardware and software:

Used only by leader:

matchIndex[] for each follower, index of highest log entry known to be replicated, initialized to 0, increases monotonically

commitIndex index of highest log entry known to be committed, initialized to 0

Used by all replicas:

id a globally unique integer that identifies the server

isLeader hint that suggests whether the server is leader

currentTerm latest term server has seen, initialized to 0

lastLogIndex index of the last log entry, is a sequentially increasing counter, initialized to 0

lastLogTerm term of the last log entry

Variables in host software:

Used only by leader:

nextIndex[] for each server, index of the next log entry to send to that server, initialized to leader's lastLogIndex+1

Used by all replicas:

votedFor candidateId that received vote in current term (or null if none)

log[] log entries; each entry contains command for state machine, and term when entry was received by leader (first index is 1)

lastApplied index of highest log entry applied to state machine (initialized to 0, increases monotonically)

C Hardware and Software Variables

Figure 14 presents the complete set of Raft protocol variables that are used by hardware and software.

LeakyScatter: A Frequency-Agile Directional Backscatter Network Above 100 GHz

Atsutse Kludze and Yasaman Ghasempour
Princeton University

Abstract

Wireless backscattering has been deemed suitable for various emerging energy-constrained applications given its low-power architectures. Although existing backscatter nodes often operate at sub-6 GHz frequency bands, moving to the sub-THz bands offers significant advantages in scaling low-power connectivity to dense user populations; as concurrent transmissions can be separated in both spectral and spatial domains given the large swath of available bandwidth and laser-shaped beam directionality in this frequency regime. However, the power consumption and complexity of wireless devices increase significantly with frequency. In this paper, we present *LeakyScatter*, the first backscatter system that enables directional, low-power, and frequency-agile wireless links *above 100 GHz*. *LeakyScatter* departs from conventional backscatter designs and introduces a novel architecture that relies on aperture reciprocity in leaky-wave devices. We have fabricated *LeakyScatter* and evaluated its performance through extensive simulations and over-the-air experiments. Our results demonstrate a scalable wireless link above 100 GHz that is retrodirective and operates at a large bandwidth (tens of GHz) and ultra-low-power (zero power consumed for directional steering and ≤ 1 mW for data modulation).

1 Introduction

Low power communication has become increasingly important in emerging applications such as home automation, smart healthcare, high-quality video streaming, and localization [22, 44, 57, 58]. The number of low-power wireless devices is expected to grow to 41 billion by 2025 [36]. While the last few years have seen rapid innovations in the design and implementation of low-power wireless communication [17, 25, 29, 33, 40, 62], existing networks are limited in the number of nodes that they can concurrently support [10, 31].

The use of frequencies above 100 GHz (henceforth referred to as the terahertz (THz) band) provides unique opportunities

for concurrent transmissions. First, the availability of a large swath of spectrum above 100 GHz will facilitate dense user populations to operate concurrently at orthogonal frequency channels. Second, narrow-beam directional transmission and reception, which is required to combat the high path loss in this regime, provides additional opportunities for simultaneous transmission through space division multiple access. The sub-THz frequencies offer the best of the RF and Optical spectrum: like RF, they can be phase modulated and experience lower penetration and reflection losses when compared to optical while still providing a large swath of continuous bandwidth and laser-shaped beams. Indeed, these properties have made THz frequencies promising for 6G wireless technology. Despite these advantages, operation at such a high frequency is fundamentally power demanding since the power consumption of the RF circuitry is proportional to the frequency. This high power consumption has even stalled the deployment of mobile 28 GHz nodes and will worsen at the THz regime [8, 46–48, 52]. Furthermore, creating directional beams requires large antenna arrays, drastically increasing the power consumption and complexity of the device. This challenge worsens under mobility when constant beam adaption is needed to maintain the link. For these challenges, most existing low-power solutions have been limited to sub-6 GHz bands [35, 45, 54], with a few recent narrow-band demonstrations at 24 GHz band [30, 37, 53].

In this paper, we present *Terahertz Leaky-Waveguide Backscatter (LeakyScatter)*, a novel architecture for frequency-agile directional backscattering above 100 GHz. Instead of generating and emitting THz signals, *LeakyScatter* piggybacks its data on the impinging THz signals that are emitted from a THz transceiver. To enable directional connectivity, we exploit the unique properties of leaky-wave antennas. Leaky-wave antennas are traveling wave structures that can be realized with metal waveguides or on CMOS. In its simplest form, a leaky-wave antenna is a parallel-plate metal waveguide having open slit(s) on one side, with the interesting characteristic that guided waves (inside the waveguide) can *leak out* into free space such that the emission

angle is correlated with the frequency of the signal [21]. These frequency-dependent radiations have been recently exploited for THz path discovery and localization [12, 13, 28] and have also been demonstrated in CMOS technology [50]. In this paper, we leverage angle-frequency coupling in leaky waveguides to enable the *first* passive ultra-wideband and retrodirective structure above 100 GHz.

Our key insight is that leaky waveguides are reciprocal devices, i.e., its reception characteristics are identical to its transmission's. When it acts as a receiver, the impinging signals couple into the waveguide only if their spectral content is in agreement with the incident angle (i.e., where the angle of emission and reception from the waveguide is frequency-dependent). Hence, we devise two symmetrical slits in LeakyScatter: one for accepting free-space ambient signals into the waveguide, and the other for leaking those signals back into the air. Specifically, a far-field active transceiver emits a THz signal toward the LeakyScatter. The impinging signal would then couple into the waveguide where it is guided toward the second slit and radiates out back to free-space forming a directional beam that points to the transceiver's location, thereby enabling retrodirectivity. We emphasize that our retrodirective structure is truly wideband and spectrally agile as LeakyScatter can operate between 100 GHz and 500+ GHz. Further, the directionality is achieved with zero power consumption. The active transceiver, however, is expected to be power demanding as it is capable of generating tunable wideband signals and steering them to any desired direction. Note that the discrepancy in RF capabilities between active transceivers and low-power nodes is often the case in backscatter wireless networks.¹

In LeakyScatter, we enable data transmission by modulating the amplitude of the THz backscattered signal.² Our key observation is that the size of the slit directly impacts the amount of coupling efficiency (or backscatter power). Yet, the physical dimension of the slits in leaky antennas are fixed upon production; instead, we control the *effective size* of the aperture by re-configuring the trajectory of guided waves inside LeakyScatter's waveguide. In particular, we employ an mm-sized electrostatic MEMS mirror inside the waveguide's cavity to dynamically and electronically guide EM signals toward the slit or steer them away from it, as shown in Fig. 1. We characterize the backscattered power as a function of the micro-mirror's orientation using ray optics principles. We then optimize the architecture of LeakyScatter for maximum link budget and modulation order.

We fabricate a custom LeakyScatter and deploy it together with our in-house THz transceiver. We present the *first*

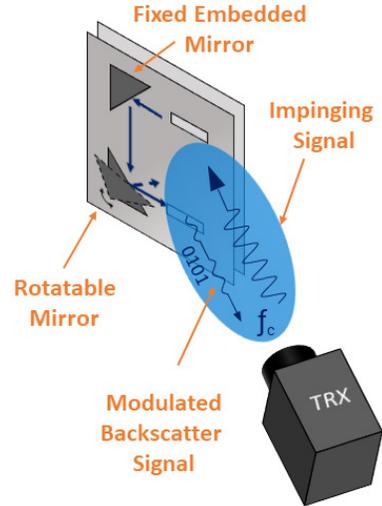

Figure 1: Illustrating the retrodirective backscatter link between our LeakyScatter and a broadband transceiver.

experimental exploration of wireless backscattering above 100 GHz. We evaluate the performance of LeakyScatter with extensive COMSOL simulations and experiments in various settings. We experimentally validate the reciprocity in leaky-wave devices, and characterize the retrodirective beams that radiate from our LeakyScatter nodes. Finally, we demonstrate low-power amplitude modulation and evaluate the feasibility of concurrent THz backscatter links in dense LeakyScatter networks.

2 Background and Related Work

2.1 Wireless Backscatter Communication

Backscatter technology is introduced for energy-efficient communication between power-constrained wireless devices [3, 20]. The underlying idea is to allow low-power nodes to piggyback their data on an ambient signal instead of generating their own RF signal, which would demand power-hungry components such as mixers, oscillators, and amplifiers [34]. In particular, an access point (AP) transmits an RF signal to the node which will then be modulated and reflected back to the AP for processing. For example, a simple On-Off Keying (OOK) can be implemented where reflecting the AP's signal translates to sending a '1' bit and absorbing the signal represents the '0' bit.

Recently, there has been significant work on extending the communication range [9, 23, 41, 56] and improving the data rate of backscatter communication links [26, 30]. In particular, employing low-power coding techniques such as chirp spread spectrum has shown promise for decoding backscattering signals below the noise floor [6]. However, while these techniques can achieve long-range communications, they often do not scale well with the number of devices, i.e.,

¹In this work, we only focus on the backscatter architecture. Designing efficient high-frequency transceiver is an active field of research and is beyond the scope of this paper.

²We emphasize that noncoherent on-off keying is identified as one of the two modes in the first standardization of sub-THz bands by the IEEE 802.15.3d task group [42].

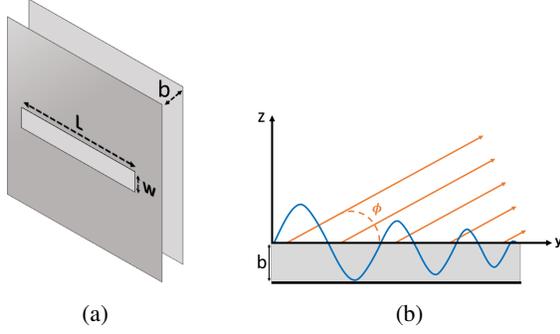

Figure 2: Parallel plate leaky waveguide: (a) front view (b) side view.

they are often limited to very few (1-2) concurrent links. The state-of-the-art protocol (NetScatter [18]) allows for concurrent transmission of 256 backscatter devices over a bandwidth of 500 KHz. NetScatter relies on the ability of the low-power nodes to generate cyclic shifted chirps, which is relatively power-demanding. Further, the number of concurrent users is inherently bounded to the bandwidth and the spectral resolution at endpoint devices.

Instead, in this paper, we take a fundamentally new approach to backscattering and introduce a spectrally-agile and retrodirective node architecture that scales the number of concurrent users through the division of signals in frequency and space. In this context, moving to higher frequencies is advantageous for two reasons: (i) the large availability of bandwidth allows for serving more concurrent users on non-overlapping channels; and (ii) directional communication (required for mmWave and THz links) provides opportunities for concurrent transmission of nodes that are sufficiently separated in space.

Therefore, unlike traditional backscatter nodes that operate below 6 GHz, our backscatter architecture aims at establishing backscatter links above 100 GHz. A few recent works have demonstrated retrodirective backscattering at mmWave bands (up to 28 GHz) using the Van Atta technique [19, 30, 37, 53]. Unfortunately, Van Atta Arrays are inherently narrow-band as the transmission lines are optimized at a particular wavelength, which is fixed (non-configurable) after fabrication.

2.2 Leaky-Wave Antennas

Leaky Wave Antennas (LWAs) belong to the general class of traveling wave antennas that can be implemented with circuits [50] or simply with an air-filled parallel-plate waveguides with an open slit on one of the plates [2]. A traveling wave inside the waveguide may “leak” into free-space through the open slit, as depicted in Fig. 2. Notably, Maxwell’s equations and the boundary condition suggest that the direction of emission from the slit is correlated with the frequency of the guided wave. By assuming infinitely thin metal plates that are infinitely conductive, the phase matching

conditions for the TE_1 mode yields [24]:

$$\phi(f) = a \sin\left(\frac{c}{2bf}\right), \quad (1)$$

where ϕ is the emission angle (relative to the waveguide plate), f is the frequency of the input signal, b is the plate separation, and c is the free-space speed of light. Eq. (1) indicates that signals with higher frequencies emit out at lower azimuth angles and vice versa.

While Eq. (1) captures the optimal emission angle as a function of frequency, in practice, the signals leaking from the waveguide can appear at a range of angles, albeit encountering different coupling losses. To understand this broader angular width, we can treat the leaky waveguide slot as a finite-length aperture, which produces a diffraction pattern in the far-field. According to Huygen’s principle [15, 55], for a diffracting aperture (i.e., slot length) of L and the dominant TE_1 mode, the far-field radiation pattern can be written as

$$G(\phi, f) \propto \int_{-L/2}^{L/2} e^{-j\beta_y y} e^{-\alpha y} e^{jk_0 \cos(\phi)y} dy \quad (2)$$

$$= \text{sinc}\left((\beta_y - j\alpha - k_0 \cos\phi)\frac{L}{2}\right),$$

where $\text{sinc}(x) = \sin(x)/x$, $k_0 = \omega/c$ is the free-space wave-number, α is the leakage attenuation, and β_y is the propagation constant. β_y can be written as $\beta_y = \sqrt{k_0^2 - (\pi/b)^2}$ when the parallel-plate waveguide has an air core. Eq. (2) also confirms the dependency of emission pattern on frequency where the peak output radiation occurs at the angle at which $\text{Re}\{(\beta_y - j\alpha - k_0 \cos\phi)\frac{L}{2}\} = 0$, yielding Eq. (1). It should be noted that the coupling efficiency and reception behavior of a leaky-wave antenna are independent of polarization [43].

Recently, leaky-wave antennas have been used in multiple sensing tasks including link discovery [12, 14], mobility tracking [13], 3D localization [28], physical-layer security [61], and even for wireless authentication [27]. However, this paper is the first work toward exploiting the angle-frequency relation and the antenna reciprocity for frequency-agile backscattering.

3 Design

In this section, we describe the underlying principles and key components of LeakyScatter.

3.1 Design Overview

The large amount of available bandwidth above 100 GHz together with directional transmission opens up opportunities for concurrent high-rate networks beyond 5G. Yet, operation at such high frequencies is fundamentally power-demanding since the power consumption of the RF circuitry is

proportional to the frequency. Further, creating directional beams would require large antenna arrays, which itself increases the power and complexity. Previously-established backscattering technology addresses the first challenge by allowing nodes to piggyback their data on an ambient signal instead of generating their own RF signal, thereby, eliminating the need for power hungry components. However, existing backscatter designs are either directional and narrow-band [30, 37, 53] or omnidirectional at much lower frequency bands (e.g., sub-6 GHz) [35, 45, 54].

Our proposed LeakyScatter is the first frequency-agile directional backscattering network at THz bands. Instead of conventional systems that use phased array antennas for beam steering, we introduce a fundamentally novel node architecture based on leaky-wave antennas. Our key observation is that a leaky wave antenna is inherently reciprocal. In particular, the first-principle model suggests that the frequency-dependent radiation in leaky-wave antennas is identical in both transmission mode (guided signals coupling out into free-space) and reception mode (free-space waves coupling into the waveguide). We leverage this interesting characteristic to build a fully-passive retrodirective node. We design a two-slit waveguide (one for receiving signals from the transceiver (TRX) and another for transmitting the signal back directionally toward the transceiver), as shown in Fig. 1. We also embed two mm-sized mirrors inside the waveguide to guide the propagation path between the two apertures.

Given the angle-frequency relationship, the TRX should choose the *correct* frequency to communicate with LeakyScatter nodes depending on the node location and orientation relative to TRX. Fortunately, single-shot angular localization with leaky-wave antennas has been successfully demonstrated in the literature [28]. Here, we assume that the TRX can localize all LeakyScatters by implementing such prior schemes. Further, we assume that the TRX has flexible ultra-wideband transmission and detection capabilities. Such asymmetry between the RF capabilities at the TRX and low-power nodes is typical in all backscatter networks.

In order to piggyback information bits on backscattered signals, we enable amplitude modulation by changing the trajectory of in-coupled waves. Specifically, a small rotation in one of the embedded mirrors would cause significant fluctuations in the amount of power leaked into free-space. Hence, we realize amplitude modulation by dynamically changing the voltage of a MEMS mirror according to the bit stream. We discuss other potential modulation strategies in Sec. 6. Finally, we emphasize that LeakyScatter is ultra-wideband (supporting bandwidths upto few 10s of GHz) and frequency-agile (supporting carrier frequencies from 100 GHz to 500 GHz), retrodirective, and scalable to large-scale networks. Next, we will illustrate the key components of LeakyScatter in detail.

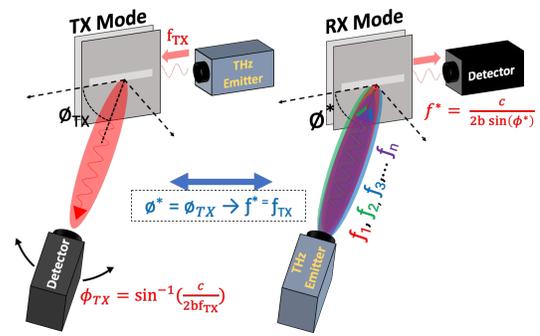

Figure 3: Illustration of reciprocity in leaky waveguide: the angle frequency coupling holds in both transmission and reception modes.

3.2 Retrodirectivity in LeakyScatter

The retrodirectivity in LeakyScatter is rooted in the antenna reciprocity of leaky-wave antennas. First, we formally model this reciprocity. Consider a tunable source, a broadband detector, and a single-slit waveguide as shown in Fig. 3. First, the tunable source excites the waveguide (TE1 mode) with a signal at frequency of f_{TX} . Given the angular-frequency coupling, the waveguide will act as a directional transmitter creating a directional beam in the far-field (labeled as TX mode in Fig. 3). The detector then measures the received power at various angles to estimate the radiation pattern of the leaked waves. Eq. (1) suggests a direct one-to-one relationship between the angle at which maximum power is received (denoted as ϕ_{TX} in Fig. 3) and f_{TX} . Next, we swap the detector and source while keeping the same waveguide. The source emits out signals at different frequencies (f_1, f_2, \dots, f_N) while the broadband detector captures the power of coupled waves at each corresponding frequency. Antenna reciprocity suggests that given a fixed leaky-antenna structure (e.g., aperture size and plate separation), and waveguide positioning (i.e., $\phi^* = \phi_{TX}$), the maximum coupling happens when $f^* = f_{TX}$, which is equal to $\frac{c}{2b\sin(\phi_{TX})}$, according to Eq. (1). We will experimentally evaluate this in Sec. 5.

LeakyScatter utilizes two symmetrical apertures, one meant for reception and another meant for transmission. Embedded within the waveguide cavity are two mirrors as illustrated in Fig. 4 to passively redirect the in-coupled signal from the receiving aperture toward the transmitting aperture. More specifically, a THz signal impinging on LeakyScatter at angle θ_{TX} interacts with the first mirror inside the cavity, which results in a 90° rotation in the propagation direction. Upon impinging on the second embedded mirror, the signal deflects in the reverse direction and moves towards the second slit. The signal then leaks out into free-space through the second slit with an emission angle of θ_{RX} . Given the reciprocity, we have $\theta_{TX} = \theta_{RX}$, as also illustrated in Fig. 4. Such retrodirectivity is essential to our backscatter networks as a single active

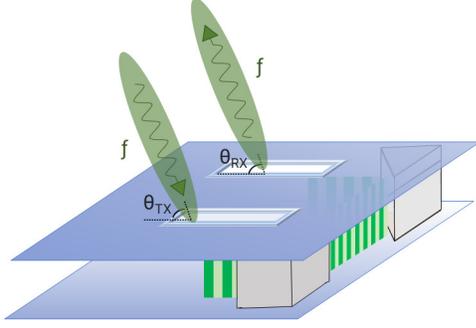

Figure 4: A schematic of LeakyScatter, showing two open slits and embedded mm-sized mirrors to guide the THz waves in between.

transceiver (co-located emitter and detector) is now able to establish a directional link with a truly passive architecture.

We can model the amount of backscattered power by incorporating internal waveguide losses as well as the far-field pattern of LeakyScatter in both TX and RX modes. Specifically, when a transceiver sends an unmodulated signal towards the waveguide, the total power that couples into the waveguide is a function of frequency, f , and the impinging angle θ_{TRX} , and can be modeled by Eq. (2). Once the impinging signals couple into LeakyScatter, they will experience propagation losses within the waveguide en route to the transmitting aperture. Finally, the waves emit out with a similar far-field behavior. Therefore, the total backscattered power (P_{bsc}) at frequency f can be modeled as:

$$P_{bsc}(f, \phi_{TRX}) \propto G^2(f, \phi_{TRX}) \times \left(\frac{1}{L_{WG}}\right), \quad (3)$$

where L_{WG} represents the incurred losses in the guided mode, ϕ_{TRX} is the relative angle between the transceiver and the LeakyScatter device. $G(f, \phi_{TRX})$ is defined in Eq. (2). We can see that the maximum backscattering power is achieved when the impinging angle and signal's frequency satisfies $Re\{(\beta_z - j\alpha - k\cos\theta)\frac{L}{2}\} = 0$. Next, we explain how L_{WG} is modulated based on the data bit stream.

3.3 Data Modulation and Demodulation

So far we have explained how LeakyScatter realizes a retrodirective communication link with an active external transceiver. Now, we explain how LeakyScatter modulates the backscattered signal to transmit information bits. Our design is based on amplitude modulation such that different backscattered power levels translate to distinct sequences of bits. Fluctuation in power level is achieved by an on-demand modification to the power loss inside the waveguide. In particular, one of the aforementioned embedded mirrors is replaced with a mm-sized rotatable MEMS mirror. By changing the mirror's orientation, we seek to control the

amount of power that is guided toward the second slit and hence can potentially leak out back to free-space.

Fig. 5 explains how a slight misalignment in the orientation of the MEMS mirror yields a non-negligible drop in the backscatter power. In principle, if the dispersion was minimal and the slit was infinitely thin, even an arbitrarily small rotation of the mirror (i.e., $\delta\theta_{rot}$) could cause zero backscattered power as the guided waves would just miss the open slit. However, in practice, due to dispersion and non-zero slit width, changing the propagation path of guided waves would yield a drop in power. The exact amount of power drop is a complicated function of the frequency, slit dimension, wave propagation constant, the leakage attenuation factor (denoted as β and α in Eq. (2)), and more importantly, the amount of rotation (i.e., θ_{rot}).

Our key insight is that the amount of radiated power is proportional to the leakage area and changing the trajectory of guided waves would impact the effective aperture. For simplicity, we consider a rectangular slit (width of W and length of L) and assume that signal leakage is uniform across the slit length. As shown in Fig. 5, when θ_{rot} increases and the guided waves are further directed away from the open slit, the effective aperture area seen by the guided waves should decrease. Using ray optics, we write a first-order approximation of the internal waveguide losses as:

$$L_{WG}(\theta_{rot}) = c_1 + c_2 \frac{A_{slit}}{A_{eff}(\theta_{rot})} = c_1 + c_2 \left| \frac{2L}{W} \tan(2\theta_{rot}) \right|, \quad (4)$$

where c_1 represents the constant losses such as propagation loss within LeakyScatter and c_2 is a constant aperture coupling loss. A_{slit} is the area of the slit and A_{eff} is the effective aperture at rotation angle θ_{rot} . Note that c_1 and c_2 is a deterministic function of the waveguide geometry (e.g., the internal path length between the two slits) and can be measured and known upon production. Clearly, L_{WG} is minimum at $\theta_{rot} = 0$ and increases with θ_{rot} . Combining

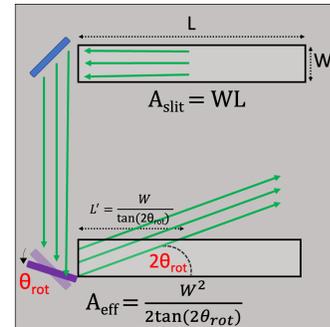

Figure 5: An electronically rotatable mm-sized mirror embedded within LeakyScatter changes the propagation path of guided waves and thus effectively controls the size of transmitting aperture seen by the guided waves.

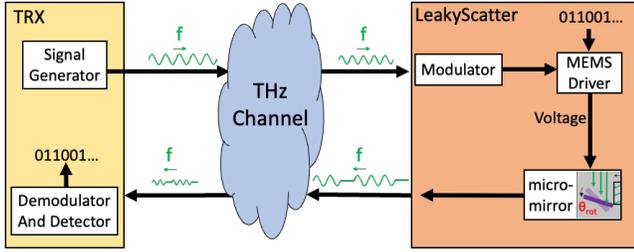

Figure 6: The block diagram of a THz backscatter network.

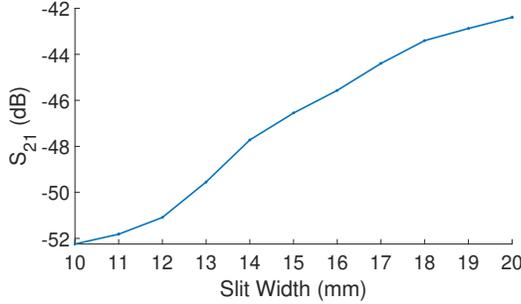

Figure 7: The impact of slit width on total backscatter gain in LeakyScatter.

