Addax aims to address many of the shortcomings of existing ad exchanges by giving agency to users, privacy to bidders, and transparency to all. Addax is compatible with both traditional exchanges and with the header bidding model (including Google’s open bidding platform). We detail these goals next.

Integrity of the auction. All parties should be able to verify that Addax’s auctions are conducted correctly, as per the auction type (first-price, second-price, etc.).

Privacy for losing bids. Addax should hide the bids of all of the losing bidders from *everyone*, even the auctioneers. One exception is that in second-price auctions, the second highest bid (which is technically a losing bid) becomes the sale price and cannot be hidden.

Privacy among bidders. Bidders should not need to learn each others’ identities or interact with one another in order to participate in an auction. Existing exchanges do not reveal this information, and neither should Addax.

High performance. Addax must ensure that auctions complete quickly, as ads need to be displayed within hundreds of milliseconds in order to preserve a good user experience and follow existing RTB requirements [10, 11].

User agency. Addax’s focus is on making the auction process accountable without exposing bidders’ information. Addax should also allow users to have a say on which kinds of ads they wish to receive. Ideally, Addax would also improve user privacy, but this is not a goal of this work. Instead, we ask that Addax make things no worse than they are today for users, and that it be compatible with other works that aim to reduce user tracking (such as Topics [16]). Appendix G expands on this compatibility aspect.

2.4 Potential solutions (baselines)

Given Addax’s desire for privacy and verifiability, one might ask whether existing tools such as homomorphic encryption or multiparty computation fit the bill. This is not the case.

Homomorphic encryption (HE). HE libraries [24–26, 61] allow the computation of additions and multiplications over encrypted data without access to plaintext values. Computing an auction, however, requires comparisons (such as “less than”) which are expensive to express with arithmetic operations as they typically require decomposing values into bits and encrypting bits separately [25, 50]. Even recent optimizations are expensive [41, 48, 64]. As we show in our evaluation (§9.2) an auction with 96 bidders using the state-of-the-art TFHE library [49, 50] takes 181 seconds. Finally, HE lacks integrity: an auctioneer is free to compute an incorrect auction. Recent work on composing verifiable computation with HE can address this, but at orders-of-magnitude cost increase [40, 54].

Secure multi-party computation (MPC). MPC frameworks [31, 65, 85] allow mutually distrusting parties to compute a function over secret inputs without revealing anything beyond the function’s outcome. It might seem natural to encode the auction as an MPC among the bidders but this is impractical when there are many bidders. An alternative is to use a *delegated* MPC setting whereby two parties (publisher and auxiliary server in our setting) run the MPC on behalf of others; bidders could send secret shares of their bids to these two parties. However, this delegated setting lacks integrity: either party is free to supply bogus shares to the MPC to cause the auction’s output to be *undetectably* incorrect. As we show in Section 9.2, addressing this introduces prohibitive costs.

Trusted execution environments (TEEs). Another possibility is to use trusted hardware. Besides side channel [43, 46, 68, 90] and integrity attacks [72, 82], TEEs alone cannot solve this problem. Appendix F discusses this in depth.

3 Addax Overview

Addax is a platform where the exchange’s duties are split among different parties. Figure 1 gives a high-level description. Addax consists of: (i) publishers who run their own SSP and who wish to show ads to fund their services, (ii) the client’s browser, (iii) auxiliary servers who help to run auctions, (iv) bidders (demand-side platforms, advertisers, other exchanges, etc.) who bid on ad slots, and (v) an append-only log (e.g., blockchain, BFT consortium) for persisting an audit trail. We discuss what happens when a user visits a page below, and give details in the sections that follow. We defer a discussion of how bidders join Addax and what information they supply to Section 7 and Appendix E.

Steps ①–②: Client visits a publisher. When a client visits a publisher, it receives the page content, along with a unique *auction id* and a list of valid ad categories that the publisher supports. Addax uses the 392 categories from the Internet Advertising Bureau’s (IAB) contextual taxonomy [10], which include things like “Humor”, “Nutrition”, etc. This metadata is embedded within the header of the page, as in header bidding (§2.1). An Addax-enabled browser, hereafter named “browser”, parses the web page and extracts this metadata.

Step ③: Advertising filtering. Addax adopts a client-based tracking approach inspired by Privad [58], Adnostic [80], and Google’s recent FLoC proposal [89]. Briefly, the browser tracks which sites the user visits over time and generates a profile of the user’s interests, which it stores locally in a SQLite database similar to how cookies are stored. After parsing a page’s ad spot metadata, the browser combines the user’s profile, the ad spot’s categories supplied by the publisher, and disallowed categories previously flagged by the user through a local configuration (e.g., to prevent categories that target children). Based on the refined information, the browser fetches bidders’ details from a bidder database. Addax supports two types of databases: an embedded database supplied by the publisher during Step ②; and a public database where bidder information is maintained on the public log (blockchain). The former is how header bidding works today while the latter option is more decentralized and gives users more agency over the ads they receive. We defer the details to Section 7.

Steps ④–⑥: Private, decentralized, and verifiable auction. The browser invites the k bidders from step ③ to an auction. To do so, it provides them with an *auction id* (unique identifier supplied by the publisher), information about the user, and information to contact the publisher and the auxiliary server. Bidders decide whether to join the auction; if so, they respond to the auxiliary server and publisher with their required materials. The auxiliary server and the publisher collaboratively run the auction and select the auction’s winner, and the auction’s sale price. Asynchronously, and off the critical path, all participants upload to the public append-only log materials needed for public auditing (§5).

Step ⑦: Notify winner and display the ad. After the auction concludes, the publisher and auxiliary server learn the outcome (but nothing else). The publisher notifies the winner and asks it for an ad tag and payment (e.g., a signed IOU). The publisher then forwards the ad tag to the browser so that it can fetch and display the ad on the designated ad spot.

Verification. Auditors can use the information on the public log to verify the auction’s outcome. By default, they only learn whether the auction was correct and the number of bidders that participated. In case that verification fails, Addax helps narrow down which parties were faulty (§5.3).

3.1 Assumptions and threat model

Addax assumes an append-only log (blockchain, BFT, etc.) and an *anytrust* model [88] where either the publisher or the auxiliary server is honest. The parties may act as follows.

Bidders. Bidders who are invited to the auction can submit bogus bids and cryptographic material. We model bidders as *covert adversaries* [36] who can deviate from the protocol arbitrarily as long as their malicious actions cannot be detected. If detected, bidders can incur financial or legal penalties, and can be banned by publishers. Addax assumes at least 2 non-colluding losing bidders (otherwise information about losing

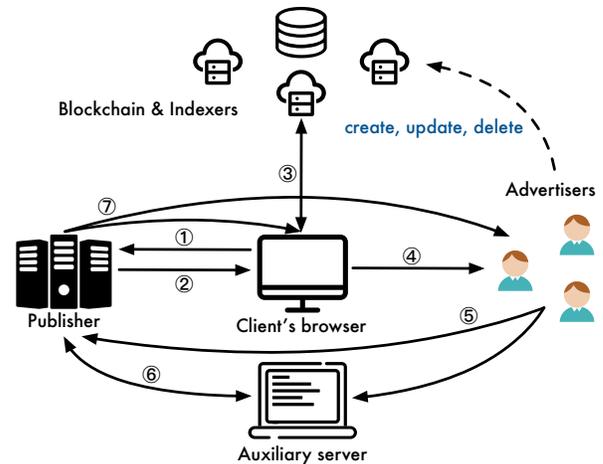

FIGURE 1—In Addax, the exchange’s functionality is divided among the publisher, browser, an auxiliary server and a blockchain.

bids can be inferred from the outcome).

Publishers and auxiliary servers. Publishers may wish to increase their revenue by lying about the auction’s outcome (e.g., forcing the winner to pay a fee higher than the second highest bid), learn the bids of losing bidders, or force users to view certain ads. Auxiliary servers may wish to bias the auction’s result to help particular bidders. We model both parties as covert adversaries since detectable misbehavior can tarnish their reputation or incur legal penalties.

3.2 Security properties

Addax’s auction protocol provides the following properties.

Completeness. If all parties are honest and the auction’s outcome is correct (e.g., the winner is the highest bidder and the sale price is the second highest bid), then Addax’s verification protocol passes with high probability.

Soundness. If a bidder, the publisher, or an auxiliary server misbehaves, Addax’s verification fails with high probability.

Privacy. Addax’s auction and verification hides all bids except the highest bid and the sale price.

4 Private ad auction

This section describes Addax’s private ad auction. We begin by describing our building blocks.

4.1 Affine-aggregatable encodings (AFE)

Prio [51] shows how one can take two or more data values and encode each of them as a vector of λ bits such that adding up the vectors and running a decoding function on the sum is equivalent to computing some boolean function f (e.g., OR, AND, XOR) on the original data values; λ is a parameter that controls the probability of the result being correct. Prio calls this and other similar transformations an *Affine-Aggregatable Encoding* (AFE). Addax uses the “OR” boolean function to compute auctions, so it could use Prio’s AFE. However, we

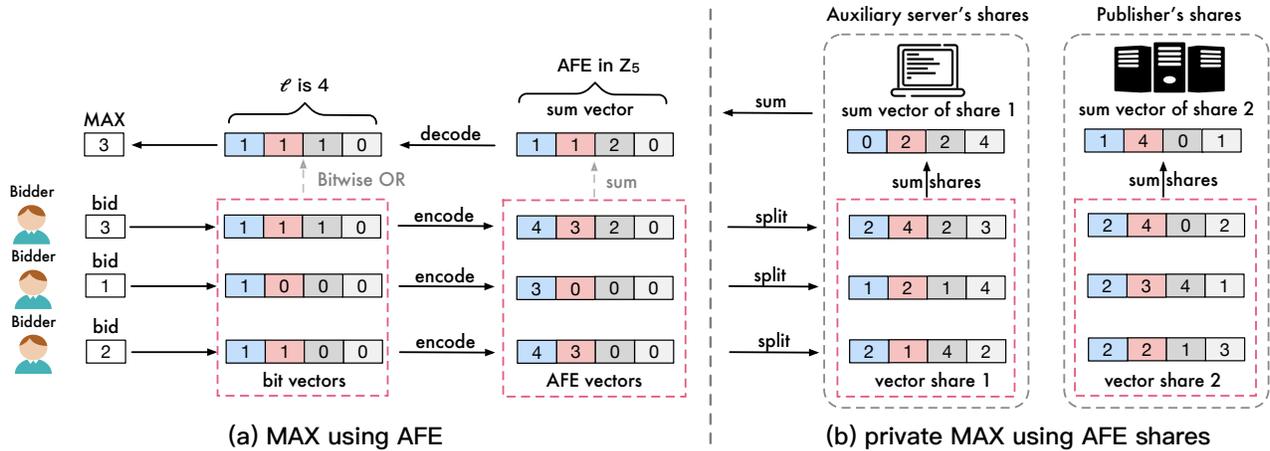

FIGURE 2—Example of (a) the MAX algorithm using AFE, and (b) the private MAX algorithm using AFE shares. In this example, $\ell = 4$ (which affects the range of bids) and we use AFE in \mathbb{Z}_5 (which affects the probability of obtaining the correct result).

depart slightly from Prio by encoding data values into a single element in \mathbb{Z}_p (the set of integers modulo a large prime p) rather than λ -sized bit vectors. This encoding is more expensive than Prio’s (since $\lambda < \log p$), but it allows Addax to add public verifiability, as we discuss in Section 5.1. Below we give our AFE for the “OR” function over bit values.

Encode OR. Given a bit $x \in \{0, 1\}$, its AFE is:

$$\text{Encode-OR}(x) = \begin{cases} 0 \in \mathbb{Z}_p & \text{if } x = 0 \\ \text{a random element} \in \mathbb{Z}_p & \text{if } x = 1 \end{cases}$$

Compute OR. Given a set of n AFE values $\{v_1, \dots, v_n\}$, which encode n bits $\{x_1, \dots, x_n\}$ with the above Encode-OR procedure, one can compute the OR of the n bits as:

$$\mathbf{v} = v_1 + \dots + v_n \in \mathbb{Z}_p$$

Decode OR. Given the sum AFE value \mathbf{v} , one can correctly recover the result of the OR operation over the underlying n bits with probability of at least $1 - 1/p$ as follows.

$$\text{Decode-OR}(\mathbf{v}) = \begin{cases} 0 & \text{if } \mathbf{v} = 0 \\ 1 & \text{otherwise} \end{cases}$$

To see why Decode-OR returns the correct value with probability $1 - 1/p$, we consider two cases. First, when all n input bits are 0. In this case, all AFE values are zeros so \mathbf{v} is guaranteed to be zero; Decode-OR always outputs the correct value of 0. Second, when at least one of the n input bits is 1. In this case, since the value is independent and uniformly random, the probability that the sum in \mathbb{Z}_p is zero is $1/p$.

4.2 Computing the MAX function with AFE

Following the approach in Prio, we show how to extend the above AFE to support MAX, which Addax uses to find the highest bid in an auction. This construction provides neither privacy nor verifiability; we add these later.

Suppose all input values are integers in the range $[0, \ell]$. Each input x is first represented in unary. That is, as a bit vector β of length ℓ ($\beta_1, \beta_2, \dots, \beta_\ell$) where $\beta_i = 1$ if and only if $i \leq x$. Observe that if we perform a bitwise OR on the unary bit vectors of all inputs, the result will be a unary bit vector where the index of the last “1” represents the maximum value across all inputs. This is the idea behind the AFE of MAX.

Encode MAX. Given a value $x \in [0, \ell]$, its AFE is a vector of ℓ values, where each value is an element in \mathbb{Z}_p . The encoding happens in two steps: (1) represent x as a bit vector β of length ℓ in unary format; and (2) for each bit β_i , encode β_i with the Encode-OR of Section 4.1. The result is a vector M with ℓ values, where $M[i]$ is the AFE value of bit β_i .

Compute MAX. Given n AFE vectors $\{M_1, \dots, M_n\}$ that encode the values $\{x_1, \dots, x_n\}$ as above, MAX is computed by adding the n vectors: $\mathbf{M} = M_1 + \dots + M_n$.

Decode MAX. Given the sum vector \mathbf{M} , one can recover the MAX of the underlying n values in two steps. First, use Decode-OR (§4.1) on each of the ℓ entries of \mathbf{M} . The result is a bit vector β of length ℓ in unary format. Second, output the highest index j for which β_j is 1. This value is the correct MAX among the n inputs if Decode-OR outputs the correct OR for all ℓ bits. This event occurs with probability $\geq (1 - 1/p)^\ell$.

Figure 2(a) gives an example of these procedures with three inputs. Below we describe how to add privacy by secret sharing the AFE vectors among multiple parties.

4.3 Private and decentralized MAX

Observe that computing the MAX of n values (x_1, \dots, x_n) using AFE vectors (M_1, \dots, M_n) requires only additions. We can split each vector M_i into two shares (M_i^1 and M_i^2) that add up to the original ($M_i = M_i^1 + M_i^2$) as depicted in Figure 2(b). Each share is made up of uniform random elements in \mathbb{Z}_p , and reveals no information about M_i without the other share.

Suppose that two non-colluding parties, Alice and Bob, are

tasked with computing the MAX of n values given n AFE vector shares. Alice receives $\{M_1^1, \dots, M_n^1\}$ and Bob receives $\{M_1^2, \dots, M_n^2\}$. Each party sums up their n shares to get two sum vector shares: M^1 for Alice and M^2 for Bob. Finally, both parties exchange their sum vector shares. Observe that by adding M^1 and M^2 , the parties can recover the sum vector $\mathbf{M} = M^1 + M^2 = M_1 + \dots + M_n$ as shown in Figure 2(a), and then use Decode-MAX to recover the max value.

4.4 Private and decentralized auction

We use the private MAX of Section 4.3 to compute an auction where the auctioneer’s duty is split between the auxiliary server and the publisher. This protocol provides privacy but not integrity (i.e., malicious actions can lead to an incorrect outcome); we add verifiability in Section 5. A bid is given by the position of the last “1” in a unary vector (e.g., $[1,1,1,0]$ and $[0,0,1,0]$ both represent 3, though the latter is ill-formed). We assume a maximum bid ℓ , and everyone bids within $[0, \ell]$.

Step 1: Set up shared secret. Before the auction starts, the publisher and the auxiliary server commit to a random secret to be used later as an unbiased source of randomness. Concretely, when the client visits the publisher, the publisher contacts the auxiliary server, notifies it of an incoming auction, and supplies to it a commitment to a uniform random secret, $secret_p$. The auxiliary server replies with its own commitment to a uniform random secret, $secret_a$. They keep these secrets hidden until Step 4.

Step 2: Encode and split bids. The browser sends an invitation to selected bidders with the auction’s id. If a bidder wishes to participate, they encode their bid using the Encode-MAX procedure (§4.2), split the resulting vector into two additive shares as discussed in Section 4.3, and generate a fresh signing and verification key pair. The verification key acts as the bidder’s *bidder id* in the auction. The bidder then sends share M^1 to the auxiliary server and share M^2 to the publisher, supplying both with the bidder id. Bidders who fail to submit their shares before a timeout are kept out of the auction.

Step 3: Find the highest bid. Before computing the auction, the auxiliary server sends to the publisher all the bidder ids that it received, the publisher matches them with the ids that it received, and responds to the auxiliary server with the intersection. The publisher and the auxiliary server then use the vector shares of bidders in the intersection in the MAX protocol of Section 4.3. If Decode-MAX produces an invalid unary vector such as $[1,0,1,0]$, the auction is aborted; when parties are honest, abort happens with negligible probability (§4.2). At the end, both parties learn the highest bid, b^* , but nothing else. To avoid parties adapting their sum vector share in response to the other’s sum vector share, parties first exchange commitments of their sum vector share; the honest party aborts if misbehavior is detected.

Lemma 1. Let b_1, \dots, b_j be the bids from j honest bidders, and let M_1, \dots, M_j be the AFE vectors resulting from running

Encode-MAX on the bids. Similarly, let M_{j+1}, \dots, M_{j+k} be AFE vectors that MAX-encode bids from k malicious bidders (these AFE vectors can represent invalid unary vectors like $[1,0,1,0]$). Decode-MAX on the sum of these $j+k$ AFE vectors outputs, with high probability, either an invalid value (invalid unary representation) or a value $\geq \max(b_1, \dots, b_j)$.

Lemma 2. Let M^1 and M^2 be sum vector shares held by the auxiliary server and publisher, respectively. During Decode-MAX, if the auxiliary server uses a different sum vector share M'^1 without having seen M^2 first or the publisher uses a different sum vector share M'^2 without having seen M^1 first, then the output of Decode-MAX is, with high probability, either an invalid value (invalid unary representation) or ℓ .

Appendix A gives proofs for both lemmas. Together they imply that malicious actions by participants lead to the resulting highest bid being invalid or at worst larger than the real highest bid. Either outcome leaks no information about honest losing bidders’ bids to the attacker (our privacy goal). Furthermore, malicious actions are detected by Addax’s verification.

Step 4: Find the winner. The publisher and the auxiliary server find the *winner* (the bidder id of the party who submitted b^*) interactively. First, both parties decommit to the secrets they generated in Step 1, check the decommitment, and XOR the secrets together to obtain $secret = secret_a \oplus secret_p$. Since at least one party is honest, $secret$ is uniformly random and independent of the bidder ids generated by the bidders; the parties use $secret$ as the seed to a pseudorandom generator (PRG). Both parties locally use the PRG to pick the same random bidder w from the set of participating bidder ids, which avoids biasing the auction towards a particular bidder in the case of ties (the PRG is for fairness not for privacy). The auxiliary server sends the b^* -th value of its share of bidder w ’s vector, $M_w^1[b^*]$, to the publisher and the publisher sends $M_w^2[b^*]$. Both parties then locally sum the two shares to obtain $M_w[b^*] = M_w^1[b^*] + M_w^2[b^*]$. Applying Decode-OR to $M_w[b^*]$ yields β_{b^*} , which is the bit of bidder w at position b^* in the unary vector (§4.2). If β_{b^*} is 0, bidder w is not the winner (since its bid must be lower than b^*). Note that learning β_{b^*} reveals no additional information. The publisher and the auxiliary server continue to pick a random bidder id w until the bit β_{b^*} of w is 1 ($n/2$ tries in expectation). In such a case, w is the winner. Finally, the auxiliary server and publisher ask w if its bid is b^* . Bidder w replies only if it receives the same query from both parties. If w ’s bid is not b^* , it sends *abort* to both parties and the auction is aborted. If there are ties (i.e., multiple bidders submitted b^*), this procedure returns a uniformly chosen one. The ids of other tied bidders remain hidden.

Lemma 3. In Step 4, if the auxiliary server sends to the publisher an AFE share that is different than what it received from the candidate winner w (i.e., different from $M_w^1[b^*]$) or the publisher sends to the auxiliary server an AFE share that is different than what it received from w , then the auction aborts

or w is declared the winner with high probability. In the latter case, w is either the real winner or a malicious bidder.

Appendix A proves this lemma. It basically means that a malicious publisher or auxiliary server can only ever make a colluding bidder the winner; they cannot cause a winner (if chosen by the PRG) to lose, nor can they make an honest losing bidder the winner (and hence learn its bid).

Step 5: Compute the sale price. The above four steps are sufficient to compute first-price auctions (the most common type) where the winner is the highest bidder and the sale price is its bid. To support second-price auctions (sometimes used by exchanges), the auxiliary server and publisher subtract the winning bidder’s vector share from the sum vector share (e.g., the auxiliary server subtracts M_w^1 from M^1). They then rerun Step 3 to obtain the second highest bid.

Lemma 4. If either the auxiliary server or the publisher misbehaves in Step 5, or a malicious bidder is declared the winner in Step 4, then the computed sale price is, with high probability, either: (1) the highest bid among all bidders; (2) the second highest bid among all bidders; or (3) ℓ .

Appendix A has the proof of this lemma, which again hides the losing bids (besides the second-highest). Furthermore, any misbehavior is eventually detected during an audit.

5 Adding public verifiability

For an auditor to verify the outcome of an auction, the auditor needs to check that (1) the highest bid b^* selected in Step 3 of the auction is correct; (2) that the bit β_{b^*} of the winning bidder is 1 in Step 4; and (3) that the value computed in Step 5 was set as the auction’s sale price. We start by making the output of AFEs publicly verifiable, and then discuss how an auditor can perform the above checks.