Eq. (4) and Eq. (3), we can write:

$$P_{bsc}(f) \propto \frac{G^2(f, \phi_{TRX})}{c_1 + c_2 \left| \frac{2L}{W} \tan(2\theta_{rot}) \right|} \quad (5)$$

Putting all pieces together, Fig. 6 depicts the block diagram of an TRX-LeakyScatter link. As shown, the modulator at LeakyScatter sets the voltage values at the micro-mirror MEMS driver according to the bit stream. The orientation of the mirror would then change the trajectory of guided waves imposing amplitude modulations. The modulated signal is steered back toward the TRX. At the TRX, the demodulation block retrieves the data bits from analyzing the measured power spectrum.

3.4 Design Optimization for Maximizing Reflection Gain

Given the link budget scarcity in backscatter networks, we aim to maximize reflection gain (i.e., backscatter power) in LeakyScatter. Here, we introduce the underlying optimizations and trade-offs that achieve this goal.

3.4.1 Slit Geometry

The slit geometry plays a key role in the coupling efficiency and directivity gain in LeakyScatter. In principle, a wider slit is desirable as it allows for a better coupling between guided waves and free-space waves. Yet, the angle-frequency relation in leaky-wave antennas only holds for very thin slits. Indeed, widening the aperture of a rectangular slit quickly

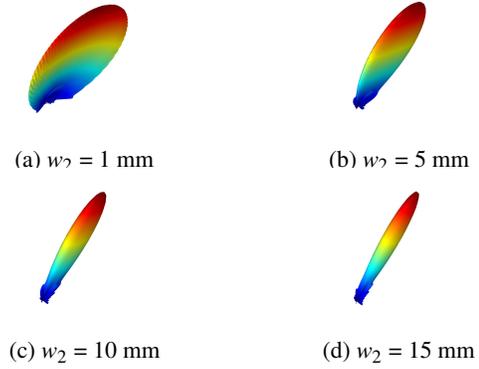

Figure 8: Far field emission pattern at various slit widths, showing higher directivity gains achieved with wider slits.

invalidates the monotonic angle-frequency coupling due to the increasingly non-uniform electric field distribution along the slit. To circumvent this issue, we employ trapezoidal apertures (also explored in [16]) to increase aperture size while maintaining the coupling relations. Such slits enable us to increase the captured energy from the receiving slit as well as the out-coupled energy that leaks back out into space. Larger slits also yield smaller diffraction, thus, ray optics models are more accurate with larger slits.

We have simulated LeakyScatter with two symmetric trapezoid slits with varying slit width. Fig. 7 presents the simulated S_{21} parameter against slit widths. The smaller width of these trapezoid-shaped slits is set at $w_1 = 1$ mm while the larger width is varied from $w_2 = 10$ mm to 20 mm in COMSOL. These results were presented in the form of S-parameters, which is a metric to describe the energy propagation across different input/output ports. Here, we define S_{21} as the ratio between the reflected energy from a LeakyScatter compared to incident energy. Hence, S_{21} is a good representative of the backscattering gain. It should be noted that the S_{21} values do not directly translate to the real-world measurements; yet, the general trend can be successfully predicted by analyzing S-parameters.

From Fig. 7, we observe a clear rise in the radiated output power (by 10dB) above its initial starting point at 10 mm. We also look into these simulations in the angular space and plot the directional far-field pattern of the backscattered signal in Fig. 8. As shown, the beams become more pencil-shaped and narrow, leading to higher directivity gains. Therefore, from both simulations, we expect a higher link budget with wider trapezoid slits. However, we emphasize an important tradeoff here: intuitively, with a wider aperture, imposing a fixed power/amplitude fluctuation of P would require a greater mirror rotation angle (θ_{rot}). Unfortunately, our embedded MEMS mirrors are extremely small (mm-sized) and thus limited in their maximum rotation angle (e.g., 5° in our setup). Further, in amplitude shift keying (ASK), the number of symbols (or modulation order) depends on our flexibility to

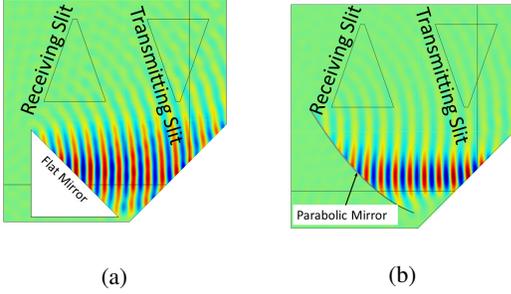

Figure 9: E-Field simulation of (a) a flat mirror and (b) an off-axis parabolic mirror showing the impact of mirror geometry on dispersion inside the waveguide.

create sufficiently distinct amplitude levels. Hence, we argue that thinner slits are more sensitive to small mirror rotations, so they support higher modulation orders. We carefully take into account the two sides of this tradeoff and fabricate LeakyScatter with the optimal slit width of $w_2 = 15$ mm.

3.4.2 Parabolic Mirror vs. Flat Mirror

The fixed mirror in LeakyScatter provides a 90-degree rotation in the trajectory of guided waves. The guided waves disperse as they travel inside the waveguide demanding a large electronically-controlled mirror to collect and rotate these waves. In order to keep the mirror size to mm-scale, we explore other possibilities for the fixed mirror. In particular, unlike flat mirrors, parabolic mirrors can focus EM radiation to a focal point. Hence, we use an 90° Off-Axis-Parabolic (OAP) mirror instead of a flat mirror to decrease dispersion in LeakyScatter. An OAP mirror is a segmented part of a parabolic mirror that diverts the incident signal by a specific angle while focusing it at the same time.

Fig. 9 illustrates the simulation results of our OAP mirror in comparison with a flat reflected surface at 173 GHz. This plot demonstrates the E-field magnitude only between the two mirrors to highlight the impact of the mirror shape. While the flat mirror successfully reflects the incident wave, it causes outward radiations as opposed to the parabolic mirror that focuses the beam to the center of the MEMS mirror. LeakyScatter thus takes advantage of an OAP mirror to accurately re-direct guided waves toward the transmitting slit and thereby increase the output power.

3.5 Concurrent Backscatter Links

The directional and wideband operation in LeakyScatter networks allows for multi-node concurrent transmissions. In particular, LeakyScatter supports a wide range of frequencies (e.g., from 100 GHz to 500 GHz). Albeit, the correct spectral band should be selected based on the angular configuration of LeakyScatter relative to the active TRX. When multiple LeakyScatter devices are sufficiently separated in the angular

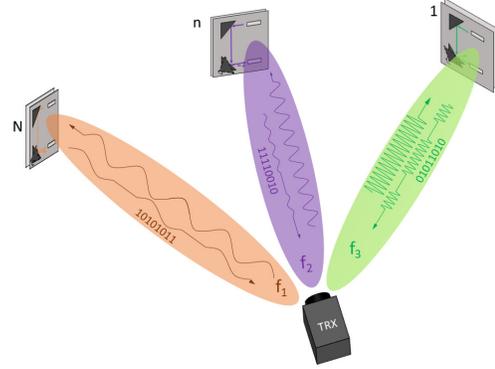

Figure 10: Concurrent transmissions of multiple LeakyScatter devices where backscattered signals can be separated in spatial and/or spectral space.

domain, they can simultaneously and independently modulate a different sub-band of the ambient wideband spectrum. This separation in the angular domain can be seen with distributed nodes at different locations around the TRX (as shown in Fig. 10) or even in co-located nodes that have different orientations. A straightforward strategy is to make TRX broadcast a pseudo-pulse in all directions to collect data from all existing nodes.³ In such a case, spatially-separated LeakyScatters will modulate different sub-bands; thus, a simple power detection across spectrum can retrieve the information of multiple backscatter nodes. We emphasize that such a scheme relies solely on power measurements. Each LeakyScatter initiates its packet with a pre-known preamble that is utilized at TRX for node identification, localization, and steady-state power calibrations.

Interestingly, the bandwidth of a backscatter link would also depend on the incident angle of THz signals on LeakyScatter. Indeed, the non-linear angle-frequency function causes the in-coupled/out-coupled spectral range (and therefore bandwidth) to also change with angle. Particularly, the operating bandwidth for a receiver located at the far-field of a typical leaky waveguide device at an angle ϕ relative to the waveguide can be described by

$$BW(\phi) = \frac{df}{d\beta} \frac{d\beta}{d\phi} \Delta\phi = \frac{c_0}{2b \cdot \sin\phi \tan\phi} \Delta\phi, \quad (6)$$

where $\Delta\phi$ is the effective angular aperture subtended by the receiver and β is the wave number of guided waves.

Eq. (6) indicates that the bandwidth is wider for lower emission angles. Hence, given a fixed application-driven bandwidth per node, a non-uniform distribution of concurrent LeakyScatters is expected across the entire angular space.

In summary, the THz LeakyScatter networks offer a two-layer protection against inter-user interference. Namely,

³Designing efficient medium access protocols for multi-node backscattering is out of the scope of this work and is a subject of future studies.

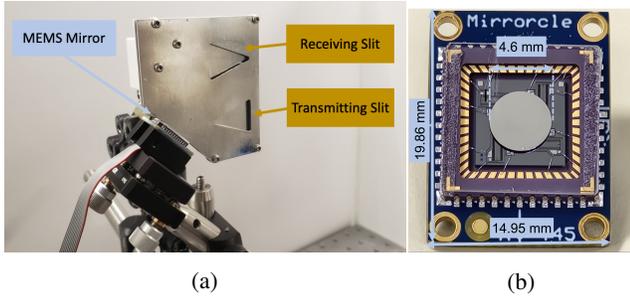

Figure 11: Our (a) fabricated LeakyScatter with (b) a 4.6 mm electrostatic MEMS mirror.

the directionality of the reflected signals offers opportunities for space division multiple access and the inherent spatial-angular correlations allow the leaky-wave backscatter nodes to operate on different sub-bands according to their angular settings. This flexible multi-band operation would be self-regulated by the LeakyScatter’s architecture at zero power costs, allowing scalability to dense user populations.

4 Experimental Platform and Methodology

We evaluate the performance of our LeakyScatter through extensive COMSOL simulations and over-the-air experiments. Our custom waveguide-based backscatter device, as illustrated in Fig. 11, is constructed with two thin metal plates held in parallel at a separation of 1 mm (i.e., $b = 1$ mm). The overall dimension is 60 mm \times 54 mm. On the front metal plate, we cut two trapezoidal shape slits with longer and shorter widths of 1 mm and 15 mm, respectively. Both slits are 20 mm long. We embed a reflecting OAP mirror that has a smooth metal surface in between the two plates (hence, the thickness of the mirror is also 1 mm). We emphasize that building such a device is cheap (only a few cents) and can be done in a machine shop. To modulate the amplitude of backscattered signals, we employ a mm-sized MEMS mirror, offering continuous rotation in both its x and y directions (with a max rotation angle of $\pm 5^\circ$). The average power consumed by the MEMS mirror is less than 1 mW for continuous full-speed operation. The mirror is controlled via a low-profile driver with max voltage of 5 V. Resonant frequencies of these mirrors range from a few kHz up to tens of kHz and change with mirror size [38].

Our system architecture assumes a tunable wideband transceiver that is able to transmit signals above 100 GHz and steer them toward LeakyScatter nodes. Hence, we use a time-domain broadband system (TeraMetrix T-Ray [1]) that produces an ultra-short pulse with a flat frequency response between 100 GHz to 400 GHz. The detector measures the electric field magnitude at a wide range of frequencies with a spectral resolution of 1.22 GHz (sampling rate of 10 THz). The emitter and detectors are both linearly polarized with a polarization extinction ratio (the ratio of transmitted/received

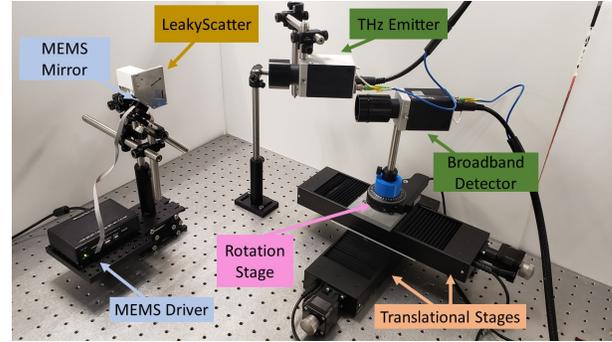

Figure 12: Our experimental setup.

power between the intended and orthogonal polarization modes) $< 20:1$. We collect raw time-domain samples and apply conventional signal processing techniques (smoothing, filtering, FFT, etc.) to isolate the signal at the spectral range of interest. Note that even though our testbed provides time-domain waveforms, LeakyScatter only uses power measurements (albeit across multiple frequencies) for data demodulation and detection.

Fig. 12 demonstrates our experimental setup consisting of the LeakyScatter and our THz emitter and detector. The emitter is configured at various settings. The detector is placed on a motorized rotation stage on top of a 2D motorized translation stage providing high-precision movement around the waveguide at various configurations. The emitter is equipped with a collimating lens that directs the THz signal into the upper slit of the waveguide.

Our evaluations are limited to an angular range of 20-60 degrees due to our transmitter’s low output power. Specifically, the transmit power above 400 GHz, which corresponds to angles below 20 degrees, is always about 6 dB or more weaker, making the reflected signal harder to observe. Additionally, signals are very noisy at < 170 GHz due to a combination of higher dispersion inside the waveguide, getting closer to the cutoff frequency (which is currently 150 GHz but can be changed by modifying the plate separation) and limited spectral resolution of the setup. A higher transmit power is needed to compensate for these losses and will be addressed with future THz transmitters. Nevertheless, we emphasize that our observations and conclusions presented in the paper hold true for all other angles.

5 Evaluation

In this section, we discuss our over-the-air experiments and evaluate the key design components of LeakyScatter.

5.1 Reciprocity

First, we experimentally characterize and compare the transmission and reception characteristics of leaky

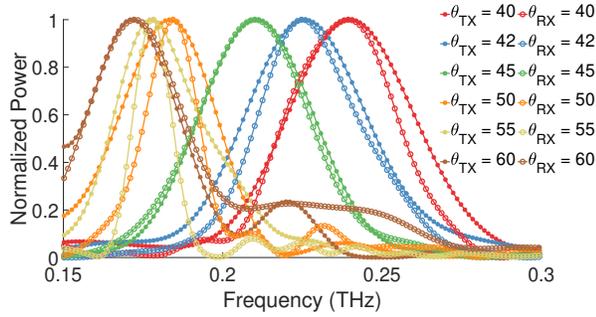

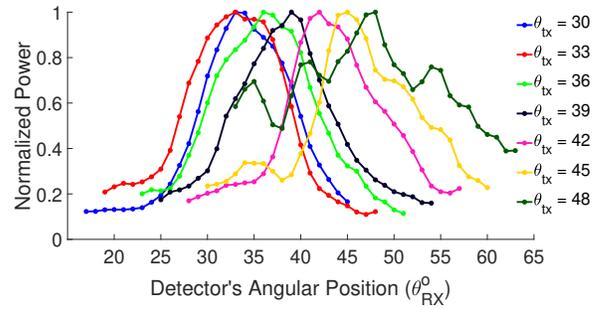

Figure 13: Experimental evaluation of the leaky-wave antenna reciprocity: The angle-frequency correlation holds in both transmission and reception modes.

waveguides to validate the reciprocity in angle frequency coupling. This is a crucial building block for designing a waveguide-based retrodirective backscatter device.

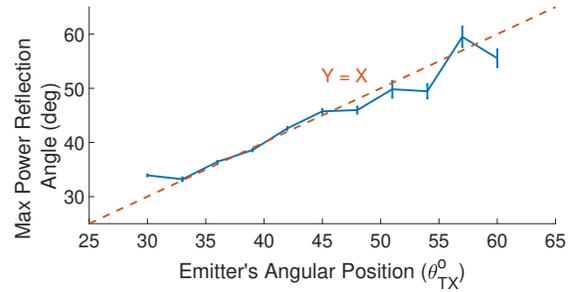

Setup. To this end, we employ two different configurations, as also shown in Fig. 3. In particular, for measuring the emission radiation pattern of a leaky-wave antenna, we focus a THz pulse into a single-slit waveguide with an external lens of focal length 75mm. The THz detector is placed on a 2D translation stage at a fixed distance where it can be configured at multiple angle directions relative to the waveguide. Similarly, our setup for measuring the reception pattern of the leaky-waveguide switches the source and the detector, i.e., the wideband source is now placed on a 2D translation stage and the detector focused into the waveguide. In both setups, the same exact waveguide was used. We configured the detector in transmission and source in reception at different angles, each corresponding to θ_{RX} and θ_{TX} from Fig. 4 respectively, ranging from 30° to 63° .

Fig. 13 shows the normalized power spectrum measurements from both reception and transmission for a few configurations, namely, 40° , 42° , 45° , 50° , 55° , and 60° . As the angle changes, we see a clear shift in the peak frequency and bandwidth in both modes (reception and transmission), obeying both equations Eq. (2) and Eq. (1). More importantly, the peak frequencies in the reception and transmission modes are in agreement, with the greatest discrepancy being a 2 GHz difference at 60° . There is, however, a discrepancy in the bandwidths of the reception and transmission measurements with the transmission bandwidths being generally larger than the reception. This is largely a result of the different distances of the detector-waveguide in transmission mode (38cm) and of the source-waveguide in reception mode (29.5cm). The shorter distance in transmission allows for a larger acceptable range of in-coupling frequencies, as opposed to the reception setup, and hence a wider bandwidth. Nevertheless, the overall spectral profiles closely follow each other.

We have experimentally illustrated that leaky-wave antennas are reciprocal, i.e., the angle-frequency relationship holds true when the antenna used in transmission and

(a)

(b)

Figure 14: Experimental characterization of retrodirectivity in LeakyScatter: (a) The measured radiation patterns at different settings; (b) the max-power backscatter angle vs. the ground truth impinging angle.

reception modes. LeakyScatter leverages this property to enable retrodirective scattering with zero power consumption.

5.2 Retrodirectivity

Next, we experimentally evaluate the retrodirectivity in LeakyScatter, which is the ability to steer the backscatter signals toward the transceiver. Such directional communications are essential for closing the link given the high path loss at 100 GHz.

Setup. To assess this, we use the setup illustrated in Fig. 12. We integrate a fixed mirror (instead of a rotating mirror) inside the waveguide to direct the guided waves from the receiving aperture toward the transmitting aperture. We try multiple impinging angles between the THz emitter and LeakyScatter (θ_{TX}). Each time, we move the THz detector on a 2D stage to measure the radiation pattern of directional backscatter signals. Recall that given the reciprocal angle-frequency coupling of leaky waveguides, we expect to observe the backscattered signal being strongest when the angle of reflection is the same as the impinging angle.

Fig. 14a presents the normalized power distribution of backscattered signal across space given several THz source configurations (θ_{TX}): 30° , 33° , 36° , 39° , 42° , 45° , and 48° . Given that our source is wideband, evaluation for each of the backscattering transmissions were restricted to spectral band where Eq. (5) gave minimal losses. As expected, in each of

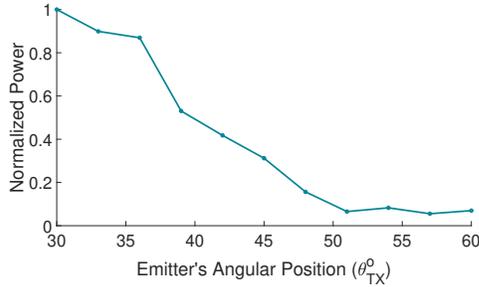

Figure 15: Normalized received power at different reflection angles.

the corresponding curves, the peak reception occurs when the reflection angle is equal to the transmission angle with a half-power beamwidth of 10.56° on average.

Fig. 14b presents these results against the expected behavior demonstrating that LeakyScatter achieves a mean error of 1.911° . We observe an increase in the overall error and fluctuations at higher impinging angles (i.e., when LeakyScatter is placed at larger angles relative to the THz emitter). We find two underlying reasons for this observation: (i) the inherent angle-frequency relationship in leaky waveguides is a nonlinear function such that the spectral profile is much more similar (less differential) at larger emission/acceptance angles. This implies that the main lobe of backscatter radiation is prone to slight misalignment when LeakyScatter is positioned at larger angles; and (ii) the overall backscattered power is not uniform at different configurations. We show the dependency of maximum reflected power with the angular location of LeakyScatter in Fig. 15. As we approach higher angles, the received power begins to drop (e.g., a drop of 10 dB is observed when the location changes from 30° to 51°). However soon after, the maximum received power begins to be less location-dependent. Although our results show that retrodirective beams can be formed, they also reveal that the directivity gain is not uniform across space. In other words, the amount of reflected power would depend on the LeakyScatter's location relative to the TRX: those positioned at smaller angles have the advantage of forming more directive/high-power backscattered links. This is to some extent a direct impact of our design specs (e.g., OAP mirror) that will be discussed later.

We have experimentally validated that our proposed backscattering architecture is retrodirective and can establish and maintain directional connectivity with an external transceiver regardless of its location.

5.3 Data Modulation

Next, we experimentally evaluate the ability of LeakyScatter to modulate the impinging signal for data transmission.

LeakyScatter modulates the reflection path within the waveguide via an electronically-controlled mirror, thus enabling ASK by imposing different reflection power (or

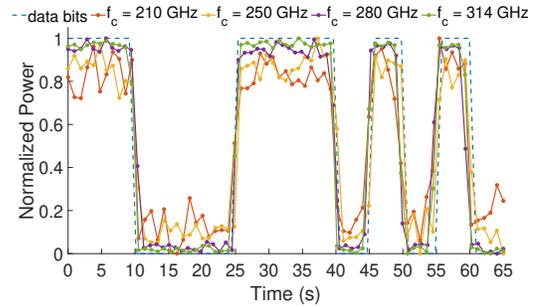

Figure 16: Measured modulated backscattered signal at various center frequencies, showing the spectral agility of LeakyScatter.

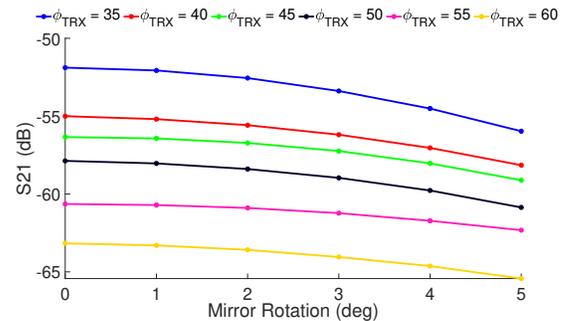

Figure 17: The sensitivity of backscatter gain (captured by S_{21} simulations) to mirror rotation in LeakyScatter.

amplitude). Specifically, we use the same setup as in 5.2 except that we employ a mm-sized MEMS mirror for digital data encoding. As an example ASK, we map the base orientation of the Mirror ($\theta_{rot} = 0^\circ$) to a “0” bit and the rotation angle of 5 degrees ($\theta_{rot} = 5^\circ$) to a “1” bit. At the detector, different power levels are translated to their corresponding bit. We emphasize that this binary ASK is evaluated as an example scheme. Higher order modulation is feasible with arbitrary encoding of symbols to the embedded mirror's orientation (i.e., reflected amplitude).

Fig. 16 shows the successfully transmitted bit stream 0011100010101 with a symbol time of 5 seconds. We repeated this experiment at different center frequencies $f_c = 210$ GHz, 250 GHz, 280 GHz, and 314 GHz (corresponding to reflection angles of 45° , 37° , 32° , and 28° respectively). Our results demonstrate a successful demodulation/detection regardless of the carrier frequency or LeakyScatter's relative angular location. However, we observe that the difference between the two power levels (representing 0 and 1) gets smaller at lower frequencies. This implies that the ASK modulation order is limited for lower frequencies.

To better understand this experimental observation, we have simulated the LeakyScatter structure in COMSOL and looked into the S-parameters of this device. Specifically, Fig. 17 plots S_{21} as a measure of the backscatter power at different mirror rotations. We repeat the simulations for several impinging angle configurations. Surprisingly, at any mirror orientation, we observe a larger S_{21} at lower impinging/reflecting angles.

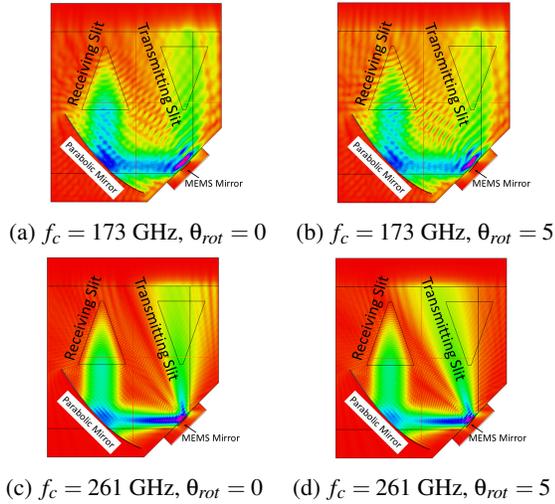

Figure 18: E-field simulations of guided waves in LeakyScatter.