5.1 Verifiable and private AFEs

We make AFEs verifiable with a procedure that takes the result of the AFE computation—the sum vector \mathbf{v} —and commitments to the inputs, and outputs whether \mathbf{v} is correct.

The key idea of our verification procedure is to observe that by their very nature, AFEs encode inputs in such a way that the desired functions (OR, MAX, etc.) can be computed with only additions. Hence, if one uses an *additively homomorphic commitment* scheme on the input AFE values, it is possible to check the result of the AFE computation without learning the inputs by adding the commitments and confirming whether the result is also a valid commitment of the output. We explain this process for the “OR” AFE of Section 4.1.

Encode V-OR. Given a bit $x \in \{0, 1\}$, its verifiable AFE is a tuple v consisting of 2 elements in \mathbb{Z}_p defined as follows. The first element in v is given by Encode-OR (§4.1). The second element in v is a non-zero uniform random element in \mathbb{Z}_p .

Commit V-AFE. Given a V-AFE tuple $v \in \mathbb{Z}_p^2$ encoding bit x with Encode V-OR, we use the Pedersen commitment [74] defined over a multiplicative group \mathbb{G} of prime order p with generators $\{g, h\}$.¹ The commitment is $c = g^{v[0]} \cdot h^{v[1]}$.

This commitment *perfectly hides* the V-AFE tuple (an adversary cannot learn the tuple from the commitment); it *binds* the tuple (a committer cannot claim to have committed to a different tuple) if the discrete log problem is hard in \mathbb{G} . It is also additively homomorphic: given a commitment $c_1 \in \mathbb{G}$ to a tuple $v_1 \in \mathbb{Z}_p^2$ and a commitment $c_2 \in \mathbb{G}$ to a tuple $v_2 \in \mathbb{Z}_p^2$, $c_3 = c_1 \cdot c_2$ is a valid commitment to the tuple $v_1 + v_2$.

Compute and Decode. Given a set of n V-AFE tuples $\{v_1, \dots, v_n\}$, which encode n bits $\{x_1, \dots, x_n\}$ with the above Encode V-OR procedure, compute the OR of the n bits by adding the V-AFE tuples component-wise: $\mathbf{v} = v_1 + \dots + v_n$. Decode V-OR calls Decode-OR on the first element in \mathbf{v} .

Verify V-OR. Given the V-AFE sum tuple \mathbf{v} which encodes the result of the Compute V-OR procedure over n V-AFE tuples $\{v_1, \dots, v_n\}$, and given a set of commitments $\{c_1, \dots, c_n\}$ to these tuples generated with the Commit V-AFE procedure, one can verify \mathbf{v} by checking if $g^{v[0]} \cdot h^{v[1]} \stackrel{?}{=} \prod_{j=1}^n c_j$. Verify V-OR outputs “ok” if the check passes, and “fail” otherwise.

The above approach generalizes to other functions (e.g., MAX) that require more complex encodings (e.g., vectors) since those encodings are just sets of AFE values. For example, a V-AFE vector is simply a vector of V-AFE tuples, and the commitment is a vector of Pedersen commitments—one for each tuple in the V-AFE vector. The approach can also be combined with secret sharing (§4.3) to hide the inputs from non-colluding parties. Specifically, the input providers (e.g., bidders in our case) generate their V-AFE vectors $\{M_1, \dots, M_n\}$ and compute the corresponding commitments $\{c_1, \dots, c_n\}$, which are made available on a public log. Then, the input providers generate secret shares for their V-AFE vectors and give these shares to the computing parties as described in Section 4.3. Finally, the computing parties combine their sum vector shares into the V-AFE vector \mathbf{M} and verify each entry with Verify V-OR and the commitments.

5.2 Verifiable, private, and decentralized auction

We now discuss how to extend the protocol of Section 4.4 with the V-AFE construction of Section 5.1 to obtain verifiability of the auction’s outcome in addition to privacy.

Recall that in Step 2 of the auction protocol (§4.4), a bidder i encodes its bid using Encode-MAX (§4.2) which produces an AFE vector M_i , where each entry in M_i is an Encode-OR (§4.1) of each bit of bidder i ’s unary-formatted bid. In our verifiable auction, the bidder instead uses the Encode V-OR procedure (§5.1), so M_i is made up of ℓ V-AFE tuples. Bidder i also creates, for each entry of M_i , a commitment using Commit

¹As an (insecure) example, the set $\{1, 3, 4, 5, 9\}$ in \mathbb{Z}_{11} forms a multiplicative group with 5 elements (its order is $p = 5$). A generator for this group is 3 since repeated multiplications of 3 with itself generates every element.

V-AFE (§5.1). Let C_i denote the corresponding vector of ℓ commitments for M_i . Bidder i then splits M_i (§4.3), and sends to the auctioneers a collision-resistant hash of C_i and the AFE vector shares (M_i^1 or M_i^2 , depending on the party).

Asynchronously, bidder i uploads to the public log (§7) its bidder id, C_i , and a signature of C_i that validates with the bidder id (recall that bidder ids are verification keys). The other steps of the auction proceed as before. At the end of the auction, the publisher and the auxiliary server upload an *audit trail* to the public log containing: (1) the auction’s outcome, consisting of the bidder id of the winner w , the highest bid b^* , and the auction’s sale price; (2) their share of the sum vector computed in Step 3 and 5 of the auction protocol; (3) the b^* -th entry of the V-AFE vector share of each candidate winner chosen in Step 4 and the seed for the PRG used; and (4) the hashes (to commitments) they received from bidders.

Deferred public verification. After the auction completes, an *auditor* can choose to verify that the auction was done correctly as follows. The auditor accesses the auction’s audit trail from the public log, and verifies that the uploaded hashes match the commitments, and all signatures on the commitments are valid. To verify the highest bid in Step 3, the auditor aggregates the sum vector shares in the audit trail to obtain \mathbf{M} . Then, the auditor computes the highest bid b^* by calling Decode-MAX on \mathbf{M} (§4.2). Finally, the auditor runs, for all $j \in [1, \ell]$, Verify V-OR (§5.1) using as input the j -th entry of \mathbf{M} (acting as the V-AFE sum value), and the j -th entry of every commitment vector submitted by the n bidders (i.e., for all $i \in [1, n]$, $C_i[j]$), as the commitment set. If all checks pass, then Step 3 was correct. The auditor performs the same actions for Step 5 to verify the second highest bid.

To verify Step 4, the auditor checks, for each of the candidate winners x , whether $g^{M_x[b^*][0]} \cdot h^{M_x[b^*][1]} \stackrel{?}{=} C_x[b^*]$. The auditor also checks that the Decode-OR of $M_w[b^*]$ is 1 (i.e., the actual winner’s bit at position b^* is indeed a 1), and the Decode-OR of $M_x[b^*]$ for all other candidate winners x is 0. Then, the auditor uses the PRG and the seed in the audit trail to check that the bidder ids of the set of candidate winners are correct and that w was the last bidder id sampled.

Theorem 1. Addax’s auction protocol with deferred verification achieves completeness, soundness, and privacy.

We give the full definitions and proofs in Appendix B. Note that detection is different from finding the party at fault.

5.3 Assigning blame

An auction may be aborted during the online phase, or deferred verification may fail. In these cases, Addax can narrow down the set of faulty parties. As parties participate in many auctions (recall that exchanges process billions of auctions per day), one could develop detection algorithms that flag those who are present in an unusually high number of aborted or failed auctions. We discuss this in more detail in Appendix D.

6 Optimizations

This section discusses two optimizations. The first adds interaction between the bidders and the auctioneers to dramatically cut costs. The second reduces interaction between the auctioneers, which lowers latency, but leaks the existence of ties.

6.1 Less communication with an interactive MAX

A major drawback of the proposed private auction protocol is that the computation and communication complexity of computing MAX using AFE vectors and their corresponding shares is $O(\ell)$, where ℓ is the highest possible bid (§4.2). Meanwhile, bids range from cents to tens of dollars; a realistic deployment would need $\ell \geq 1,000$, which is too costly. In this section we show how to modify the auction protocol to add r rounds of interaction between bidders and the *auctioneers* (publisher and auxiliary server) in exchange for reducing computation and communication complexity to $O(r \cdot \ell^{1/r})$.

High-level idea. In Figure 2, bidders first represent their bids as a unary bit vector, and then use Encode-OR on each bit to create vector M . This vector is then split into shares M^1 and M^2 . The auctioneers aggregate their shares locally and then exchange their sum vector shares to construct the sum vector \mathbf{M} . This vector is then decoded into a unary bit vector that contains the result of max. Observe that if the bidders were to use Encode-OR only on the last two bits of their bit vectors (the gray and light gray cells), they would obtain the last 2 entries of M , which would then be split into the last two entries of M^1 and M^2 , and would become the last 2 entries of the sum vector shares, and finally of \mathbf{M} . Decoding these two entries of \mathbf{M} results in the last two bits of the final unary bit vector (in the example these bits are 1 and 0). The fact that the last bit is 0 means that the max value must be $< \ell$. The fact that the penultimate bit is 1 means that the max value must be $\geq \ell - 1$. Hence, encoding and sharing only a subset of bidders’ unary bit vectors is enough to compute the max value. Of course, in this example we knew ahead of time which two elements to pick to get a tight upper and lower bound on the max. In our protocol, the auctioneers do r rounds of k -ary search ($k = \ell^{1/r}$) to find the consecutive positions at which the final unary bit vector changes from a 1 to a 0, which yields the max.

Protocol. Using the notation of Section 4.3, each bidder i sends $\lceil \ell^{1/r} \rceil$ entries of the AFE vector shares M^1 and M^2 to the auctioneers in each round. The entries sent in each round are evenly distributed between the current lower and upper bounds on the maximum bid (initially set to 1 and ℓ , respectively). For each of the chosen entries j , the auxiliary server runs the Compute-OR procedure (§4.1) by aggregating the shares it receives from each bidder i : $M^1[j] = \sum_i M_i^1[j]$. Likewise, the publisher computes $M^2[j] = \sum_i M_i^2[j]$. The publisher and the auxiliary server then exchange their sum shares for each entry j , allowing the reconstruction of $\mathbf{M}[j] = M^1[j] + M^2[j]$. Calling Decode-OR (§4.1) on $\mathbf{M}[j]$ returns whether bit β_j in the unary vector is 1 or 0. If β_j is 1, the highest bid $b^* \geq j$. Else, $b^* < j$.

This establishes a new lower and upper bound on b^* with respect to the exchanged entries. After r rounds, the number of entries sent by each bidder to each auctioneer is $\leq r \cdot \lceil \ell^{1/r} \rceil$.

In this protocol, bidders transmit a subset of the entries that they send to the auctioneers in the non-interactive variant, and hence they reveal less information. But there is one downside: bidders or an auctioneer can adaptively send inconsistent shares in response to partial information (e.g., knowledge that the max is in a given range). This could affect the auction’s integrity. Addressing this issue requires extending the protocol with two extra safeguards: (1) an asynchronous step to find the sale price bidder which is similar to Step 4 in Section 4.4; and (2) generating a zero-knowledge proof that the sale price bidder’s AFE vectors are valid without leaking the original AFE vector. Appendix C describes these steps in detail and proves the following two lemmas.

Lemma 5. If either the auxiliary server or the publisher misbehaves, or malicious bidders issue inconsistent AFE shares, the above interactive protocol leaks no more information about losing bidders’ bids than the non-interactive variant.

Lemma 6. If either the auxiliary server or the publisher misbehaves, or malicious bidders issue inconsistent AFE shares, the above protocol (with the extra safeguards) ensures that malicious actions are detected during an audit.

6.2 Lower latency by leaking the existence of ties

Of all the steps in the auction protocol, finding the winner (§4.4, Step 4) is the most expensive since each interaction between the publisher and the auxiliary server occurs over WAN. This step consists of two parts: (1) pick a random candidate winner w , and (2) exchange the b^* -th entry of w ’s AFE vector shares to determine whether w indeed had the highest bid—trying again otherwise. The iterated nature of this algorithm aims to find one of the highest bidders at random (as soon as a highest bidder w is found, the auctioneers halt). One can eliminate this cost if one is willing to leak the number of ties. The protocol is simple: the publisher and auxiliary server exchange the b^* -th entry of the vector shares of *all* bidders. In the absence of ties, after decoding, only one bidder will have a 1 and all others will have a 0. If there are ties, multiple bidders will have a 1 at position b^* , and the auctioneers use the PRG to break the tie. Addax adopts this tradeoff.

We note that the added leakage is actually minor given that in the interactive protocol (Step 4), one learns that it took k tries to find the winner. In an auction with no ties, k would be $n/2$ in expectation, so the value of k already leaks some information about the number of potential ties that may exist.

7 Search and filtering

In Addax, bidders register to participate in auctions by storing their information (e.g., ad categories, domain of their bidding service) on a public tamper-proof log, and auction participants

also use this log to create an audit trail (§5.2). Our implementation uses the Algorand blockchain [3] to maintain the log, though we could have used a BFT consortium or a trusted party (if one exists). Addax also needs a way to *search* the blockchain. This is typically done by downloading the entire blockchain and locally searching for the desired objects. Of course, this is onerous for browsers, as no user would ever maintain a copy of the blockchain just to receive ads. Instead, our implementation uses the Purestake indexer [14]. The downside is that one must trust this indexer. One way to remove this assumption is to use a verifiable search engine for blockchains [69].

Even with the Purestake indexer, querying data is slow: it takes seconds to get a response. Therefore, Addax keeps a copy of the log in *untrusted* cache servers; Addax then queries Purestake asynchronously to verify the cache servers’ results. Querying cache servers takes only a few milliseconds.

In the rest of this section we describe how browsers do local filtering and fetch advertisers’ data. We discuss how browsers interact with the Algorand blockchain in Appendix E.

7.1 Filtering and inviting advertisers

Upon visiting a page with ads and obtaining a list of allowed categories from the publisher, the browser queries the cache server to get bidders who match these categories. The browser caches bidder information and only sends “if-modified-since” requests to the cache server to reduce communication. Borrowing ideas from Privad [58] and Adnostic [80], the browser assigns a preference score for each of the returned bidders. The browser then picks the top k bidders and invites them to join the auction, supplying them with information about the publisher and the user. Depending on the configuration of Addax, the user information can be empty (for generic ads), include a group or topic id (as in FLoC [89] and Topics [16]), or include cookies and demographic information. Since the publisher’s revenue depends on bids, and bidder valuations are based on user information, different publishers can require different levels of information disclosure to access their content. This is similar to how publishers detect ad blocking software and request that users disable it.

8 Implementation

Addax consists of 2.2K lines of C++ and 400 lines of Python and PyTeal [15] for Algorand smart contracts. Addax’s client-side tracking is done outside the browser and interacts with Chrome via native messaging [9]. We use OpenSSL 3.0.0 [12] for basic cryptographic operations (e.g., `BN_rand` as the PRG). Addax’s Pedersen commitment (§5.1) is defined over elliptic curve `secp192r1`, as is the Schnorr signature scheme [78] that bidders use to sign their log entries. Elements in V-AFE vectors are defined over the 192-bit field used in `secp192r1`.

Baselines. To contextualize our contributions, we implement baselines using state-of-the-art homomorphic encryption (HE) and secure two-party computation (2PC) frameworks:

- *CKKS* on *SEAL* [25, 47]: HE for arithmetic operations.
- *TFHE* [49, 50]: HE for boolean operations.
- *MASCOT* on *MP-SPDZ* [65, 66]: Arithmetic 2PC.
- *ag2pc* on *EMP toolkit* [85, 86]: Boolean 2PC.

Homomorphic encryption. The publisher generates cryptographic keys and sends the public key to bidders. Bidders send bids encrypted with the public key to the auxiliary server, who runs the auction over ciphertexts and supplies the result to the publisher for decryption with the secret key. For *SEAL* we implement and measure the *maxId* algorithm by Cheon et al. [48] which is the best known way to find the ciphertext with the max value. While this is a subset of running an auction, this one step is already more expensive than Addax’s full auction protocol. For *TFHE* we implement the whole auction. Neither baseline provides integrity.

Multiparty computation. Advertisers commit to their bids and send them to the publisher and auxiliary server alongside additive shares of their bids and the commitment randomness. Inside the MPC, the auxiliary server and publisher reconstruct the bids and the commitment randomness from their shares, check that the commitments match, and the bids are the committed values, and then run the auction using the bids. For commitments we use $H(rand||bid)$ and assume H is a random oracle. We use hash functions already implemented and optimized for these frameworks (e.g., SHA3, SHA256, MiMC).

9 Evaluation

This section studies the following questions:

1. What are the costs of Addax’s auction for each party?
2. How does Addax’s auction compare with alternatives?
3. What is the resource overhead of deploying Addax over a non-private and unverifiable exchange?
4. How expensive is the verification procedure?

Appendix E.3 discusses the cost of interacting with the log.

Evaluation environment. We run our experiments across AWS data centers to account for Addax’s decentralized nature. The publisher is in US East (Ohio) on a c5.2xlarge instance, the auxiliary server in US West (OR) on a c5.2xlarge instance, and bidders in US West (CA) on c5.12xlarge instances. We use standard Ubuntu 20.04 for all of them. PureStake exposes a REST API and runs on servers in Ontario, CA, and OR.

Method and metrics. Our key metrics are the end-to-end latency, total network communication, and throughput of the auction procedure. This includes the events after the browser fetches the page from the publisher and initiates the auction, but before the browser fetches and displays the ad on the user’s screen. In short, we measure the overhead of Addax over the status quo of using a centralized non-private ad exchange. We report the mean over 20 trials and one standard deviation. *We focus on second-price auctions in this evaluation*, as they are the more complex type of auction. If Addax is used for first-price auctions, the costs are 30% lower: auctions with

	Size (MB)	Generation (ms)	
AFE vector shares	0.48	87.55	
Materials (non-interactive)	0.25	537.9	
Materials (interactive)	1.705	1,802.0	
		Non-interactive	4-round
Communication (MB)	0.48	0.0144	0.0034

FIGURE 3—Size of AFE vector shares and other materials (e.g., commitments), their generation time, and the total communication between a bidder and one auctioneer under different Addax variants.

96 bidders complete within 440 ms, and Addax can sustain a throughput of 360 auctions per second per core.

Parameters. Prior reports [92] suggest that the typical number of bidders (usually demand-side platforms) in an auction is under 30. We experiment with up to 96 bidders, but Addax could handle more with little extra latency since most of the latency comes from round trips between the two servers and is not impacted by the number of bidders. We set $\ell = 10,000$, which supports bid ranges consistent with those observed in practice [93]. This results in a probability of computing the wrong MAX of $\approx 1 - (1 - \frac{1}{2^{192}})^{10,000}$, which is negligible.

Our baseline implementations are generous: we use 13-bits for bids (4/5 of our bid range) and do not measure the time to receive shares or ciphertexts from bidders for any of them.

9.1 Microbenchmarks: Addax’s auction protocol

To answer our first research question we microbenchmark the operations of each of the auction participants.

Bidder’s cost. Before the auction starts, bidders encode their bids, commit to the encodings, and send their shares to the auctioneers. Figure 3 depicts the time required to generate an AFE vector, and the verification materials in both the non-interactive protocol (§5) and the interactive variant (§6.1) using 8 CPU threads. For the latter we include the cost of the safeguards detailed in Appendix C.2. As shown in the figure, generating these materials is more expensive than the time budgeted for an auction. However, AFE vectors are made up of random elements; the only dependence on bids is whether to use a uniform element or a zero (§4.1). As a result, all materials can be precomputed and kept aside. Furthermore, their generation is parallelizable: we get a $5.83\times$ speedup with $6\times$ more cores. We expect bidders to be able to maintain their desired throughput, albeit at a higher cost (\$) than they incur today.

When the auction starts and the bidder decides on its bid, it can draw from the set of pre-generated materials to construct bid-specific AFE vector shares, commitments, and proofs. With pre-generated materials, bidders respond in 10 ms.

Local auction computation. To determine the costs to the auxiliary server and the publisher we run a microbenchmark where both auctioneers run on the same machine, are given all materials (e.g., AFE shares), and compute the auction without the effects of network latency. Figure 4a shows the time for

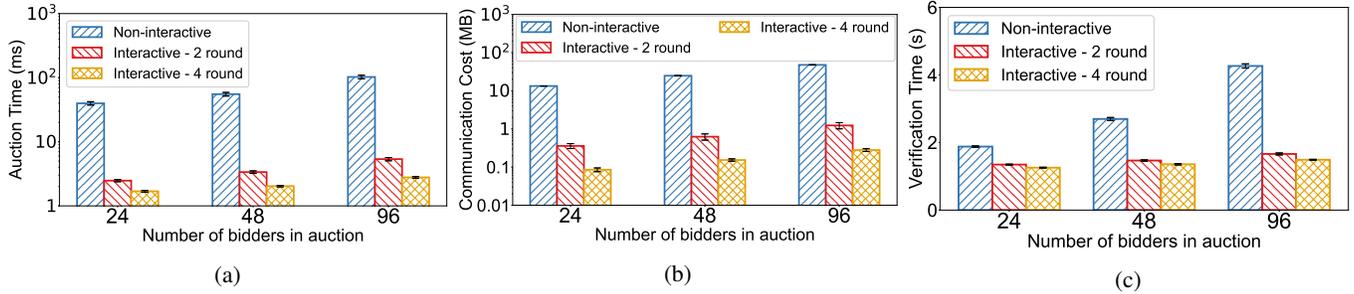

FIGURE 4—Cost of running and verifying an auction across Addax’s variants. Figure (a) depicts the processing time incurred by each auctioneer; (b) depicts the communication costs for each auctioneer; and (c) depicts the costs to an auditor.

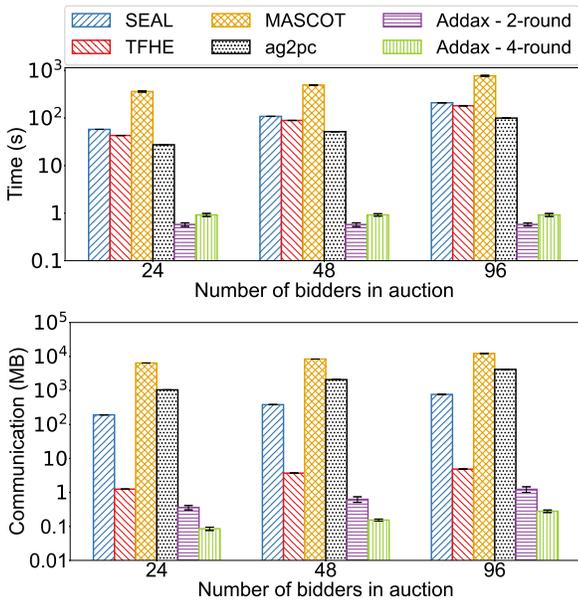

FIGURE 5—End-to-end latency and communication costs for an auction in Addax and several baselines over WAN.

different Addax variants. Compared to the non-interactive protocol, Addax with 4 rounds (§6.1) requires fewer operations since it acts on a tiny subset of the entries of the AFE vector, and reduces computation time for a 96 bidder auction from 102 ms to 2.8 ms. Interactivity also reduces communication costs for effectively the same reason (acts on fewer entries). As we show in Figure 4b, the size of the AFE shares exchanged between bidders and each auctioneer in the non-interactive variant of Addax with 96 bidders is 47.68 MB, whereas it is 0.28 MB with 4-rounds and 1.23 MB with 2-rounds.

9.2 End-to-end performance

The above microbenchmarks give an idea of the computation and communication costs that are expected when running auctions with Addax. However, the metric that actually matters is end-to-end latency over WAN. Figure 5 shows the computation and communication costs of Addax’s end-to-end protocol over a WAN deployment, from the time that the publisher starts the auction, to the time the winner is notified. This figure

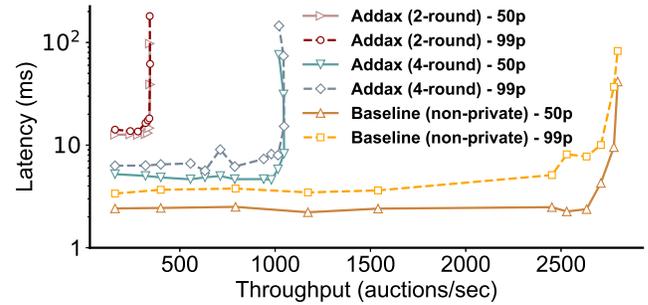

FIGURE 6—Median and 99-percentile response time and server throughput for Addax and a non-private baseline for an auction with 96 bidders. Each data point represents the latency and the throughput achieved at a given load (low and to the right is better).

also shows the baselines described in Section 8.

In terms of auction latency, Addax’s 2-round variant is by far the most efficient option, often by orders of magnitude compared to the baselines. Addax’s 2-round variant beats the 4-round variant due to fewer WAN RTTs at a slight increase in the amount of communication. At 96 bidders, the browser receives an ad tag from Addax in 579 ms; behind the scenes, the auctioneers exchange 1.23 MB of data to compute the auction. Of this time, the servers only spend 5 ms computing; the rest is network latency. Thus, having more bidders will not meaningfully increase the end-to-end latency of Addax.

For comparison, studies [1, 7, 20, 87] show that page loading times today take several *seconds*, so we expect Addax to run auctions asynchronously as the page loads without significantly impacting the user experience.

9.3 Costs over a non-private unverifiable baseline

To understand the additional computational resources required to deploy Addax, we compare its throughput on a c5.2xlarge instance (4-core VM) to a baseline that simply finds the highest and second highest bids (the only non-trivial computation is establishing a TLS session between the browser and the publisher). We run an open-loop workload with varying load and with all inputs already in-memory, so we do not measure network latency. Figure 6 gives the results.

Addax’s 2-round and 4-round variant achieve $8.1\times$ and

	Non-interactive	2-round	4-round
Auctioneers	1.932	0.056	0.025
Bidders	0.250	0.250	0.250
Winner	0.250	0.730	0.730
Sale price bidder	0.250	1.705	1.705

FIGURE 7—Total size (MB) of the audit information that parties must upload to the public log in an auction of 96 bidders.

2.7× lower throughput than the baseline. As Addax requires two servers, this translates to 16.2× and 5.4× more computation resources to maintain the same throughput as the baseline. This suggests that Addax could process the high volume of auctions that exchanges process today while providing integrity and privacy guarantees—albeit at a premium cost.

9.4 Cost of verification

In this section we evaluate the cost for auction participants to supply the necessary materials to leave an audit trail, and for an auditor to validate the correctness of an auction.

Leaving an audit trail. After the auction finishes, participants upload their audit materials (§5.2–§5.3) to Algorand. This takes around 0.8 sec. Figure 7 gives the size of the materials that each party uploads for a 96-bidder auction. In the interactive variants, the winner uploads its full AFE vector, and the sale price bidder uploads its full AFE vector with a random mask and proofs as described in Appendix C.5.

Verification time. Verification requires downloading the materials from Algorand, checking the hash of commitments, and checking the recovered AFE sum vectors and bit encodings (§5.2). Auditors also need to validate that AFE vectors from the winner and sale price bidder are valid (§C.2). Figure 4c depicts the time of verification. In the non-interactive variant, deserializing commitments and verifying the two sum vectors takes most of the time. In contrast, in the interactive variants the expensive step is validating the winner and sale price bidders’ AFE vectors. To verify a 96-bidder auction, the non-interactive variant requires 4.27 sec, while the 2-round and 4-round variants take 1.66 sec and 1.49 sec, respectively.

10 Related work

This section describes other efforts that relate to Addax.

Advertising. There is a rich literature in privacy preserving ads [35, 44, 52, 57–59, 75, 76, 80], but none focuses on private and verifiable auctions. VEX [35] provides verifiability but the auctioneer learns all bids. Privad [58, 59], Adnostic [80], FloC [89], Topics [16], and others [37, 57, 76] reduce the collection of user information, but auctions are still conducted by a party that learns all bids and cannot be audited.

Private and verifiable auctions. In other domains, there is work on private or verifiable auctions. Parkes et al. [73] provide auction integrity but the auctioneer learns all bids, unlike

Addax. Other works [62, 67] provide privacy but not integrity. Finally, there are several multiparty protocols [38, 42] where the bidders jointly compute the auction. This is worse than our MPC baseline in Section 8 in that here bidders actively participate in the protocol rather than merely generating shares. This does not scale to more than a handful of bidders.

11 Discussion

Addax departs from the status quo by introducing accountability to an opaque ecosystem. While this is a disruptive change, there are two things on Addax’s favor. First, the ad-tech industry already uses browsers to kickstart auctions and invite bidders [4] and newer proposals like Google’s FLEDGE [33] push even more functionality to browsers include client-side tracking. Second, Addax is incrementally deployable: an Addax-enabled browser can send an HTTP X-header indicating its support of the protocol, and interested publishers can respond with Addax-based ad spots while continuing to offer traditional ads to other users. Furthermore, we think many missing features can be implemented in Addax.

Content curation. A key role of exchanges is to prevent *malvertising* (the use of ads to spread malware) or ads that can damage the publisher’s brand. On the one hand, content curation is hard even in centralized environments: reports of malicious actors leveraging ad networks to distribute malware are common [8]. On the other hand, since advertisers publish their information on Addax’s public log, one could imagine requiring advertisers to upload their ads as well. Then, just like existing services scan blockchains for anomalous transactions, they can scan Addax’s log to detect and flag malicious ads.

Fraud prevention. Many existing mechanisms to prevent *publisher fraud* (e.g., using clickbots to increase revenue) [79] still work in our setting. For example, bidders can still observe anomalous changes in ad traffic from a publisher, and can perform randomized auditing with *bluff ads* [60] (uninviting ads unlikely to be clicked by real users). Other techniques that collect hard-to-fake signals from a device with the aim of detecting bots [18, 21] could also be used, but more work is needed to port them to our context.

Conversions. Analytics are also critical to the ad ecosystem. Currently, advertisers and publishers rely on third-party cookies to track when a user performs an action after viewing an ad (a “conversion”). A recent proposal [94] shows how this can be done without cookies and without learning the user’s identity; this approach is compatible with Addax’s architecture.

Trust-performance tradeoff. Our description of Addax uses 2 parties but the protocols naturally generalize to k auxiliary servers; if either the publisher or any of the k auxiliary servers is honest, Addax provides its guarantees. Of course, as the number of parties increases the costs also increase. This tradeoff can be taken into account at deployment time.

A Proofs for lemmas

Proof of Lemma 1. Let h be the maximum bid among all honest bidders. The event claimed in Lemma 1 is equivalent to one of two cases: (1) Decode-MAX outputs a valid unary bit vector whose value is larger than or equal to h ; or (2) Decode-MAX outputs an invalid unary bit vector. Consider the opposite event where Decode-MAX outputs a valid unary bit vector whose value is smaller than h . We denote the probability of this event as $\Pr(\text{opposite})$. $\Pr(\text{opposite}) \leq \Pr(\text{Decode-OR outputs } 0 \text{ at position } h) \leq 1/p$. Therefore, the probability that the output of Step 3 is greater than or equal to h or is an invalid unary bit vector is $1 - \Pr(\text{opposite}) \geq 1 - 1/p$. In our construction p is a large prime, and hence $1 - 1/p \approx 1$.

Proof of Lemma 2. Let two parties hold additive shares for a given AFE value that was produced by Encode-OR. Let one of the parties be honest and the other malicious. Without seeing the share held by the honest party, the probability of the malicious party generating a share that results in Decode-OR outputting 0 is $1/p$: the malicious party would have to correctly guess the exact value needed to make the two shares add up to 0, and shares are uniformly random values in \mathbb{Z}_p . Thus, the probability of a malicious party generating AFE shares which lead to Decode-OR outputting 1 is $1 - 1/p$.

We use $\Pr(b)$ to denote the probability that Decode-MAX outputs b , and $\Pr(\text{invalid})$ to denote the probability that Decode-MAX outputs an invalid bit vector. Decode-MAX outputs b means that the decoded bit vector is $\underbrace{[1, \dots, 1, 0, \dots, 0]}_b$.

Thus, $\Pr(b) = (1/p)^{\ell-b} \cdot (1 - 1/p)^b$.

$$\begin{aligned}
\Pr(0) + \dots + \Pr(\ell - 1) &< (1/p)^\ell + \dots + (1/p)^1 \\
&= \frac{1 - (1/p)^{\ell+1}}{1 - \frac{1}{p}} \\
&< \frac{1}{p-1} \\
\Pr(\ell) + \Pr(\text{Invalid}) &= 1 - (\Pr(0) + \dots + \Pr(\ell - 1)) \\
&\geq 1 - \frac{1}{p-1}
\end{aligned}$$

In our construction p is a large prime, so $1 - \frac{1}{p-1} \approx 1$.

Proof of Lemma 3. From Lemma 2 (and its proof), if a malicious party uses a bogus share for one of the bits, Decode-OR outputs 1 with probability $\geq 1 - 1/p$. Thus, if a malicious publisher or auxiliary server ever sends a bogus AFE share, Decode-OR would output 1 with high probability, leading to that candidate w becoming the winner. The auxiliary server and publisher then need to get acknowledgment from bidder w on whether its bid b_w is b^* . If w is honest and $b_w \neq b^*$, the auction aborts. If w is honest and $b_w = b^*$, w is the real winner, as b^* is greater than or equal to the real highest bid among all honest bidders with high probability. If w is malicious, it could abort or can choose to be the winner at its own discretion. If the latter, it must pay the second-highest bid (sale price).

Proof of Lemma 4. We consider two cases: (1) bidder w is honest and the real winner (highest bidder); (2) bidder w is a malicious bidder and not the highest bidder. We denote b as the computed sale price in Step 5.

For case (1), if the two auctioneers do not misbehave and use the correct inputs from bidders to compute Step 5, then b is the real sale price (i.e., the second highest bid) among all bidders. If a malicious auctioneer (auxiliary server or publisher) sends a sum vector share that is not computed correctly from bidders' inputs (i.e., the malicious auctioneer sends a sum vector share that is not $\sum_{i=1}^N M_i^1 - M_w^1$) in Step 5 when computing the sale price, b would be ℓ with high probability (Lemma 2).

For case (2), if the two auctioneers do not misbehave and use the correct inputs from bidders to compute Step 5, Step 5 finds the highest bid among all bidders excluding bidder w . Thus, b equals the highest bid among all bidders. If a malicious auctioneer sends an incorrect sum vector share (not computed correctly from the inputs of all bidders) in Step 5, then b is ℓ with high probability (Lemma 2).

B Proof for Addax's security properties

This section proves that Addax meets its security properties, which include auction completeness, soundness, and privacy.

Completeness. When all parties are honest, Addax's completeness relies on the probability of Decode-MAX being successful when it is used to find the highest bid and the sale price. Further, it relies on the probability of Decode-OR being

successful when finding the id of the winner and the second highest bidder (recall this happens interactively by calling Decode-OR on a particular entry in the AFE sum vector of a candidate winner). In the worst case, Decode-OR might be run on up to n candidate winners ($2n - 1$ times for candidate winners and sale price bidders in the interactive variant). The probability of success is $\geq (1 - 1/p)^{2\ell} \cdot (1 - 1/p)^n$, and is $\geq (1 - 1/p)^{2\ell} \cdot (1 - 1/p)^{2n-1}$ in the interactive variant.

Soundness. There are three scenarios which result in an incorrect outcome: (1) publisher and auxiliary server are honest and some bidders are malicious; (2) either the publisher or the auxiliary server is malicious and all bidders are honest; (3) either the publisher or the auxiliary server is malicious and some bidders are malicious and colluding with the malicious auctioneer.

When bidders are malicious, they can: (A1) encode bids into an invalid unary bit vector (e.g., [1,0,0,1]), then generate AFE shares for such invalid unary bit vector and submit them to the publisher and auxiliary server; (A2) provide inconsistent commitments which are not commitments to the AFE it generates or provide inconsistent hash values of their commitments; (A3) claim to be the winner even when they are not. When one of two computing servers is malicious, it could: (B1) send incorrect sum vectors for the highest bid or sale price; (B2) send incorrect AFE shares when finding the winner or the bidder of the sale price.

All malicious behaviors above except (A1) would lead to failure of verification using commitments with high probability due to Pedersen commitments being computationally binding and the hash function being collision resistant. Specifically, after all bidders send a hash of their commitments, they are bound to their AFE vectors. When the random seed used to find the winner and sale price bidder is fixed, the winner and the sale price bidder (in the interactive variant) are also bound. This effectively fixes the outcome of the auction.

(A1) may still pass verification but the outcome of the auction will still be correct since we do not explicitly check whether inputs from all bidders are valid or not. In the non-interactive auction protocol, Addax can treat the highest index with bit one of the decoded bit vector as the bid of the bidder (e.g., [1,0,1,0] corresponds to bid 3). Thus, an invalid AFE vector does not affect the outcome of the auction. And we only need to check the case of (A1) in the interactive variant. If a bidder who submitted an invalid AFE vector does not become the winner or the bidder of the sale price, then they do not affect the auction's outcome. Thus, auditors need only check whether the winner and bidder of the sale price provided valid AFE vectors. We discuss how to do this in Appendix C.

Privacy. We will prove Addax's privacy guarantees using a simulation proof [70]. A simulation proof is done by first defining an ideal functionality \mathcal{F} . One can think of it as the function that one would run if one had access to a trusted third party. This ideal functionality will provide some output that is avail-

able to everyone, but it will keep all inputs and internal values secret. We want to show that a protocol is as good as the ideal functionality in terms of what information it leaks: anything that an adversary can learn from interacting and observing the output of Addax, the adversary can learn from interacting and observing the output of the ideal functionality. To prove this, we build a simulator *Sim* that interacts with the ideal functionality \mathcal{F} and obtains only the outputs that \mathcal{F} provides without having access to the inputs of the honest parties. If the simulator can produce a *view* (a transcript of all messages sent and received by all parties) that is computationally indistinguishable from the view produced by the execution of the original protocol, we say that the protocol is as secure as the ideal functionality.

To show the security of Addax, we first define a variant that we call Addax-V. This variant differs from the original Addax in that instead of deferring *all* verification to after the protocol finishes, Addax-V verifies the outcome of each computation step (i.e., the highest bid, the winner, and the sale price) immediately after the step completes. If at any step verification fails, the protocol stops without moving forward. Note that we could deploy Addax-V itself, but it would be inefficient; Addax instead moves the verification to the asynchronous step so that it is not part of the critical path of real-time ad auctions.

We will show that Addax-V is as secure as the ideal functionality \mathcal{F} ; then we will prove that the original Addax protocol with deferred verification is as secure as Addax-V.

Below we give Addax-V's protocol. For simplicity, we omit the exchange of hash values between P_1 and P_2 before sending messages, and whenever Decode-MAX outputs an invalid bit vector, it is assumed that P_1 or P_2 aborts. We also assume that the two auctioneers find the winner (or bidder of sale price) sequentially starting from the first bidder and stopping when the winner (or bidder of sale price) is found.

Addax-V's auction protocol

Step 1 (Bidders encode and send AFE shares):

- Each bidder i among the n bidders encodes its bid as a V-AFE vector M_i , splits it into additive shares M_i^1 and M_i^2 , and generates commitments C_i (§5.1).
- Bidder i sends M_i^1 to P_1 and M_i^2 to P_2 , and C_i to both P_1 and P_2 .

Step 2 (Compute highest bid):

- P_1 sets $s_1 = \sum_{i=1}^n M_i^1$; P_2 sets $s_2 = \sum_{i=1}^n M_i^2$.
- P_1 and P_2 exchange s_1 and s_2 , compute $S = s_1 + s_2$, and run Decode-MAX on S to get b^* .
- P_1 and P_2 use commitments to verify whether b^* is correct (§5.2) and abort if it fails.

Step 3 (Find winner):

For $i = 1$ to n , P_1 and P_2 repeat the following:

- P_1 sends $M_i^1[b^*]$ to P_2 , and P_2 sends $M_i^2[b^*]$ to P_1 .

- P_1 and P_2 set $\beta_i = \text{Decode-OR}(M_i^1[b^*] + M_i^2[b^*])$.
- If β_i is 1, then i is the winner (set $w = i$); else continue. If $i = n$ and $\beta_i = 0$, then P_1 and P_2 abort.
- P_1 and P_2 ask bidder w if its bid is b^* . If w says no, P_1 and P_2 abort. Else, P_1 and P_2 use commitments to validate w is correct (§5.2) and abort if it fails.

Step 4 (Compute sale price):

- P_1 sends $m_1 = \sum_{i=1}^n M_i^1 - M_w^1$ to P_2 , and P_2 sends $m_2 = \sum_{i=1}^n M_i^2 - M_w^2$ to P_1 .
- P_1 and P_2 compute $sp = \text{Decode-MAX}(m_1 + m_2)$.
- P_1 and P_2 use commitments to verify whether sp is correct (§5.2) and abort if it fails.

Note that whenever there is a party that sends *abort*, the protocol terminates and all parties are notified. The detailed process of termination works as follows.

If an auctioneer (either P_1 or P_2) wants to send *abort*, it directly sends *abort* to all bidders and another auctioneer. If a bidder wants to send *abort* when asked whether b^* is its bid, it replies “no” and sends *abort* to the two auctioneers. The two auctioneers then forward the *abort* message to all the bidders.

Now we define an *ideal functionality* that captures the privacy properties of Addax-V's protocol. Let $n = h + k$ be the total number of bidders, where the first h bidders are honest (non-adversarial) and the last k bidders are malicious (actual position is irrelevant). The two auctioneers are denoted as P_1 and P_2 . Without loss of generality, we assume an adversary that corrupts P_1 and k bidders. The ideal functionality is:

Ideal functionality \mathcal{F} of Addax-V's auction protocol

Inputs: h bids b_1, \dots, b_h from h honest bidders and a *cheat* message (an integer from 1 to 4) from P_1 .

Outputs: (b^*, w, sp) are computed as:

- $b^* = \max(b_1, \dots, b_h)$.
- w , such that $b_w = b^*$ while $b_1 \neq b^*, \dots, b_{w-1} \neq b^*$ (i.e., w is the first bidder whose bid is b^*).
- $sp = \max(b_1, \dots, b_{w-1}, b_{w+1}, \dots, b_h)$ (i.e., the maximum bid excluding b_w).

\mathcal{F} conditionally outputs the above computed values depending on the value of *cheat*.

- When *cheat* is 1: \mathcal{F} outputs b^* to P_1 and nothing to P_2 .
- When *cheat* is 2: \mathcal{F} outputs (b^*, w) to P_1 and b^* to P_2 .
- When *cheat* is 3: \mathcal{F} outputs (b^*, w, sp) to P_1 and (b^*, w) to P_2 .
- When *cheat* is 4: \mathcal{F} outputs (b^*, w, sp) to both P_1 and P_2 .

Note that the ideal functionality \mathcal{F} also provides an interface

to take an *abort* message as input which allows terminating the execution of a protocol by the simulator.

Now we see how the ideal functionality \mathcal{F} captures the privacy properties of Addax-V's protocol. In the real world execution of Addax-V's protocol, there are five different cases: (1) verification in Step 2 fails; (2) verification in Step 2 passes, verification in Step 3 fails, and P_1 does not learn the real winner; (3) verification in Step 2 passes, verification in Step 3 fails, and P_1 learns the real winner; (4) verification in Step 2 and 3 passes but verification in Step 4 fails; and (5) all verification passes.

When *cheat* message to \mathcal{F} is set to 1, the outputs of \mathcal{F} capture cases (1) and (2) above. And when *cheat* is set to other values, the outputs of \mathcal{F} capture the remaining three cases, respectively. Thus, the outputs of \mathcal{F} capture all different cases of real world execution of Addax-V.

Lemma 7. The Addax-V auction protocol securely implements ideal functionality \mathcal{F} under the assumption that the commitment scheme is binding and hiding and that p is large enough to ensure that Decode-OR and Decode-MAX produce incorrect outputs with negligible probability.

Proof. We now build a simulator *Sim* that interacts with the ideal functionality \mathcal{F} which at most leaks the highest bid b^* , the winning bidder's index w , and the sale price sp . Note that the simulator below simulates all the five different cases (when the protocol aborts in different steps) of real world execution in Addax-V. We use \mathcal{A} to denote the adversary who can corrupt P_1 and k malicious bidders. Note that P_1 and P_2 are symmetric and do the same computation in the protocol. Thus, the proof below also applies to an adversary who corrupts P_2 .