Further, the power drop caused by the mirror’s rotation is generally more pronounced at smaller angles (e.g., an S_{21} drop of 2.25 dB at $\theta_{TRX} = 60^\circ$ vs. a 4.1 dB drop at $\theta_{TRX} = 35^\circ$). Note that this trend holds for negative rotations (not shown).

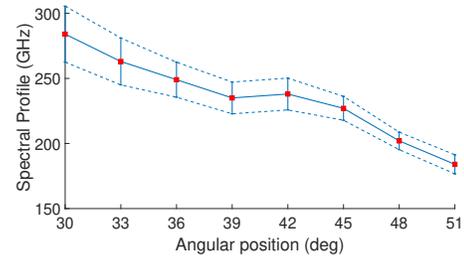

To find the underlying reason, we looked further into the simulated E-field inside the waveguide at the same device configurations. Fig. 18 depicts this with an in-coupled signal of 173 GHz and 261 GHz signal at rotation angles $\theta_{rot} = 0$ and $\theta_{rot} = 5$. Interestingly, we observe less dispersion for the higher frequency tone; i.e., the guided waves are much more directed (laser-like) at 261 GHz, especially as they interact with the embedded parabolic mirror. The propagation path of guided waves can thus be more precisely controlled via a rotating mirror. There is a clear drop in the amount of power at the second (transmitting) slit due to the 5° mirror rotation. This implies that the ASK modulation order (i.e., the number of symbols which here correlate with the number of distinct power levels using an electronically-controlled rotating mirror) is frequency-dependent with higher frequencies offering higher modulation orders.

We have experimentally demonstrated that we can piggyback information bits on the backscattered signal with LeakyScatter. Interestingly, a higher modulation order can be achieved at higher frequencies due to their small dispersion and laser-like behavior in guided mode.

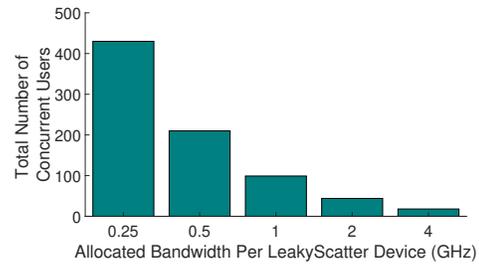

5.4 Multiple Concurrent LeakyScatters

Finally, we investigate the user capacity in LeakyScatter networks. We consider a single transceiver and emulate multi-node backscattering by placing the LeakyScatter at various locations and collecting the raw power spectrum.

First, we experimentally evaluate the half-power bandwidth at various TRX-LeakyScatter angular configurations. As discussed in Sec. 3.5, we expect larger half-power bandwidths

(a)

(b)

Figure 19: Experimental characterization of user density: (a) Spectral band of operation in LeakyScatter when configured at various impinging angles; (b) Total concurrent LeakyScatter nodes given their application-driven bandwidth requirements.

at lower incident angles. Fig. 19a confirms this claim through experimental analysis where the bandwidth of backscatter links are captured across different angular positions (all at a fixed distance of 34 cm from LeakyScatter). This observation suggests that the concurrent user capacity (given a per-user bandwidth) is also non-uniform across space, and dependent on the incident angle with a similar trend.

Fig. 19b shows the emulated total number of concurrent users across the angular domain. We assume directional pencil-shaped beams (1° of beamwidth) at TRX⁴. Further, we emulate five different bandwidths for backscatter communication. Note that in practice, this number is application-dependent. According to Fig. 19b, LeakyScatter can establish 430 simultaneous non-overlapping links with a spectral allocation of 0.25 GHz per user. Similarly, 18 users can be supported at a spectral allocation of 4 GHz each. We emphasize that different backscatter nodes modulate different portions of the spectrum (according to their location and orientation); thereby, having multiple nodes is a simple extension of a single LeakyScatter as the signals are orthogonal in frequency. In the future, we will experimentally implement a multi-backscatter network using a multi-beam multi-frequency emitter.

We have experimentally demonstrated that by taking advantage of LeakyScatter’s retrodirectivity and spectral agility, we can support multiple concurrent backscatter nodes in dense user settings.

⁴For simplicity, we consider the far-field scenario in which the backscatter range is much larger than the dimension of the physical LeakyScatter nodes.

6 Discussion and Limitations

In this section, we discuss the opportunities and limitations in THz backscatter networks as well as our future directions.

Mobility Support with LeakyScatter. One of the main challenges in directional communication is maintaining beam alignment despite nodal mobility. LeakyScatter offers a retrodirective link which means the backscatter beam will always point back toward the broadband TRX regardless of device motion. Interestingly, this will be accompanied by a change in the spectral profile observed at the TRX. This opens the door for simultaneous data transmission and localization, an emerging paradigm for 6G wireless systems. Note that leaky-wave antennas have been used recently for angular positing in unmodulated and active settings (non backscattering) [11, 13, 28]. This paper is the *first* effort that exploits the angle-frequency coupling in leaky-wave devices for enabling low-power frequency-agile backscattering at the sub-THz regime.

Communication Range and Coverage. A common concern in all backscattering networks is the limited communication range, i.e., the range of a backscatter link is always smaller than an active TX-RX link due to lack of amplification at the backscatter. This issue worsens in sub-THz and THz frequencies that suffer from increased propagation attenuation. Yet, our experimental results demonstrate the feasibility of closing a link at frequencies as high as 314 GHz without any amplifications and via an ultra-low-power broadband emitter/detector. Our source has an average output power of 400 nW across 5 THz non-uniformly. Our current implementation of LeakyScatter, however, has an operating bandwidth of approximately 400 GHz which upon calculation yields a 260 nW average power output. Even under such stringent power budgets, a communication range of half a meter was achieved. This is owed to the directionality at LeakyScatter which compensates for the higher path loss. Note that our communication range is similar to the numbers reported by prior work that uses an active leaky-wave antenna [13, 28] which implies that the limitation in range is a direct result of the employed low-power source and not the architecture of LeakyScatter. Employing more realistic TRX can scale up the transmitter-receiver distance as links at WLAN-scale distances (100+) meters have already been demonstrated above 100 GHz [59, 60].

We note that LeakyScatter is limited in angular coverage of 90° . Prior work proposed a periodic arrangement of slits to extend the coverage of leaky-wave antennas to 180° [32]. To extend the coverage to 360° , open slits on both ends are needed. One potential design is to use three aluminum plates such that two of the plates contain periodic slits and the ‘center plate’ acts as the common ‘back plate’. We will investigate these architectures in the future.

Fabrication Cost and Power Consumption. LeakyScatter

can be easily fabricated with two thin metal plates, spacers, and an electronically-controlled mirror. Prior work has realized leaky-wave antennas via integrated circuits, i.e., in 65nm CMOS with an area size of 3mm^2 [50]. The small form factor, ease of fabrication, and low cost make such designs suitable for various IoT applications. The integrated broadband emitter/detector, however, can be power demanding. We emphasize that such asymmetry between the transceiver and the backscatter tag is typical in these networks [34]. Nevertheless, ongoing research continues to develop efficient low-power THz transmitter and detectors suitable for future handheld devices [5, 49, 51].

Higher Order Modulation. We have introduced a novel low-power physical layer architecture for THz communication by showing the feasibility of passive THz backscattering; nevertheless, further extensive study is needed for a full-stack demonstration. Additionally, the current achievable data-rates fall behind the speeds promised within the THz regime. The underlying bottleneck is the speed of the electro-static MEMS mirrors which can be addressed through novel modulation strategies. Building high-speed THz modulators is itself an emerging field of research, with recent advances in materials (e.g., carbon nanotubes and graphene) showing promise [4, 7, 39]. In this paper, we consider a noncoherent on-off keying modulation scheme, which is one of the two identified modes in the recent standardization of the IEEE 802.15.3d task group [42]. Nevertheless, in the future, we will explore not only coherent modulation techniques and higher-order amplitude-phase schemes, but also optical modulation techniques, such as via variation in waveguide’s electromagnetic permittivity, for larger data-rates.

7 Conclusion

In this paper, we present LeakyScatter, a novel structure that enables low-power directional backscattering above 100 GHz. LeakyScatter adopts the inherent dependency of emission angle on frequency in LWAs to passively redirect the signals back in the same direction from which they were transmitted. The proposed architecture utilizes a metal parallel-plate waveguide with two open slits. Data transmission is facilitated via a mm-sized MEMS mirror that modulates the reflection loss (i.e., amplitude of backscattered link) according to the bit stream. Our over-the-air experiments show that LeakyScatter is ultra-wideband and spectrally-agile operating at few 100s of GHz, opening unique opportunities for dense user implementations.

Abstract

Offloading the beamforming task from the endpoints to the metasurface installed in the propagation environment has attracted significant attention. Currently, most of the metasurface-based beamforming solutions are designed and optimized for operation on a single ISM band (either 2.4 GHz or 5 GHz). In this paper, we propose RF-Bouncer, a compact, low-cost, simple-structure programmable dual-band metasurface that supports concurrent beamforming on two Sub-6 ISM bands. By configuring the states of the meta-atoms, the metasurface is able to simultaneously steer the incident signals from two bands towards their desired departure angles. We fabricate the metasurface and validate its performance via extensive experiments. Experimental results demonstrate that RF-Bouncer achieves 15.4 dB average signal strength improvement and a $2.49\times$ throughput improvement even with a relatively small 16×16 array of meta-atoms.

1 Introduction

It is a common practice for wireless communication systems to leverage beamforming technique to improve the throughput and extend the communication range. Higher beamforming gain requires a larger number of antennas installed on the communication endpoints. Two practical challenges hinder the deployment of radio systems with a large antenna array. First, the majority of today's IoT devices have to be small in size due to cost and form factor constraints, leaving no space for a large array. Second, the radio chains connected to each antenna increase hardware costs and power consumption.

Recently, offloading the beamforming from the communication endpoints to a metasurface deployed in the propagation environment has attracted significant attention [4, 14]. RFocus [4] leverages a metasurface that consists of thousands of simple 2-way RF switches to beamform the incoming signal towards the receiver. Due to the limited programmability of

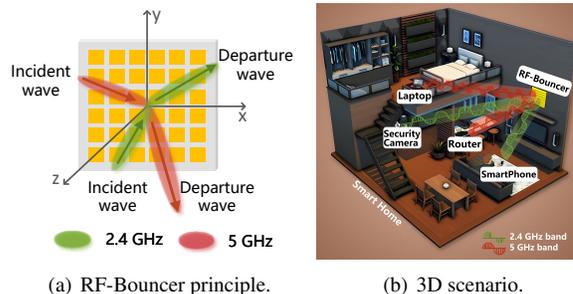

Figure 1: RF-Bouncer's metasurface simultaneously steers the incident signal towards the target directions at two bands, improving the overall performance of dual-band concurrent communication in a complex 3D indoor environment.

the RF switch, *i.e.*, switch on for reflecting and switch off for no reflection, RFocus needs huge number of meta-atoms to work efficiently and robustly. RFlens [14] upgrades the metasurface with a dedicated meta-atom that resembles a 1-bit phase shifter and thus achieves reasonable beamforming performance with only 256 functional meta-atoms.

We observe that most of the current metasurface-based beamforming solutions focus on optimizing communication performance on single frequency band, for example, RFocus works for frequencies below 3 GHz while RFlens is optimized for 5 GHz band. But, these two Sub-6 ISM bands at 2.4 GHz and 5 GHz accommodate three wireless protocols widely used for communication between IoT devices: Wi-Fi, Bluetooth and ZigBee. Due to the densely deployed IoT devices, concurrent wireless transmissions over two Sub-6 ISM bands are very common. A naive solution to extend existing solutions to support dual-band operation is to install two meta-surfaces, one for a single band. Such a solution not only requires more deployment space to accommodate the extra metasurfaces but also results in higher costs. Stacking one metasurface on top of another [42] is another option to support the dual-band operation, resulting in a complicated circuit design. More recent attempts [11, 14, 26, 32] employ varactor to adjust phase, which incurs a high insertion loss [26, 32] and require a precise

*Co-primary authors, both authors contributed equally to this research.

†Corresponding author.

and sophisticated DC voltage control backend [11, 14].

In this paper, we propose to design an area-efficient, low-cost, and simple-structure programmable dual-band metasurface that supports concurrent beamforming on two ISM bands. By concurrent beamforming we mean the metasurface is able to simultaneously steer the two incident signals from two ISM bands towards their desired departure angles, just as shown in Figure 1. The locations of the two pairs of transceivers are random in practice, so our metasurface should work with an arbitrary combination of two incident angles and two departure angles in 3-D space, as shown in Figure 1 (b).

Designing a dual-band metasurface is challenging. Generally, to maximize the communication efficiency, the electric length of the RF components (meta-atoms) should match the wavelength of the signal. There exists a large discrepancy in the wavelength of signals from two widely separated bands, for example, the wavelength is 12 cm and 6 cm for signals at frequency 2.4 GHz and 5 GHz, respectively. Therefore, it is difficult to fabricate hardware with fixed physical dimensions but multiple resonance frequencies.

To solve the problem, we propose a novel meta-atom that has two resonant frequencies (bi-resonant), by integrating two antenna structures. The basic structure of our meta-atom is a metal-backed patch square structure. By adjusting its physical dimensions, we successfully fix its resonant frequency to the first ISM band (2.4 GHz). To generate an additional resonant frequency, we propose to etch slots on the patch, since the slots impact the path of the stimulated current and thus the resonant frequency, according to antenna theory [5]. By fine-tuning the location, the number and the physical dimensions of the slots on the patch, we successfully generate the second resonant frequency at the second ISM band (5 GHz) without affecting the first resonant frequency.

To empower the meta-atoms with dual-band programmability, we embed two PIN diodes into carefully selected positions of the patch on the meta-atom. Each PIN diode functions similarly to an RF switch, and two PIN diodes provide four "on/off" states. Depending on the state of the PIN diodes, the meta-atom introduces different amount of phase shifts to its reflected signal, resembling a 2-bit phase shifter.

Based on our programmable dual-band metasurface, we implement a dual-band beamforming algorithm that can quickly configure the states of all meta-atoms to accurately steer the incident signal towards the desired departure angle. We also design a beam alignment algorithm to adjust the configurations of meta-atoms in real-time to handle user mobility.

We build a prototype of RF-Bouncer's metasurface by embedding 16×16 meta-atoms inside an area of $0.35 \times 0.35m^2$. Owing to its small form factor, RF-Bouncer's metasurface can be attached to the facades of the ambient environment such as walls, furniture, and advertisement boards. Hence, RF-Bouncer can easily cope with complex indoor environments, as shown in Figure 1. Extensive experiments demonstrate that even with the small-size prototype, RF-Bouncer enables

15.4 dB average signal strength improvement and a $2.49 \times$ throughput improvement. RF-Bouncer also works robustly across protocols (e.g., Bluetooth, Zigbee and Wi-Fi), and in complex radio environments (3D and even NLoS).

Contributions. The main contributions of RF-Bouncer are: (i) We design a programmable dual-band metasurface that supports concurrent beamforming over two ISM bands¹. (ii) We implement a dual-band beamforming algorithm that can quickly configure the metasurface to simultaneously steer the incident signals of two bands towards their desired departure directions. (iii) We fabricate RF-Bouncer's metasurface and validate its effectiveness in a wide range of practical scenarios.

2 Related Work

Metasurfaces and smart surfaces. Metasurfaces are three-dimensional, periodic, and artificial structures [6, 10, 17, 30]. By manipulating the phase/ amplitude of electromagnetic waves, it can beamform or re-steer the signals towards an intended direction, so as to extend the network coverage. MilliMirror [28] utilizes a 3D printed metasurface to re-steer mmWave beams to illuminate coverage blind spots. Although promising, such metasurfaces are not configurable. To enable programmability, prior studies focus on adding electronic components (i.e., varactors [8, 12, 15] or PIN diodes [35, 40, 41]) into the metasurface. Another line of literature improves indoor network coverage by designing and deploying smart surfaces in the environment to manipulate wireless channels. These smart surfaces generally consist of non-periodic but adjustable electronic components [4, 13, 39]. While the above methods have shown great promise, they mostly focus on single-link optimizations and are not yet optimized for dual-band concurrent links or 3D coverage. Unlike them, RF-Bouncer aims to simultaneously support dual-band wireless links (e.g., 2.4 GHz and 5 GHz) and targets indoor 3D network coverage improvement.

Expanding indoor wireless coverage. To expand the wireless coverage, several systems [9, 16, 20, 27, 36] deploy passive reflectors near the AP to reflect the incident signal to enhance the link SNR. Such reflectors, however, cannot be re-configured, resulting that they cannot adapt to dynamic indoor environments. Instead, RF-Bouncer can dynamically configure the metasurface to reshape incident beams, thus adapting to dynamic indoor environments. Alternatively, some studies improve indoor wireless coverage by installing multiple APs [24, 25, 29, 34] or RF relays [2, 7, 18] in the environment. Yet, when applying to a new wireless standard or working frequency band, these approaches require updating protocols or hardware, which is cumbersome and high implementation cost. In contrast, RF-Bouncer is a standard-agnostic and cost-effective solution to enhance indoor wireless coverage.

¹The design of RF-Bouncer is available at: https://github.com/ZYF-PhD/RF-Bouncer_OpenSource

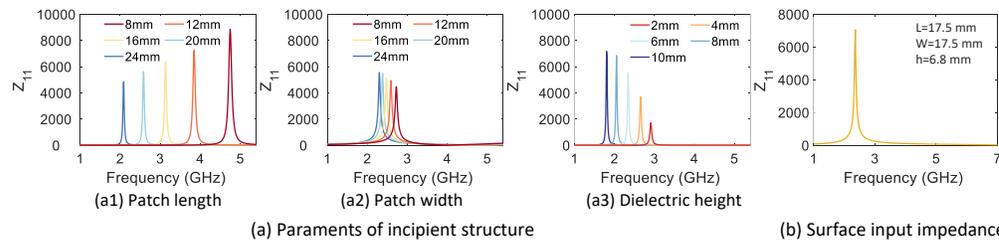

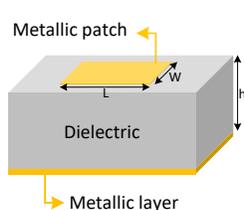

Figure 2: The incipient structure of meta-atom. Figure 3: Impact of the parameters of the incipient structure and the surface input impedance across operating frequencies.

Dual-band design. Many efforts have been devoted to designing dual-band metasurfaces. Stacking two metasurfaces with two resonant frequencies is a straightforward solution [42], which however results in complicated circuit design. Some studies [22, 37] exploit polarization orthogonality to enable dual-band reflectarray antenna, one polarization for each band, while RF-Bouncer supports dual-band with the same polarization, without requiring low-cost IoT devices to rotate when switching the working frequency bands. [23] propose a metasurface structure that supports dual-band but only produces two symmetrical reflected beams, lacking programmability in controlling the departure direction. Some recent attempts [11, 32] employ varactor to adjust phase, which incurs a high insertion loss [26, 32] and requires a precise and sophisticated DC voltage control backend [11, 14]. [3] also supports dual-band operation, but focuses on blocking the signal from one band (either 2.4 GHz or 5 GHz) from penetrating through, whose purpose is entirely different from RF-Bouncer. The most relevant work is [31], which proposes a similar structure to support dual-band frequencies of the same polarization, but it only focuses on simulation and merely fabricates two meta-atoms as a proof-of-concept prototype. Compared with the existing dual-band design, RF-Bouncer leverages PIN diodes and a simple square patch to achieve a programmable dual-band metasurface that supports dual-band operation with the same polarization. Due to the simplicity of its structure, the proposed metasurface is easy to fabricate and thus can be easily embedded into the environment to support various IoT devices. Furthermore, RF-Bouncer designs a dual-band beam-forming algorithm that can quickly configure the states of all meta-atoms to accurately steer the incident signal towards the desired departure angle, which has not been implemented by any of the prior works.

3 Hardware Design of the Metasurface

In this section, We introduce the design of the meta-atom followed by a description of the overall architecture of the whole metasurface.

3.1 Design Goal and Challenges

Design goals. To support diverse IoT devices in complex indoor environments, we have the following two design goals

for RF-Bouncer’s metasurface:

Goal 1: Concurrent dual-band communication. The metasurface must support concurrent wireless communication over two widely separated frequency bands, *e.g.*, 2.4 GHz and 5 GHz in our current implementation.

Goal 2: Dual-band programmability. The metasurface should have dual-band programmability to facilitate concurrent beam-forming for communication at two frequency bands.

Design challenges. To achieve of design goals, we also face the following design challenges:

Challenge 1: Discrepancy in electric length. To maximize the communication efficiency, the electric length (physical size) of the meta-atoms depends on the operating frequency, *i.e.*, the electric length should be half of the signal wavelength. There exists a large discrepancy in the electric length of two widely separated bands, for example, the electric length is 6 cm and 3 cm for signals at frequency 2.4 GHz and 5 GHz, respectively. Therefore, it is difficult to fabricate hardware with a fixed physical dimension but multiple resonance frequencies.

Challenge 2: Enabling programmability. Empowering the meta-atoms with programmability without affecting the reflection efficiency is the second challenge.

3.2 Design of Meta-Atoms

In this section, we first introduce the hardware architecture of the meta-atoms followed by the description of the programmability of meta-atoms.

3.2.1 Dual-band Meta-Atoms

The basic structure. We propose to build our meta-atom based on the *metal-backed patch square structure*, which consists of three tightly connected layers: a metallic square patch on the top, a dielectric cuboid in the middle, and a metallic sheet at the bottom, just as shown in Figure 2. According to the cavity model theory [19], the resonant frequency of such a patch structure is given as:

$$f = \frac{c}{2\sqrt{\epsilon_{re}}} \cdot \frac{1}{l_e} \quad (1)$$

where c is the free-space speed of light. The parameter ϵ_{re} is effective dielectric constant of the dielectric cuboid, which is

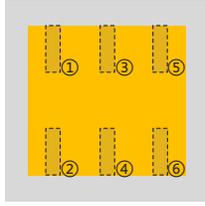

Figure 4: Different locations of slots in the meta-atom.

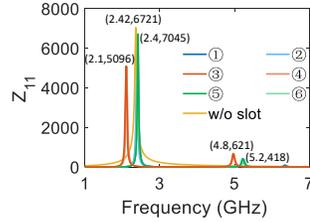

Figure 5: Surface impedance under different single slots.

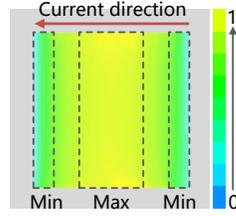

Figure 6: Current distribution of the incipient patch.

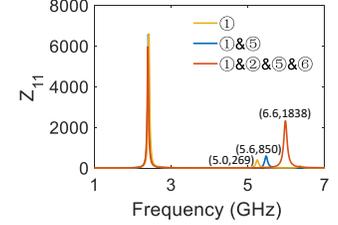

Figure 7: Surface impedance with different number of slots.

given as:

$$\epsilon_{re} = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left(1 + \frac{12h}{w}\right)^{-\frac{1}{2}} \quad (2)$$

where ϵ_r is the fundamental dielectric constant of the material that makes up the dielectric cuboid, w is the width of the patch, and h is the height of the dielectric cuboid. The parameter l_e is the effective length of the patch, which is given as:

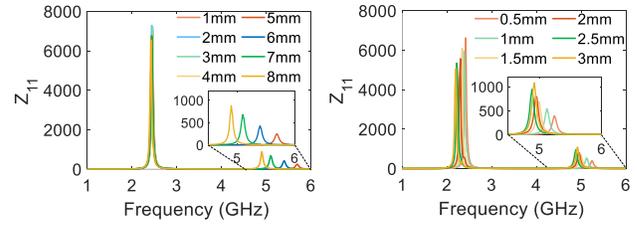

$$l_e = l + 0.824h \cdot \frac{(\epsilon_{re} + 0.3)\left(\frac{w}{h} + 0.264\right)}{(\epsilon_{re} - 0.258)\left(\frac{w}{h} + 0.8\right)} \quad (3)$$

where l is the length of the patch. We know from Eqn. 1, 2, and 3 that the resonate frequency of the structure is determined by the length l , the width w of the patch, and the height h of the dielectric cuboid.

To embed more meta-atoms within one metasurface, we prefer area-efficient design, *i.e.*, smaller width w and length l . We leverage High Frequency Structure Simulator (HFSS) to conduct comprehensive simulations to quantitatively examine the relationship between the resonant frequency and the physical dimension of the meta-atoms. From the result in Figure 3 (a), we observe that, for a fixed dielectric cuboid height h , decreasing the w and l results in increased resonant frequency. Therefore, to maintain the resonant frequency at 2.4 GHz, an area-efficient meta-atom inevitably leads to a thick dielectric cuboid. To balance the size of meta-atom and thickness of the metasurfaces, we conduct extensive off-line simulations and chose the combination of $w = 17.5mm$, $l = 17.5mm$ and $h = 6.8mm$ for our meta-atom. The final result is illustrated in Figure 3 (b), from which we see that the resonance frequency is indeed at 2.4 GHz.

Dual-band operation. To empower the meta-atom with a dual-band capability, we propose to fine-tune the metal-backed patch square structure to generate a second resonant frequency at 5 GHz while keeping the first resonant frequency at 2.4 GHz. Inspired by the theory of slot antenna [5], we propose to etch slots on the patch to generate additional resonant frequency, since the slots on the patch would change the path of the stimulated current and thus the resonant frequency. The final patch structure and thus the resonant frequency depends on the location and the number of slots we etch to the patch.

To study the relationship between the location of the slot and the resonant frequency, we pick six candidate slot positions on the patch, as shown in Figure 4 and leverage HFSS

(a) The length of slot.

(b) The width of slot.

Figure 8: The impact of different slot lengths and widths.

simulation to calculate the resonant frequency. We plot the simulation results in Figure 5, from which we observe that the slots located at the edge of the patch, *i.e.*, the slots ①, ②, ⑤, and ⑥, have minimum impact on the first resonant frequency, but indeed generate the second resonant frequency. The slots at the center, *i.e.*, the slots ③ and ④, however, significantly change the first resonant frequency (shifting it from 2.4 GHz to 2.1 GHz). To explain the rational behind such a phenomenon, we plot the current distribution of the original frequency (2.4 GHz) is shown in Figure 6. We see that the distribution is highly unbalanced: the current at the edge is much weaker than the current at the center of the patch. According to [21], narrow slots located close to the current minima have a minor perturbation to the original resonant frequency. Consequently, we should etch the slots at the edge of the patch to maintain the first resonant frequency at 2.4 GHz.

Even though a new resonant frequency is successfully excited, the reflected signal by the meta-atom is weak at the new resonant frequency, since the impedance between the meta-atom and the free space is close to each other. Specifically, the reflection coefficient Γ of an antenna measures the portion of re-radiated signal, whose value is given as $\Gamma = \frac{Z_{11} - Z_0}{Z_{11} + Z_0}$, where $Z_0 = 120\pi\Omega$ is the impedance of free space. We can see that a larger difference between Z_{11} and Z_0 means more power of the incident signal re-radiates. To obtain more energy from reflective signal, we propose to increase the surface impedance and thus increase the impedance difference between Z_{11} and Z_0 . Our solution is to etch multiple slots at locations with small current to form an antenna array. Figure 7 depicts the Z_{11} of the meta-atom, with the number of etched slots varying from one to four. We see that the surface impedance indeed increases with the number of slot increases, but the second resonance frequency also diverges from the desired 5 GHz.

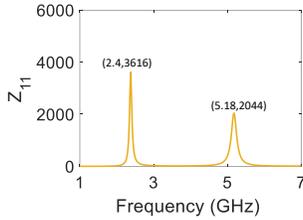

Figure 9: Surface impedance of final slot size.

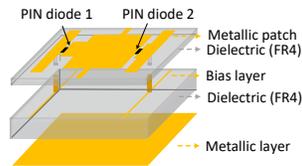

Figure 10: Modified meta-atom structure.

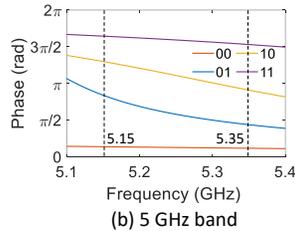

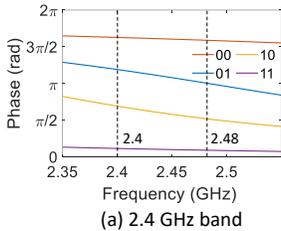

Figure 11: Reflection phase of different frequency bands.

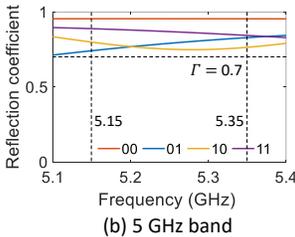

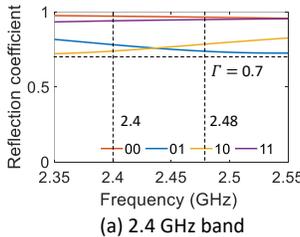

Figure 12: Reflection coefficient of 2.4 GHz and 5 GHz.

We, therefore, further fine-tune the physical dimensions of the slots to shift the second resonant frequency back to 5 GHz. We use HFSS to calculate the impedance of the meta-atom with varying slot length l_s and width w_s , and plot the results in Figure 8. We see that the increase of both l_s and w_s leads to a decrease in second resonant frequency. We choose the combination of $l_s = 7mm$ and $w_s = 0.5mm$ as our final solution. The final impedance of the meta-atom is plotted in Figure 9, from which we see that our optimized meta-atom not only shifts the resonant frequency back but also maximizes the reflection efficiency at two operating frequency bands.

3.2.2 Empowering Programmability for Meta-Atoms

To empower the meta-atom with phase-shifting capability, our basic solution is to embed tunable electronic components into the metallic patch. By programming the state of the electronic components, we change the surface impedance of meta-atom and thus the introduced phase shifts. Specifically, we select PIN diodes as our basic tunable electronic component. We select PIN diodes over varactors because PIN diode only requires two different DC voltage levels rather than precise and continuous voltage values, significantly reducing the design complexity and insertion loss [14]. We etch a rectangle slot under “U” slots and embed two PIN diodes into each slot, just as shown in Figure 10 (Please refer to Appendix A for the detailed design). By controlling the DC voltage, we obtain four

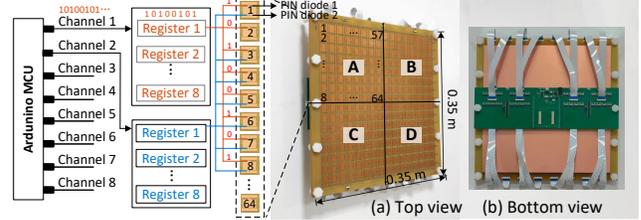

Figure 13: The control architecture of the RF-Bouncer.

stages for each meta-atom, resulting in four phase shifts. We employ HFSS to simulate the phase and reflection coefficient of each stage, and plot the results in Figure 11. We see that the phase difference between each state is about $\pi/2$ at 2.4 GHz and 5 GHz frequency bands. In addition, from Figure 12, we find that the reflection coefficient is stably higher than 0.7 in each stage at two separated frequency bands, implying each state has small impact on the power of the reflective signal. Thus, we can use the final meta-atom as a 2-bit phase shifter.

3.3 Metasurface by Assembling Meta-Atoms

RF-Bouncer’s metasurface is designed by assembling multiple optimized meta-atoms, We build a prototype of RF-Bouncer’s metasurface that consists of 16×16 meta-atoms. All the meta-atoms are evenly distributed inside an area of $0.35 \times 0.35m^2$, with a distance of $19.5mm$ between adjacent meta-atoms, as shown in Figure 13. To reconfigure the PIN diode states of each meta-atom, we embed a bias layer to transmit DC bias voltage to each PIN diode (SMP1340-040LF PIN diodes [1]).

The controller. To configure the whole metasurface, we design a control circuit module consisting of a Arduino DUE controller and 64 SN74LV595 shift registers to provide different DC voltages (0 V or 5 V) for each meta-atom. Specifically, we divide the entire MTS board into 4 zones, as shown in Figure 13. For each zone, we use two channels in the Arduino MCU to transmit a data stream with 128 bits to control 128 PIN diodes. Due to limited GPIO pins, each channel connects 8 registers to store 64 bits. Once the enabled port is triggered, each register transmits 8 different DC voltages to respectively control 8 PIN diodes in each meta-atom. Via the above set up, the controller is now able to independently configure the state of each meta-atom’s PIN diode. In our system, RF-Bouncer’s power consumption is only at the level of mW since the metasurface itself does not emit any power.

4 Beamforming Through RF-Bouncer

4.1 Problem Formulation

RF-Bouncer supports dual-band beamforming in 3-D space. Given the angle $\theta_i = (\alpha_i, \beta_i)$ of the incident signal, by applying appropriate phase shift $\gamma_{m,n}$ on a matrix of $M \times N$

meta-atoms, RF-Bouncer's metasurface beamforms the incident signal towards arbitrary angle $\theta_d = (\alpha_d, \beta_d)$ in the 3-D space, where α and β represent the azimuth and elevation angle, respectively, just as shown in Figure 14. RF-Bouncer has the following two working modes:

Single-band mode. In this mode, RF-Bouncer focuses on finding the phase shift $\gamma_{m,n}$ of every meta-atom that enables the metasurface beamforming the incident signal at a single frequency band (either 2.4 GHz or 5 GHz) towards an arbitrary angle in 3-D space. RF-Bouncer works in this mode when there only exists wireless communication over a single frequency band.

Dual-band mode. In this mode, RF-Bouncer must find the optimal phase shift $\gamma_{m,n}$ for every meta-atom so that the metasurface simultaneously beamforms the wireless signals at 2.4 GHz and 5 GHz with incident angle $\theta_i^{2.4G}$ and θ_i^{5G} , towards the departure angle of $\theta_d^{2.4G}$ and θ_d^{5G} , respectively. RF-Bouncer works in this mode if there exist concurrent dual-band transmissions.

4.2 Single Band Beamforming

For the purpose of illustration, we begin the introduction of RF-Bouncer's single-band beamforming algorithm with a simple case where we beamforming in 2-D space using a metasurface consists of two meta-atoms. We then generalize the algorithm to beamforming in 3-D space with a metasurface consisting of a matrix of $M \times N$ equally spaced meta-atoms.

A two-element linear array in 2-D space. We use the example of a two-element linear array to illustrate our beamforming algorithm. As shown in Figure 15 (a), the signal travels different distances before reaching two meta-atoms of the array, resulting in phase differences. Supposing the phase of signal received by the first meta-atom is 0, then the phase vector induced by the incident path is given as:

$$\phi^I(\theta_i, f_c) = \frac{2\pi f_c}{c} \cdot d \begin{bmatrix} 0 \\ \cos \theta_i \end{bmatrix} \quad (4)$$

where f_c is the central frequency of the wireless signal and d is the distance between two meta-atoms. Similarly, the signal departure also results in phase difference. The phase vector induced by the departure path is given as:

$$\phi^T(\theta_d, f_c) = \frac{2\pi f_c}{c} \cdot d \begin{bmatrix} \cos(\pi - \theta_d) \\ 0 \end{bmatrix} \quad (5)$$

The meta-atoms shift the signal by $\gamma = [\gamma_1, \gamma_2]^T$ before reflecting the signal, just as shown in Figure 15 (b). Therefore, the phase of the signals reflected by two meta-atoms along the wavefront at the departure angle θ_d is given as:

$$\phi(\theta_i, \theta_d, f_c, \gamma) = \phi^I + \gamma + \phi^T = \frac{2\pi f_c}{c} \cdot d \begin{bmatrix} \cos(\pi - \theta_d) \\ \cos \theta_i \end{bmatrix} + \begin{bmatrix} \gamma_1 \\ \gamma_2 \end{bmatrix} \quad (6)$$

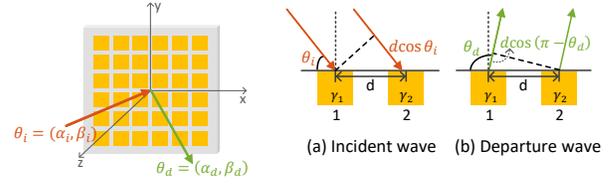

Figure 14: A metasurface in 3D space.

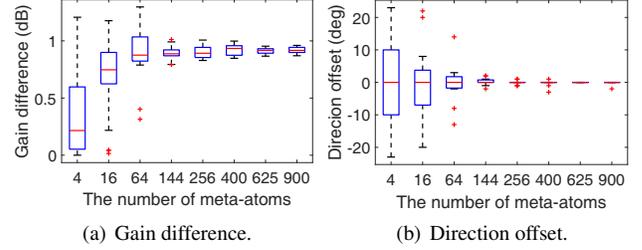

Figure 15: Beamforming gain difference and direction offset between the continuous solution $\gamma_{m,n}$ and the discrete solution $Q_{2\text{-bit}}(\gamma_{m,n})$ after quantization.

Beamforming the signal towards departure angle θ_d requires signals adding constructively, *i.e.*, the phase of signal reflected by all the meta-atoms must be the same. In the above two-element case, the phase shifts γ applied to two meta-atoms should satisfy the following equation:

$$\gamma_2 - \gamma_1 = \frac{2\pi f_c}{c} \cdot d (\cos(\pi - \theta_d) - \cos \theta_i) \quad (7)$$

If we set the phase shift of the first meta-atom to zero, *i.e.*, $\gamma_1 = 0$, the phase shift of the second meta-atom can be directly calculated according to the above equation.

Generalization. We now generalize the above beamforming algorithm to a metasurface embedded with a matrix of $M \times N$ meta-atoms in 3-D space. The phase vector of the incident path in 3-D space becomes:

$$\phi^I(\theta_i, f_c) = \frac{2\pi f_c}{c} \cdot d \begin{bmatrix} 0 & \dots & (N-1)v_i \\ \dots & \dots & \dots \\ (M-1)u_i & \dots & (M-1)u_i + (N-1)v_i \end{bmatrix} \quad (8)$$

where $u_i = \cos \alpha_i \sin \beta_i$ and $v_i = \sin \alpha_i \sin \beta_i$. Similarly, the phase vector of the departure path is given as

$$\phi^T(\theta_i, f_c) = \frac{2\pi f_c}{c} \cdot d \begin{bmatrix} (M-1)u_d + (N-1)v_d & \dots & (N-1)v_d \\ \dots & \dots & \dots \\ 0 & \dots & (M-1)u_d \end{bmatrix} \quad (9)$$

where $u_d = \cos \alpha_d \sin \beta_d$ and $v_d = \sin \alpha_d \sin \beta_d$. Combing Eqn 8 and 9 with Eqn 6, we have enough equations to derive the phase shifts $\gamma_{m,n}$ that we should apply to each meta-atom of the metasurface.

Discrete phase shifts of meta-atoms. The optimal phase shift $\gamma_{m,n}$ we calculate according to above section is continuous. Recall that each meta-atom in the metasurface is essentially a 2-bit phase shifter that only provides four possible phase

shifts: $0, \frac{\pi}{2}, \pi$ and $\frac{3\pi}{2}$. We apply the following quantization rule to find the discrete solution of phase shifts $\gamma_{m,n}$:

$$Q_{2\text{-bit}}(\gamma_{m,n}) = \begin{cases} 0, & \textit{otherwise} \\ \pi/2, & \textit{if } \pi/4 \leq \gamma_{m,n} < 3\pi/4 \\ \pi, & \textit{if } 3\pi/4 \leq \gamma_{m,n} < 5\pi/4 \\ 3\pi/2, & \textit{if } 5\pi/4 \leq \gamma_{m,n} < 7\pi/4 \end{cases} \quad (10)$$

Phase quantization brings phase error and inevitably degrades the beamforming performance. To quantitatively investigate the impact of phase quantization, we traverse all the possible combinations of incident angle θ_i and departure angle θ_d and calculate one continuous solution $\gamma_{m,n}$ and one discrete solution $Q_{2\text{-bit}}(\gamma_{m,n})$ for each combination (θ_i, θ_d) . We calculate the gap of the beamforming gain and beamforming direction between the continuous solution and the discrete solution and plot the results in Figure 16. We clearly see that with the number of meta-atoms in the metasurface increases, the gap of beamforming gain stabilizes at 1 dB, while the direction offset decreases and eventually gets very close to zero. This result is in line with the prior work [35]. RF-Bouncer's metasurface has $16 \times 16 = 256$ meta-atoms so the degradation of the beamforming performance becomes negligible.

4.3 Dual-band Beamforming

Challenge. For single band beamforming, we are able to calculate the optimal phase shifts $\hat{\gamma}_{m,n}$ of every meta-atom that strictly meeting the requirement of the beamforming: the signal reflected by all meta-atom has exact the same phase so they superimpose constructively at the receiver. Ideally, if each meta-atom is able to compensate the signal with two arbitrary phase shifts at two operating frequency band, then a naive solution would be separately finding the optimal phase shifts for two frequency band, *i.e.*, $\hat{\gamma}_{m,n}^{2.4G}$ for 2.4 GHz band and $\hat{\gamma}_{m,n}^{5G}$ for 5 GHz band, and then applying the optimal phase shifts to each meta-atom. Our meta-atom, however, only has 2-bit programmability (four states) and thus provides four fixed combination of phase shifts at two frequency band. Specifically, for each state $\eta_{m,n}$, the phase shifts at two frequency band can be derived via a known mapping:

$$\begin{aligned} \gamma_{m,n}^{2.4G} &= P_{2.4G}(\eta_{m,n}) \\ \gamma_{m,n}^{5G} &= P_{5G}(\eta_{m,n}) \end{aligned} \quad (11)$$

We list the mapping between the state of meta-atom and the phase shifts introduced by the meta-atom at that state at both 2.4 GHz and 5 GHz band in Table 1.

Due to each meta-atom's limited phase combinations at two frequency bands, it is impossible to simultaneously implement the optimal phase shifts $\hat{\gamma}_{m,n}^{2.4G}$ and $\hat{\gamma}_{m,n}^{5G}$ on our metasurface. Consequently, it is also impossible to find analytical solutions that strictly meet the phase requirement of the beamforming. Instead, we turn to search for the optimal combination of

$\eta_{m,n}$	$P_{2.4G}$	P_{5G}	$\eta_{m,n}$	$P_{2.4G}$	P_{5G}
00	$3\pi/2$	0	10	$\pi/2$	π
01	π	$\pi/2$	11	0	$3\pi/2$

Table 1: The mapping between the state of meta-atom and the phases shift the meta-atom at that state introduces to signals with central frequency of 2.4 GHz and 5 GHz.

states $\eta_{m,n}$ of meta-atom that maximize the total gain of the main lobes of the metasurface's beamforming patterns at two frequency bands.

Dual-band link optimization. Given the incident angle $\theta_i^{2.4G}$, the strength of the 2.4 GHz signal reflected by the metasurface along the departure angle $\theta_d^{2.4G}$ is given as:

$$\begin{aligned} S_{2.4G}(\theta_i^{2.4G}, \theta_d^{2.4G}, \eta) &= a_{2.4G}(\theta_d^{2.4G}) \sum_{i=1}^M \sum_{j=1}^N e^{j\phi(\theta_i^{2.4G}, \theta_d^{2.4G}, f_{2.4G}, \gamma)} \\ &= a_{2.4G}(\theta_d^{2.4G}) \sum_{i=1}^M \sum_{j=1}^N e^{j\phi(\theta_i^{2.4G}, \theta_d^{2.4G}, f_{2.4G}, P_{2.4G}(\eta_{m,n}))} \end{aligned} \quad (12)$$

where $a_{2.4G}(\theta_d^{2.4G})$ represents the amplitude of 2.4 GHz signal reflected by each meta-atom along direction $\theta_d^{2.4G}$, whose value is identical across all identical meta-atoms. Similarly, the strength of 5 GHz signal reflected by the metasurface can be represented as:

$$S_{5G}(\theta_i^{5G}, \theta_d^{5G}, \eta) = a_{5G}(\theta_d^{5G}) \sum_{i=1}^M \sum_{j=1}^N e^{j\phi(\theta_i^{5G}, \theta_d^{5G}, f_{5G}, P_{5G}(\eta_{m,n}))}. \quad (13)$$

Our goal is to search for the optimal meta-atom states η^* that maximizes the total signal strength along direction $\theta_d^{2.4G}$ and θ_d^{5G} , given incident signal angle $\theta_i^{2.4G}$ and θ_i^{5G} :

$$\eta^* = \arg \max_{\eta} \left(\left| S_{2.4G}(\theta_i^{2.4G}, \theta_d^{2.4G}, \eta) \right| + \left| S_{5G}(\theta_i^{5G}, \theta_d^{5G}, \eta) \right| \right). \quad (14)$$

To prevent over-optimizing single band and thus guarantee the fairness between two bands, we further adjust our objective function to:

$$\eta^* = \arg \min_{\eta} \left(\left(\left| S_{2.4G}^* \right| - \left| S_{2.4G}(\theta_i^{2.4G}, \theta_d^{2.4G}, \eta) \right| \right) + \left(\left| S_{5G}^* \right| - \left| S_{5G}(\theta_i^{5G}, \theta_d^{5G}, \eta) \right| \right) \right) \quad (15)$$

where $S_{2.4G}^*$ and S_{5G}^* are the theoretical maximum signal strength achieved when we single-band beamform on 2.4 GHz and 5 GHz band using continuous phase shifters, respectively. We employ genetic algorithm (GA) algorithm [33] to solve our optimization problem described in Eqn 15. To speed up the search, instead of generating a random initial population, we use the coding patterns optimized for each single frequency band as a set of initial chromosomes in the initial population of the GA algorithm.

We conduct an experiment to verify the effectiveness of the proposed dual-band links optimization algorithm. In this

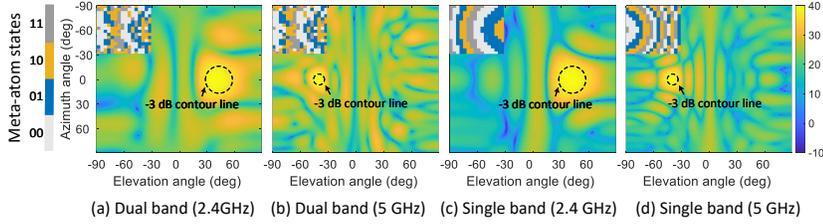

Figure 17: The beam patterns of single-band links and dual-band links, respectively.

experiment, we set the incident angle of 2.4 GHz and 5 GHz signal to $(\alpha_i^{2.4G} = 0^\circ, \beta_i^{2.4G} = 0^\circ)$ and $(\alpha_i^{5G} = 0^\circ, \beta_i^{5G} = 0^\circ)$, respectively. The desired beamforming direction of 2.4 GHz and 5 GHz signal are set to $(\alpha_d^{2.4G} = 0^\circ, \beta_d^{2.4G} = 40^\circ)$ and $(\alpha_d^{5G} = 0^\circ, \beta_d^{5G} = -40^\circ)$, respectively. After applying the optimal state $\eta_{m,n}^*$ to each meta-atom, the beam pattern of the whole metasurface is plotted in Figure 17, from which we could see that: 1) the two mainlobes obtained by dual-band beamforming well match the desired angles; 2) the sidelobe levels are much lower than the mainlobe levels. In addition, the mainlobe beamwidth of the 2.4 GHz band is wider than the 5 GHz band. The reason is that the size of the meta-atom is more suitable for 5 GHz band, but this issue can be easily solved by increasing the number of meta-atoms to generate a narrow beam of mainlobe [38]. 3) dual-band beamforming has a lower gain about 3 dB than single-band beamforming, while the -3 dB beamwidth is only slightly wider than single-band beamforming (Figure 17 (c) and (d)).

4.4 Harnessing the Ambient Multipath

We observe that there exists some meta-atoms that contribute negligible power or even have negative impact on the main lobe, but significantly affect the distribution of the side lobes, especially when the metasurface is configured for dual-band operation. To demonstrate such a phenomenon, we change the states of a small group of meta-atoms in Figure 17 (a) and (b), and plot the 3-D beam patterns of the new metasurface configuration in Figure 18. Comparing the beam patterns in these two figures, we see that the direction and gain of main lobes still retain, but the side lobes change dramatically. The signal of the side lobes does not travel directly towards the receiver, but may still reach the receiver after being reflected by diverse objects in the propagation environment. We propose to further improve the signal strength by adjusting the pattern of side lobes of the metasurface.

The key challenge we face is to select the group of meta-atoms that mainly affects the side lobes. Since the target meta-atoms have negligible or even negative impact on the main lobe, the phase of the signal reflected by the target meta-atoms must be misaligned (difference larger than $\pi/2$) with the phase of the main lobes. Without loss of generality, we denote the desired beamforming directions at 2.4 GHz and 5 GHz bands are $(\alpha_{2.4G}, \beta_{2.4G})$ and $(\alpha_{5G}, \beta_{5G})$, respectively.

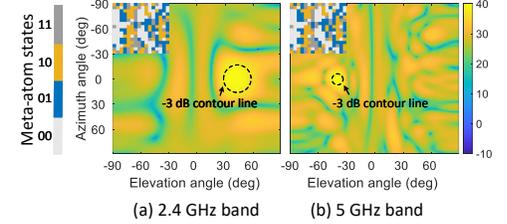

Figure 18: The beam patterns when changing negative meta-atoms.