Simulator *Sim*

Step 1 (Generate random V-AFE vectors):

- \mathcal{F} gives its output to *Sim*. This output depends on which of the five cases of the real world execution we are simulating (based on the *cheat* message).
- For the h honest bidders, *Sim* assigns a bid to each of them in such a way that one of the bids is b^* and all other bidders' bids are set as smaller than or equal b^* .
- If w is included in the output of \mathcal{F} , the honest bidder w 's bid is the one that is set to b^* .
- If sp is included in the output of \mathcal{F} , a random honest bidder's bid (excluding w) is set to sp and all other bids are set as smaller than or equal to sp .
- *Sim* encodes the h honest bidders' bids into h V-AFE vectors and generates commitments (§5). It then splits the V-AFE vectors into additive shares, and sends one of the V-AFE shares and the commitment of each honest bidder to \mathcal{A} .
- \mathcal{A} generates V-AFE shares and commitments for the k malicious bidders. It sends one of the V-AFE

shares and the commitment of each of the k malicious bidders to *Sim*.

- At this point, \mathcal{A} has shares M'_1, \dots, M'_n and *Sim* has shares M''_1, \dots, M''_n . They both get commitments C'_1, \dots, C'_n .

Step 2 (Compute highest bid):

- *Sim* computes $s'_2 = \sum_{i=1}^n M''_i$, and sends it to \mathcal{A} .
- \mathcal{A} sends a V-AFE vector s'_1 (s'_1 should be $\sum_{i=1}^n M'_i$ if it follows the protocol, or some vector generated based on its cheating strategy) to *Sim*.
- *Sim* computes $b'^* = \text{Decode-MAX}(s'_1 + s'_2)$.
- If $b'^* \neq b^*$, *Sim* sends *abort*.

Step 3 (Find winner):

For $i = 1$ to n , *Sim* and \mathcal{A} repeat:

- *Sim* sends $M''_i[b'^*]$ to \mathcal{A} , and \mathcal{A} sends v_i (v_i should be $M'_i[b'^*]$ if it follows the protocol, or a vector generated based on its cheating strategy) to *Sim*.
- *Sim* computes $\beta'_i = \text{Decode-OR}(M''_i[b'^*] + v_i)$.
- If $\beta'_i = 1$, then $w' = i$; else continue to the next round. If $i = n$ and $\beta'_i = 0$, *Sim* sends *abort* to \mathcal{A} .
- After finding w' , if bidder w' is malicious, *Sim* asks \mathcal{A} whether the bid of w' is b'^* . If \mathcal{A} replies with no, *Sim* sends *abort*.
- If bidder w' is an honest bidder and $w' \neq w$, *Sim* sends *abort* to \mathcal{A} .
- If $w' \neq w$, *Sim* sends *abort* to \mathcal{A} .

Step 4 (Compute sale price):

- *Sim* sends $m'_2 = \sum_{i=1}^n M''_i - M''_{w'}$ to \mathcal{A} , and \mathcal{A} sends m'_1 (m'_1 should be $\sum_{i=1}^n M'_i - M'_{w'}$ if it follows the protocol, or a V-AFE vector generated based on its cheating strategy) to *Sim*.
- *Sim* computes $sp' = \text{Decode-Max}(m'_1 + m'_2)$.
- If $sp' \neq sp$, *Sim* sends *abort*.

Note that whenever Decode-MAX outputs an invalid bit vector, we assume that *Sim* sends *abort*. When *Sim* wants to send *abort*, it notifies \mathcal{A} and the ideal functionality \mathcal{F} , and \mathcal{F} forwards *abort* and outputs to all honest parties. When \mathcal{A} wants to abort, it sends *abort* to *Sim*, *Sim* forwards *abort* to the ideal functionality \mathcal{F} , and \mathcal{F} forwards *abort* and outputs to all honest parties. In the simulation, as long as each party receives one *abort* message, it terminates. Finally, for simplicity whenever \mathcal{A} and *Sim* exchange messages (e.g., V-AFE shares), *Sim* asks \mathcal{A} to send first.

Analyzing the views. When *cheat* is set to 3 or 4 in the ideal world (ideal functionality), which corresponds to the real world (Addax-V) protocol proceeds to the step of computing the sale price, \mathcal{A} learns the entire view in both worlds. The view of \mathcal{A} in the ideal world is: $\{\sum_{i=1}^n M'_i, w', b'^*, sp', M''_w, M''_1[b'^*], \dots, M''_{w'}[b'^*], M''_1, \dots, M''_n, C'_1, \dots, C'_n\}$. In

the real world (Addax-V), \mathcal{A} 's view includes: $\{\sum_{i=1}^n M_i^2, w, b^*, sp, M_w^2, M_1^2[b^*], \dots, M_w^2[b^*], M_1^1, \dots, M_n^1, C_1, \dots, C_n\}$.

When *cheat* is set to 1, \mathcal{A} 's view in ideal world only includes: $\{\sum_{i=1}^n M_i^2, b^*, M_1^1, \dots, M_n^1, C_1, \dots, C_n\}$. In the real world, the corresponding view of \mathcal{A} includes: $\{\sum_{i=1}^n M_i^2, b^*, M_1^1, \dots, M_n^1, C_1, \dots, C_n\}$.

When *cheat* is set to 2, \mathcal{A} 's view in ideal world only includes: $\{\sum_{i=1}^n M_i^2, w', b^*, M_1^2[b^*], \dots, M_{w'}^2[b^*], M_1^1, \dots, M_n^1, C_1, \dots, C_n\}$. In the real world, the corresponding view of \mathcal{A} includes: $\{\sum_{i=1}^n M_i^2, w, b^*, M_1^2[b^*], \dots, M_w^2[b^*], M_1^1, \dots, M_n^1, C_1, \dots, C_n\}$.

V-AFE shares are uniformly random elements in \mathbb{Z}_p , and commitments to V-AFE vectors are hiding, thus they have the same distribution. For w, b^*, sp and w', b^*, sp' , their distributions are also identical. M_w and $M_{w'}$ are both generated by encoding bid b^* into V-AFE vectors, thus having the same distribution. $\sum_{i=1}^n M_i - M_w$ and $\sum_{i=1}^n M_i - M_{w'}$ are both generated following the requirement that the highest bid among all remaining bidders (excluding bidder w and bidder w') is sp , thus having the same distribution. $M_1[b^*], \dots, M_{w-1}[b^*]$ and $M_1[b^*], \dots, M_{w'-1}[b^*]$ are zeros. These say that in the simulation, bidder 1 to bidder $w' - 1$ are not the winner, and in the real world protocol, bidder 1 to bidder $w - 1$ are not the winner. $M_{w'}[b^*]$ and $M_w[b^*]$ are encodings of bit 1.

As a result of the above exhaustive case analysis, both the real world view and the ideal world view are identically distributed. Consequently, an adversary for Addax-V learns nothing beyond what is revealed by the ideal functionality. \square

Lemma 8. Addax's protocol does not leak more information to the adversary than the variant Addax-V.

Proof. The only difference between the variant and the original protocol is that in the original protocol, the adversary learns the entire view of $\{\sum_{i=1}^n M_i^2, w, M_w^2, M_1^2[b^*], \dots, M_w^2[b^*], M_1^1, \dots, M_n^1, C_1, \dots, C_n\}$, while in Addax-V, it stops after aborts in Step 2 or 3, and only learns a partial view.

In the original protocol, the malicious auctioneer always learns the correct highest bid regardless of how it behaves, as the honest auctioneer always sends the correct sum of AFE shares. From Lemma 3, if an incorrect bidder is claimed as the winner and the protocol does not abort after finding winner, the incorrect winner w' must be malicious. And in the original protocol, the auctioneers would proceed to compute the sale price with the *incorrect* winner w' . In this case, the AFE vector of the malicious bidder, $M_{w'}$, is revealed to the auctioneers and auditors.

In Step 4, when computing the sale price, the adversary receives $\sum_{i=1}^n M_i^2 - M_{w'}^2$ from the honest party P_2 . Adversary knows $M_{w'}^2$ since it's from a malicious bidder, and $\sum_{i=1}^n M_i^2$ is already learned in Step 2 to compute the highest bid. Thus, in the original protocol, when the protocol proceeds to Step 4 with an incorrect winner w' , it can only learn the same amount of information as what it learned in Step 2 (Lemma 4).

Now we can conclude that the original protocol does not leak more information about *honest* bidders' bids compared to the Addax-V variant, where verification is not deferred. \square

C Safeguarding interactive Addax

In the non-interactive protocol, the underlying value of a bit encoding is defined as the rightmost position among all the non-zero values. For instance, both $[1,1,1,0]$ and $[1,0,1,0]$ are the encodings of value 3. The above encoding neither brings issues for privacy nor integrity, but under the interactive variant, this encoding does not work. See an example below.

Suppose a malicious bidder submits an invalid AFE vector which yields an invalid bit vector $[1,1,0,1]$, and all other bidders submit $[1,0,0,0]$. When finding the winner interactively, two auctioneers will first check the first and the third positions. Since the corresponding results are 1 and 0, the next position to be checked should lie in between the first and the third entry, which, in this example, is the second position. As a result, the highest bid found is 2, which means the bidder wins the auction with bid 2.

Therefore, in the interactive variant, Addax checks whether the AFE vectors of the winner and the bidder of the sale price correspond to valid unary bit encodings. To this end, we add the following two extra steps: (1) an asynchronous procedure for finding sale price bidder (we need this to find *whose* bit encoding to validate); and (2) proving that a bidder's AFE vector is valid without leaking its original AFE vector (we need this to avoid leaking the *third-highest bid*). Note that in the interactive variant of the first-price auction, we also need to prove the winner's AFE vector is valid while hiding its original value so the *second-highest bid* is not leaked.

C.1 Asynchronous: find sale price bidder

The invalid encoding as above impacts the outcome of an auction (if it is not aborted) if the malicious bidder is the winner or the bidder of sale price (if the malicious bidder is neither of these, it has no effect). Therefore, Addax requires validating the AFE vector of the sale price bidder. To this end, Addax has to find its bidder id, though not the real identity. We make the tradeoff of leaking such bidder id in order to keep the completion of the auction within hundreds of milliseconds with this extra asynchronous step.

Specifically, the auxiliary server and publisher first find its bidder id by running Step 4 of Section 4.4 on all AFE vectors except the winning one. This is done *after* the auction is complete and off the latency-critical path (hence why we say this is an *asynchronous* step). Verifiers can check, ex post facto, whether the AFE encodings of the second-highest bidder were valid or not. Similarly to Lemma 3, the bidder found in this step is either the real bidder of the sale price or a malicious bidder.

C.2 Checking the validity of a V-AFE vector

Insecure strawman. To check the validity of V-AFE vectors we can let the vectors be revealed in the clear and check the validity by ensuring they are in the right unary bit form, and are consistent with the Pedersen commitments. However, if we do this for the second-highest bidder’s V-AFE vector, this would result in leaking the third-highest bid—subtracting the V-AFE vectors of the winner and sale price bidder from the overall sum vector (\mathbf{M}) reveals the sum of V-AFE vectors of the remaining bidders, thus leaking their maximum bid. We provide the following construction to check validity of the V-AFE vector of the sale price bidder without leakage.

Secure check for AFE validity. In a nutshell, the idea is that in Step 1 of the auction protocol (§ 4.4), bidders additionally generate a V-AFE vector \mathbf{vr} with a random mask \mathbf{r} for their original V-AFE vector \mathbf{v} , such that we can still check the validity of \mathbf{v} by utilizing \mathbf{vr} .

Specifically, the bidder first generates the random mask \mathbf{r} , which is a vector of ℓ random non-zero elements in \mathbb{Z}_p and \mathbf{vr} is the element-wise product between the two $\{r_1 \cdot v_1, \dots, r_\ell \cdot v_\ell\}$. Since $r_i \cdot v_i = 0$ if and only if $v_i = 0$ (for $1 \leq i \leq \ell$), therefore, as long as \mathbf{vr} is decoded to be a valid bit vector, so is \mathbf{v} .

When generating commitments for V-AFE vector \mathbf{v} , a bidder also generates commitments to \mathbf{vr} and a proof that the underlying messages in the above two commitments indeed differ by a multiplicative factor \mathbf{r} . Concretely, the bidder uses a *Sigma protocol* [78], which is type of very simple and efficient zero-knowledge proof (with the *Fiat-Shamir heuristic* [53] it is made into a non-interactive proof) to prove that, for each element cr_i in the commitments of \mathbf{vr} and c_i in commitments of \mathbf{v} , there exists a non-zero r_i which satisfies $cr_i = c_i^{r_i}$. We give details about the above zero-knowledge proof in Appendix C.4. Appendix C.3 proves the binding and hiding properties of the commitment to \mathbf{vr} (which is slightly different than standard Pedersen commitments).

During verification, the sale price bidder reveals only its \mathbf{vr} , and an auditors: (1) verify whether \mathbf{vr} is consistent with its commitment; (2) check that the decoded result of \mathbf{vr} is a valid AFE encoding; (3) verify the zero-knowledge proof with respect to the commitments of \mathbf{v} and \mathbf{vr} .

A key optimization to this process is as follows. Observe that in the interactive variant the two auctioneers only compute the sum vector of partial entries (e.g., they may only use the first 100 entries to compute based on the lower/upper bounds derived). Thus, the sale price bidder need only hide its original AFE vector for those entries (by using the above \mathbf{vr} and zero-knowledge proofs for those entries); the sale price bidder can actually reveal its original AFE encoding for the other entries without need for proofs. The result is that auditors need only check the zero-knowledge proofs for the partial entries used to compute the sale price.

Remark. First, the above approach only hides non-zero values in \mathbf{v} , (i.e., it leaks whether a value in \mathbf{v} is zero or not). This

is because for entries with zero values in the V-AFE vector of sale price bidder, those entries in the sum vector are also zeros, as the sum vector computed in Step 5 (§4.4) decodes to the bid of the sale price bidder. Thus, learning those entries with zero values does not leak the bids of any other bidders.

Second, an adversary may use zeros in the random mask \mathbf{r} to flip non-zero values into zero, which might turn an invalid AFE vector into a valid one. To check that a bidder did not use zero as random mask, for each tuple vr_i in \mathbf{vr} , we check that the second element of vr_i is not zero.

C.3 Commitment to a V-AFE tuple with random mask

Given a V-AFE tuple $v = (a, b)$, its tuple with a random mask r is $vr = (r \cdot a, r \cdot b)$. The commitment is as follows. Let \mathbb{G} be a group of prime order p and let $\{g, h\}$ be two random generators $\{g, h\}$ of \mathbb{G} . The commitment is $g^{r \cdot a} \cdot h^{r \cdot b}$.

The reason why the above is slightly different than standard Pedersen commitments is that the randomness (the exponent of h in Pedersen) is sampled uniformly at random and independent of the exponent of g , whereas here there is a relationship between the exponent of g (which is $r \cdot a$) and the exponent of h (which is $r \cdot b$).

Lemma 9. Let $c = g^{r \cdot a} \cdot h^{r \cdot b}$ be a commitment to $vr = (r \cdot a, r \cdot b)$. Then c perfectly hides vr , and computationally binds vr if the discrete logarithm problem is hard in \mathbb{G} .

Perfect hiding. The commitment perfectly hides both r and a . Let $x \in \mathbb{Z}_p$ be an element such that $g = h^x$ (this is well defined since h is a generator and hence there exists an x such that $h^x = g$). Given r, a, b , for any a' there exist r' and b' such that $g^{r \cdot a} \cdot h^{r \cdot b} = g^{r' \cdot a'} \cdot h^{r' \cdot b'}$. And r', b' satisfy that $r' = \frac{x \cdot r \cdot a + r \cdot b}{x \cdot a' + b'}$. Thus, the commitment hides a . Using a similar proof, we can show that the commitment also hides r .

Binding. We now prove that for a message $m = r \cdot a$, the commitment $g^{r \cdot a} \cdot h^{r \cdot b}$ binds m . Specifically, our goal is to show that, if an adversary can find a different message $m' = r' \cdot a'$ and some randomness b' such that $g^{r \cdot a} \cdot h^{r \cdot b} = g^{r' \cdot a'} \cdot h^{r' \cdot b'}$, then it can break discrete log for the instance $(g, h = g^x)$. Note here we only assume $m' \neq m$, and it does not mean $r' \neq r$ or $a' \neq a$.

Suppose the adversary finds such r', a', b' as above, which implies $r \cdot a + r \cdot b \cdot x = r' \cdot a' + r' \cdot b' \cdot x$ where $h = g^x$ for some x (i.e., $r \cdot a - r' \cdot a' = (r' \cdot b' - r \cdot b) \cdot x$). If $r' \cdot b' = r \cdot b$, then the above equation means $r \cdot a = r' \cdot a'$, which contradicts with our assumption that $m' \neq m$. If $r' \cdot b' \neq r \cdot b$, then the adversary can compute $x = (r' \cdot b' - r \cdot b)^{-1} (r \cdot a - r' \cdot a')$, which means now the adversary solves discrete log for instance $(g, h = g^x)$.

C.4 Zero-knowledge proof of commitment relation

The prover, which is the bidder in our case, wants to prove that there exists a secret element $r \in \mathbb{Z}_p$ such that commitments cr and c satisfy $cr = c^r$. Figure 8 gives the pseudocode for how the prover generates the non-interactive proof π . The prover first samples a random element r' from \mathbb{Z}_p , and computes $u =$

Prover ($c, r, cr = c^r$)	Verifier ($c, cr = c^r, \pi = (u, v, z)$)
$r' \xleftarrow{R} \mathbb{Z}_p$	$v \stackrel{?}{=} H(c, cr, u)$
$u \leftarrow c^{r'}$	$c^z \stackrel{?}{=} u \cdot cr^v$
$v \leftarrow H(c, cr, u)$	
$z \leftarrow r' + v \cdot r$	
output $\pi = (u, v, z)$	

FIGURE 8—Non-interactive zero-knowledge proof of knowledge of secret r using the Fiat-Shamir Heuristic. H is a random oracle and its range is \mathbb{Z}_p (heuristically instantiated with a secure hash function).

$c^{r'}$. The prover then computes $H(c, cr, u)$ as the challenge v . H is modeled as a random oracle but heuristically instantiated with a collision-resistant hash function. Finally, the prover computes $z = r' + v \cdot r$. The prover sends $\pi = (u, v, z)$ to the verifier, and the verifier checks π as described in Figure 8.

C.5 Proofs of lemmas 5 and 6

Below we prove the Lemmas for the interactive variant of Addax which leverages the safeguards described in this section.

Proof of Lemma 5. The non-interactive protocol and interactive variant differ in the following two places: (1) in interactive variant, computing MAX only uses partial entries; (2) in interactive variant, Addax checks validity of winner and sale price bidder’s AFE vectors with additional verification materials (Appendix C.2).

For (1), in the non-interactive protocol, adversary learns the entire sum vector \mathbf{M} , while in the interactive variant, it only learns $r \cdot \lceil \ell^{1/r} \rceil$ entries of \mathbf{M} (§6.1). It therefore leaks no more information about bids than the non-interactive protocol.

For (2), in the interactive protocol, the winner w reveals its full AFE vector, and the sale price bidder needs to provide materials as in Appendix C.2. In the non-interactive protocol, w ’s full AFE vector can already be inferred from Step 3 (which computes \mathbf{M}) and Step 5 (which computes $\mathbf{M} - M_w$), so this leaks no additional information. And additional materials provided in the interactive variant leak no more information of bids than the sale price as detailed in Appendix C.2.

Proof of Lemma 6. Integrity is ensured in the non-interactive protocol as per Theorem 1. The only difference in the interactive variant is that if either the winner or the sale price bidder submits an invalid AFE vector, it can lead to the k -ary search in the interactive protocol to converge to an incorrect value. As we discuss in Appendix C, Addax adds checks to ensure that the AFE vectors of the winner and sale price bidder are both correct, and hence the k -ary search converges to the same value as in the non-interactive protocol.

D Subsets of faulty parties

An auction may be aborted during the online phase, or deferred verification may fail due to a lack of enough materials on the public log (e.g., commitments, sum shares), or due to inconsistent materials such as the bidder sending invalid shares

to auctioneers, or an auctioneer claiming it received one value when a bidder submitted another. Figure 9 gives pseudocode for how Addax narrows down the parties at fault. Below is a text explanation for the pseudocode.

Auction aborts. An auction may abort for two reasons: (1) Decode-MAX outputs an invalid bit vector; or (2) the chosen winner or sale price bidder claims that their bids do not equal the found highest bid or sale price. For case (1), if verification on the decoded sum vectors passes, then it implies that some bidders provided invalid AFE vectors. Addax assigns blame to all participating bidders as potentially malicious. If verification of the sum vectors fails, Addax assigns blame to all bidders, the publisher, and the auxiliary server. For case (2), auditors check the shares revealed by the publisher and auxiliary server, and check whether they are consistent with the corresponding commitments. If they are not consistent, Addax assigns blame to the specific bidder (winner or second highest bidder), publisher, and auxiliary server. If it is consistent, and that entry decoded to 0, Addax assigns blame to the auxiliary server and the publisher; if the entry decoded to 1, Addax assigns blame only to the corresponding bidder.

Lack of materials. Participants may not upload all required materials to the public log, which prevents auditors from verifying the auction. Bidders are bound to their bidder ids which should be uploaded by the publisher and auxiliary server. An auditor can easily tell who did not upload the required materials and assign blame to that set of participants.

Inconsistent views between publisher and auxiliary server. The publisher and auxiliary server may provide an inconsistent view for messages they send and receive. For example, the publisher may claim that it receives sum vector M from the auxiliary server, while the auxiliary server claims that it sends M' to the publisher. In this case, Addax assigns blame to both publisher and auxiliary server. If publisher and auxiliary server upload different views of hash values of certain bidder, Addax assigns blame to the publisher, auxiliary server, and the specific bidder, as the bidder may send inconsistent hash values on purpose.

Inconsistency between hash values and commitments. Auditors may find that hash values of commitments uploaded by publisher and auxiliary server are inconsistent with that uploaded by the bidder. Addax assigns the blame to that particular bidder (since publisher and auxiliary server are assumed to not collude).

Inconsistent AFE sum vectors or bit encodings. Verification on sum vectors or revealed bit encodings to find the winner may fail. If verification on sum vectors fails, Addax assigns blame to publisher, auxiliary server and all bidders. If verification on specific bidder’s bit encoding fails, Addax assigns blame to publisher, auxiliary server and the specific bidder.

Invalid AFE vector. The winner needs to upload its full AFE vector and the bidder of sale price needs to upload its full AFE

42:      blame(bidder)

```

FIGURE 9—Pseudocode of how to assign blames in Addax, see texts for more details.

vector with random mask (§C.2), the commitments and non-interactive zero-knowledge proofs. An auditor needs to check the winner’s AFE vector decodes to be a valid bit vector. Also, an auditor must check whether the AFE vector with random mask is consistent with the supplied commitments, whether it decodes to be a valid bit vector, and verify the proofs. If the check fails, Addax assigns blame to the specific bidder. If the check passes, even if verification on the sum vectors fails, Addax explicitly knows that these two bidders are honest, and can avoid assigning blame to them. Addax will then protect their identities.

D.1 Narrow down faulty bidders when both auctioneers are honest

There are some cases (e.g., line 8 in Figure 9) where Addax can only assign blame to all of the bidders due to the fact that

a malicious auctioneer could collude with bidders. However, if both auctioneers were honest (how one would establish this is orthogonal, though likely hard), Addax can identify the specific bidders who provided inconsistent AFE vectors and commitments. To detect such faulty bidders, each of the two auctioneers computes the commitment over its local V-AFE vector share of a bidder and reveals the commitment. They then verify whether multiplying these two commitments from both auctioneers yields the commitment submitted by the bidder. If not, then Addax can blame the bidder.

E Interacting with the public log

E.1 A brief primer on Algorand

Accounts and Transactions. An account in Algorand consists of a key pair. Transactions include payment, key registration, and asset transferring. Each transaction is created by one account and must be signed with its corresponding secret key.

Smart contracts and application calls. Smart contracts are programs that run on the blockchain with user-defined functionality. Each smart contract is specified with a unique ID. Application calls are transactions used to invoke functions in smart contracts like RPC calls. To interact with a smart contract, an account needs to join the smart contract first. The `opt-in` call allows one account to join one smart contract instance while a `close-out` call allows one account to leave. Addax maintains one smart contract per ad category which includes all advertisers’ information in that category. When one advertiser belongs to multiple categories, it joins all related smart contracts. There is no upper bound on the number of accounts that can join one smart contract in Algorand. Bidders invoke application calls defined in the running smart contract to insert, update, or delete their own information.

Indexer. Indexers are special nodes which provide RESTful interfaces to search for transactions or states of certain apps by answering SQL-like queries. For example, it can answer queries to search for all transactions that happened during a certain period in one smart contract instance with a query like: `SELECT * from transactions WHERE appID = {ID of App} AND after-time = {start} AND before-time = {end};`

E.2 Workflow of a deployed smart contract

There are two kinds of smart contracts in Algorand, stateful ones which have their own storage and stateless ones which do not. Storage in smart contracts consists of several key-value pairs which can be read and written. There is *global storage* which maintains the state of the smart contract instance and *local storage*. All opted-in accounts have their own local storage. All storage can be read by anyone and updated via application calls. Application calls for writing local storage can only be invoked by its owner account.

Addax maintains one stateful smart contract per ad category which includes all advertisers in that category. When one advertiser belongs to multiple categories, it joins all related