Then, the phase of mainlobe is given as:

$$PM_{2.4G} = \angle \sum_{m=1}^M \sum_{n=1}^N e^{j\phi(\theta_i^{2.4G}, \theta_d^{2.4G}, f_{2.4G}, P_{2.4G}(\eta_{m,n}^*))} \quad (16)$$

$$PM_{5G} = \angle \sum_{m=1}^M \sum_{n=1}^N e^{j\phi(\theta_i^{5G}, \theta_d^{5G}, f_{5G}, P_{5G}(\eta_{m,n}^*))} \quad (17)$$

where $\eta_{m,n}^*$ is the optimal states of meta-atoms we calculated according to Eqn 15. Then, we find separate sets of target meta-atoms at two frequency bands, respectively:

$$TU_{2.4G} = \left\{ \{m, n\} \mid \left| PM_{2.4G} - \phi(\theta_i^{2.4G}, \theta_d^{2.4G}, f_{2.4G}, \gamma_{m,n}) \right| \geq \frac{\pi}{2} \right\}, \quad (18)$$

$$TU_{5G} = \left\{ \{m, n\} \mid \left| PM_{5G} - \phi(\theta_i^{5G}, \theta_d^{5G}, f_{5G}, \gamma_{m,n}) \right| \geq \frac{\pi}{2} \right\}, \quad (19)$$

where m and n vary from 1 to 16 in our system. Finally, we select the intersection of two sets of target meta-atoms as the final solution:

$$TU = TU_{2.4} \cap TU_5. \quad (20)$$

The intersection TU includes meta-atoms that have negligible or even negative impact for 2.4 GHz and 5 GHz band simultaneously, so we are safe to change the states of the meta-atoms in TU to adjust the side lobes while at the same time guarantees minimum impact on main lobes of two band. We iterate all possible combinations of state and choose the one that provides best signal quality. It is worth noting that when the number of variable meta-atoms is large, it could take a long time for exhaustive search. To reduce the search time, one potential solution is to divide the whole metasurface into several parts. For each part, the variable meta-atoms change their state in the same way. Therefore, the number of exhaustive search will be reduced to a small number. For example, we divide the whole metasurface into 4 parts. Therefore, all possible combinations of state will be reduced to 512 (i.e., 4^4). Assuming Wi-Fi packets are collected at a rate of 1,000 packets per second, the search time will be 0.5 seconds.

4.5 Beam Alignment

To accurately beam the reflected signal towards the receiver, we need to know the signal incident angle θ_i and departure

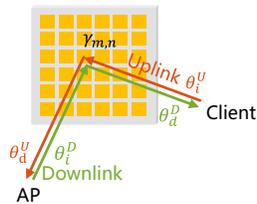

Figure 19: Illustration of uplink and downlink.

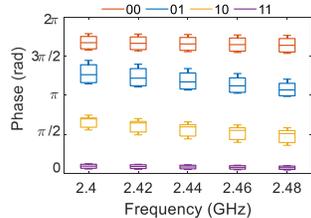

Figure 20: Phase offset under different incident angles.

angle θ_d . We observe that in a typical Wi-Fi system, the access point is static for most of the cases. Therefore, the signal incident and departure angle is fixed and known for downlink and uplink Wi-Fi communication, respectively (Figure 19). We propose to search for the unknown angle, *i.e.*, incident angle for uplink and departure angle for downlink.

Beam search for downlink. For downlink communication, we need to search for the departure angle θ_d . In n -th round of beam search, the metasurface configures its meta-atoms to point the main lobe towards a specific angle θ_d^n . After receiving one packet under such a configuration, the receiver embeds one bit inside its ACK to inform the metasurface whether the received signal quality has increased or not comparing with the previous configuration, *i.e.*, bit 1 represents increase and bit 0 means decrease. We equip the metasurface with a Wi-Fi receiver to overhear the ACK. After iterating all possible departure angles, we select the θ_d that provides the highest received signal quality as our results.

To speed up the searching process, we implement a two-stage searching algorithm. In the first stage, we search with a relatively large step size of 20° . After obtaining the rough direction, we then search with a small step size of 5° to fine-tune the results. A step size of 5° is fine-grain enough since the beamforming gain only decreases less than 1 dB at directions that are 2.5° apart from the beamforming direction, according to both our simulation and empirical results.

Bidirectional communication. We observe that, due to reciprocity, we only need to perform beam search in one direction. First, according to *channel reciprocity*, the phase shifts that should be applied to each meta-atom for beamforming is the same even when we swap the value of the incident angle θ_i and departure angle θ_d . As shown in Figure 19, the signal travels exactly the same distance no matter the AP or the client is the sender, introducing the same amount of phase variations. Therefore, the phase shifts required to meet the phase requirement of beamforming is also the same.

Second, the optimized meta-atom introduces the same amount of phase shifts to the signal, regardless of the signal incident angle. To verify that, we use HFSS to calculate the phase shifts introduced by meta-atom by varying the incident angle, operating frequency and state of meta-atom. We plot the distribution of phase shifts in Figure 20, from which we see that the phase variations introduced by the meta-atom is stable. According to the above analysis, the configuration

of the metasurface used for beamforming in one direction also works in the opposite direction. Such an observation significantly accelerates convergence of the beam alignment algorithm, especially when the client moves.

5 Evaluation

Experimental setup. For controlled experiments, we use USRP N210 software-defined radios with a UBX-40 daughterboard as the radio transmitter (Tx) and receiver (Rx). We conduct extensive experiments in three indoor environments to evaluate the performance of RF-Bouncer: a $140 m^2$ duplex with two-bedroom, a $160 m^2$ apartment and a spacious corridor environment with corner. In the default experimental setting, 2.44 GHz and 5.25 GHz are selected as the operating frequency of the 2.4 GHz band and 5 GHz band, respectively. The Tx is deployed in the normal direction of the metasurface.

5.1 Hardware Verification

Dual-band beamforming verification. This experiment compares beamforming results between single-band and dual-band coding patterns. We configure the metasurface using single-band coding patterns of 2.4 GHz and 5 GHz, and optimization dual-band coding patterns, respectively. The Rx moves along a semicircle (3 m radius) from -90° to 90° with a step of 10° , while the Tx stays in the center. The Tx-metasurface distance sets as 0.5 m. Figure 21 demonstrates that both single-band and dual-band coding pattern can achieve effective beamforming results, but dual-band beamforming results come at the cost of slight decreases of signal strength or slight shift of the direction on the mainlobe.

The performance of beamforming in dual-band. To evaluate the beamforming performance of dual-band, we keep the Tx-metasurface distance sets as 0.5 m. We default $\alpha = 0^\circ$ and only vary β in the following experiments. We move the Rx along a semicircle (3 m radius) from -90° to 90° with a step of 10° . The results are shown in Figure 22, we can clearly see that the effective beamforming ranges of 2.4 GHz and 5 GHz are both $[-60^\circ, 60^\circ]$. Although the $-3dB$ beamwidth becomes wider and beamforming gain becomes lower when the beamforming direction is towards the boundary, the correct directionality is retained. It is worth noting that the beamforming gain of 0° is slightly decreased since the Tx blocks the link between metasurface and Rx. In addition, the performance will be significantly dropped when the beamforming direction is over the boundary. In conclusion, the effective field-of-view (FoV) of beamforming is $[-60^\circ, 60^\circ]$.

The effective incident angles. We conduct experiments in the corridor to explore the effective range of incident angles. For the convenience of expression, we only mention β in the following and default $\alpha = 0^\circ$. To determine the range, we first vary incident angles by changing the direction of Tx from

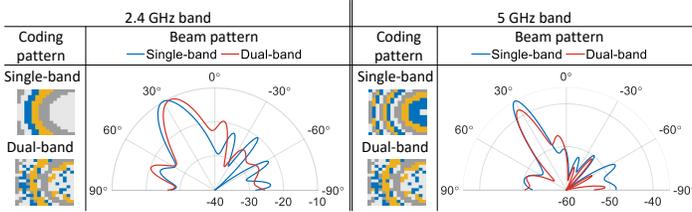

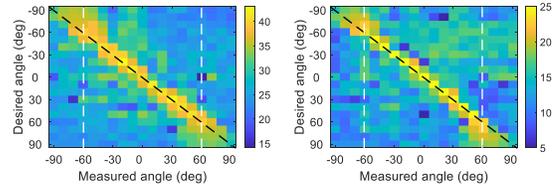

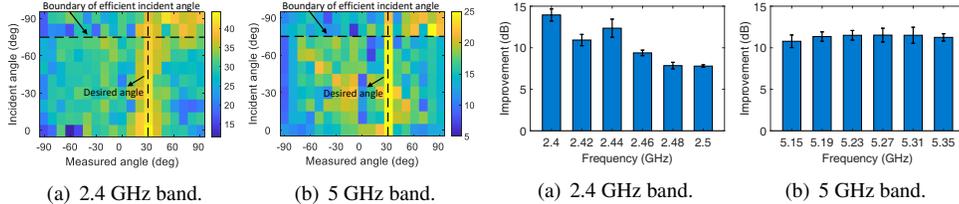

Figure 21: Results of single and dual band coding patterns.

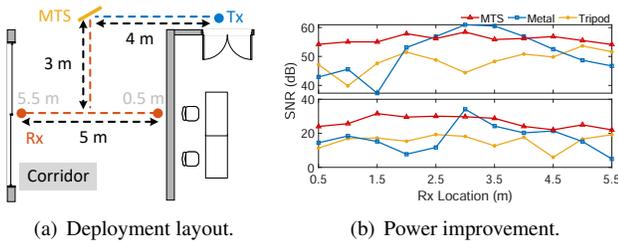

Figure 26: The performance of different reflectors.

-90° to 0° with a step of 10° and set the Tx-metasurface distance as 0.5 m. Then, we move Rx along a semicircle (3 m radius) from -90° to 90° with a step of 10° to obtain different beam patterns under different incident angles. The desired beamforming direction is set towards 30° . The results are shown in Figure 23, from which we see that RF-Bouncer can achieve beamforming effectively in the desired direction when the incident angle varies from -70° to 0° . However, the beamforming gain and direction of the mainlobe can not be guaranteed due to the incident wave being almost parallel (i.e., from -90° to -80°) to the metasurface. In addition, because of the symmetry of metasurface, the same experimental results will appear in $[0^\circ, 70^\circ]$. To summarize, RF-Bouncer can work well as long as Tx is located in $[-70^\circ, 70^\circ]$.

Performance across different spectrums. In this experiment, we validate the performance of RF-Bouncer across different operating frequency bands. The distance of Tx-metasurface is 0.5 m, and the direction of the incident wave is perpendicular to the metasurface. The distance between Rx and metasurface is set to 3 m. The direction of the emergent wave focuses on $(30^\circ, 0^\circ)$ and Rx is located in the same direction. One case is from 2.4 GHz to 2.5 GHz with a step of 0.02 GHz. Figure 24(a) shows the SNR can be increased by over 7.79 dB (up to 13.94 dB). Another case is from 5.15 GHz to 5.35 GHz with a step of 0.04 GHz. Figure 24(b) shows the SNR can be improved by over 10.78 dB (up to 11.5 dB). Therefore, RF-

Bouncer can be applied to ubiquitous commercial IoT devices working in 2.4 GHz and 5 GHz bands.

5.2 Communication Performance

Multipath augmentation verification. To examine the effectiveness of multipath augmentation described in Section 4.4, we conduct experiments in a representative 3D scenario (Figure 28 (a)). Specifically, we fix the location of the transmitter and randomly move the receiver to 30 locations. Then, for each location, we respectively collect the measurements with/without multipath augmentation at 2.4 GHz and 5 GHz. Figure 25 plots the CDF of signal strength improvement at two frequency bands. We can see that the median improvements with/without multipath augmentation at 2.4 GHz and 5 GHz are respectively 4.32 dB, 5.38 dB and 4.43 dB, 5.89 dB. These results demonstrate that our multipath augmentation scheme can effectively harness the ambient multipath to improve the link SNR.

The performance of different reflectors. By placing RF-Bouncer at a corridor intersection, the blind spot around the corner can be illuminated. We conduct an experiment in a spacious corridor environment, as shown in Figure 26(a). The metasurface is placed at the corner, receiving signals from $(-45^\circ, 0^\circ)$, and reflecting a fan beam from $(-85^\circ, 0^\circ)$ to $(5^\circ, 0^\circ)$. The Tx is 4 m away from the metasurface; whereas Rx is 3 m away moved across a 5 m distance. Figure 26(b) compares the RSS with metasurface, a metal plane reflector with the same size as the metasurface, and the tripod without reflectors. While the metal plane creates a stronger mainlobe towards the specular direction, the RSS drastically drops as the Rx is moved to anomalous directions. In contrast, RF-Bouncer reshapes the incidental beam to cover a wider angular range and thus a larger region around the corner.

Multi-bit beamforming verification. The 2-bit metasurface

Figure 31: Performance under concurrent transmissions.

designed by RF-Bouncer can be backward compatible to realize the 1-bit programmable function. In this experiment, we compare the performance between 2-bit, 1-bit, and without metasurface (referred to w/o MTS). The Tx-metasurface distance is set to 0.5 m and Rx is located at $(30^\circ, 0^\circ)$ of metasurface. We then vary the Rx-metasurface distance from 1 m to 10 m by the step of 1 m to measure the SNR improvement. Figure 27 demonstrates that compared w/o MTS, 1-bit and 2-bit programmable functions both can significantly enhance the SNR, but the improvement of 2-bit is larger than 1-bit. For example, when compared between 2-bit and 1-bit, the minimum, median, and maximum SNR increase by 1.22 dB, 3.52 dB, and 4.91 dB across the 2.4 GHz band, and 1.29 dB, 2.81 dB, and 4.54 dB across the 5 GHz band, respectively.

Performance under 3D scenario. We test the SNR improvement achieved by RF-Bouncer in a representative $140 m^2$ 3D scenario (Figure 28(a)). Due to the deployment limitation, we mount the Tx and metasurface on tripods and place them at the same height up the ground. The distance of Tx-metasurface is 0.5 m. Both Rx and Tx work in the 5 GHz band. The Rx is located at 9 different locations. The height of the Rx from the ground varies from 10 cm to 5 m. The elevation angle of Rx varies from -30° to 30° and the azimuth angle of Rx varies from -30° to 40° . We measure the SNR improvement by using directional and omnidirectional antenna,

respectively. Figure 28(b) shows the improvement in different channel conditions. Almost all signal strength improvements under different positions are above 2.5 dB and up to 13.5 dB. Furthermore, due to indoor multipath, the improvement of omni-directional antenna at some positions (i.e., P_6 and P_7) in the 3D scenario is higher than directional antenna. In contrast, the improvement of P_9 is negative due to the following reasons: 1) the azimuth angle between P_9 and metasurface exceeds the effective beamforming FoV of metasurface, leading RF-Bouncer can not provide beamforming gain to it; 2) the reinforced concrete between floors blocks the LoS between Tx and Rx, causing most energy of the incident signal reflects to other directions. This issue can be easily solved by deploying multiple metasurfaces.

Throughput across different IoT devices. RF-Bouncer aims to enhance the signal energy of IoT devices in the NLoS scenario. Hence, in this experiment, we test IoT devices (i.e., CC2530, CSRBC417, KT6368A, nRF52832, ESP32, WARPv3) operating different frequency bands (i.e., 2.4 GHz and 5 GHz) with various protocols (i.e., Zigbee 3.0, SPP 2.0, SPP 2.1, BLE 5.0, 802.11 b/g/n, and 802.11 a/g) in a corner NLoS scenario. We use *iperf* to measure TCP throughput for ESP32 and use the WARPLab environment for the WARPv3 boards. The NLoS deployment layout is shown in Figure 29(a). We set the Tx-metasurface distance and Rx-metasurface distance as 1.4 m and 2 m, respectively. The incident angle of metasurface is $(20^\circ, 0^\circ)$ and the emerging angle is $(-40^\circ, 0^\circ)$. The results with metasurface and without metasurface (referred to w MTS and w/o MTS) are shown in Figure 29(b). We can see that the minimum, median, and maximum throughput gain are 115%, 137%, and 249%, respectively. These results imply that RF-Bouncer is transparent to the working protocols and frequencies.

SISO and MIMO links. We now evaluate the throughput performance in SISO and MIMO communication systems. Specifically, we use two laptops equipped with AR9580 wireless cards as the transmitter and receiver, each of them has three antennas and works on the 801.11n protocol. Then, we fix the transmitter location and move the receiver to 10 locations, as shown in Figure 30(a). At each location, we respectively change the communication mode, varying from 1×1 , 2×2 and 3×3 , and use *iperf* toolbox to collect throughput measurements. Figure 30(b) shows that as the number of antennas used in communication system increases, the

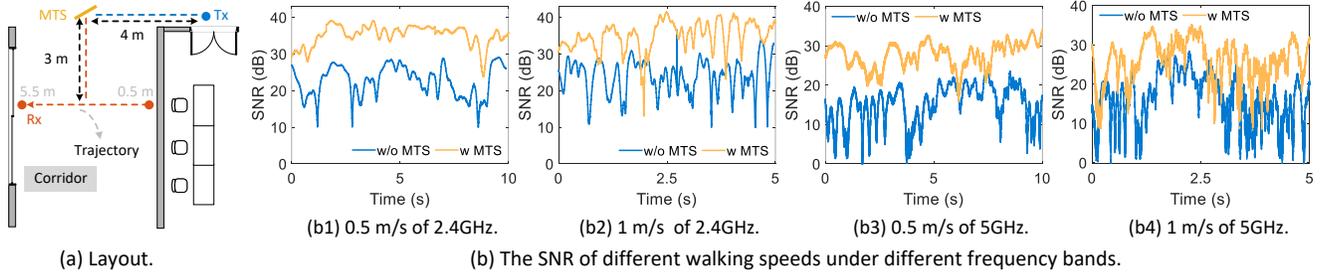

Figure 32: Experimental results of different walking speeds under different frequency bands.

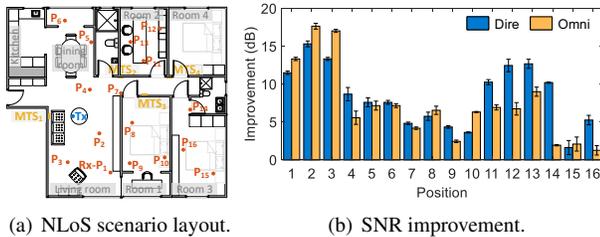

Figure 33: Whole-house coverage under cooperative work.

throughput improvement increases in both frequency bands. For example, RF-Bouncer can achieve a median throughput improvement of 1.88Mbps, 3.37Mbps, 4.38Mbps, and 2.96Mbps, 4.22Mbps, 4.87Mbps for 1×1 , 2×2 and 3×3 at 2.4 GHz and 5 GHz, which corresponds to an improvement of up to 50% compared with the baseline in each case.

Concurrent transmissions. In this experiment, we evaluate RF-Bouncer’s performance in the presence of concurrent wireless links at 2.4 GHz and 5 GHz. Specifically, we fix two transmitters working at 2.4 GHz and 5 GHz in two different locations, and move two corresponding receivers to nine different location combinations. The detailed deployment is presented in Figure 31(a). In each location combination, the coding pattern of metasurface is obtained based on Sec. 4.3, and we then collect the measurements to calculate the SNR improvement when there is no metasurface. The results in Figure 31(b) shows that RF-Bouncer can simultaneously improve the SNR of two concurrent wireless links. For example, RF-Bouncer can achieve an average SNR improvement of 9.01 dB and 12.08 dB for 2.4 GHz and 5 GHz, respectively. This demonstrates that RF-Bouncer can work well for dual-band concurrent wireless transmissions.

5.3 Performance under Mobility

In this section, we examine the performance of RF-Bouncer in a mobile environment. We place the transmitter at a fixed location and move the receiver along a predefined trajectory with two constant speeds: 0.5 m/s (slow) and 1.0 m/s (normal). In each speed case, RF-Bouncer controller configures the metasurface in real time to accurately beam the reflected signal towards the receiver. The detailed sweep mechanism is referred to Sec. 4.5. Then, we collect the measurements

to calculate the SNR during the receiver’s movement. Figure 32 shows the real-time SNR measurements with/without metasurface (referred to w MTS and w/o MTS) in 2.4 GHz and 5 GHz. We can see that RF-Bouncer can consistently achieve a SNR improvement compared to the case without metasurface at both different speeds and different frequency bands. These results demonstrate that RF-Bouncer can work well in mobile environments. In addition, we can observe that the performance of RF-Bouncer in slow speed works better than high speed. This is because RF-Bouncer has more time to beam the signal towards the receiver. We thus will explore the high speed scenario of RF-Bouncer in future work.

5.4 Coverage Extension

Whole-house coverage under cooperative work. By placing multiple metasurfaces (MTSs) in the complex whole-house scenario, the signal coverage can be efficiently expanded. We conduct an experiment in a 160 m² place with four rooms (Figure 33(a)). Four MTSs are cooperating. MTSs independently control and the working range of each MTS is disjoint. We note that this experiment does not consider how to select a good MTS route in the central control end to achieve good performance. Instead, we manually selected a routing route to perform beamforming for each location. Specifically, the transmitter in this experiment is fixed at one location and four MTSs are also pre-fixed at different locations. The route starts at MTS₁, goes through MTS₂ and MTS₃, and ends at MTS₄. Coverage includes the living room, the dining room, and three rooms. Note that missing areas that are not currently covered - such as the kitchen, room 4, and the bathrooms - can be easily covered by deploying more MTSs in the future. We set the Tx-MTS distance to 1 m and measure the SNR improvement in different locations. RSS from P₁ to P₆ is controlled by MTS₁; from P₇ to P₁₀ is controlled by MTS₂; from P₁₁ to P₁₃ is controlled by MTS₃; and from P₁₄ to P₁₆ is controlled by MTS₄. The results of using the omnidirectional/directional antenna (referred to Omni and Dire) and with/without the MTS (referred to w MTS and w/o MTS) are shown in Figure 33(b). We can clearly see that 1) the signal coverage can be efficiently expanded by leveraging multiple MTSs collaborative with each other; 2) the SNR is generally improved (above 1.26 dB and up to 17.65 dB) in NLoS envi-

ronments by the MTS, while the enhancements of different distances are different due to multipath; 3) MTS can achieve good performance even without LoS path between MTS and Rx (i.e., through the wall); 4) regardless of the antenna pattern, RF-Bouncer can improve the SNR.

Corner coverage expansion. In this experiment, we show how RF-Bouncer expands the wireless coverage at the corner scenario. As shown in Figure 34, we collect measurements with/without metasurface in both downlink and uplink for each location. From Figure 34, we can see that without metasurface, most locations around the corner have a lower SNR, especially for 5 GHz links, which only have an average SNR of 4.24 dB and 3.67 dB in downlink and uplink, respectively. This is because a signal of higher frequency has more severe path attenuation. In contrast, with the help of RF-Bouncer metasurface, most locations around the corner significantly improved SNR in both downlink and uplink at 2.4 GHz and 5 GHz. For example, RF-Bouncer can achieve an average SNR improvement of 10.30 dB (up to 26.16 dB) and 8.10 dB (up to 24.19 dB) for 2.4 GHz and 5 GHz downlinks, while an average SNR improvement of 8.78 dB (up to 25.27 dB) and 8.54 dB (up to 17.01 dB) for 2.4 GHz and 5 GHz uplinks. These results demonstrate that 1) RF-Bouncer can well expand the wireless coverage at the corner scenario; 2) RF-Bouncer can achieve good performance when Tx and Rx locations vary over a wide range of angles; 3) RF-Bouncer can work well for downlink and uplink simultaneously.

6 Discussion

Multiple metasurfaces cooperation. Cooperating multiple metasurfaces across rooms can effectively expand the wireless coverage, which is an interesting and challenging direction. In our current implementation, we manually calculate the configuration of each metasurface offline (which cannot guarantee the optimal performance) and send the configuration to each controller. In the future work, we will design an algorithm that can automatically configure the networked metasurfaces. In addition, current metasurface only consists of 256 meta-atoms with a size of $0.35 \times 0.35 m^2$, such a small aperture would lead to a wide beam at 2.4 GHz, which results in a worse coverage between different metasurfaces in the case of installing multiple metasurfaces. This is a limitation of our current version. Thus, to avoid this issue, one possible method is to design a larger aperture metasurface to generate a narrow beam of mainlobe.

Operation frequency. Our current design has a bandwidth of 200 MHz (from 5.15 GHz to 5.35 GHz), which covers 17 WiFi channels at 5 GHz. Since commercial devices go all the way to 5.8 GHz of spectrum, we thus will optimize our meta-atom’s design to enlarge the effective working band to cover additional 5 GHz channels in the follow-up work.