```

3: function CREATE(info)
4:   ls.id ← gs.counter
5:   gs.counter ← gs.counter + 1
6:   ls.info ← info
7: function UPDATE(newInfo)
8:   ls.info ← newInfo
9: function DELETE
10:  delete(ls.info, ls.id)

```

FIGURE 10—Pseudocode of smart contract, *gs* is global state, *ls* is local storage of each advertiser. Init function is called when smart contract is initialized. Create, Update, Delete functions are called by advertisers.

smart contracts. Figure 10 shows the functionalities provided by the deployed smart contracts in Addax. Each smart contract is created by an INIT function to initialize an incremental counter starting from zero in global storage. Advertisers can invoke CREATE, UPDATE and DELETE functions. CREATE is the opt-in application call in Addax that opts an advertiser into the smart contract of its category and write information into the invoker’s local storage. Local information of advertisers can include brand name, all categories the advertiser belongs to, domain and port of ad server, protocols and serialization formats supported, etc. The UPDATE call is invoked by opted-in advertisers to update their local information. Advertiser invokes DELETE to clear all information stored in local storage and leave this smart contract instance.

E.3 Costs of interacting with public log

In this section, we answer the question of costs for interacting with the public log and for querying the indexer. We use the PureStake indexer which provides a REST API that one can use to upload and retrieve information from the Algorand blockchain. PureStake has servers all over the world as they contract with Cloudfront. In our experiments, requests to PureStake that originate from AWS US East (Ohio) contact servers in Ontario. Requests that originate from the AWS US West (California) contact servers in California. Requests that originate from AWS US West (Oregon) contact servers in Oregon. PureStake then takes care of broadcasting the transaction to the Algorand peer-to-peer network.

The size of advertisers’ information (§E.1) uploaded to Algorand to participate in Addax is 960 bytes. We experiment with a modest number of advertisers. The reason that we do not have tens of thousands of advertisers is that creating a new advertiser requires creating an Algorand account (new email address, password, account verification, etc.) which is time-consuming. Nevertheless, we semi-automate this painstaking process and generate 1,000 accounts.

Time for advertisers’ operations. In Figure 11, we evaluate the time of advertisers’ operations (invoking CREATE,

UPDATE or DELETE application call) on the Algorand blockchain. We vary whether advertisers belong to one or multiple categories, and also vary the distribution of the number of opted-in advertisers for a given category. Figure 11a shows the results of an advertiser interacting with Algorand where the advertiser belongs to a single category while varying the number of advertisers registered for that category. Figure 11b shows the results when the advertiser belongs to multiple categories, all of which have 500 advertisers registered. Finally, Figure 11c shows the results when the advertiser belongs to six different categories, while each category contains a different number of advertisers. In Scenario 1, each category contains 100 advertisers. In Scenario 2–4, the numbers of advertisers in each category are [50, 100, 100, 100, 100, 150], [50, 50, 50, 100, 150, 200], and [50, 50, 50, 100, 100, 250].

As can be seen, the time for these three operations remains nearly constant when the number of opted-in advertisers in one category grows. It takes about 8–8.5 seconds for invoking one application call to one category (i.e., one smart contract instance). Most of the overhead (about 7 seconds) comes from advertisers waiting for confirmation from the blockchain that this operation has finished successfully. Advertisers can directly invoke application calls and leave without having to wait for confirmation. Indeed, this is what the browser does when uploading its audit materials as described in the Leaving an audit trail paragraph of Section 9.4.

The costs of these operations grow linearly with the number of categories to which an advertiser belongs, regardless of the number of opted-in advertisers in each category.

Time for querying the indexer. We also evaluate the costs for querying the indexer for updates during certain period of time under different scenarios. The time for querying the indexer is also the time to verify the query results from cache servers. Figure 12a shows the time to query indexer for updates of multiple categories. Each category contains 500 advertisers. We simulate 20% updates in each category, namely 100 transactions happened during the period we search for. Figure 12b shows the time to query the indexer for updates of one category with 1,000 advertisers but with different percentages of updates during the period of search.

We find that querying one category generally takes about 0.8 seconds, and this number would grow slightly if the number of total updates (i.e., transactions) grows. This is due to the fact that as the total number of updates grows, the data fetched from the indexer grows as well. Also, the time to query the indexer for updates of multiple categories grows linearly with the number of categories queried. This is because to query N categories, the querier needs to send N requests to the indexer.

F What about TEE-based solutions

In principle, one might be able to design a solution that leverages TEEs to provide privacy and public verifiability for online ad auctions. However, this is not a trivial task, since TEEs:

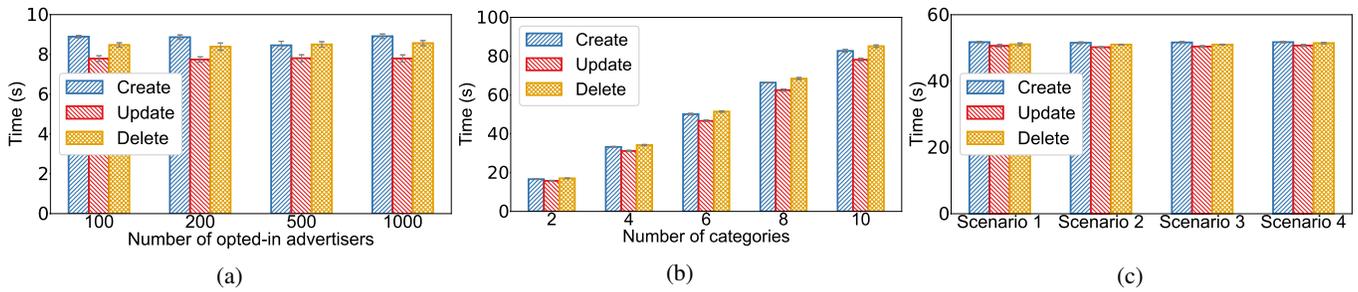

FIGURE 11—Time for advertisers’ operations on the Algorand blockchain under different settings (see text).

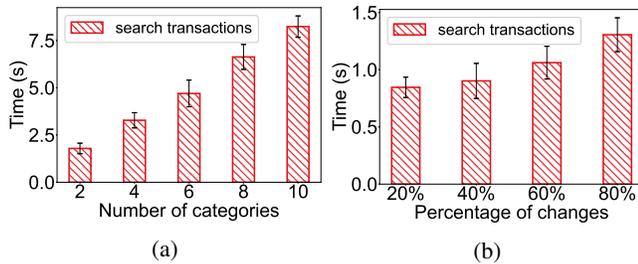

FIGURE 12—Time to query indexer for updates in certain period under different scenarios.

- Require the release of code that runs inside the enclave. This includes the auction protocol, the encryption/decryption code to recover plaintext bids, and signing code for creating a proof that can be publicly audited.
- Require careful auditing or formal verification of all the code running inside the enclave to ensure the exchange operator (who is running the TEE) did not inject backdoors or other vulnerabilities that can obviate the TEE.
- Intel SGX in particular requires trusting an Intel cloud server during remote attestation (cloud services like Azure’s Attestation Service [29] can also be used). In either case, trusting such servers might not be that different of an assumption than the anytrust model in Addax.
- Require additional mechanisms to prevent replay attacks. For example, suppose an operator runs an auction, invites 10 bidders, and passes as input their 10 encrypted bids to TEE (TEE internally has a key to decrypt bids). The TEE then outputs the winner and sale price in the clear. The operator could then run the same auction again but passing only a subset of the bids (these are all valid encrypted bids under a key known to the TEE). The TEE then outputs a winner and sale price in the clear, so the attacker could quickly discover all bids. In contrast, replay is not possible in Addax since the auction is either completed so both auctioneers forward the result to the publisher, or aborted so at least one honest auctioneer forwards an abort result to the publisher (and the publisher displays a generic ad).

G Compatible user privacy features

One of Addax’s goals is to have a flexible enough design to be compatible with various efforts that aim to improve

user-privacy (these efforts are orthogonal but they are also complementary to Addax).

Bidding on groups rather than individuals. User activities are tracked as advertisers need to gather enough information about different users’ browsing and purchasing preferences. The information is used by advertisers to decide how to bid for a user. Addax’s design is compatible with Google’s recent Topics proposal [16] which locally groups users into groups. In particular, Topics enhances the browser to keep track of the user’s interest and assigns to the user a Topic identifier. Once this identifier exist, Addax can send this identifier to the selected bidders instead of sending them more demographic information (§7). An advertiser would then decide how to bid for each group of users without learning information about the individual user for which it is bidding. The obvious caveat here is that the current Topics proposal is not perfect and there have been various privacy concerns voiced [5, 6, 17].

Measuring conversions without learning individual’s data. Measuring the effectiveness of an ad after the auction is essential for advertisers. However, the current way of measuring conversions leaks users’ sensitive information about which websites are visited. There is a recent effort [34] that provides a mechanism to measure the return on investment (ROI) and conversions without requiring the advertiser to learn information about a specific user. At the end of the measurement, advertisers see a differentially private histogram of all users’ conversions, which is sufficient for them to determine the effectiveness of their campaigns. In Addax, after the auction finishes, advertisers could apply this approach to privately gather data about conversions for analysis while being more sensible to users’ privacy concerns. This mechanism is compatible with Addax as it occurs *after* the auction completes.

SPEEDEX: A Scalable, Parallelizable, and Economically Efficient Decentralized EXchange

Abstract

SPEEDEX is a decentralized exchange (DEX) that lets participants securely trade assets without giving any single party undue control over the market. SPEEDEX offers several advantages over prior DEXes. It achieves high throughput—over 200,000 transactions per second on 48-core servers, even with tens of millions of open offers. SPEEDEX runs entirely within a Layer-1 blockchain, and thus achieves its scalability without fragmenting market liquidity between multiple blockchains or rollups. It eliminates internal arbitrage opportunities, so that a direct trade from asset \mathcal{A} to asset \mathcal{B} always receives as good a price as trading through some third asset such as USD. Finally, it prevents certain front-running attacks that would otherwise increase the effective bid-ask spread for small traders. SPEEDEX’s key design insight is its use of an Arrow-Debreu exchange market structure that fixes the valuation of assets for all trades in a given block of transactions. We construct an algorithm, which is both asymptotically efficient and empirically practical, that computes these valuations while exactly preserving a DEX’s financial correctness constraints. Not only does this market structure provide fairness across trades, but it also makes trade operations commutative and hence efficiently parallelizable. SPEEDEX is prototyped but not yet merged within the Stellar blockchain, one of the largest Layer-1 blockchains.

1 Introduction

Digital currencies are moving closer to mainstream adoption. Examples include central bank digital currencies (CBDCs) such as China’s DC/EP [90], commercial efforts [65, 75], and many decentralized-blockchain-based stablecoins such as Tether [104], Dai [9], and USDC [17]. These currencies vary wildly in terms of privacy, openness, smart contract support, performance, regulatory risk, solvency guarantees, compliance features, retail vs. wholesale suitability, and centralization of the underlying ledger. Because of these differences, and because financial stability demands different monetary policy in different countries, we cannot hope for a one-size-fits-all global digital currency. Instead, to realize the full potential of digital currencies (and digital assets in general), we need an ecosystem

where many digital currencies can efficiently interoperate.

Effective interoperability requires an *exchange*: an efficient system for exchanging one digital asset for another. Users post offers to trade one asset for another on the exchange, and then the exchange matches mutually compatible offers together and transfers assets according to the offered terms. For example, one user might offer to trade 110 USD for 100 EUR, and might be matched against another user who previously offered to trade 100 EUR for 110 USD. A typical exchange maintains *orderbooks* of all of the open trade offers.

The ideal digital currency exchange should, at minimum,

- not give any central authority undue power over the global flow of money,
- operate transparently and auditably,
- give every user an equal level of access,
- enable efficient trading between every pair of currencies (make effective use of all available liquidity), and
- support arbitrarily high throughput, without charging significant fees to users.

Scalability is crucial for a piece of financial infrastructure that must last far into the future, as the number of individuals transacting internationally continues to grow. Furthermore, the above feature list is by no means complete; a deployment may want any number of additional features, such as persistent logging, simplified payment verification [89], or integrations with legacy systems, each of which slows down the system’s performance. Scalability, viewed from another angle, enables the system to add features without decreasing overall transaction throughput (at the cost of additional compute hardware).

The gold standard for avoiding centralized control is a *decentralized exchange*, or DEX: a transparent exchange implemented as a deterministic replicated state machine maintained by many different parties. To prevent theft, a DEX requires all transactions to be digitally signed by the relevant asset holders. To prevent cheating, replicas organize history into an append-only blockchain. Replicas agree on blockchain state through a Byzantine-fault tolerant consensus protocol, typically some variant of asynchronous or eventually synchronous Byzantine agreement [46] for private blockchains

or synchronous mining [89] for public ones.

Unfortunately, existing DEX designs cannot meet the last three desiderata.

Equality of Access In existing exchange designs, users with low-latency connections to an exchange server (centralized or not) can spy on trades incoming from other users and *front-run* these trades. For example, a front-runner might spy an incoming sell offer, and in response, send a trade that buys and immediately resells an asset at a higher price [38, 82]. In a blockchain, where a block of trades is either finalized entirely or not at all, this front-running can be made risk-free. More generally, some users form special connections with blockchain operators to gain preferential treatment for their transactions [55]. This special treatment typically takes the form of ordering transactions in a block in a favorable manner. The result is hundreds of millions of dollars siphoned away from users [95].

Effective Use of Liquidity Existing exchange designs are filled with arbitrage opportunities. A user trading from one currency *A* to another *B* might receive a better overall exchange rate by trading through an intermediate *reserve* currency *C*, such as USD. Users must typically choose a single (sequence of) intermediate asset(s), leaving behind arbitrage opportunities with other intermediate assets. This challenge is especially problematic in the blockchain space, where market liquidity is typically fragmented between multiple fiat-pegged tokens.

Computational Scalability DEX infrastructure must also be scalable. The ideal DEX needs to handle as many transactions per second as users around the globe want to send, without limiting transaction rates through high fees. Trading activity growth may outpace Moore’s law, and should not be limited by the rate of increase of single-CPU-core performance. An ideal DEX should handle higher transaction rates simply by using more compute hardware.

Unfortunately, folk wisdom holds that DEXes cannot scale beyond a few thousand transactions per second. Naïve parallel execution would not be replicable across different blockchain nodes. This wisdom has led to many alternative blockchain scaling techniques, such as off-chain trade matching [108], automated market-makers [24], transaction rollup systems [15, 19], and sharded blockchains [6] or side-chains [92]. These approaches either trust a third party to ensure that orders are matched with the best available price, or sacrifice the ability to set traditional limit orders that only sell at or above a certain price (reducing market liquidity). Offchain rollup systems, sharded chains, and side-chains further fragment market liquidity, leading to cross-shard arbitrage and worse exchange rates for traders.

A challenge for on-chain limit-order DEXes is that the order of operations affects their results. Typically, a DEX matches each offer to the reciprocal offer with the best price: e.g., the first offer to buy 1 EUR might consume the only offer priced at 1.09 USD, leaving the second to pay 1.10 USD. Each trade is a read-modify-write operation on a shared orderbook

data structure, so trades must be serialized. This serialization order must be deterministic in a replicated state machine, but naïve parallel execution would make the order of transactions dependent on non-deterministic thread scheduling.

1.1 SPEEDEX: Towards an Ideal DEX

This paper disproves the conventional wisdom about on-chain DEX performance. We present SPEEDEX, a fully on-chain decentralized exchange that meets all of the desiderata outlined above. SPEEDEX gives every user an equal level of access (thereby eliminating a widespread class of risk-free front-running), eliminates internal arbitrage opportunities (thereby making optimal use of liquidity available on the DEX), and is capable of processing over 200,000 transactions per second when deployed on 48-core machines (Figure 3). SPEEDEX is designed to scale further when given more hardware.

Like most blockchains, SPEEDEX processes transactions in blocks—in our case, a block of 500,000 transactions every few seconds. Its fundamental principle is that transactions in a block commute: a block’s result is identical regardless of transaction ordering, which enables efficient parallelization [51].

SPEEDEX’s core innovation is to execute every order at the same exchange rate as every other order in the same block. SPEEDEX processes a block of limit orders as one unified batch, in which, for example, every 1 EUR sold to buy USD receives exactly 1.10 USD in payment. Furthermore, SPEEDEX’s exchange rates present no arbitrage opportunities within the exchange; that is, the exchange rate for trading USD to EUR directly is exactly the exchange rate for USD to YEN multiplied by the rate for YEN to EUR. These exchange rates are unique for any (nonempty) batch of trades. Users interact with SPEEDEX via traditional limit orders, and SPEEDEX executes a limit order if and only if the batch’s exchange rate exceeds the order’s limit price.

This design provides two additional economic advantages. First, the exchange offers liquid trading between every asset pair. Users can directly trade any asset for any other asset, and the market between these assets will be at least as liquid as the most liquid market path through intermediate reserve currencies. Second, SPEEDEX eliminates a class of front-running that is widespread in modern DEXes. No exchange operator or user with a low-latency network connection can buy an asset and resell it at a higher price, within the same block. (Note that this is not every type of front-running; §8 and §10 contrast SPEEDEX’s guarantees with those of other mitigations, and how they can be combined.)

Furthermore, this economic design enables a scalable systems design that is not possible using traditional order-matching semantics. Unlike every other DEX, the operation of SPEEDEX is efficiently parallelized, allowing SPEEDEX to scale to transaction rates far beyond those seen today. Transactions within a block commute with each other precisely because trades all happen at the same shared set of exchange rates. This means that the transaction processing engine has no

need for the sequential read-modify-update loop of traditional orderbook matching engines. Account balances are adjusted using only hardware-level atomics, rather than locking.

1.2 SPEEDEX Overview

SPEEDEX is not a blockchain itself; rather, it is a DEX component that can be integrated into any blockchain. A copy of the SPEEDEX module should run inside every replica of a blockchain using the system. SPEEDEX does not depend on any specific property of a consensus protocol, but automatically benefits from throughput advances in consensus and transaction dissemination (such as [56]). SPEEDEX heavily uses concurrency and benefits from uninterrupted access to CPU caches, and as such is best implemented directly within blockchain node software (instead of as a smart contract).

We implemented SPEEDEX within a custom blockchain using the HotStuff consensus protocol [115]; this implementation provides the measurements in this paper. We created a second implementation as a component of the Stellar blockchain [84], which is considering a Layer-1 SPEEDEX deployment.

Implementing SPEEDEX introduces both theoretical algorithmic challenges and systems design challenges. The core algorithmic challenge is the computation of the batch prices. This problem maps to a well-studied problem in the theoretical literature (equilibrium computation of *Arrow-Debreu Exchange Markets*, §A.1); however, the algorithms in the theoretical literature scale extremely poorly, both asymptotically and empirically, as the number of open limit orders increases.

We show that the market instances which arise in SPEEDEX have additional structure not discussed in the theoretical literature, and use this structure to build a novel algorithm (based on the Tâtonnement process of [53]) that, in practice, efficiently approximates batch clearing prices. We then explicitly correct approximation error with a follow-up linear program.

Our algorithm’s runtime is largely independent of the number of limit orders—each Tâtonnement query has a runtime of $O(\#\text{assets}^2 \cdot \lg(\#\text{offers}))$ and the linear program has size $O(\#\text{assets}^2)$. This gives a crucial algorithmic speedup because in the real world, the number of currencies is much smaller than the number of market participants. (The experiments of §6 and §7 use 50 assets and tens of millions of open offers.)

On the systems design side, to implement this exchange, we design natural commutative transaction semantics and implement data structures designed for concurrent, batched manipulation and for efficiently answering queries about the exchange state from the price computation algorithm.

In recent years, the economics literature has begun discussing the use of batched trading systems in traditional markets to combat front-running and externalities associated with high-frequency trading [30, 41, 43]. This literature focuses only on the case of trading between two assets (where price computation is simple) or where all trades use a single *numeraire* currency [44]. Our contribution to this line of work is to demonstrate the feasibility of a batch trading system

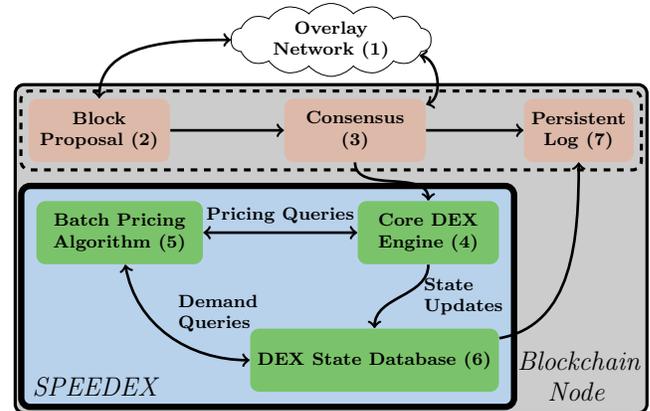

Fig. 1. Architecture of SPEEDEX module (4, 5, 6) inside one blockchain node.

that exchanges many assets and many numeraire currencies simultaneously, thereby expanding the design space of implementable market structures.

2 System Architecture

SPEEDEX is an asset exchange implemented as a replicated state machine in a blockchain architecture (Fig. 1). Assets are issued and traded by *accounts*. Accounts have public signature keys authorized to spend their assets. Signed transactions are multicast on an overlay network (Fig. 1, 1) among block producers. At each round, one or more producers propose candidate blocks extending the blockchain history (Fig. 1, 2). A set of *validator* nodes (generally the same set or a superset of the producers) validates and selects one of the blocks through a consensus mechanism (Fig. 1, 3). SPEEDEX is suitable for integration into a variety of blockchains, but benefits from a consensus layer with relatively low latency (on the order of seconds), such as BA* [71], SCP [84], or HotStuff [115].

The implementation evaluated here uses HotStuff [115], while the Stellar blockchain implementation relies on Stellar’s existing consensus protocol, SCP [88].

Most central banks and digital currency issuers maintain a ledger tracking their currency holdings. SPEEDEX is not intended to replace these primary ledgers. Rather, we expect banks and other regulated financial institutions to issue 1:1 backed token deposits onto a blockchain that runs SPEEDEX and provide interfaces for moving money on and off the exchange. These assets could be digital-native tokens as well; any divisible and fungible asset can integrate with SPEEDEX.

SPEEDEX supports four operations: account creation, offer creation, offer cancellation, and send payment. Offers on SPEEDEX are traditional limit orders. For example, one offer might offer to sell 100 EUR to buy USD, at a price no lower than 0.91 USD/EUR. Offers can trade between any pair of assets, in either direction. Another offer, for example, might offer to sell 100 USD in exchange for EUR, at a price no lower than 1.10 EUR/USD.

What makes SPEEDEX different from existing DEXes is the manner in which it processes new orders. Traditional

exchanges process trades sequentially, implicitly computing a matching between limit orders. SPEEDEX, by contrast, processes trades in batches (typically, one batch would consist of all of the limit orders in one block of the blockchain).

In a blockchain, all of the transactions in a block are appended at the same clock time, so there is no reason *a priori* why a DEX should pick one ordering over another. SPEEDEX, by design, imposes no ordering whatsoever between transactions in a block. Side effects of a transaction are only visible to other transactions in future blocks.

Logically, when the SPEEDEX core engine (Fig. 1, 4) receives a finalized block of trades, it applies all of the trades at exactly the same time and computes an unordered set of state changes, which it passes to its exchange state database (Fig. 1, 6). This database records orderbooks and account balances, and is periodically written to the persistent log (Fig 1, 7).

2.1 SPEEDEX Module Architecture

To implement an exchange that operates replicably where trades in a block are not ordered relative to each other, SPEEDEX requires a set of trading semantics such that operations *commute*.

Traditional exchange semantics are far from commutative: one offer to buy an asset is matched with the lowest priced seller, and the next offer to buy is matched against the second-lowest priced seller, and so on. Hence, every trade can occur at a slightly different exchange rate.

Instead, to make trades commutative, SPEEDEX computes in every block a *valuation* $p_{\mathcal{A}}$ for every asset \mathcal{A} . The units of $p_{\mathcal{A}}$ are meaningless, and can be thought of as a fictional valuation asset that exists only for the duration of a single block. However, valuations imply exchange rates between different assets—every sale of asset \mathcal{A} for asset \mathcal{B} occurs at a price of $p_{\mathcal{A}}/p_{\mathcal{B}}$. Unlike traditional exchanges, SPEEDEX does not explicitly compute a matching between trade offers. Instead, offers trade with a conceptual “*auctioneer*” entity at these exchange rates. Trading becomes commutative because all trades in one asset pair occur at the same price.

The main algorithmic challenge is to compute valuations where the exchange *clears*—i.e., the amount of each asset sold to the auctioneer equals the amount bought from the auctioneer.

When the auctioneer sets exact clearing valuations, an offer trades fully with the auctioneer if its limit price is strictly below the auctioneer’s exchange rate, and not at all if its limit price exceeds the auctioneer’s rate. When the limit price equals the exchange rate, SPEEDEX may execute the offer partially. Note that an exchange is a zero-sum system; as compared to sequential execution, some users may see better prices and some may see worse, but SPEEDEX guarantees that no user’s price is worse than their minimum limit price.

Theorem 1. *Exact clearing valuations always exist. These valuations are unique up to rescaling.*¹

¹And technical conditions (§A.3), e.g. everything clears an empty market.

Theorem 1 is a restatement of a general theorem of Arrow-Debreu exchange market theory [57] (§A.3).

Concretely, whenever the core SPEEDEX engine (Fig 1, 4) receives a newly finalized block, one of its first actions is to query an algorithm that computes clearing valuations (Fig 1, 5). It then uses the output of this algorithm to compute the modifications to the exchange state (Fig 1, 6).

As valuations that clear the market always exist for any set of limit orders, there is no adversarial input that SPEEDEX cannot process. And because these valuations are unique, SPEEDEX operators do not have a strategic choice between different sets of valuations. SPEEDEX’s algorithmic task is to surface information about a fundamental mathematical property of a batch.

Unfortunately, we are not aware of a practical method to compute clearing prices exactly. (The number of bits required to represent exact clearing prices may be extremely large [57], and in a natural extension of the SPEEDEX model [96] the clearing prices are not even rational.) SPEEDEX therefore uses *approximate* clearing prices.

At nonexact clearing prices, the conceptual auctioneer will not have enough of some asset(s) to pay out all offers willing to accept the market price. SPEEDEX addresses this deficit in two ways. First, the auctioneer proportionally reduces the amount it pays out to offers by a small fraction—in other words, it charges a commission. Commissions are common for exchanges, whether decentralized or not, though SPEEDEX does it for market clearing rather than profit reasons. To avoid incentivizing high trading costs, the implementation returns commissions to the asset issuers, and one goal of our price computation algorithm’s design is to make this commission as low as computationally practical. Second, the auctioneer can refrain from filling some marketable offers. Whereas in a perfect Arrow-Debreu exchange market, offers at the market price may be partially filled or not filled, in SPEEDEX the same applies to offers very close to the market price, even if they still beat the market price by a small percentage.

SPEEDEX always rounds trades in favor of the auctioneer. Our implementation burns collected transaction fees and accumulated rounding error (effectively returning them to the issuer by reducing the issuer’s liabilities). The Stellar implementation eliminates the fee and returns the accumulated rounding error to asset issuers.