Unwanted interference induced by metasurface. Deploy-

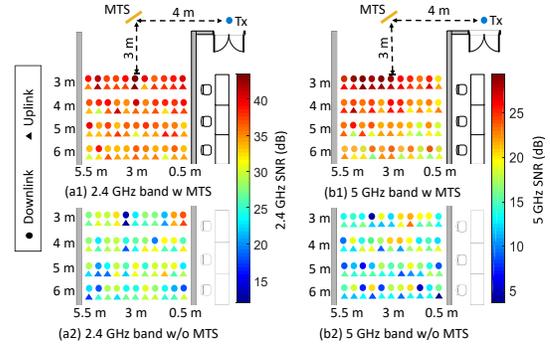

Figure 34: Corner coverage extension.

ing a smart surface to amplify some of the signals could possibly lead to interference, especially when there are multiple concurrent wireless links. But the possibility is small since the metasurface is beamforming the signal towards a specific direction, instead of omnidirectional reflection. Also, if the whole area is covered with metasurfaces, we could minimize interference by coordinating the metasurfaces.

Practicality and scalability of RF-Bouncer. The current version of RF-Bouncer needs to deploy a metasurface for each room, causing a huge cost. Fortunately, its cost can be minimized through mass fabrication. Meanwhile, due to the thin surface nature of metasurface, it can potentially be embedded into the environment (e.g., furniture and walls) to reduce the footprint, promoting its widespread deployment. In addition, since each metasurface has a FoV (i.e., $[-60^\circ, 60^\circ]$ for RF-Bouncer’s metasurface), by deploying a metasurface in the public area (e.g., the corridor), we can only use a single metasurface to reflect signal into many rooms, so as to avoid each room requires installing a metasurface.

7 Conclusion

We have designed, fabricated, and validated RF-Bouncer, a 2-bit dual-band reflecting metasurface to expand indoor wireless coverage. By encoding the phase shifting values, RF-Bouncer can simultaneously manipulate electromagnetic waves in two ISM bands. In addition, RF-Bouncer is transparent to protocols, so as to support diverse commercial IoT devices. Field study shows that RF-Bouncer can enable 15.4 dB average signal strength improvement.

beam control. *IEEE Journal on Emerging and Selected Topics in Circuits and Systems*, 10(1):20–28, 2020.

A Appendix

Figure 35 illustrates the structure of optimal unit-cell and Table 2 summarizes the optimal unit-cell parameter configurations. We place two PIN diodes with the opposite orientation on the upper patch layer as shown in Figure 35(b). The bias current supported by a DC voltage regulator flows from the bias line and flows to the patch through two vertical via-holes. Then, it flows to the GND line after passing through PIN diodes. Under the different DC voltage levels, each PIN diode switches to “ON” or “OFF” state and thus the opening directions of each patch have four states, as shown in Figure 36. Depending on the sign of the bias current, the meta-atom introduces a phase shifting of 0 , $\pi/2$, π , or $3\pi/2$. In addition, in order to decouple the influence between each bias line, we partition the whole metasurface into 4 areas (e.g., A, B, C,

and D in Figure 13, so the maximum number of bias lines passing through a unit-cell is reduced from 16 to 8.

Therefore, we can consider the meta-atom as a 2-bit phase shifter, corresponding to four electromagnetic responses. In order to independently adjust each meta-atom’s phase, we employ a bias line layer to control the states of the PIN diode within each meta-atom.

Abstract

Massive MIMO (multiple-in multiple-out) is a key wireless technique to get higher bandwidth in modern mobile networks such as 5G. The large amount of computation required for massive MIMO baseband processing poses a challenge to the ongoing softwarization of radio access networks (RAN), in which mobile network operators are replacing specialized baseband processing chips with commodity servers. Existing software-based systems for massive MIMO fail to scale to increasingly larger MIMO dimensions with an ever-increasing number of antennas and users. This paper presents a new scalable distributed system called Hydra, designed to parallelize massive MIMO baseband processing while minimizing the overhead of distributing computation over multiple machines. Hydra's high scalability comes from reducing inter-server and inter-core communication at different stages of baseband processing. To do so, among other techniques, we take advantage of hardware features in modern commodity radios in novel ways. Our evaluation shows that Hydra can support over four times larger MIMO configurations than prior state-of-the-art systems, handling for the first time, 150×32 massive MIMO with three servers.

1 Introduction

Massive MIMO is a key wireless technique to increase spectral efficiency in modern mobile networks such as 5G. Massive MIMO refers to using a large number of radio antennas to simultaneously serve a large number of users on the same frequency resources. Mobile network operators today are deploying multi-user massive MIMO to handle the increasing demand from mobile users [16]. For example, T-Mobile recently demonstrated the benefits of massive MIMO in a setup with 64 antennas serving eight concurrent users [12], achieving an impressively high total downlink bandwidth of 5.6 Gbps. A promising way to handle the demand for higher spectral efficiency and mobile bandwidth is to increase the massive MIMO dimensions: the number of radio antennas, and the number of users served simultaneously [17, 26, 28].

While the previous-generation LTE networks typically used small MIMO configurations (e.g., four antennas), massive MIMO deployments with 64 antennas are already commonplace in 5G, and future deployments could use hundreds of antennas [16]. For example, AirSpan's Air5G 7200 already supports 128 transmit and 128 receive antennas [2].

This paper tackles the challenge of scalably supporting increasing massive MIMO dimensions in *virtualized* RANs (vRAN). With vRANs, mobile network operators are replacing specialized RAN hardware, such as ASICs and DSPs for wireless signal processing, with commodity x86 servers [5, 10, 11, 13, 15]. RAN virtualization offers important benefits, such as mitigating vendor lock in and increasing RAN flexibility and feature velocity. However, massive MIMO remains a challenge for software-based RANs [8]. This is due to the extremely high computational requirements of massive MIMO, in the presence of tight millisecond-scale latency deadlines. For example, the largest massive MIMO configuration considered in this paper—150 antennas and 32 users—requires our system (Hydra) to use 71 CPU cores, cumulatively handling 80.6 Gbps of fronthaul traffic, within a latency deadline of 2.5 ms.

Our goal is to design a system that can efficiently scale to increasing massive MIMO dimensions by using the resources of more servers, to handle the requirements of 5G and future radio technologies. Key to Hydra's scalability is a set of new techniques that we design to scalably distribute massive MIMO computation among a pool of servers while minimizing the distribution overhead from inter-server and inter-core communication. Existing projects that implement massive MIMO baseband processing in software, such as Agora [17] and BigStation [28], lack a path for scaling to increasing MIMO dimensions. One the one hand, single-machine systems like Agora and Intel's FlexRAN [3] are limited to the CPU and network bandwidth resources of only one machine. One the other hand, the BigStation project studies the opportunities for distributing multi-user MIMO computation, but does not seek to optimize the distribution overhead, which is the focus of this work.

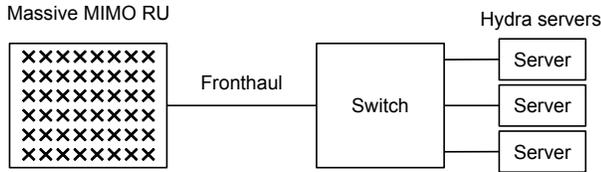

Figure 1: The architecture of a virtualized and distributed massive MIMO baseband processing system.

A massive MIMO baseband processing system (also called a baseband unit, or BBU) connects to a multi-antenna radio unit (RU) over a wired fronthaul link (Figure 1). In our setup, the BBU consists of one or more servers in a datacenter, connected to the fronthaul via an Ethernet switch. The RU and the BBU exchange packets containing in-band and quadrature (IQ) samples for hundreds or thousands of Orthogonal Frequency Division Multiplexing (OFDM) subcarriers. The BBU’s computation consists of a pipeline of stages, each with a different type of parallelism [18, 28]. Hydra’s design includes three key new ideas (summarized below) to map these BBU computation stages and the inter-stage shuffling of intermediate data to different hardware components, while minimizing inter-server and intra-server communication for scalability.

Taking the uplink direction as an example, the computation stages are as follows (Figure 2). First, antenna-parallel processing converts each antenna’s time-domain IQ samples into the frequency domain using a fast Fourier transform (FFT). Second, subcarrier-parallel processing converts each subcarrier’s per-antenna IQ sample streams into demodulated per-user streams. Third, user-parallel processing runs forward error correction on the per-user streams, converting them to user bit streams. The BBU connects these stages using communication mechanisms that shuffle the outputs of one stage into the inputs of the next stage.

Our first two ideas reduce inter-server communication (compared to BigStation), and the third reduces intra-server communication (compared to Agora).

1. **BBU-RU interface.** We identify that an existing hardware feature in modern RUs—the ability to perform FFT and generate separate packets for configurable subcarrier ranges—can be used to build a scalable distributed system for massive MIMO. Note that these RU abilities were not originally intended to build scalable distributed systems (Section 3.1); instead, we found a novel use case of these abilities. These FFT-capable RUs exchange frequency-domain IQ samples with the BBU, instead of time-domain IQ samples like in BigStation. Hydra routes packets for different subcarrier ranges to different servers, partitioning the fronthaul traffic and feeding the subcarrier-parallel pipeline stage with near-zero overhead. Compared to BigStation’s design

in which BBU servers run FFT and shuffle subcarrier ranges in software, our approach reduces inter-server communication by up to 66.4%.

2. **Within the BBU cluster.** Due to abundant parallelism, massive MIMO BBU processing offers many options to distribute computation within the server pool, at the cost of inter-server communication. For example, BigStation shuffles the BBU’s intermediate data over the network within the subcarrier-parallel stage, and predicts benefits from splitting individual matrix inverse operations across servers. Such inter-server communication limits BBU scalability. To minimize inter-server communication in Hydra, we observe that the subcarrier-parallel stage transforms the data dimension from antennas to users, and massive MIMO by nature uses much fewer users than antennas. Therefore, we delay inter-server communication until after the subcarrier-parallel stage, shuffling only a small fraction of the BBU’s input data rate among its servers.
3. **Within one server.** Within a machine, Hydra affinitizes the processing of an OFDM subcarrier to a CPU core. This ensures that the same CPU cores process a subcarrier through multiple subcarrier-parallel BBU sub-stages, eliminating inter-core shuffling of intermediate outputs. Hydra also avoids centralized scheduling of BBU tasks, which reduces inter-synchronization overhead, and prevents a single thread from becoming a bottleneck. This allows Hydra to use up to 47% fewer CPU cores than Agora’s design (Section 5.6).

Besides the above key ideas, we also dynamically increase or decrease the number of CPU cores used, to efficiently handle the varying demands in mobile networks and reduce the energy consumption. We build Hydra starting from Agora’s open source implementation. Our evaluation with an RU emulator shows that the number of antennas and users that Hydra can handle scales with the number of servers. With three servers, Hydra handles 150×32 MIMO, which has 2.3x more antennas and 2x more users than the prior state of the art single-machine system (Agora). With a larger 18-node cluster of old servers, Hydra handles 256×32 MIMO. Our evaluation also shows Hydra reduces CPU use by 46% when the traffic demand is low, compared to the corresponding system without dynamic core scaling.

2 Background and motivation

Antennas at a multi-user massive MIMO RU receive wireless signals that are a combination of several users’ transmissions. Each antenna has associated hardware that digitizes these signals into per-subcarrier IQ samples (typically represented as fixed-point complex values), assembles the IQ samples into packets, and transmits them to the BBU over a wired fronthaul link. The BBU’s task is to recover the bits

transmitted by each user from these jumbled complex numbers.

Doing so requires a huge amount of signal processing on the IQ samples, including matrix operations and forward error correction. This high computation cost is justified by the corresponding improvements in spectral efficiency. Note that although server hardware is an important contributor to operating expenditure, spectrum is often the most valuable resource in mobile networks.

2.1 Massive MIMO basics

Traditional single-user base stations allows at most one user to communicate with the base station on a given frequency resource (i.e., a subcarrier), avoiding inter-user interference. Multi-user MIMO uses interference canceling to allow a mobile base station to serve multiple users concurrently on the same subcarrier. Multi-user MIMO exploits *spatial* diversity, which means that different users are separated in physical space and therefore have different channels to the RU. Massive MIMO refers to multi-user MIMO with a large number (typically 32 or more) of base station antennas.

An $M \times N$ massive MIMO configuration uses M RU antennas to simultaneously serve N user antennas. On a given subcarrier, we can represent the signals transmitted by the N user antennas using an $N \times 1$ complex-valued column vector $x_{N \times 1}$. The signal $y_{M \times 1}$ received by the RU is a mixture of all users' transmissions. y can be modeled as $\approx W_{M \times N} \times x_{N \times 1}$, where W is the "channel matrix", i.e., $W_{i,j}$ is the wireless channel between antenna i and user j .

Zero-forcing receivers. The BBU's main task then is to jointly process the signals y from all RU antennas to recover the users' signals x . Importantly, the BBU can do this joint processing for each subcarrier in parallel. The joint processing consists of two steps. First, the BBU estimates the channel matrix W by using "pilot" transmissions from the users that have well-known numerical values, and are separated in time or frequency to avoid inter-user interference. Second, with the common "zero-forcing" approach, the BBU then computes the pseudo-inverse of the channel matrix W , as $H = (W^*W)^{-1}W^*$. For subsequent non-pilot data transmissions, the BBU recovers an approximation of x by computing $H \times y$, in a process called *equalization*.

After reconstructing x , the BBU performs *demodulation* to map the complex numbers to bits. The demodulated bits contain both user data bits and parity bits, appended by the radio protocol.

Finally, the BBU *decodes* the demodulated output via a forward-error correction (FEC) algorithm to produce the users' bits. Similar to Agora [17], Hydra uses 5G's Low Density Parity Check (LDPC) algorithm for decoding.

2.2 Massive MIMO baseband processing

Our goal in Hydra is to distribute massive MIMO BBU processing among a pool of servers using the fewest number

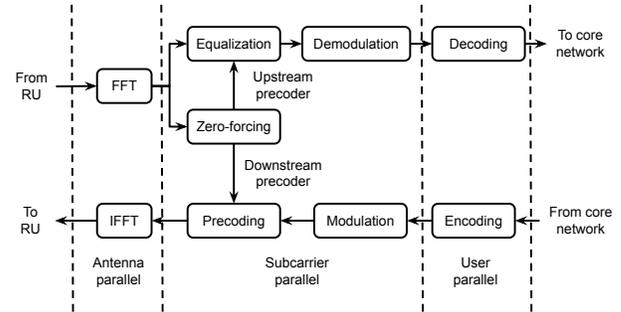

Figure 2: Massive MIMO processing pipeline.

of CPU cores and servers, achieved by minimizing distribution overheads from inter- and intra-server communication. We next discuss the two aspects of the massive MIMO processing pipeline that are crucial for designing a scalable distributed system: (1) the opportunity for distribution presented by the different types of parallelism in each stage, (2) and the scalability challenge posed by the need to shuffle data from one pipeline stage's output to the next stage's input (which we colloquially call the "data shuffling overhead").

Through the paper, we use the largest massive MIMO configuration supported by Hydra as a running **example** for exposition: 150×32 MIMO; with a typical 20 MHz configuration: 2048 subcarriers, out of which 1200 subcarriers carry data and the rest are used for guard bands; and 1 ms "slots" (discussed next).

Slots and symbols. Wireless protocols such as 4G and 5G divide time into slots. Each slot duration is typically further subdivided into 14 *symbol* durations. In each symbol duration, each RU antenna sends packets to the BBU containing IQ samples for all subcarriers. The radio protocol reserves pre-configured symbols for pilot signals from users, which are used for channel estimation. Similar to prior work [18, 28], we use the first symbol for pilots.

2.2.1 Types of parallelism

As noted by prior work [18, 28], massive MIMO baseband processing exhibits parallelism in different dimensions at different stages of the processing pipeline. This allows BBUs to divide the processing among multiple workers (i.e., CPU cores or servers). Figure 2 shows the three dimensions of parallelism for both uplink and downlink.

In the first antenna-parallel stage, the BBU performs FFT on the 150 antenna streams in parallel, converting time-domain IQ samples into frequency-domain samples. This step also eliminates the guard subcarriers and retains the 1200 subcarriers. The second frequency-parallel stage consists of three sub-stages: the BBU performs channel inversion, equalization, and demodulation for the 1200 subcarriers in parallel. The BBU may amortize the high cost of

matrix inversion by assuming that the channel matrix for some small configurable number of consecutive subcarriers is the same. In the third user-parallel stage, the BBU performs FEC decoding for each user independently.

2.2.2 Challenge: Inter-stage data shuffling

Massive MIMO processing is not perfectly parallelizable because the type of parallelism changes at each stage of massive MIMO processing, requiring shuffling the output of one stage to the input of another stage. One of our design goals in Hydra is to minimize this shuffling overhead.

Antenna-parallel to subcarrier-parallel shuffling.

Consider a thread T_{fft} that has computed the FFT for a fronthaul packet in the antenna-parallel stage. At this point, T_{fft} has data for all 1200 subcarriers. T_{fft} must then transmit data from different subcarrier ranges to the subcarrier-parallel stage threads processing the corresponding subcarrier ranges. This transmission uses shared-memory for destination threads on the same machine, and over-the-network transmission for remote threads.

Subcarrier-parallel to user-parallel shuffling. Consider a thread T_{sc} that has finishes the subcarrier-parallel stage (i.e., demodulation) for its partition of subcarriers. At this point, T_{sc} has data for all users, and must transmit different user ranges to threads running user-parallel processing.

In Section 3, we discuss how Hydra avoids the overhead of both explicit and implicit *intra*-stage data shuffling in prior BBU designs.

2.3 The need for distributed computing

Our goal for building a scalable distributed design for massive MIMO BBUs is to provide a path for scaling to massive MIMO's ever-increasing computational demands. If massive MIMO vRANs are limited to a single server, they will suffer from limited mobile bandwidth, spectral efficiency, and have a less competitive feature set compared to traditional BBUs based on specialized hardware. Note that while this paper focuses on increasing antennas and users as the main driver for higher computation requirements, other important factors such as increasing the frequency bandwidth (e.g., 20 MHz to 100 MHz) and decreasing the slot size (e.g., 1 ms to 0.5 ms) also substantially increase the computation resources required and fronthaul traffic bandwidth.

PHY latency deadlines. The radio protocol's NACK (negative acknowledgment) turnaround time imposes a latency deadline on BBU processing. For example, in 4G and 5G, in case of an irrecoverable bit error on the uplink, the BBU must send a downlink NACK to the user within four slots (i.e., within 4 ms). In this work, we set Hydra's latency deadline to 2.5 ms at the 99.99-th percentile, to allow 1.5 ms for the MAC to schedule the downlink NACK.

High computational requirements. The number of CPU cores required to meet the BBU's latency deadline in-

creases with MIMO dimensions, eventually exceeding the capacity of a single machine and necessitating a distributed design. For example, even after our optimizations, Hydra requires two servers to support 128×32 MIMO, and three servers to support 150×32 MIMO. Our 150×32 massive MIMO configuration requires 71 CPU cores. Note that although servers with very large numbers (100+) of high performance cores are available today, vRAN operators typically deploy smaller servers due to constraints such as power draw and fleet homogeneity. We explain these factors in detail next.

Limitation of single-machine systems. The CPU requirement of large MIMO configurations such as 150×32 (71 cores) is too high for a single vRAN server. This is because vRAN servers are deployed in small edge datacenters that have limited energy and space budgets, which precludes using beefy servers (e.g., quad-socket servers with 100+ cores). vRAN servers are typically single-socket or mid-range dual-socket servers. For example, HPE's servers targeted for vRAN have at most 28 CPU cores [14]. Similarly, Dell's reference architecture for vRAN has 40 cores per server [4].

In addition, massive MIMO servers co-exist with vRAN servers handling other workloads, such as BBUs for non-massive RUs, and virtualized implementations of higher cellular protocol layers (e.g., MAC). Datacenter operators prefer maintaining a uniform fleet of servers, i.e., it is uncommon to deploy special high core-count servers for just one workload. Therefore, a distributed design that can support massive MIMO workloads in typical vRAN servers is useful.

Another advantage of not relying on high-end beefy servers, which we have currently not explored in this work, is cheaper fault tolerance. vRAN deployments must provide extremely high availability since they are part of the critical phone infrastructure. One way to limit vRAN downtime is to deploy some servers as hot backups. Maintaining a beefy backup server to guard against the failure of a single beefy server is more expensive compared to maintaining a smaller backup server to guard against failure of one of Hydra's servers.

2.4 Limitations of prior distributed designs

BigStation [28] is the state-of-the-art design for virtualized distributed massive MIMO baseband processing. BigStation was designed around a decade ago for 4G MIMO processing, supporting up to 12 antennas and 12 users. BigStation's design (Figure 3) has two limitations:

High inter-core and inter-server communication. BigStation was designed for relatively small MIMO configurations, and aimed to meet latency deadlines with the weaker CPU cores available in 2012. Thus, BigStation aggressively distributes decomposable BBU tasks among CPU cores in the cluster (Section 3.2). As the MIMO dimension

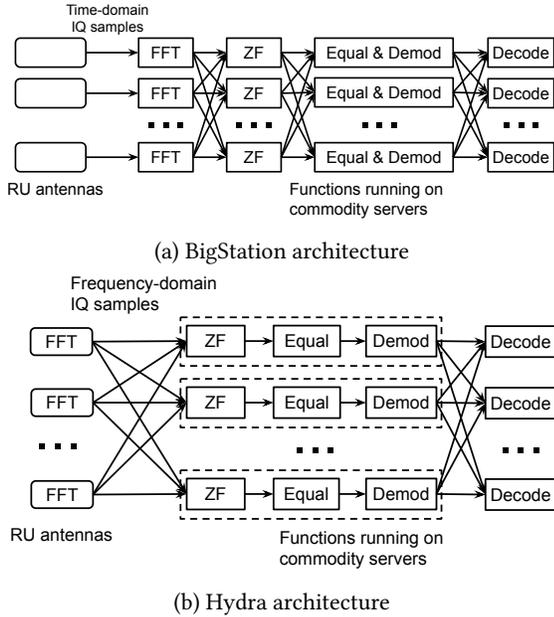

Figure 3: Architecture comparison between BigStation and Hydra (uplink). Unlike BigStation, Hydra shuffles data only after the subcarrier-parallel stage. “ZF”, “Equal”, “Demod”, and “Decode” are short for zero-forcing, equalization, demodulation, and LDPC decoding, respectively.

increases, the communication overhead in BigStation becomes significant and limits its scalability. In contrast, today we have higher MIMO dimensions and more powerful CPU cores that can individually complete the required MIMO operations within the radio protocol’s deadline. Therefore, Hydra’s design centers on keeping computation local on a CPU core to the extent possible.

Time-domain fronthaul traffic. BigStation was designed for older RUs that lacked FFT support (Section 3.1). To handle the large number of antennas in massive MIMO, BigStation’s servers spend a correspondingly large amount of CPU cycles in (a) performing FFT and IFFT, and (2) sending, receiving, and shuffling IQ samples (Section 4). For example, in the uplink direction, the servers first receive time-domain IQ samples from antennas, perform FFT, and then shuffle the frequency-domain IQ samples among each other to enter the subcarrier-parallel processing stage.

2.5 Motivation and challenges for Hydra

The above limitations of single-server and distributed MIMO BBUs motivated us to create a new distributed design. The key challenge in Hydra is: how can we distribute massive MIMO BBU processing among a pool of workers (servers or CPU cores) with minimal overhead? An ideal design is to perfectly parallelize the workload among the BBU servers without any inter-server communication.

When splitting massive MIMO BBU processing for an RU

with fronthaul traffic F_{bw} Gbps among N servers, the minimal network communication each server must handle is $C_{min} = F_{bw}/N$ Gbps. Our design achieves close to perfect parallelism with only 20% additional inter-server communication compared to C_{min} (Section 5.2).

3 Design

We next describe Hydra’s three main design components. Our design focuses on reduces communication overhead, with three approaches: (1) using the ability of modern RUs to run FFT and split packets into subcarrier ranges (Section 3.1), (2) shuffling data between servers at a stage that minimizes inter-server traffic (Section 3.2), and (3) avoiding inter-core data movement and coordination within a server (Section 3.3).

For brevity, similar to prior work [18, 24, 29] we primarily focus on uplink processing, which is often more computationally intensive than downlink processing due to the higher cost of channel decoding compared to encoding. Interestingly, we find that downlink processing can be costlier than uplink on some server architectures (Section 5.2).

3.1 Scalable fronthaul traffic partitioning

Massive MIMO radios generate a high rate of fronthaul traffic. For a scalable design with minimal overhead, it is critical to not re-shuffle any substantial fraction of the fronthaul traffic between servers. Doing so adds overhead in terms of CPU cycles, latency, and datacenter network bandwidth use. We show that the new ability in modern RUs to run FFT and generate separate packets for different subcarrier ranges allows partitioning the fronthaul traffic among Hydra’s servers with zero overhead. This reduces the amount of traffic that each server must handle before the subcarrier-parallel stage by up to 66.4% compared to BigStation.