2.2 Design Properties

Computational Scalability SPEEDEX’s commutative semantics allow effective parallelization of DEX operation. Because transactions within a block are not semantically ordered, DEX state is identical regardless of the order in which transactions are applied. This exact replicability is, of course, required for a *replicated* state machine. The order-independence also means SPEEDEX transactions can be executed in parallel by all available CPU cores despite the fact that thread interleaving is nondeterministic in multicore machines. Almost all coordination occurs via hardware-level

atomics (e.g., atomic add on 64-bit integers) without spinlocks.

SPEEDEX stores balances in accounts, rather than in discrete, unspent coins (often called “UTXOs”). It also supports single-currency payment operations, which are simpler than DEX trading. Hence, SPEEDEX disproves the popular belief [85, 97] that account-based ledgers are not compatible with horizontal scalability.

No risk-free front running Well-placed agents in real-world financial markets can spy on submitted offers, notice a new transaction T , and then submit a transaction T' (that executes before T) that buys an asset and re-sells it to T at a slightly higher price. In some blockchain settings, T' can be done as a single atomic action [55]. However, since every transaction sees the same clearing prices in SPEEDEX, back-to-back buy and sell offers would simply cancel each other out. Relatedly, because every offer sees the same prices, a user who wishes to trade immediately can set a very low minimum price and be all but guaranteed to have their trade executed, but still at the current market price.

Risk-free front-running is one instance of the widely discussed “Miner Extractable Value” (MEV) [55] phenomenon, in which block producers reorder transactions within a block for their own profit (or in exchange for kickbacks). By eliminating the ordering of transactions within a block, SPEEDEX eliminates a large source of MEV. However, this does not eliminate every type of front-running manipulation, such as delaying victim transactions to a future block (see §8).

No (internal) arbitrage and no central reserve currency

An agent selling asset \mathcal{A} in exchange for asset \mathcal{B} will see a price of $p_{\mathcal{A}}/p_{\mathcal{B}}$. An agent trading \mathcal{A} for \mathcal{B} via some intermediary asset \mathcal{C} will see exactly the same price, as $\frac{p_{\mathcal{A}}}{p_{\mathcal{C}}} \cdot \frac{p_{\mathcal{C}}}{p_{\mathcal{B}}} = \frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$. Hence, one can efficiently trade between assets without much pairwise liquidity with no need to search for an optimal path. By contrast, many international payments today go through USD because of a lack of pairwise liquidity. The multitude of USD-pegged stablecoins in modern blockchains further fragments liquidity. Of course, there can still be arbitrage between SPEEDEX and external markets.

3 Commutative DEX Semantics

To propose or execute a block of transactions, the SPEEDEX core engine performs the following three actions.

- 1 For each transaction in the block (in parallel), check signature validity, collect new limit offers, and compute available account balances after funds are committed to offers or transferred between accounts. When proposing a block of transactions, SPEEDEX discards potentially invalid transactions.
- 2 When proposing a block, compute approximate clearing prices and approximation correction metadata.
- 3 Iterate over each offer, making a trade or adding it to the resting orderbooks (based on the prices and metadata).

For transaction processing in step 1 to be commutative, it

must be the case that the step 1 output effects (specifically: create a new account, create a new offer, cancel an existing offer, and send a payment) of one transaction have no influence on the output effects of another transaction. This means that one transaction cannot read some value that was output by another transaction (in the same block), and that whether one transaction succeeds cannot depend on the success of another transaction.

To meet the first requirement, traders include all parameters to their transactions within the transaction itself. The second requirement necessitates precise management of transaction side effects. At most one transaction per block may alter an account’s metadata (such as the account’s public key or existence), and metadata changes take effect only at the end of block execution. Similarly, an offer cannot be created and cancelled in the same block. As payments and trading are the common case, we do not consider these restrictions a serious limitation.

SPEEDEX must also ensure that no account is overdrawn. That is to say, after processing all transactions in a block, the unlocked balance of every account must be nonnegative (where an open offer locks the offered amount of an asset for the duration of its lifetime). Unlike most distributed ledgers, SPEEDEX cannot simply deem the second of two conflicting transactions to fail—after all, transactions have no ordering. Instead, our implementation requires a block proposer to ensure that a block cannot cause overdrafts; every node rejects blocks that violate this property. To generate valid blocks, proposers use a conservative process outlined in §K.6. The design requires passing information from the SPEEDEX database (Fig 1, 6) to the proposal module (Fig 1, 2).

The core remaining technical challenge is the batch price computation (Fig 1, 5).

4 Price Computation

4.1 Requirements

As discussed earlier, in every block, SPEEDEX computes batch clearing prices and executes trades in response to these prices. Every DEX is subject to two fundamental constraints:

- **Asset Conservation** No assets should be created out of nothing. As discussed in §2, offers in SPEEDEX trade with a virtual auctioneer. After a batch of trades, this auctioneer cannot be left with any debt. We do allow the auctioneer to burn some surplus assets as a fee.
- **Respect Offer Parameters** No offer trades at a worse price than its limit price.

Additionally, SPEEDEX should facilitate as much trade volume as possible. (Otherwise, the constraints could be vacuously met by never trading.) Furthermore, price computation must be efficient, as it occurs for each block of trades, every few seconds. Finally, SPEEDEX should minimize the number of offers that trade partially; asset quantities are stored as integer multiples of a minimum unit, so each partial trade risks accumulating a rounding error of up to one unit.

4.2 From Theory To Practice

The problem of computing batch clearing prices is equivalent to the problem of computing equilibria in linear Arrow-Debreu Exchange Markets (§A). Our algorithm is based on the iterative Tâtonnement process from this literature [53].

However, the runtimes of the theoretical algorithms scale very poorly, both asymptotically and empirically. They also output approximate equilibria for notions of approximation that violate the two fundamental constraints above (for example, Definition 1 of [53] permits equilibria to mint new assets and to steal from a user).

We develop a novel algorithm for computing equilibria that runs efficiently in practice (§6) and explicitly ensures that (1) asset amounts are conserved and (2) every offer trades at exactly the market prices, and only if the offer’s limit price is at or below the batch exchange rate. First, Tâtonnement approximates clearing prices (§5). We show that the structure of the types of trades in SPEEDEX lets each iteration run in time logarithmic in the number of open limit offers (via a series of binary searches), giving an algorithm asymptotically faster than that within the theoretical literature.

We then explicitly correct for the approximation error with a linear program (§D). Crucially, the size of this linear program is linear in the number of asset pairs, and has no dependence on the number of open trade offers. The linear program ensures that, no matter what prices Tâtonnement outputs, (1) asset amounts are conserved, and (2) no offer trades if the batch price is less than its limit price.

To be precise, our algorithm outputs the following:

- **Prices:** For each asset \mathcal{A} , SPEEDEX computes an asset valuation $p_{\mathcal{A}}$. One unit of \mathcal{A} trades for $p_{\mathcal{A}}/p_{\mathcal{B}}$ units of \mathcal{B} .
- **Trade Amounts:** For each asset pair $(\mathcal{A}, \mathcal{B})$, SPEEDEX computes an amount $x_{\mathcal{A}, \mathcal{B}}$ of asset \mathcal{A} that is sold for asset \mathcal{B} (again, at exchange rate $p_{\mathcal{A}}/p_{\mathcal{B}}$).

For every asset pair $(\mathcal{A}, \mathcal{B})$, SPEEDEX sorts all of the offers selling \mathcal{A} for \mathcal{B} by their limit prices, and then executes the offers with the lowest limit prices, until it reaches a total amount of \mathcal{A} sold of $x_{\mathcal{A}, \mathcal{B}}$ (tiebreaking by account ID and offer ID).

As a bonus, this method ensures that at most one offer per trading pair executes partially, minimizing rounding error.

5 Price Computation: Tâtonnement

Tâtonnement is an iterative process; starting from an (arbitrary) initial set of prices, it iteratively refines them until the prices reach a stopping criterion.

Each iteration of Tâtonnement starts with a *demand query*. The *demand* of an offer is the net trading of the offer (with the auctioneer) in response to a set of prices, and the demand of a set of offers is the sum of the demands of each offer. Tâtonnement’s goal is to find prices such that the amount of each asset sold to the auctioneer matches the amount bought from it (in other words, the net demand is 0).

Example 1. Suppose that a limit order offers to sell 100 USD

for EUR with a minimum price of 0.8 EUR per USD. If the candidate prices are such that $\alpha = \frac{p_{USD}}{p_{EUR}} > 0.8$, then the limit order would like to trade, and its demand is $(-100 \text{ USD}, 100\alpha \text{ EUR})$. Otherwise, its demand is $(0 \text{ USD}, 0 \text{ EUR})$.

Iterative Price Adjustment. If more units of an asset are demanded from the auctioneer than are supplied to it (a positive net demand, meaning a deficit for the auctioneer), then the auctioneer raises the price of the asset. Otherwise, the auctioneer has a surplus, so it lowers the price of the asset. Implementing this process effectively requires careful numerical normalization in response to differences in prices and trade volumes, which we describe in detail in §C.1.

Tâtonnement repeats this process until the current set of prices is sufficiently close to the market clearing prices (or it hits a timeout). Specifically, Tâtonnement iterates until it has a set of prices such that, if the auctioneer charges a commission of ϵ , then there is a way to execute offers such that:

- 1 The auctioneer has no deficits (assets are conserved)
- 2 No offer executes outside its limit price bound
- 3 Every offer with a limit price more than a $(1 - \mu)$ factor below the auctioneer’s exchange rate executes in full.

The last condition is a formalization of the notion that SPEEDEX should satisfy as many trade requests as possible. Informally, an offer with a limit price equal to the auctioneer’s exchange rate is indifferent between trading and not trading, while one with a limit price far below the auctioneer’s exchange rate strongly prefers trading to not trading.

5.1 Efficient Demand Queries

Implemented naively, Tâtonnement’s demand queries would consist of a loop over every open exchange offer. This is impossibly expensive, even if the loop is massively parallelized. Concretely, one invocation of Tâtonnement can require many thousands of demand queries. Every demand query therefore must return results in at most a few hundred microseconds.

This naïve loop appears to be required for the (more general) problem instances studied in the theoretical literature. However, all of the offers in SPEEDEX are traditional limit orders that sell one asset in exchange for one other asset at some limit price. An offer with a lower limit price always trades if an offer with a higher limit price trades. Therefore, SPEEDEX groups offers by asset pair and sorts offers by their limit prices. We drive the marginal cost of this sorting to near zero by using an offer’s limit price as the leading bits (in big-endian) of the keys in our Merkle tries (§K.5).

SPEEDEX can therefore compute a demand query with a sequence of binary searches (§G). Individual binary searches can run on separate CPU cores. The number of open offers (say, M) on an exchange is vastly higher than the number of assets traded (say, N). Our experiments in §7 trade $N = 50$ assets with $M =$ tens of millions of open offers; the complexity reduction from $O(M)$ to $O(N^2 \lg(M))$ is crucial.

0.003%, and attempted to clear offers with limit prices more than $1 - \mu$ below the market prices, for $\mu = 2^{-10} \approx 0.1\%$ (§B).

Experiment Results. The experiment ran for 500 blocks. Each block created about 25,000 new offers and a few thousand cancellations and payments.

Tâtonnement computed an equilibrium quickly in 350 blocks, and in the remainder, computed prices sufficiently close to equilibrium that the follow-up linear program facilitated the vast majority of possible trading activity.

We measure the quality of an approximate set of prices by the ratio of the “unrealized utility” to the “realized utility.” The utility gained by a trader from selling one unit of an asset is the difference between the market exchange rate and the trader’s limit price, weighted by the valuation of the asset being sold. Note that the units do not matter when comparing relative amounts of “utility.”

In the blocks where Tâtonnement computed an equilibrium quickly, the mean ratio of unrealized to realized utility was 0.71% (max: 4.7%), and in the other blocks, the mean ratio was 0.42% (max: 3.8%).

Recall that Tâtonnement terminates as soon as a stopping criteria is met; roughly, “does the supply of every asset exceed demand,” so one mispriced asset will cause Tâtonnement to keep running. However, every Tâtonnement iteration continues to refine the price of every asset. This is why Tâtonnement actually gives more accurate results in the batches it found challenging. A deployment might enforce a minimum number of Tâtonnement rounds.

Qualitatively, Tâtonnement correctly prices assets with high trading volume and struggles on sparsely traded assets (as might be expected from Fig. 2). Tâtonnement also adjusts its price adjustment rule in response to recent market conditions (§C.1), a tactic which is less effective on volatile assets.

Should this pose a problem in practice, a deployment could choose to vary the approximation parameters by trading pair.

7 Evaluation: Scalability

We ran SPEEDEX on four r6id.24xlarge instances in an Amazon Web Services datacenter. Each instance has 48 physical CPU cores divided over two Intel Xeon Platinum 8375CL chips (32 total cores per socket, 24 of which are allocated to our instances), running at 2.90GHz with hyperthreading enabled, 768GB of memory, 4 1425GB NVMe drives connected in a RAID0 configuration. We use the XFS filesystem [102]. These experiments use the HotStuff consensus protocol [115], and do not include Byzantine replicas or a rotating leader.

Experiment Setup. These experiments simulate trading of 50 assets. Transactions are charged a fee of $\epsilon = 2^{-15}$ (0.003%). We set $\mu = 2^{-10}$, guaranteeing full execution of all orders priced below 0.999 times the auctioneer’s price. The initial database contains 10 million accounts. Tâtonnement never timed out, and typically required fewer than 1,000 iterations.

Transactions are generated according to a synthetic data

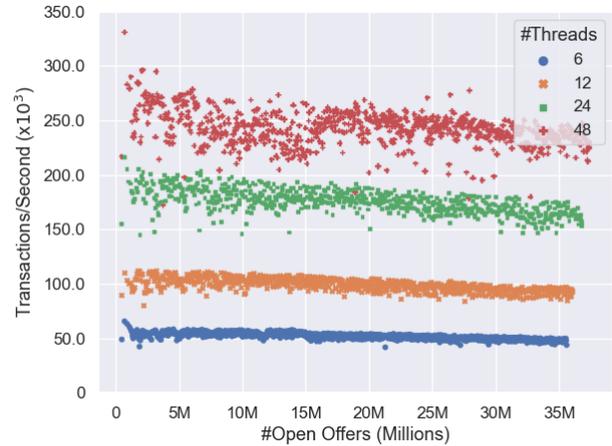

Fig. 3. Transactions per second on SPEEDEX, plotted over the number of open offers.

model—every set of 100,000 transactions is generated as though the assets have some underlying valuations, and users trade a random asset pair using a minimum price close to the underlying valuation ratio. The valuations are modified (via a geometric Brownian motion) after every set. Accounts are drawn from a power-law distribution.

Each set is split into four pieces, with one piece given to each replica. Replicas load these sets sequentially and broadcast each set to every other replica. Each replica adds received transactions to its pool of unconfirmed transactions.

Replicas propose blocks of roughly 500,000 transactions. In these experiments, each block consists of roughly 350,000–400,000 new offers, 100,000–150,000 cancellations, 10,000–20,000 payments, and a small number of new accounts. We generate 5,000 sets of input transactions. Some of these transactions conflict with each other and are discarded by SPEEDEX replicas. Each experiment runs for 700–750 blocks.

Every five blocks, the exchange commits its state to persistent storage in the background (via LMDB [50], §K.2).

Performance Measurements. Fig. 3 plots the end-to-end transaction throughput rate of SPEEDEX as the number of worker threads inside SPEEDEX increases. The x-axis plots the number of open offers on the exchange.

Most importantly, Fig. 3 demonstrates that SPEEDEX can efficiently use its available CPU hardware. The speedup is near-linear, until the number of threads approaches the number of CPU cores—from 6 to 12, $\sim 1.9x$, from 12 to 24, $\sim 1.8x$, and from 24 to 48, $\sim 1.4x$. The thread counts are only for the number of threads directly for SPEEDEX’s critical path, and not for many of the tasks that the implementation must perform in the background, such as logging data to persistent storage (logging the account database uses 16 threads), consensus, and garbage collection, and these threads begin to contend with SPEEDEX as the number of SPEEDEX worker threads increases.

Secondly, Fig. 3 demonstrates the scalability of SPEEDEX with respect to the number of open offers. The number of open

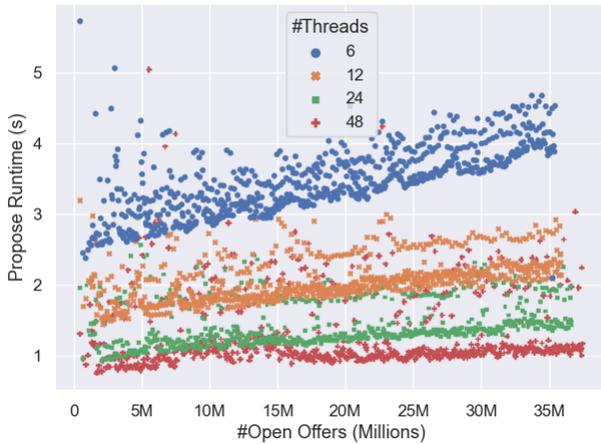

Fig. 4. Time to propose and execute a block, plotted over the number of open offers.

offers SPEEDEEX works with in these experiments is already quite large, but most importantly, as the number of open offers goes from 0 to the 10s of millions, SPEEDEEX’s transaction throughput falls by only $\sim 10\%$. This slowdown is primarily derived from a Tâtonnement optimization (the precomputation outlined in §9.2). Tâtonnement is the one part of SPEEDEEX that cannot be arbitrarily parallelized, so we design our implementation towards making it as fast as possible. An implementation might skip this work in some parameter regimes.

To focus on the performance of SPEEDEEX, Figs. 4 and 5 plot the time to propose and execute blocks, and to validate and execute proposals, respectively, when we disable signature verification (which is trivial to parallelize). First, note that both proposal and validation scale with the number of threads; validation scales better than proposal due to the aforementioned Tâtonnement optimization. Second, note that validating and executing a proposal from another replica is substantially faster than proposing a block; this lets a replica that is somehow delayed catch up.

The runtime variation in Fig. 4 results from the fact that SPEEDEEX without signature verification runs too quickly for our persistent logging implementation.

SPEEDEEX is not a consensus protocol, and these experiments (one consensus invocation every few seconds) do not come close to stressing the consensus throughput of Hotstuff. However, network bandwidth requirements necessarily scale (at least) linearly with transaction rate. Recent work, such as [56, 79, 113], develops consensus protocols that maximally use available network bandwidth. However, integrating SPEEDEEX with any consensus protocol requires understanding the tradeoffs between batch size, transaction rate, and consensus frequency. Fig. 6 plots this tradeoff running SPEEDEEX on the same transaction workload as in Fig. 3. We also ran SPEEDEEX with more replicas on different hardware and observed the same scalability trends, as outlined in §L (albeit with lower overall throughput on weaker hardware).

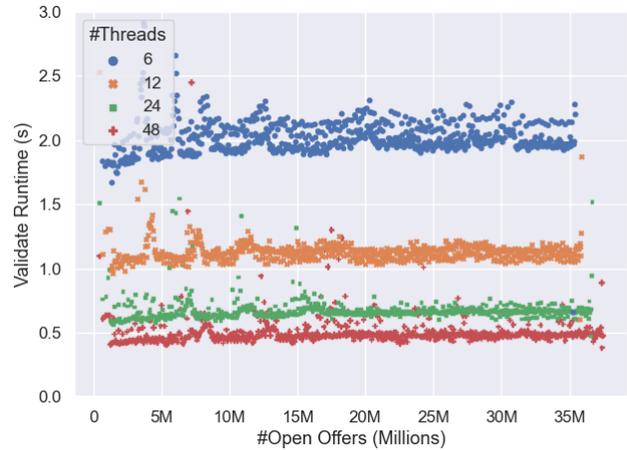

Fig. 5. Time to validate and execute a proposal, plotted over the number of open offers (measurements from one replica).

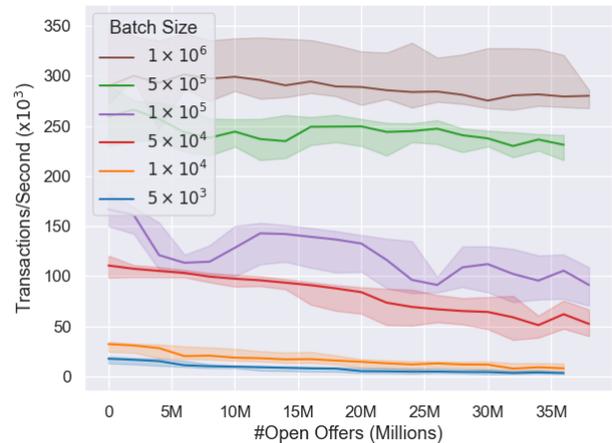

Fig. 6. Median transaction rates, varying block size and number of open offers (grouped into buckets of 2M). Shaded areas plot 10th to 90th percentiles.

Conclusions. To reiterate, SPEEDEEX achieves these transaction rates while operating fully on-chain, with no offchain rollups and no sharding of the exchange’s state. To make SPEEDEEX faster, one can simply give it more CPU cores, without changing the transaction semantics or user interface. This scaling property is unique among existing DEXes.

7.1 Alternative Scaling Techniques

Traditional Exchange Semantics. The core logic of just an exchange system can be implemented extremely efficiently with almost no code. The logic of the constant product market maker UniswapV2 [24], for example, is less than 10 lines of simple arithmetic code. An orderbook-based exchange requires more code but can still be made very fast, as most operations modify only a small number of data objects. We implemented a bare-bones orderbook exchange with two assets using the same data structures as in SPEEDEEX—each transaction checks the orderbook for a matching offer or offers and either makes appropriate transfers or adds the new offer to the

orderbook. These operations are extremely fast when the number of accounts is small; our implementation runs ~ 1.7 million of these transactions per second when there are only 100 accounts. However, every database lookup becomes slower as the number of accounts grows; when there are 10 million accounts in the database (as in the above experiments), throughput falls 8x to $\sim 210,000$ per second. Yet that is before adding all of the other SPEEDEEX features one needs in a real DEX, such as state hashes, transaction fees, structures for simple payment verification [89], replication, or durable logging. The scalability of the full SPEEDEEX implementation lets it surpass that rate even when slowed down by all of these features.

Note that every orderbook operation affects every subsequent transaction—each transaction influences the exchange rate observed in the next transaction—and as such, their execution cannot be parallelized. SPEEDEEX’s design, therefore, enables parallel execution of what would otherwise be a strictly serial workload. To isolate the effect of SPEEDEEX’s parallelizable semantics on its transaction throughput, we therefore turn to a workload that does not touch the DEX at all—one where every transaction is a payment between random accounts.

Optimistic Concurrency Control. A widely explored class of alternative designs for parallel transaction execution use optimistic concurrency control, and of these approaches the most closely related state of the art design appears to be Block-STM [70], which is deployed in Aptos [22]. This approach optimistically executes batches of transactions, retrying after conflicts as necessary.

We therefore design the measurements of Fig. 7 to mirror the experiments in [70]. The “Aptos p2p” transactions in [70] are payments between two random accounts, and consist of 8 reads of 5 writes. Each of our payments consists of two data reads (source account public key and last committed sequence number), two atomic compare_exchange operations (subtract payment and fee from source), an atomic fetch_xor (reserve sequence number), and an atomic fetch_add (add payment to destination)—implemented without atomics, this would be 6 reads and 4 writes. All payments are of the same asset.

Fig. 7 plots the throughput rates of SPEEDEEX on this transaction workload for the parameter settings measured in Block-STM (Figs. 7 and 8, [70]). Note that for large batch sizes, the transaction throughput is largely independent of the number of accounts, even though every transaction in the two account setting contends with every other transaction. Furthermore, unlike Block-STM, SPEEDEEX achieves near-linear scalability on sufficiently large batches. For small batch sizes, a large number of accounts actually slows down SPEEDEEX, largely due to increased sensitivity to cache performance and our system’s NUMA (two socket) architecture on small timescales. We also ran this experiment on a single-socket system (an AWS c5a.16xlarge, as in [70]), and found only negligible impact of the number of accounts on throughput. Fig. 7 was run with hyperthreading disabled, to compare against Block-STM experiments. The rest of our experiments were run with hy-

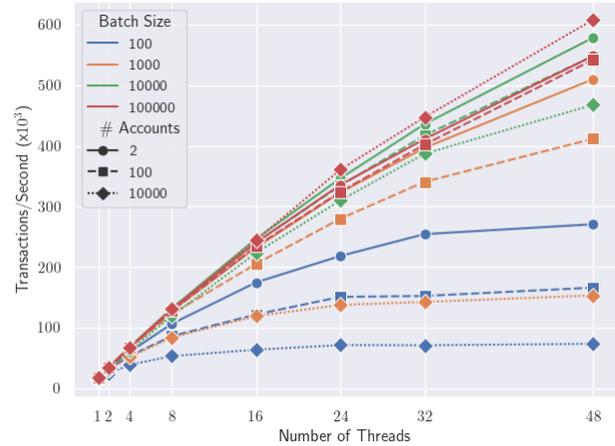

Fig. 7. Throughput of SPEEDEEX on batches of payment transactions with varying thread counts (average of 100 trials).

perthreading enabled (because of the many background tasks in SPEEDEEX); enabling hyperthreading on this payments workload causes a negligible performance degradation for large batches (approximately 1-6%), and a larger (up to 25%) on small batches. As a baseline, §J graphs the performance of Block-STM on these parameter settings on our hardware.

We also ran SPEEDEEX on an only-payments workload with 10 million accounts and 50 assets, and measured a throughput of approximately 375k, 215k, 114k, and 60k transactions per second using 48, 24, 12, and 6 threads, respectively (a 34.8x, 20.0x, and 10.6x, and 5.6x speedup over the single-threaded measurement). We disabled data persistence for these trials—again, the logging off of the critical path contends with SPEEDEEX at these transaction rates, especially for payment transactions that modify two accounts, instead of just one (as when creating an offer). The throughput reached 255k transactions per second with data persistence enabled.

Production Systems. Finally, we ran the Ethereum Virtual Machine (Geth 1.10 [10]) on a workload of UniswapV2 [24] transactions, and measured a rate of ~ 3000 transactions per second (a result in line with other Ethereum benchmarks [107]). The Loopring exchange, built as an L2 rollup on Ethereum, claims a maximum rate of ~ 2000 per second [23], a number calculated from Ethereum’s per-block computation limit [21], which is in turn set based on the real computational cost of serial transaction execution [26, 45, 47, 91]. Precise measurements of the Stellar blockchain’s orderbook DEX suggest that its implementation could handle ~ 4000 DEX trades per second.

8 Design Limitations and Mitigations

Latency. Batch trading inherently introduces latency (between order submission and order execution) not present on traditional, centralized exchanges, simply because an order cannot execute until a batch has been closed and clearing prices have been computed. This latency is already present in a blockchain context (a transaction is not finalized until

the consensus protocol adds it to a block), so in this context, SPEEDEX introduces no additional latency.

The latency may have downstream economic effects. Market-making may be more (or less) profitable operating in a batch system, which could lead to reduced (or increased) liquidity. Budish et al. [30] argue that batch trading (between 2 assets) would reduce costs for market-makers, which could lead to increased liquidity. However, they study a higher batch frequency (approximately once per millisecond); our lower batch frequency is less studied (see Q9, [41]).

Tâtonnement Nondeterminism. The algorithms evaluated in §6 can be viewed as a randomized approximation scheme, which raises the question of whether a malicious operator can manipulate the approximation. Note that the level of approximation error (as defined in §B) can be measured, so non-anonymous node operators can be penalized for malfeasance. When regulation is not possible, Tâtonnement can be made deterministic by fixing a set of control parameters for each instance and choosing the solution with the lowest approximation error (or lowest unrealized utility, §6.2). The Stellar implementation uses a static set of control parameters with one Tâtonnement instance. Node operators could also compete to compute prices accurately, as in [7].

Nondeterministic Overdraft Prevention. SPEEDEX needs to prevent an account from spending more than its balance of an asset. As discussed in §3, our implementation considers a proposal valid only if no account is overdrawn after applying the block. This design complicates pipelining of consensus with execution, gives plausible deniability for delaying transactions, and is incompatible with cryptographic commit-reveal schemes.

Instead, given a fixed block of transactions, an implementation could first compute, for each account, the total amount of each asset debited from the account (before applying any credits). If there is any possibility for an account to overdraw in this block, then this amount must exceed the account's balance. As such, to ensure that no accounts overdraw, the implementation can remove all transactions from accounts that might overdraw. Note that this determination is made on a per-account basis, before any transactions are removed, so this filtering requires only one, parallelizable pass over a block of transactions, adding only minimal overhead (§I). Furthermore, only accounts that attempt to overdraw are affected.

Other commutativity conflicts, such as cancelling an offer twice or reusing a sequence number, can be handled similarly, by removing all transactions involved in these conflicts. Note that using these filtering criteria, removing a transaction cannot cause a commutativity conflict. The Stellar blockchain plans this approach.

Other Types of Front-Running. The set of pending transactions is public in many blockchains. One might estimate the clearing prices in a future batch and arbitrage the batch against low-latency markets. This could lead to negative externalities

(see [42], footnote 1), and could merit combining SPEEDEX with a commit-reveal scheme such as [52, 117]. Such a design requires the deterministic overdraft-prevention scheme above.

Malicious nodes might also delay transactions. An implementation could buffer several blocks of transactions from a consensus protocol into a single SPEEDEX batch. If even one of these consensus blocks is from an honest replica (that does not censor transactions), a user could ensure that their transaction cannot be delayed from one SPEEDEX batch to the next (by broadcasting to all replicas). This requires a consensus protocol with sufficient *chain quality* [67]. Alternatively, some DAG-based protocols [56, 79] simultaneously commit many blocks of transactions from different replicas. Grouping these blocks into one SPEEDEX batch, instead of ordering them arbitrarily, achieves the same censorship-resistance property. These designs would likewise require the deterministic overdraft-prevention scheme.