Quantifying fronthaul bandwidth. For example, the fronthaul bandwidth in our running example configuration (Section 2.2)—150×32 MIMO, 20 MHz frequency bandwidth (2048 subcarriers, 1200 data subcarriers), 1 ms slots with 14 symbols—is 80.6 Gbps, assuming that the RU performs FFT and eliminates guard subcarriers: Each of the 150 antennas generates one packet with 1200 subcarriers (four bytes per IQ sample) for each of the 14 symbols in a slot. Therefore, the BBU receives 150×1200×4×14 bytes every millisecond, totaling 80.6 Gbps.

Note that most of the factors listed in Section 2.3 cause the fronthaul bandwidth to increase linearly. For example, using 100 MHz bandwidth with 0.5 ms slots is a common configuration in 5G deployments. This increases the fronthaul bandwidth by 5.5x to 444 Gbps by (1) increasing from 1200 to 3300 data subcarriers (4096 total subcarriers), and (2) doubling the rate at which the BBU receives packets.

To better describe the advantages of Hydra’s fronthaul traffic partitioning approach, we begin by first discussing BigStation’s approach. We compare the datacenter network

System	Receive rate	Transmit rate
BigStation	47.3 Gbps	12.9 Gbps
Hydra	20.2 Gbps	0 Gbps

Table 1: Comparison of datacenter network bandwidth used in BigStation and Hydra before the subcarrier-parallel stage. These numbers are for a 150-antenna RU and 20 MHz bandwidth with 1 ms slots.

bandwidth handled by each machine before the subcarrier-parallel stage in BigStation and Hydra, assuming each BBU design uses a cluster of four machines, and our running example MIMO configuration.

BigStation’s approach BigStation uses RUs without FFT support, and therefore operates on time-domain IQ sample packets, with 2048 IQ samples each (one IQ sample per subcarrier). In our example MIMO configuration, the fronthaul bandwidth for BigStation is therefore $80.6 \times 2048 / 1200 = 137.5$ Gbps. BigStation partitions the fronthaul traffic by antenna: each of the four BigStation servers receives packets for an exclusive range of 32 antennas, i.e., $137.5 / 4 = 34.4$ Gbps.

BigStation’s servers then run FFT on the time-domain IQ sample packets and drop the guard subcarriers, retaining 1200 subcarriers. To feed the next subcarrier-parallel stage (Section 2.2.2), each server must send 75% of the 1200 subcarriers to other machines. This corresponds to $32 \times (0.75 \times 1200) \times 4 \times 14$ bytes per millisecond, or 12.9 Gbps. Symmetrically, each server also receives 12.9 Gbps of shuffling input from the other three servers.

Hardware capabilities of modern radios The O-RAN alliance [9] defines specifications for various components and interfaces in 5G vRAN deployments. There are two hardware capabilities in modern O-RAN-compliant RUs that allow us to design new ways to partition fronthaul traffic. (1) FFT support. O-RAN’s fronthaul specification [7] requires RUs to support FFT. Running FFT at the RU reduces fronthaul bandwidth requirement by dropping guard subcarriers at the RU. For example, in our 20 MHz configuration with 2048 subcarriers and 1200 data subcarriers, running FFT at the RU cuts down fronthaul bandwidth by 41%. Since FFT is cheap to implement, it is widely included in RUs. This O-RAN feature benefits massive and non-massive RUs alike (e.g., small cells in a city that have low-bandwidth connections to the BBU).

(2) O-RAN also requires the RU to support configurable “fragmentation” (Section 3.5 in the fronthaul spec [7]) of its IQ sample packets on both the uplink and the downlink. This is needed to support fronthaul networks with different MTUs (a fronthaul packet with 1200 subcarriers requires 4800 bytes, which exceeds Ethernet’s typical 1500-byte MTU), and to allow the BBU to request only certain

frequency ranges from the RU. The latter is useful for reducing fronthaul traffic during low load when only a few frequency resources are in use.

Hydra’s approach We found a novel use case of these two RU abilities, which is different from what they were originally designed for (i.e., reducing fronthaul traffic or handling different MTUs): distributing massive MIMO fronthaul traffic among a pool of servers with zero overhead.

Fortunately, O-RAN RUs do not fragment packets at arbitrary boundaries, such as in the middle of an IQ sample. With such an implementation of fragmentation, Hydra’s servers would need to re-shuffle some IQ samples between servers before the subcarrier-parallel processing stage. Instead, each fragment contains a contiguous range of subcarriers, and the BBU can configure these ranges over its control plane connection to the RU. In Hydra, we use as many equally-sized ranges as the number of servers. If the number of subcarriers is not a multiple of the number of servers, one server gets a slightly larger range than others.

For example, in a four-server Hydra cluster, we configure the RU to send four packets per antenna in each symbol duration. The four packets contain IQ samples for data subcarrier ranges 0–299, 300–599, 600–899, 900–1199. We then route the i^{th} packet to server i . Each Hydra server therefore receives $80.6 / 4 = 20.2$ Gbps and sends no datacenter network traffic before entering the subcarrier-parallel stage.

Table 1 compares the amount of traffic received and sent by each server before the subcarrier-parallel stage in BigStation and Hydra for our example configuration. Hydra’s total bi-directional bandwidth requirement per-server (20.2 Gbps) is 66.4% percent lower than BigStation’s (60.2 Gbps). Our evaluation shows that using FFT-capable RUs with subcarrier range fragmentation reduces the number of CPU cores needed by Hydra by up to 46% (Section 5.5).

3.2 Scalable PHY computation partitioning

After partitioning subcarriers, Hydra still needs to run the subcarrier-parallel stage (i.e., zero-forcing, equalization, and demodulation), and the user-parallel stage (i.e., decoding). There are several possible approaches to partitioning this remaining computation among Hydra’s servers. We observe that the massive MIMO processing pipeline progressively reduces the amount of data transferred between pipeline stages. Hydra minimizes the amount of inter-server data shuffling by delaying shuffling to the last stage of the MIMO processing pipeline (decoding). Compared to BigStation’s design, Hydra’s servers shuffle up to 42% less data (Section 3.2.2).

3.2.1 Hydra’s approach

Recall that in our running example, the i^{th} Hydra server S_i receives IQ samples for subcarriers $[300 \times i, 300 \times (i + 1))$. S_i runs all the subcarrier-parallel processing sub-stages for these 300 subcarriers locally, i.e., without shipping any com-

putation to remote servers. After demodulation, S_i creates 32 per-user output buffers, each with 300 entries for the corresponding users' transmissions on each subcarrier. The decoding for 75% of these users happens on other servers, so S_i ships its outputs for those users over the network.

Rationale. The transition point between subcarrier-parallel and user-parallel stages offers an efficient point for shipping computation across servers. This is because the subcarrier-parallel stage reduces the amount of data flowing through the BBU's uplink pipeline: The equalization step for a subcarrier transforms per-antenna samples into per-user samples, and the number of antennas in massive MIMO is substantially larger than the number of users. For example, 64×8 is the typical massive MIMO configuration in today's 5G deployments. In our running 128×32 massive MIMO example, equalization shrinks the pipeline's flow by 4x.

3.2.2 BigStation's approach

The main alternative to our approach is computation and data shipping even within the subcarrier-parallel stage. For example, unlike Hydra, the computation for a given subcarrier in BigStation happens on different servers: BigStation reserves a set of its servers for only matrix inversion. These servers then ship the computed inverses to other servers running equalization and demodulation.

Comparison with Hydra. In our running example with 150×32 MIMO, we assume that groups of 32 subcarriers (as many as the number of users to avoid inter-user interference during pilot transmission) have the same channel matrix. Therefore, there are $1200/32$ channel matrices, and each matrix is $150 \times 32 \times 8 = 38400$ bytes in size. Shipping these matrices over the network in each millisecond slot duration requires 11.5 Gbps.

Shuffling data between the subcarrier-parallel stage and the user-parallel stage for this MIMO configuration cumulatively requires 16 Gbps for a three-server BBU (Section 5.2). This shuffle is required in both Hydra and BigStation, but it is the only shuffle required in Hydra. Therefore, Hydra's inter-server shuffle bandwidth (16 Gbps) is 42% lower than BigStation's (11.5 Gbps + 16 Gbps) for this configuration.

Alternative approaches. Similarly, early versions of our system aimed to maximize parallelism in the MIMO BBU by dynamically shipping individual matrix inversion and multiply operations over the cluster. Our thinking was in line with BigStation's hypotheses [28, Section 5.3] that for very large MIMO systems, the matrix inverse and multiply operations may need to be partitioned across servers. However, such an approach is unnecessary and inefficient: distributing individual MIMO matrix operations is unnecessary because modern CPU cores are individually powerful enough to meet the BBU's deadline. For example, computing the pseudo-inverse of a 150×32 channel matrix takes only around 150 μ s on our servers. Our evaluation shows

that confining a subcarrier's processing to a single server (a single core) works well on today's hardware. In addition, shipping the matrix operations adds overhead by shipping a huge amount of matrix contents over the network, requiring similar bandwidth to the fronthaul bandwidth.

3.3 Scaling within a machine

In our goal to build a scalable distributed system for massive MIMO baseband processing, we also had to create new optimizations for the processing within a single machine. We found that our baseline Agora system has a large amount of overhead from inter-core data movement and synchronization. We next describe two optimizations to reduce inter-core data movement and synchronization that we made on top of Agora. Our evaluation shows that these optimizations are crucial: without them, for some large MIMO configurations, Hydra either fails to support the configuration, or requires over 2x more CPU cores (Section 5.6).

Subcarrier-to-core affinity Recognizing the high cost of inter-core communication, we design Hydra to use the same CPU core for all the subcarrier-parallel sub-stages for a given subcarrier. In contrast, Agora centers its design around fine-grained task distribution, so a random core runs any individual matrix inverse or matrix multiply. Although this is a straightforward way of parallelizing MIMO processing that provides flexibility in allocating tasks to cores, it incurs a large amount of inter-core communication.

In Agora, the CPU core that computes the channel matrix inverse for a subcarrier (C_i) is almost always different from the CPU cores that run equalization and demodulation for that subcarrier (C_e). Note that a given channel matrix inverse computed from the pilot symbols is used for equalization in 13 subsequent data symbols. This creates overhead by repeatedly moving the computed matrix inverse from C_i 's private caches to C_e 's caches. It also reduces the cache efficiency of all cores, since the same matrix contents are duplicated in several caches.

In Hydra, the same CPU core performs channel matrix inversion, equalization, and demodulation for a given subcarrier. This eliminates inter-core cache movement and duplication of cached data.

No central coordinator thread. Agora uses a coordinator-worker thread design, in which a single coordinator thread communicates with worker threads via shared-memory queues. The coordinator thread queues task descriptors to the workers (e.g., the address and dimension of a source matrix to invert), and receives completions from workers. We find that in Agora's design, the worker threads spend a substantial amount of time blocked and waiting for work from the coordinator. This happens because the coordinator must schedule a large number of tasks, restricting performance. In contrast, Hydra's threads use shared-memory counters to track dependencies in the

Task	Without HT	With HT
Invert a 150×32 matrix	2.9 K/sec	4.8 K/sec
Equalization (32×150 times 150×1)	0.96 M/sec	1.23 M/sec
Precoding (150×32 times 32×1)	0.67 M/sec	0.72 M/sec
LDPC decoding (one UE)	20.2 K/sec	23.3 K/sec
LDPC encoding (one UE)	48.5 K/sec	60.0 K/sec

Table 2: Comparison of single-core processing rate with and without Hyper Threading (HT) for 150×32 MIMO.

MIMO pipeline, avoiding the coordinator bottleneck. In addition, since we also use subcarrier-to-core affinity, there are over 10x fewer cross-core task dependencies in Hydra than in Agora.

3.4 Downlink processing

The BBU’s downlink pipeline is the reverse of the uplink pipeline. A separate MAC layer sends per-user data to Hydra’s user-parallel threads, which perform LDPC encoding, and send the corresponding subcarrier ranges to Hydra’s subcarrier-parallel workers. Subcarrier-parallel workers then apply the precoder matrix that they computed during uplink processing (the precoder is the transpose of the channel matrix inverse) to transform per-user streams to per-antenna streams. The packet I/O threads on each machine then combine the outputs of each subcarrier-parallel worker to generate one packet for the machine’s assigned subcarrier range, which is then sent to the RU.

4 Implementation

We implement Hydra in C++ for Linux, building on top of Agora’s open-source codebase. Similar to Agora, (1) we use Intel MKL for matrix operations accelerated with AVX-512 SIMD instructions, (2) we use Intel’s FlexRAN library [6] for LDPC decoding and encoding.

Thread types in Hydra. A Hydra deployment consists of one or more Hydra processes running on different servers in a cluster. Each Hydra process launches three sets of threads, each pinned to a different core: (1) packet IO threads, (2) subcarrier-parallel threads, and (3) user-parallel threads. Packet IO threads send and receive fronthaul traffic, and shuffle BBU pipeline data between servers. Each subcarrier-parallel and user-parallel thread is assigned a static range of subcarriers or range of users, respectively. For each MIMO dimension, we use the fewest number of threads for each thread type (currently determined manually) required to handle the maximum workload.

Hyper Threading. While Agora disables Hyper Threading (HT), we find that enabling it improves the performance of massive MIMO processing by reducing the negative impact of memory stalls. Massive MIMO processing generates a large memory footprint (e.g., 1200 150×32 matrices, or 11.5 MB), causing misses in the CPU’s L1–L3 caches, which reduce CPU efficiency. Hyper Threading hides the impact

of these memory stalls by overlapping memory accesses with compute, e.g., by allowing one logical thread to use a SIMD unit while another logical thread is stalled. Table 2 shows that for 150×32 MIMO, using HT improves a single core’s throughput by 7.5%–65.5% for different PHY routines measured in isolation in micro benchmarks. For end-to-end runs, we were able to fit 150×32 MIMO processing in three servers only with HT enabled. For smaller MIMO configurations that we were able to test both with and without HT, using HT reduces the number of physical CPU cores needed by Hydra, e.g., from 68 to 53 cores for uplink processing for 128×32 MIMO.

Dynamic CPU core utilization. Since mobile networks experience highly variable workloads, it is important for the BBU to scale its energy consumption with the workload [1]. For example, cell sites in residential areas have high utilization during the day time, but almost no utilization at night. Hydra scales its CPU usage with the workload as follows.

For every slot, the MAC layer (not included in our system yet) communicates the set of users active on each subcarrier to Hydra. If during a slot with low load, the base station has fewer active users than the number of users permitted by the MIMO dimension, Hydra puts the corresponding user-parallel threads to sleep. Similarly, if a slot’s MAC configuration has some subcarriers not assigned to any user, Hydra puts the corresponding subcarrier-parallel threads to sleep. While this approach is fairly simple, we believe that it works well because mobile networks experience highly bursty workload patterns, with significant periods of zero load. For example, recent measurements show that a 4G cell is fully idle in 75% of the slots [20]. During zero-load periods, Hydra disables most of its threads, keeping only the packet I/O threads active. The CPU cores yielded by Hydra may be used by other co-located latency-tolerant edge workloads such as machine learning and analytics [20].

5 Evaluation

This section presents our evaluation of Hydra’s performance, the effectiveness of our design choices, and comparisons with design choices made by prior massive MIMO baseband processing systems (i.e., Agora and BigStation).

For evaluation, we created a complete version of BigStation based on the original design [29]. To focus the evaluation on the distributed system design differences between BigStation and Hydra, we also implement all of Hydra’s single-machine optimizations for BigStation.

5.1 Evaluation setup

5.1.1 Server setup

We run our evaluation in two clusters. For most experiments, we use a “main” cluster of four commodity servers, with three servers running our distributed BBU, and one server acting as a fronthaul traffic generator emulating an

RU (Section 5.1.2). All servers are connected to an Arista 7060 switch with 100 GbE single-port Mellanox ConnectX-5 NICs. Each server has two Intel Xeon Silver 4216 CPUs (2.1 GHz, AVX512 support), with 16 cores per CPU. We use at most 29 cores per server to leave some cores for the OS to avoid kernel thread starvation.

To demonstrate our design’s scalability to more servers than available in our main cluster, we use another cluster in CloudLab [19] consisting of 27 servers, with up to 18 servers for the BBU, and nine servers for emulating the RU. These servers are less powerful than our main cluster’s servers. All servers are connected to Mellanox 2410 switches with a Mellanox ConnectX-4 25 GbE NIC. Each server has one ten-core Intel E5-2640v4 CPU (2.4 GHz, no AVX512 support).

As is typical in vRAN systems [3, 18], we configure each server to reduce jitter: we run our processes as real-time processes with the highest scheduling priority, and remap OS interrupts to an unused core. Our experiments run in a dedicated cluster without network congestion and therefore experience no packet loss. Unless specified otherwise, the experiments run in the main cluster.

5.1.2 Emulated fronthaul traffic generator

Since O-RAN-compatible massive MIMO radios are not readily available today, we emulate the fronthaul traffic with a software-based generator, using Agora’s DPDK-based generator as a starting point. The generator applies a Rayleigh fading channel with Gaussian noise (25 dB signal-to-noise ratio). Agora’s generator emulates a basic RU without FFT support, transmitting time-domain IQ samples; we modify it to emulate an O-RAN radio: our generator runs FFT, discards guard subcarriers, and splits packets into multiple subcarrier ranges, one per Hydra server. In addition, for the packet for a given subcarrier range, the generator uses the network address (IP and MAC address) for the corresponding Hydra server.

In the CloudLab cluster, which has 25 GbE, the fronthaul bandwidth exceeds a single server’s NIC bandwidth for MIMO configurations with over 46 antennas. To overcome this, we split the traffic generation for the antennas across multiple servers. All servers are time-synchronized to a sub-microsecond accuracy with PTP, and agree on the first slot’s start time during initialization. We also add generator support to change the set of active subcarriers and users to emulate high and low load scenarios.

5.1.3 Wireless parameters

Our wireless settings are similar to Agora: all experiments use a 20 MHz configuration with 1200 data subcarriers (2048 total subcarriers), 1 ms slot duration, and 64 QAM modulation. We use 1/3 LDPC code rate and base graph #1, with a LDPC lifting size (“Z”) up to 104. This configuration results in 29.7 Mbps data rate per user, or 950 Mbps for 32 users. Since our primary focus is performance, our experiments

use the peak load where all subcarriers and users are active, unless mentioned otherwise.

5.2 End-to-end performance

Figure 4 shows the number of CPU cores and servers needed by Hydra and BigStation to support different massive MIMO configurations. We show the numbers for both uplink and downlink processing. We run the experiment for 100 seconds, spanning 100k 1 ms slots. To support a MIMO dimension, the BBU must satisfy two constraints: (1) the BBU’s 99.99th percentile latency must be below 2.5 ms (Section 2.3), and the BBU must have a throughput of one slot per slot duration (1 ms in our case) to keep up with the RU. Hydra supports up to 150×32 MIMO with three BBU servers. For 150×32 MIMO, Hydra uses 71 cores for uplink processing, or 83 cores for downlink processing.

Interestingly, we find that in our main cluster, Hydra’s downlink processing is more expensive than uplink. This is the opposite of measurements in the Agora paper, as well as our CloudLab measurements for Hydra (Section 5.4.3). This happens because downlink precoding (0.72 M/s per core for 32×150 by 150×1 multiplications) is more expensive than uplink equalization (1.23 M/s per core for 150×32 by 32×1 multiplications) on our main cluster (Table 2).¹ In our CloudLab cluster, the lack of AVX512 instructions reverses this effect (i.e., downlink becomes cheaper than uplink) by making LDPC decoding far more expensive than LDPC encoding: decoding is 10x more expensive than encoding on CloudLab, compared to 2.5x more expensive on our main cluster.

5.2.1 Comparison with BigStation

BigStation supports only up to 128×16 MIMO with the three servers. For MIMO configurations that BigStation supports, Hydra uses only around half the CPU cores for uplink processing, and between 30–40% fewer CPU cores for downlink processing. BigStation’s worse performance comes from two factors. First, BigStation spends additional CPU cycles for running FFT in software instead of the RU, and shuffling a larger amount of data between servers than Hydra. Second, the higher network I/O and data shuffling generates more memory pressure and inter-core communication than Hydra, reducing BigStation’s compute efficiency.

We provide a detailed accounting of Hydra’s and BigStation’s CPU usage below, with 128×16 downlink processing (the most challenging downlink configuration supported by BigStation) as the example.

- **Packet I/O.** BigStation uses 24 cores for packet I/O, compared to only four for Hydra.
- **IFFT.** BigStation uses six cores for IFFT processing, whereas Hydra uses the RU’s ability to perform IFFT.

¹We are investigating the root cause of this difference by studying Intel MKL’s implementation of matrix multiplication.

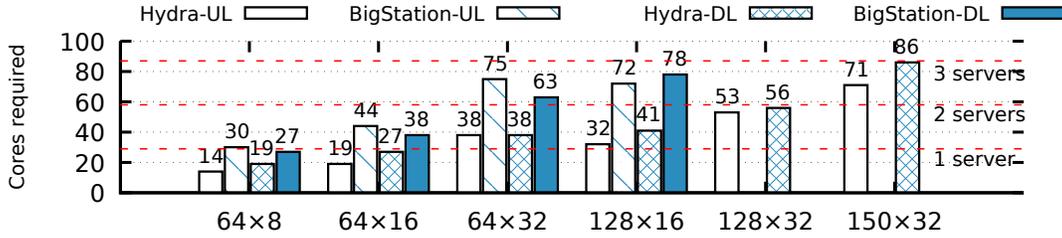

Figure 4: Number of cores and servers required to support different massive MIMO settings for Hydra and BigStation in uplink (UL) and downlink (DL) mode. BigStation supports up to 128×16 , so the bars for larger configurations are not shown.

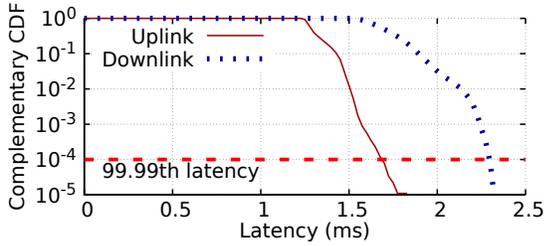

Figure 5: Complementary CDF of Hydra’s latency for 150×32 uplink and downlink processing.

- **Subcarrier processing.** BigStation uses 33 cores for subcarrier-parallel processing (six cores for zero-forcing, and 27 cores for precoding). Hydra uses 31 cores for its combined subcarrier processing stage.
- **LDPC encoding.** BigStation uses nine cores for LDPC encoding, compared to six for Hydra.

5.3 Comparison with Agora

Hydra supports Agora’s largest 64×16 MIMO configuration with one server for both the uplink and downlink. Different from Agora’s single-server design, Hydra allows using two servers to support 128×32 MIMO, and three servers to support 150×32 MIMO.

For a single-server performance comparison, we compare Hydra’s performance with the numbers published in the Agora paper [18]. This is because we were unable to reproduce numbers comparable to those reported in Agora due to hardware differences, e.g., we use weaker CPUs (16-core Xeon Silver 4216, \$900 per CPU) than those used in Agora’s evaluation (16-core Xeon Gold 6130, \$1900 per CPU). For 64×16 uplink processing, Hydra uses 19 CPU cores compared to Agora’s 28 (including Agora’s two packet I/O cores); for downlink processing, Hydra uses 27 cores compared to Agora’s 23.

5.4 Hydra’s performance details

5.4.1 Tail latency

Figure 5 shows that Hydra successfully meets our latency target of sub-2.5 ms 99.99th percentile latency for Hydra’s

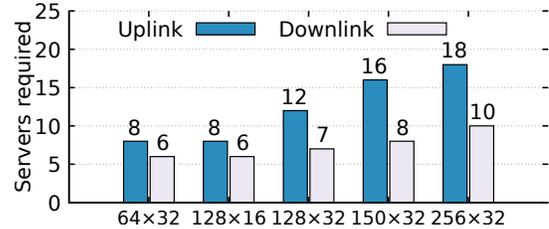

Figure 6: Number of servers required to support different massive MIMO settings in the CloudLab cluster.

largest-supported 150×32 MIMO configuration. For the uplink, Hydra’s *maximum* latency is only 1.8 ms, and its 99.99th percentile tail latency is 1.7 ms. For the downlink, Hydra’s *maximum* and 99.99% latency are both 2.3 ms.

5.4.2 Additional network traffic

For 150×32 MIMO, Hydra processes 80.6 Gbps of fronthaul traffic, and cumulatively shuffles only 16 Gbps among servers, or 20% additional traffic. (Since there are three servers, each server transmits two-thirds of $32 \times 400 \times 6$ bytes per data symbol. Since we use 64 QAM modulation, our demodulation stage represents each subcarrier’s sample with 6 bits.)

5.4.3 Server scalability

We use the CloudLab cluster to study how Hydra’s design scales with an increasing number of servers. Figure 6 shows how Hydra supports higher massive MIMO dimensions as the number of servers increases in the CloudLab cluster. Hydra supports 256×32 MIMO with 18 servers for uplink processing, or with 10 servers for downlink processing. For the regime studied, the number of servers needed for uplink processing scales roughly linearly with the number of antennas: for 32 users, Hydra needs 8, 12, and 18 servers for 64, 128, and 256 antennas, respectively. There is room for further scaling since Hydra does not hit a scalability bottleneck at 256×32 ; this scale was limited by only the number of CloudLab servers we managed to reserve.

Different from our main cluster, downlink processing is cheaper than uplink processing in the CloudLab cluster. This is primarily because LDPC decoding is 10x more ex-

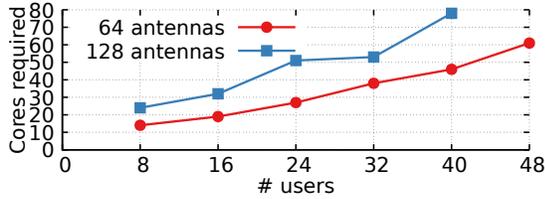

Figure 7: Minimum number of CPU cores required to support different massive MIMO settings.

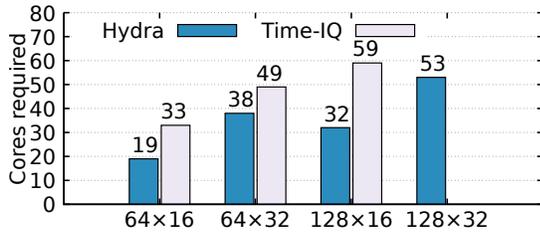

Figure 8: CPU cores needed by Hydra and Time-IQ for different massive MIMO configurations (uplink).

pensive than encoding on CloudLab servers, but only 2.5x more expensive on our main cluster.

5.4.4 User scalability

Figure 7 shows the minimum of CPU cores required to support an increasing number of users for two antenna configurations: 64 antennas and 128 antennas. We find that Hydra can scalably support more users by using more cores. Using LDPC accelerators (e.g., Intel’s ACC100 accelerators) can allow Hydra to support even more users.

5.5 Benefits of leveraging RU features

To quantify the performance benefits of offloading FFT and subcarrier range splitting to the RU, we created a variant of Hydra called “Time-IQ” that works with time-domain IQ samples. Time-IQ runs FFT in software on the BBU servers to generate frequency-domain IQ samples, which it then shuffles among the servers for the subcarrier-parallel stage. Figure 8 compares the number of cores needed by Hydra and Time-IQ to support four different massive MIMO settings. Hydra uses 42%, 22%, and 46% fewer CPU cores for the 64x16, 64x32, and 128x16 configurations, respectively. Time-IQ is unable to support the 128x32 MIMO configuration with the 87 cores available in our cluster, whereas Hydra supports this configuration with 53 cores.

Next, we then run both Time-IQ and Hydra for 128x16 massive MIMO using 59 cores (the minimum CPU cores required by Time-IQ) and measure the 99.99-th tail latency breakdown. Figure 9 shows the 99.99-th percentile completion time for each of the three pipeline stages (the antenna-parallel FFT stage, the subcarrier-parallel stage, and the user-parallel decoding stage). Time-IQ has higher latency than Hydra due to the additional FFT processing in soft-

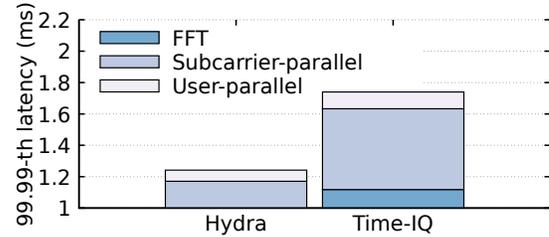

Figure 9: 99.99-th tail latency breakdown for Hydra and Time-IQ design for 128x16 MIMO (uplink) with 59 cores. The figure starts at 1 ms because it takes 1 ms to receive all IQ samples from RU antennas.

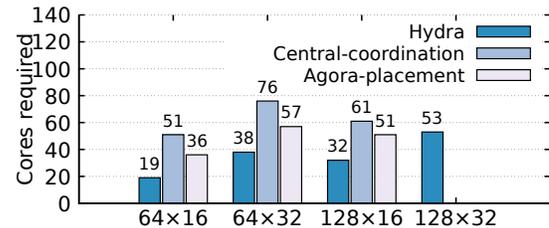

Figure 10: CPU cores needed by Hydra, Central-Coordination, and Agora-Placement for different massive MIMO dimensions (uplink).

ware, and a longer subcarrier-parallel stage. Time-IQ’s subcarrier-parallel stage is longer because it must shuffle frequency-domain IQ samples between the antenna-parallel stage and the subcarrier-parallel stage.

5.6 Impact of intra-server optimizations

We next evaluate the effectiveness of our optimization to reduce inter-core communication (Section 3.3): affinitizing the processing of subcarriers to CPU cores, and avoiding a central coordinator thread for task scheduling. We created two variants of Hydra for this measurement: The first variant, called “Agora-Placement,” works without a coordinator thread, but uses Agora’s random assignment of tasks to CPU cores, which increase inter-core data movement and reduces cache effectiveness. The second variant, called “Central-Coordination,” affinitizes subcarrier processing to CPU cores, but uses a coordinator thread to schedule tasks to workers. Figure 10 shows that reducing inter-core communication and avoiding centralization of task coordination logic is crucial for performance. In addition, the two variants are unable to support 128x32 MIMO with three servers.

For example, using a coordinator thread for task scheduling can more than double the number of CPU cores needed. We verify that this happens because of the large amount of time that worker threads in Central-Coordination spend in waiting for work from the coordinator thread. For example, with 128x32 MIMO and 53 cores (the minimum needed by Hydra to support 128x32), workers cores in the Central-

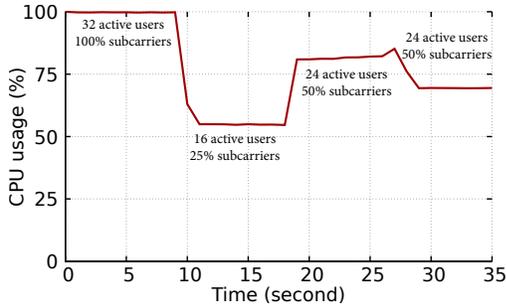

Figure 11: Hydra’s CPU usage with a dynamic workload.

Coordination design spend around 0.5 ms on average in every millisecond slot waiting for the coordinator. In contrast, Hydra’s workers spend only 0.14 ms on average waiting on shared-memory counters to saturate.

5.7 Dynamic CPU core scaling

We next evaluate the efficiency of Hydra’s dynamic CPU core scaling mechanism. We run Hydra under 150×32 massive MIMO with 1200 data subcarriers, and dynamically change the number of active users and active data subcarriers. We change the workload in four stages, and each stage lasts for 8–10 seconds. The four stages are 1) 32 active users and 100% active subcarriers, 2) 16 active users and 25% active subcarriers, 3) 24 active users and 50% active subcarriers, and 4) 24 active users and 25% active subcarriers.

In a production RAN, the MAC layer sends commands to the PHY informing it about the number of active users and subcarriers in every slot; the PHY can use this information to adjust its CPU utilization [20]. Since we do not currently have a MAC layer, Hydra servers read per-slot configuration from a configuration file. Figure 11 shows the real-time CPU usage of Hydra over time, normalized to 71 cores at 100% load. Hydra first utilizes full CPU resource for the first stage, and reduces the CPU usage to 54% in the second stage. Hydra then dynamically changes the CPU usage to 80% and 70% in the third and the fourth stage.

6 Related Work

Software-based RAN processing. The use of commodity servers for high-performance PHY processing was pioneered by Sora [27], which demonstrated the use of modern CPU features such as SIMD for wireless signal processing for WiFi. The Sora project later led to BigStation [28], which was the first to use a distributed system to handle the high computation requirements of multiuser MIMO. Agora is a more recent project that focuses on massive MIMO processing within a single server. Hydra builds upon these designs by combining the single-machine design of Agora with ideas from BigStation, but focuses on minimizing the overheads in distributing massive MIMO computation. Intel’s FlexRAN [3] is a production-grade single-machine

PHY implementation is 5G NR-compliant and is used in large-scale vRAN deployments [10]. However, FlexRAN is closed-source, with a few open-source components like their LDPC encoder and decoder. Hydra’s design could benefit from FlexRAN’s other high-performance signal processing blocks, such as matrix inversion and demodulation.

Hardware-based RAN processing. The LuMaMi testbed [24] is a massive MIMO processing system that uses specialized hardware (e.g., FPGAs and PCIe switches). LuMaMi can handle 100×10 massive MIMO with 0.5 ms slots. While LuMaMi and Hydra cannot be compared apples-to-apples, it is interesting to note that Hydra can handle a substantially larger MIMO configuration (i.e., 150×32), although with a more relaxed latency deadline (1 ms slots). We believe that comparing software-only and hardware-based approaches for massive MIMO processing is an interesting avenue for future research.

Quantum computing approaches such as QuA-Max [23] and ParaMax [22] have recently been proposed to tackle the high computational cost of massive MIMO. While our work uses linear MIMO methods (i.e., zero-forcing equalization and precoding), quantum-based approaches can handle more expensive non-linear methods like sphere decoding [21, 25]. Since sphere decoding can be too expensive for a single server, Hydra’s techniques may be used to distribute the work among multiple servers.

7 Conclusion

We have presented the design of Hydra, a new distributed design for scalable massive MIMO processing in software. Hydra focuses its design on reducing the overhead in distributing massive MIMO computation among a pool of servers. Our design leverages features of modern RUs in novel ways to partition the fronthaul traffic with zero overhead, uses an efficient split for shuffling inter-server data between the MIMO pipeline’s stages, and reduces inter-core communication and coordination for processing within a machine. The result is that Hydra can support much larger MIMO configurations than prior state-of-the-art, demonstrating support for 150×32 MIMO for the first time in software. Importantly, we have demonstrated that massive MIMO processing can be efficiently distributed over multiple servers, using only 20% additional network I/O compared to the required fronthaul traffic. We believe that our design can be used to scalably support even more challenging MIMO configurations in the future.

Acknowledgments. We thank the NSDI reviewers for their helpful feedback. We are grateful to Jian Ding and Rahman Doost-Mohammady for their feedback, and help with the Agora code. We also thank Lin Zhong for early discussions on the project. Junzhi Gong and Minlan Yu are supported in part by the NSF CNS-1955422 and CNS-1955487.

Abstract

Interactive mobile applications like web browsing and gaming are known to benefit significantly from low latency networking, as applications communicate with cloud servers and other users' devices. Emerging mobile channel standards have not met these needs: 5G's general-purpose eMBB channel has much higher bandwidth than 4G but empirically offers little improvement for common latency-sensitive applications, while its ultra-low-latency URLLC channel is targeted at only specific applications with very low bandwidth requirements.

We explore a different direction for wireless channel design to address the fundamental bandwidth-latency tradeoff: utilizing two channels – one high bandwidth, one low latency – simultaneously to improve performance of common Internet applications. We design DChannel, a fine-grained packet-steering scheme that takes advantage of these parallel channels to transparently improve application performance. With 5G channels, our trace-driven and live network experiments show that even though URLLC offers just 1% of the bandwidth of eMBB, using both channels can improve web page load time and responsiveness of common mobile apps by 16-40% compared to using exclusively eMBB. This approach may provide service providers important incentives to make low latency channels available for widespread use.

1 Introduction

Low latency is critical to interactive applications such as web browsing, virtual and augmented reality, and cloud gaming. For web applications, even an increase of 100 ms latency can result in as much as 1% revenue loss, as noted by Amazon [21]. Emerging VR, AR, and cloud gaming applications also rely on low latency to deliver a seamless user experience. For instance, VR requires 20 ms or lower latency to avoid any simulator sickness [19].

Current mobile broadband, serving general Internet applications such as web browsing and video streaming, have not yet delivered consistent low latency performance, in part due to the inherent trade-off between latency and bandwidth [22]. One approach is to provide two separate channels (or services) – one optimizing for bandwidth, the other optimizing for latency – with different types of user applications assigned to them. 5G NR follows this pattern with its enhanced mobile broadband (eMBB) and ultra-reliable and low-latency communication (URLLC) channels. eMBB, which serves general-purpose Internet use, is heavily focused on delivering gigabit bandwidth. This channel will be useful for streaming

media but offers little to no improvement for latency-sensitive applications, such as web browsing [34, 35, 50]. Experimentally, web page load time in existing 5G deployments, even in close-to-ideal circumstances (a stationary device and a channel with little utilization), is similar to 4G for pages smaller than 3 MB in size and about 19% faster than 4G for pages larger than 3 MB [34]. This is due to 5G eMBB having 28 ms or larger latency, broadly similar to 4G [34]. Our measurements of 5G mmWave showed similar results, at around 22 ms in ideal conditions.

Meanwhile, 5G URLLC promises an exciting capability of very low latency, in the range of 2 to 10 ms [6], but compromises severely on bandwidth, making it unsuitable for common mobile applications. Our experiments emulating web browsing (the most widely used mobile application [44], and far from the most bandwidth-intensive application) over URLLC with 2 Mbps bandwidth show web page load times would be $5.87\times$ worse than with eMBB. Hence, neither using URLLC alone nor using eMBB alone provides good performance. As the latency-bandwidth trade-off is fundamental, this separation between a high bandwidth channel (HBC) and a low latency channel (LLC) is likely to persist; 6G, for example, is also expected to include both [54].

We believe, however, that the availability of two channels offers an opportunity to deal with the fundamental latency-bandwidth tradeoff in a new way, beyond simple static assignment of an application to a single channel. Specifically, we argue that *by using high bandwidth and low latency channels in parallel on mobile devices, significant performance and user experience improvements are possible for latency-sensitive applications*. Here, we explore this hypothesis for the case of web browsing and web-based mobile applications.

Mapping an application's traffic to HBC and LLC is difficult since we have to use LLC's bandwidth very selectively. Indeed, the main deployed transport-layer mechanism to combine multiple channels, MPTCP [49], assumes two interfaces that are each of significant bandwidth, with the goal of aggregating that bandwidth or supporting failover. LLC's bandwidth, however, is a rounding error compared to HBC's. Other works – particularly Socket Intents [42] and TAPS [38] – exploit multi-access connectivity through application-level input, which we prefer to avoid to ease deployment and expand relevance to other applications in the future; therefore we expect new mechanisms are necessary.

To solve these problems, we design DChannel, a system that leverages parallel channels to improve the performance of mobile applications. DChannel comprises two modules

running at either end of the channels – namely, in the mobile device OS and in a gateway device operated by the service provider. Central to the approach is a packet steering scheme that operates at the network layer (i.e., IP packets) without requiring any application input. Such fine-grained, per-packet decisions (as opposed to, for example, HTTP object-level steering) are key to making effective use of the limited LLC bandwidth. To decide which packets are worth accelerating, since LLC bandwidth is extremely limited, DChannel treats the channel as an expensive resource and calculates the benefit and cost of utilizing the LLC for each packet. Finally, since the parallel channels could occasionally confuse the transport layer with out-of-order delivery, DChannel employs a reordering buffer in the mobile device and gateway.

To evaluate our design with a concrete scenario, we leverage 5G's eMBB and URLLC as our HBC and LLC. We evaluate the benefit of DChannel in our experimental testbed (§4). Our testbed includes a prototype that can capture and steer application traffic, and a high-fidelity trace-driven network emulator that emulates cellular network latency variability and delay caused by radio resource control (RRC) state transitions [41]. We gather two types of real 5G eMBB traces – mmWave and lowband – in three different scenarios: stationary, low mobility, and high mobility. Our evaluations cover popular web applications such as web browsing and Android mobile applications. Using the testbed, we evaluate our packet steering scheme and compare it with prior approaches such as MPTCP [2] and ASAP [29]. We also evaluate DChannel in live 5G eMBB networks. Our key findings are as follows:

- DChannel, which requires little per-connection state and no application knowledge, yields superior performance compared to the other evaluated schemes—object-level steering, static packet-size-based steering, as well as prior work, MPTCP and ASAP [29], which used multiple channels in other settings.
- Compared with exclusively utilizing the eMBB, allocating a modest bandwidth of 2 Mbps to URLLC allows DChannel to improve web page load time (PLT). Under conditions that are ideal for eMBB (a stationary client with a line of sight to the base station and full signal strength), DChannel reduces PLT by 20% and 33% in 5G mmWave and low-band settings, respectively. Under more challenging mobile conditions, DChannel improves PLT by 37% and 42% in 5G mmWave and low-band, respectively.
- In addition to web browsing, we evaluated three Android mobile apps in a live environment and find DChannel improves apps responsiveness by 16% on average.
- Somewhat surprisingly, DChannel improves *sustained throughput* in our mobile 5G setting by roughly 10% – a useful side benefit of accelerating the TCP control loop in dynamic environments.

Finally, we discuss deployment strategies, challenges, and future opportunities. We believe our basic techniques can apply to a variety of latency-sensitive applications, and open new opportunities for app developers and cellular providers.

2 Background and Motivation

2.1 Channels in 5G

5G wireless networks are designed to support applications with very different service level requirements. The 5G standard known as New Radio (NR) specifies three service models: (1) enhanced mobile broadband (eMBB) for standard high-data-rate Internet and mobile connectivity, (2) ultra-reliable low-latency communication (URLLC) for mission-critical and latency-sensitive applications, and (3) massive machine-type communications (mMTC) for large-scale IoT deployments. We describe eMBB and URLLC in more depth.

(1) Enhanced Mobile Broadband: This service focuses on providing high-data-rate mobile access. It is considered an upgrade to 4G mobile broadband that will satisfy the ever-increasing demand for mobile and wireless data. 5G eMBB can operate either at the low-frequency bands below 6 GHz which we refer to as low-band or the high-frequency bands around 28 GHz/39 GHz which we refer to as millimeter wave (mmWave). The mmWave bands are a key new technology in 5G as they offer 10× the bandwidth that is currently available to 4G LTE networks [4], enabling user throughput of around 1 Gbps [15].

Providers like Verizon, AT&T, and T-Mobile have already deployed both the low-band and mmWave 5G in several major US cities, including Chicago, Atlanta, New York, and Los Angeles [9–11, 34]. A recent measurement study on commercial mmWave 5G networks in the US shows TCP throughput of up to 2 Gbps for download and 60 Mbps for upload, with a mean RTT of 28 ms measured between the client and the first-hop edge server right outside the cellular network core [34]. The measurements were performed, however, in conditions favorable to mmWave such as line-of-sight, no mobility, and few clients.

eMBB latency is expected to be higher as the number of users increases and as users move. This is because radio access networks (RANs) operating in the mmWave bands use very directional beams to compensate for high signal attenuation, making them vulnerable to blockage and mobility. High data rate communication is possible only when the RAN access point aligns its beam towards the user [27]. This process, commonly referred to as beam alignment, can introduce significant delays, especially when users are moving, which requires the access point to keep realigning the beam of each user [23, 27]. Furthermore, the user or other obstacles can easily block the beam, leading to unreliable and inconsistent performance both in terms of changes in throughput and highly variable RTT [3, 32, 34]. Our own experiments in Chicago also confirm this and show that the RTT can vary sig-

nificantly even for stationary clients and is further exacerbated while walking or driving. This is because 5G eMBB mainly optimizes for high data rates, focusing less on reliability and low latency.

(2) Ultra-Reliable Low-Latency Communication: Unlike eMBB, this channel focuses on providing highly reliable, very low latency communication at the cost of limited throughput. It aims to support mission-critical and emerging applications with stringent latency and reliability requirements such as self-driving cars, factory automation, and remote surgery. While the URLLC channel is yet to be deployed in practice, the standard specifies a target 0.5 ms air latency between the client and the RAN (1 ms RTT) with 99.999% reliability for small packets (e.g. 32 to 250 bytes) [15]. It also specifies a target end-to-end latency (from a client to a destination typically right outside the cellular network core) of 2 to 10 ms with throughput ranging between 0.4 to 16 Mbps depending on the underlying application [6]. URLLC is expected to operate in the sub-6 GHz frequency bands (e.g. 700 MHz or 4 GHz) and operators are expected to use network slicing to provide dedicated resources to URLLC clients in order to guarantee consistent performance in terms of latency and reliability across both the radio access network (RAN) and the cellular core [6]. Finally, client access to the URLLC channel will be controlled by the network operators. The access control network slicing mechanisms, however, are left to the operators’ own implementations [8].

2.2 Web browsing traffic

While we evaluate several applications, web browsing is the major focus of this work and serves as a running example.

A single web page may contain tens to hundreds of relatively small-sized web objects distributed across multiple servers and domains. Consequently, web browsing traffic is characterized by its often short and bursty flows. A study across Alexa Top 200 pages found that the median number of objects in a page is 30, while the median object size is 17 KB [48]. Fetching these web objects translates to many HTTP request-and-response interactions across many short flows. The browser fires a page load event when it finishes rendering a page, which is used to determine Page Load Time (PLT), a performance metric for web browsing. Although PLT has some shortcomings, the alternatives are not free from issues, and PLT is most widely used. PLT is typically dominated by DNS lookup, connection establishment, and TCP convergence time—which require little throughput but are highly dependent on RTT. Prior work also showed that increasing TCP throughput beyond ≈ 16 Mbps offers little improvement in PLT [45].

Of course, web page loading is affected by client CPU and server delay, in addition to network delay. Prior work found that 35% of the PLT is spent in client-side computations [47]. But the above characteristics, combined with the fact that mobile CPUs have been getting increasingly powerful [26],

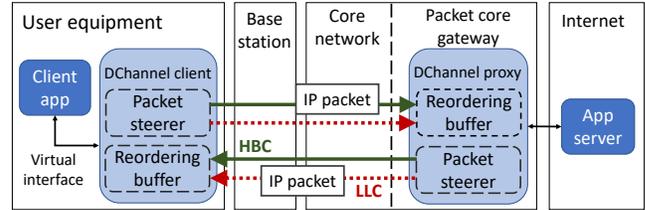

Figure 1: *The overview of DChannel. It has two main components: packet steerer that steers application traffic to LLC and HBC, and reordering buffer that reorders packets coming from LLC.*

still suggest that network latency plays an important part in mobile web performance. Moreover, a significant portion of network latency lies in the “last mile” connection of the cellular network. Many other mobile apps also rely on HTTP-based interaction with cloud services, resulting in similar network performance requirements.

3 DChannel Design

3.1 High-Level Architecture

To steer application traffic in both uplink and downlink channels, there will be two main components, one in the mobile client device and one in the mobile core network (Figure 1).

On the client, applications interact with the network through a network interface as usual. In our prototype, this is a special virtual TUN interface designated for traffic that should utilize both the HBC and LLC. The client-side agent captures outgoing packets on this interface and implements an algorithm to steer traffic between the two channels. The agent also captures incoming traffic on both channels and merges it into the virtual interface, after buffering it as needed to reorder packets (§3.6).

The proxy-side agent performs symmetric functions using the same algorithms – steering traffic headed towards the client, and merging and reordering traffic outbound to the Internet. This agent runs in the service provider’s network, on a gateway at the point where the separate HBC and LLC channels begin. The exact location of the proxy-side agent may depend on the service provider’s internal architectural choices; note that it is not necessarily located at the RAN base station, because the LLC’s latency optimizations may extend into the packet core (e.g., for prioritized queuing and routing) [5].

The next subsections detail how we design the steering component, in several steps, as it is the more complex component. After that, we describe the reordering buffer.

3.2 Steering Granularity

To build the packet steering module, we begin with the question of the granularity, and corresponding layer, at which steering should occur. We considered splitting at two different layers: the application layer and the network layer.

Application-layer splitting refers to steering application requests and responses to the appropriate channels. In the context of web browsing, this approach translates to requesting and delivering web objects (in the form of HTTP requests) on either LLC or HBC. Application-layer splitting is broadly similar to Socket Intents [42].

Object-level splitting may benefit from application-level knowledge about web objects, which vary in size and priority. Since LLC is bandwidth constrained, LLC can only deliver small objects faster than HBC.¹ Web pages have complex dependency structures, and certain objects can be on the critical path for web page loading. These critical-path objects need not necessarily be small in size. Small objects might have low priorities such that accelerating them will not improve load time and thus would waste LLC bandwidth. In contrast, high-priority objects can be large such that sending those to LLC will be slower than HBC. Application-level input could help distinguish between these cases.

But object-level splitting has two drawbacks. First, we want to avoid requiring application input, which creates deployment hurdles and extra work for developers. Second, it misses opportunities for latency improvement. A web object that's not small enough to be sent over LLC will still involve small and latency-sensitive DNS lookups, TCP connection establishment, TLS handshaking, and ACKs. Accelerating this traffic could significantly reduce object delivery time. We later demonstrate (§5.3) that object-level splitting is less effective than finer-grained packet-level steering.