Linear Program Scalability. The runtime to solve the linear program increases dramatically beyond 60-80 assets, limiting the number of assets in a SPEEDEX batch. A deployment could take advantage of market structure—there are many assets (e.g., stocks) in the real world, but most are linked to one geographic area or economy, and are primarily traded against one currency. We formally show in §E that in this case, the price computation problem can be decomposed between core pricing (i.e., numeraire) currencies and the external stocks. After running Tâtonnement on the core currencies, each stock can be priced on its own relative to a core currency. This lets SPEEDEX support real-world transaction patterns with an arbitrary number of assets and a small number of pricing currencies.

§D points out that setting the commission to 0 simplifies the linear program to one that is more algorithmically tractable at larger numbers of assets. The Stellar implementation uses this version of the linear program.

Limited Trade Types. Trades on SPEEDEX are limited to trades selling a fixed amount of one asset in exchange for as much as possible of another. SPEEDEX does not implement offers to buy a fixed amount of an asset in exchange for as little as possible of another. These buy offers admit the same logarithmic transformation as in §5.1, but make the price computation problem PPAD-hard, a complexity class that is widely conjectured to be algorithmically intractable in polynomial time (§H). One could compute prices using only sell offers and integrate buy offers in the linear programming step.

Ramseyer et al. [96] show how to integrate Constant Function Market Makers (CFMMs) [28] into the exchange market framework and Tâtonnement. The Stellar implementation uses this integration with its own CFMMs.

9 Implementation Details

The standalone SPEEDEX evaluated in §6 and §7 is a blockchain using HotStuff [115] for consensus. A leader node periodically mints a new block from the memory pool and

feeds the block to the consensus algorithm. Other nodes apply the block once it has been finalized by consensus. A faulty node can propose an invalid block. Consensus may finalize invalid blocks, but these blocks have no effect when applied.

The implementation is available open source at <https://github.com/scslab/speedex> and consists of ~30,000 lines of C++20, plus ~5,000 lines for our Hotstuff implementation. It uses Intel's TBB library [8] to manage parallel work scheduling, the GNU Linear Programming Kit [86] to solve linear programs, and LMDB [50] to manage data persistence (for crash recovery).

Exchange state is stored in a collection of custom Merkle-Patricia tries; hashable tries allow nodes to efficiently compare state (to check consensus) and build short state proofs.

The rest of this section outlines additional design choices built into SPEEDEX. Additional design choices in §K. All optimizations (save §9.1) are implemented in the evaluated system.

9.1 Blockchain Integration

An existing blockchain with its own (non-commutative) semantics can integrate SPEEDEX by splitting block execution into phases: first applying all SPEEDEX transactions (in parallel), then applying legacy transactions (sequentially). SPEEDEX's scalability lets a blockchain charge only a marginal fee for transactions (to prevent spam). A proof-of-stake integration of SPEEDEX could penalize faulty proposals.

SPEEDEX's economic properties are desirable independent of scalability. The initial Stellar implementation uses two-phase blocks, but the SPEEDEX phase is still implemented sequentially. As a result, the initial implementation is simple (adding only ~5,000 lines to the server daemon) and the primary benefits are economic. However, because the transaction semantics are commutative, engineers can work to parallelize the implementation as needed, without formally upgrading the protocol (which is more difficult than releasing a software update).

9.2 Caches and Tâtonnement

Tâtonnement spends most of its runtime computing demand queries. Each query consists of several binary searches over large lists, so the runtime depends heavily on memory latency and cache performance. Towards the end of Tâtonnement, when the algorithm takes small steps, one query reads almost exactly the same memory locations as the previous query, so the cache miss rate can be extremely low.

Instead of querying the offer tries directly, we precompute for each asset pair a list that records, for each unique limit price, the amount of an asset offered for sale below the price (§G). Laying out this information contiguously improves cache performance.

We also execute the binary searches of one Tâtonnement iteration in parallel. One primary thread computes price updates and wakes helper threads. However, each round of Tâtonnement is already fast on one thread—with 50 assets and

millions of offers, one round takes 400–600 μ s. To minimize synchronization latency and avoid letting the kernel migrate threads between cores (which harms cache performance), we operate these helper threads via spinlocks and memory fences. In the tests of §6, we see minimal benefit beyond 4–6 helper threads, but this suffices to reduce each query to 50–150 μ s.

Finally, there is a tradeoff between running more copies of Tâtonnement with different settings and the performance of each copy. More concurrent replicas of Tâtonnement mean more cache traffic and higher cache miss rates.

We accelerate the rest of Tâtonnement by exclusively using fixed-point arithmetic (rather than floating-point).

9.3 Batched Trie Design

Our tries use a fan-out of 16 and hash nodes with the 32-byte BLAKE2b cryptographic hash [34]. Both the layout of trie nodes and the work partitioning are designed to avoid having multiple threads writing to the same cache line.

The commutativity of SPEEDEX's semantics opens up an efficient design space for our data structures, which need only materialize state changes once per block. Tries need only recompute a root hash once per block, for example, instead of after every modification. Threads locally build tries recording insertions, which are merged together in one batch operation (which is also parallelizable by redividing local tries into disjoint key ranges). Deletions (when offers are cancelled) are implemented via atomic flags on trie nodes; to enable efficient cleanup of deleted nodes, each node stores the number of deleted nodes beneath it. To facilitate efficient work distribution, each node also stores the number of leaves below it.

SPEEDEX builds in every block an ephemeral trie that logs which accounts are modified; specifically, it maps an account ID to a list of its transactions and to the IDs of transactions from other accounts that modified it. This enables construction of short proofs of account state changes. This trie also uses the same key space as the main account state trie, which lets SPEEDEX use the ephemeral trie to efficiently divide work on the (much larger) account trie.

Memory allocation for an ephemeral trie is trivial because no ephemeral trie node is carried over from one block to the next. Every thread has a local arena, allocation simply increments an arena index, and garbage collection means just setting the index to 0 at the end of a block. We find it to be not a problem if some of the memory in the arena is wasted; we allocate the potential children of an ephemeral trie node contiguously, so a node need only store a 4-byte base pointer (buffer index) and a bitmap denoting the active children. This lets each ephemeral trie node fit in one 64-byte cache line.

10 Related Work

Blockchain Scaling. Our approach is inspired by Clements et al. [51], who improve performance in the Linux kernel through commutative syscall semantics.

Chen et al. [49] speculatively execute Ethereum transactions

to achieve a $\sim 6x$ overall execution speedup. Other approaches to concurrent execution include optimistic concurrency control [70, 111], invalidating conflicting transactions [27], broadcasting conflict resolution information [29, 60], or partitioning transactions into nonconflicting sets [35, 74, 116]. This problem is related to that of building deterministic databases and software transactional memory [94, 105, 110]. Li et al. [83] build a distributed database where some transactions are tagged as commutative.

Empirical work [66, 98] finds that a small number of Ethereum contracts, often token contracts, are historically responsible for the majority of conflicts that limit optimistic execution. A recent Solana [112] outage resulted in part when many transactions conflicted on one orderbook contract [99].

Project Hamilton [85] develops a CBDC payments platform. The authors find that totally-ordered semantics become a performance bottleneck. Unlike SPEEDEX, which stores asset balances in accounts, this system requires the more restrictive unspent transaction output (UTXO) model.

Some systems move transaction execution off-chain, into so-called “Layer-2” networks, each with different capabilities, performance, interoperability, and security tradeoffs [11, 13, 18, 21, 78, 92, 93]. Other blockchains [6, 27, 103, 109, 118] split state into concurrently-running shards, at the cost of complicating cross-shard transactions.

(Distributed) Exchanges. Budish et al. [42, 43] argue that exchanges should process orders in batches to combat automated arbitrage and improve liquidity.

Other defenses against front-running include cryptographic commit-reveal schemes [52, 72, 100, 117] or “fair” ordering schemes that assume a bounded fraction of malicious nodes [40, 80, 119]. The front-running attacks that SPEEDEX prevents are not guaranteed to be blocked in these schemes. For example, a replica might plausibly front-run a transaction in [80] by investing in lower-latency network links between itself and other replicas than other replicas have with each other, and commit-reveal schemes do not prevent statistical front-running (guessing the contents of a transaction).

Some blockchains build limit-order DEX mechanisms natively [2, 16] or as smart contracts [14]. Smart contracts known as Automated Market-Makers (AMMs) [24, 64, 73, 87] facilitate passive market-making on-chain [28].

0x and a past version of Loopring [19, 108] allow settlement on-chain of orders matched off-chain, in pairs or in cycles. StarkEx [15, 36] gives cryptographic tools to prove correctness of an off-chain exchange.

CoWSwap [5, 7] uses mixed-integer programming to clear offers in batches of at most 100 [20]. Solvers compete to produce the best solution. The former Binance DEX [3] computed per-asset-pair prices in each block. The Penumbra DEX uses homomorphic encryption to privately make batch swaps against an AMM, but cannot let users set limit prices [12].

Price Computation. Our algorithms solve instances of the special case of the Arrow-Debreu exchange market [33] where every utility function is linear. Equilibria can be approximated in these markets using combinatorial algorithms such as those of Jain et al. [77] and Devanur et al. [58] and exactly via the ellipsoid method and simultaneous diophantine approximation [76]. Duan et al. [62] construct an exact combinatorial algorithm, which Garg et al. [69] extend to an algorithm with strongly-polynomial running time. Ye [114] gives a path-following interior point method, and Devanur et al. [57] construct a convex program. Codenotti et al. [53, 54] show that a version of the Tâtonnement process [32] converges to an approximate equilibrium in polynomial time. Garg et al. [68] give another algorithm based on demand queries.

11 Conclusion

SPEEDEX is a fully on-chain DEX that can scale to more than 200,000 transactions per second with tens of millions of open trade offers. SPEEDEX requires no offchain rollups and no sharding of the exchange’s logical state. To make SPEEDEX faster, one can simply give SPEEDEX more CPU cores, without changing the semantics or user interface. Because SPEEDEX operates as a logically-unified platform, instead of a sharded network, SPEEDEX does not fragment liquidity between subsystems and creates no cross-rollup arbitrage.

In addition, SPEEDEX displays several independently useful economic properties. It eliminates risk-free front running; any user who can get their offer to the exchange before a block cutoff time can get the same exchange rate as every other trader. SPEEDEX also eliminates internal arbitrage, which disincentivizes network spam. And finally, SPEEDEX eliminates the need to transact through intermediate, reserve currencies, instead allowing a user to trade directly from one asset to any other asset listed on the exchange, with the same or better market liquidity as the trader would have gotten by trading through a series of intermediate currencies.

SPEEDEX is free software, available at <https://github.com/scslab/speedex>.

Appendix A Mathematical Model Underlying SPEEDEX

Mathematically, SPEEDEX relies on a correspondence between a batch of trade offers and an instance of a linear Arrow-Debreu Exchange Market [33]. Specifically, SPEEDEX’s batch computation is equivalent to the problem of computing equilibria in these markets.

A.1 Arrow-Debreu Exchange Markets

The Arrow-Debreu Exchange Market is a classic model from the economics and theoretical computer science literature. Conceptually, there exists in this market a set of independent *agents*, each with its own *endowment* of goods. Each agent has some set of preferences over possible collections of goods. These goods are tradeable on an open market, and agents, all at the same time, make any set of trades that they wish with the market (or *auctioneer*), not directly with each other.

Definition 1 (Arrow-Debreu Exchange Market). *An Arrow-Debreu Exchange Market consists of a set of goods \mathcal{A} and a set of agents $j \in \{1, \dots, M\}$. Every agent j has a utility function $u_j(\cdot)$ and an endowment $e_j \in \mathbb{R}_{\geq 0}^{|\mathcal{A}|}$.*

When the market trades at prices $p \in \mathbb{R}_{\geq 0}^{|\mathcal{A}|}$, every agent sells their endowment to the market in exchange for revenue $s_j = p \cdot e_j$, which the agent immediately spends at the market to buy back an optimal bundle of goods $x_j \in \mathbb{R}_{\geq 0}^{|\mathcal{A}|}$ - that is, $x_j = \operatorname{argmax}_{x: \sum_{\mathcal{A} \in \mathcal{A}} p_{\mathcal{A}} x_{\mathcal{A}} \leq s_j} u_j(x)$.

There are countless variants on this definition. Typically the utility functions are assumed to be quasi-convex. Some variants include stock dividends, corporations, production of new goods from existing goods, and multiple trading rounds. SPEEDEX uses only the model outlined above—SPEEDEX looks only at snapshots of the market, i.e., once per block, and computes batch results for each block independently.

One potential objection to the above definition is that it assumes that the abstract market has sufficient quantities available so that every agent can make its preferred trades. We say that a market is at *equilibrium* when agents can make their preferred trades and the market does not have a deficit in any good.

Definition 2 (Market Equilibrium). *An equilibrium of an Arrow-Debreu market is a set of prices p and an allocation x_j for every agent j , such that for all goods \mathcal{A} , $\sum_j e_{\mathcal{A},j} \geq \sum_j x_{\mathcal{A},j}$, and x_j is an optimal bundle for agent j . The inequality for asset \mathcal{A} is tight whenever $p_{\mathcal{A}}$ is nonzero.*

Note that an equilibrium includes both a set of market prices and a choice of a utility-maximizing set of goods for each agent. Say, for example, there are two goods \mathcal{A} and \mathcal{B} , and one unit of each is sold by other agents to the market. If two agents are indifferent to receiving either good, then the equilibrium must specify whether the first receives \mathcal{A} or \mathcal{B} , and vice versa for the second. It would not be a market equilibrium for both of these agents to purchase a unit of \mathcal{A} and no units of \mathcal{B} .

A.2 From SPEEDEX to Exchange Markets

SPEEDEX users do not submit abstract utility functions to an abstract market. However, most natural types of trade offers can be encoded as a simple utility function.

Specifically, our implementation of SPEEDEX accepts limit sell orders of the following form.

Definition 3 (Limit Sell Offer). *A Sell Offer $(S, \mathcal{B}, e, \alpha)$ is request to sell e units of good S in exchange for some number k units of good \mathcal{B} , subject to the condition that $k \geq \alpha e$.*

The user who submits this offer implicitly says that they value k units of \mathcal{B} more than e units of S if and only if $k \geq \alpha e$. These preferences are representable as a linear utility function.

Theorem 2. *Suppose a user submits a sell offer $(S, \mathcal{B}, e, \alpha)$. The optimal behavior of this offer (and the user’s implicit preferences) is equivalent to maximizing the function $u(x_S, x_B) = \alpha x_B + x_S$ (for x_S, x_B amounts of goods S and \mathcal{B}).*

Proof. Such an offer makes no trades if $p_S/p_B < \alpha$ and trades in full if $p_S/p_B > \alpha$.

The user starts with k units of S . In the exchange market model, the user can trade these k units of S in exchange for any quantities x_S of S and x_B of \mathcal{B} , subject to the constraint that $p_S x_S + p_B x_B \leq k p_S$.

The function $u(x_S, x_B) = \alpha x_B + x_S$ is maximized, subject to the above constraint, by $(x_B, x_S) = (0, k)$ precisely when $p_S/p_B < \alpha$ and by $(x_B, x_S) = (k p_S/p_B, 0)$ otherwise (and by any convex combination of the two when $p_S/p_B = \alpha$). These allocations correspond exactly to the optimal behavior of a limit sell offer. \square

Note that these utility functions have nonzero marginal utility for only two types of assets, and are not arbitrary linear utilities. Ramseyer et al. [96] find anecdotal evidence that this subclass of utility functions may be analytically more tractable than the case of general linear utilities.

A.3 Existence of Unique* Equilibrium Prices

Theorem 3. *All of the market instances which SPEEDEX considers contain an equilibrium with nonzero prices.*

Proof. All of the utilities of agents derived from limit sell offers are linear (Theorem 2), and have a nonzero marginal utility on the good being sold.

This means our market instances trivially satisfy condition (*) of Devanur et al. [57]. Existence of an equilibrium with nonzero prices follows therefore from Theorem 1 of [57]. \square

In fact, all of the equilibria in a market instance contain the same equilibrium prices, unless there are two sets of assets across which no trading activity occurs. In such a case, one might be able to uniformly increase or decrease all the prices together on one set of assets, relative to the other set of assets.

Theorem 4. Suppose there are two equilibria (p, x) and (p', x') and there exist two assets \mathcal{A} and \mathcal{B} for which $p_{\mathcal{A}}/p_{\mathcal{B}} < p'_{\mathcal{A}}/p'_{\mathcal{B}}$.

Then it must be the case that there is a partitioning of the assets $\mathcal{A}_1, \mathcal{A}_2$ with $A \in \mathcal{A}_1, B \in \mathcal{A}_2$ such that both equilibria include no trading activity across the partition.

Proof. Consider the set of offers trading from \mathcal{A} to \mathcal{B} . Let $Z_{\mathcal{A}, \mathcal{B}}(r)$ be the set of amounts of asset \mathcal{A} that may be sold (when every agent receives an optimal bundle) by these offers to the market at an exchange rate $r = p_{\mathcal{A}}/p_{\mathcal{B}}$. Observe that if $r_1 < r_2$, then every $z_1 \in Z_{\mathcal{A}, \mathcal{B}}(r_1)$ is no more than than any $z_2 \in Z_{\mathcal{A}, \mathcal{B}}(r_2)$ (as sell offers always prefer higher exchange rates).

At the equilibrium (p, x) , let $z_{\mathcal{A}, \mathcal{B}}$ be the total amount of \mathcal{A} sold for \mathcal{B} for every asset pair (and $z'_{\mathcal{A}, \mathcal{B}}$ similarly for (p', x')). Note that $z_{\mathcal{A}, \mathcal{B}} \in Z_{\mathcal{A}, \mathcal{B}}(p_{\mathcal{A}}/p_{\mathcal{B}})$.

Suppose that there exists a pair of assets \mathcal{A}, \mathcal{B} as in the theorem statement. Then there exists a set of assets \mathcal{A}_1 such that for every asset pair $C \in \mathcal{A}_1$ and $\mathcal{D} \notin \mathcal{A}_1$, $p_C/p_{\mathcal{D}} < p'_C/p'_{\mathcal{D}}$.

For each of these asset pairs, we must have that $z_{C, \mathcal{D}} \leq z'_{C, \mathcal{D}}$, $z_{\mathcal{D}, C} \geq z'_{\mathcal{D}, C}$, and $\frac{p_C}{p_{\mathcal{D}}} z_{C, \mathcal{D}} \leq \frac{p'_C}{p'_{\mathcal{D}}} z'_{C, \mathcal{D}}$. Combining these equations gives

$$p_C z_{C, \mathcal{D}} - p_{\mathcal{D}} z_{\mathcal{D}, C} \leq (p'_C z'_{C, \mathcal{D}} - p'_{\mathcal{D}} z'_{\mathcal{D}, C}) p_{\mathcal{D}} / p'_{\mathcal{D}}$$

Each of these inequalities is tight if and only if $z_{C, \mathcal{D}} = 0$.

It is without loss of generality to rescale p' so that $p_{\mathcal{D}}/p'_{\mathcal{D}} < 1$ for all $\mathcal{D} \notin \mathcal{A}_1$. Thus,

$$p_C z_{C, \mathcal{D}} - p_{\mathcal{D}} z_{\mathcal{D}, C} \leq (p'_C z'_{C, \mathcal{D}} - p'_{\mathcal{D}} z'_{\mathcal{D}, C})$$

Because (p, x) and (p', x') are equilibria, we must have that

$$\begin{aligned} 0 &= \sum_{C \in \mathcal{A}_1} \sum_{\mathcal{D} \notin \mathcal{A}_1} p_C z_{C, \mathcal{D}} - p_{\mathcal{D}} z_{\mathcal{D}, C} \\ &\leq \sum_{C \in \mathcal{A}_1} \sum_{\mathcal{D} \notin \mathcal{A}_1} p'_C z'_{C, \mathcal{D}} - p'_{\mathcal{D}} z'_{\mathcal{D}, C} \end{aligned}$$

But the second inequality is tight only if each $z_{C, \mathcal{D}} = 0$.

Hence, (p', x') can only be an equilibrium if there exists a partitioning of the assets that separates \mathcal{A} and \mathcal{B} , and for which there is no trading activity between the sets in either equilibrium. \square

Corollary 1. Let (p, x) be an equilibrium.

Construct an undirected graph $G = (V, E)$ with one vertex for each asset, and an edge $e = (\mathcal{A}, \mathcal{B}) \in E$ if, at equilibrium, any \mathcal{A} is sold for \mathcal{B} or any \mathcal{B} is sold for \mathcal{A} .

If G is connected, then the market equilibrium prices p are unique (up to uniform rescaling).

Proof. If the theorem hypothesis holds, then for any other equilibrium (p', x') , it must be the case that for every asset pair $(\mathcal{A}, \mathcal{B})$, $p_{\mathcal{A}}/p_{\mathcal{B}} = p'_{\mathcal{A}}/p'_{\mathcal{B}}$. By Theorem 4, if this did not hold, then there would exist a partitioning of V into two sets of assets, across which there is no trading at equilibrium (p, x) (contradicting the assumption that G is connected). \square

Appendix B Approximation Error

SPEEDEX measures two forms of approximation error: first, every trade is charged a ϵ transaction commission, and second, some offers with in-the-money limit prices might not be able to be executed (while preserving asset conservation). Formally, the output of the batch price computation is a price $p_{\mathcal{A}}$ on each asset \mathcal{A} , and a trade amount $x_{\mathcal{A}, \mathcal{B}}$ denoting the amount of \mathcal{A} sold in exchange for \mathcal{B} .

Formally, we say that the result of a batch price computation is (ϵ, μ) -approximate if:

- 1 Asset conservation is preserved with an ϵ commission. The amount of \mathcal{A} sold to the auctioneer, $\Sigma_{\mathcal{B}} x_{\mathcal{A}, \mathcal{B}}$, must exceed the amount of \mathcal{A} bought from the auctioneer, $\Sigma_{\mathcal{B}} (1 - \epsilon) \frac{p_{\mathcal{B}}}{p_{\mathcal{A}}} x_{\mathcal{B}, \mathcal{A}}$.
- 2 No offer trades outside of its limit price. That is to say, an offer selling \mathcal{A} for \mathcal{B} with a limit price of r cannot execute if $\frac{p_{\mathcal{A}}}{p_{\mathcal{B}}} < r$.
- 3 No offer with a limit price “far” from the batch exchange rate does not trade. That is to say, an offer selling \mathcal{A} for \mathcal{B} with a limit price of r must trade in full if $r < (1 - \mu) \frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$.

Intuitively, the lower the limit price, the more an offer prefers trading to not trading.

This notion of approximation is closely related to but not exactly the same as notions of approximation used in the theoretical literature on Arrow-Debreu exchange markets (e.g., [53], Definition 1). In particular, we find it valuable in SPEEDEX to distinguish between the two types of approximation error (and measure each separately) and SPEEDEX must maintain certain guarantees exactly (e.g., assets must be conserved, and no offer can trade outside its limit price).

Appendix C Tâtonnement Modifications

C.1 Price Update Rule

One significant algorithmic difference between the Tâtonnement implemented within SPEEDEX and the Tâtonnement described in Codenotti et al. [53] is the method in which Tâtonnement adjusts prices in response to a demand query. Codenotti et al. use an additive rule that they find amenable to theoretical analysis. If $Z(p)$ is the market demand at prices p , they update prices according to the following rule:

$$p_{\mathcal{A}} \leftarrow p_{\mathcal{A}} + Z_{\mathcal{A}}(p) \delta \quad (1)$$

for some constant δ . The authors show that there is a sufficiently small δ so that Tâtonnement is guaranteed to move closer to an equilibrium after each step.

The relevant constant is unfortunately far too small to be usable in practice, and more generally, we want an algorithm that can quickly adapt to a wide variety of market conditions (not one that always proceeds at a slow pace).

First, we update prices multiplicatively, rather than additively. This dramatically reduces the number of required rounds, especially when Tâtonnement starts at prices that are far from the clearing prices.

$$p_{\mathcal{A}} \leftarrow p_{\mathcal{A}}(1 + Z_{\mathcal{A}}(p)\delta) \quad (2)$$

Second, we normalize asset amounts by asset prices, so that our algorithm will be invariant to redenominating an asset. It is equivalent to trade 100 pennies or 1 USD, and our algorithm performs better when it can take that kind of context into account.

$$p_{\mathcal{A}} \leftarrow p_{\mathcal{A}}(1 + p_{\mathcal{A}}Z_{\mathcal{A}}(p)\delta) \quad (3)$$

Next, we make δ a variable factor. We use a heuristic to guide the dynamic adjustment. Our experiments used the l^2 norm of the price-normalized demand vector, $\sum_{\mathcal{A}}(p_{\mathcal{A}}Z_{\mathcal{A}}(p))^2$; other natural heuristics (i.e. other l^p norms) perform comparably (albeit not quite as well). In every round, Tâtonnement computes this heuristic at its current set of candidate prices, and at the prices to which it would move should it take a step with the current step size. If the heuristic goes down, Tâtonnement makes the step and increases the step size, and otherwise decreases the step size. This is akin to a backtracking line search [31, 39] with a weakened termination condition.

$$p_{\mathcal{A}} \leftarrow p_{\mathcal{A}}(1 + p_{\mathcal{A}}Z_{\mathcal{A}}(p)\delta_i) \quad (4)$$

Finally, we normalize adjustments by a trade volume factor $v_{\mathcal{A}}$. Without this adjustment factor, computing prices when one asset is traded much less than another asset takes a large number of rounds, simply because the lesser traded asset's price updates are always of a lower magnitude than those of the more traded asset. Many other numerical optimization problems run most quickly when gradients are normalized (e.g., see [37]).

$v_{\mathcal{A}}$ need not be perfectly accurate—indeed, knowing the factor exactly would require first computing clearing prices—but we can estimate it well enough from the trading volume in prior blocks and from trading volume in earlier rounds of Tâtonnement (specifically, we use the minimum of the amount of an asset sold to the auctioneer and the amount bought from the auctioneer). Real-world deployments could estimate these factors using external market data.

Putting everything together gives the following update rule:

$$p_{\mathcal{A}} \leftarrow p_{\mathcal{A}}(1 + p_{\mathcal{A}}Z_{\mathcal{A}}(p)\delta_i v_{\mathcal{A}}) \quad (5)$$

The step size is represented internally as a 64-bit integer and a constant scaling factor. As mentioned in §5.2, we run several copies of Tâtonnement in parallel with different scaling factors and different volume normalization strategies and take whichever finishes first as the result.

C.1.1 Heuristic Choice

A natural question is why do we use the seemingly theoretically unfounded l^2 norm of the demand vector as our line-search

heuristic. A typical line search in an optimization context uses the convex objective function of the optimization problem (e.g., [39]). Devanur et al. [57] even give a convex objective function for computing exchange market equilibria, which we reproduce below (in a simplified form):

$$\sum_{i: mp_i < \frac{p_{S_i}}{p_{B_i}}} p_{S_i} E_i \ln\left(mp_i \frac{p_{S_i}}{p_{B_i}}\right) - y_i \ln(mp_i) \quad (6)$$

for mp_i the minimum limit price of an offer i that sells E_i units of good S_i and buys good B_i , and $y_i = x_i p_{S_i}$ for x_i the amount of S_i sold by the offer to the market.

This objective is accompanied by an asset conservation constraint for each asset \mathcal{A} :

$$\sum_{i: S_i = \mathcal{A}} y_i = \sum_{i: B_i = \mathcal{A}} y_i \quad (7)$$

However, unlike the problem formulation in [57], Tâtonnement does not have decision variables $\{y_i\}$. Rather, Tâtonnement pretends offers respond rationally to market prices, and then adjusts prices so that constraints become satisfied. As such, mapping our algorithms onto the above formulation would mean that $y_i = p_{S_i} E_i$ if $mp_i < \frac{p_{S_i}}{p_{B_i}}$ and 0 otherwise (although §C.2 would slightly change this picture). This would make the objective universally 0, and thus not useful.

We could incorporate the constraints into the objective by using the Lagrangian of the above problem, which gives the objective

$$\sum_{\mathcal{A}} \lambda_{\mathcal{A}} \left(\sum_{i: S_i = \mathcal{A}} y_i(p) - \sum_{i: B_i = \mathcal{A}} y_i(p) \right) \quad (8)$$

for a set of langrange multipliers $\{\lambda_{\mathcal{A}}\}$.

We write $y_i(p)$ to denote that in this formulation, offer behavior is directly a function of prices. It appears difficult to use equation 8 directly as an objective to minimize, as it is nonconvex and the gradients of the functions $y_i(\cdot)$ are numerically unstable (even with the application of §C.2).

However, observe that equation 8 is another way of writing “the l^1 norm of the net demand vector” (weighted by the langrange multipliers). We use the l^2 norm instead of the l^1 to sidestep the need to actually solve for these multipliers.

An observant reader might notice that the derivative of Equation 8 with respect to $\lambda_{\mathcal{A}}$ is the amount by which (the additive version of) Tâtonnement updates $p_{\mathcal{A}}$. This might suggest using $p_{\mathcal{A}}$ in place of $\lambda_{\mathcal{A}}$ in equation 8. However, that search heuristic performs extremely poorly.

C.2 Demand Smoothing

Observe that the demand of a single offer is a (discontinuous) step function; an offer trades in full when the market exchange rate exceeds its limit price, and not at all when the market rate is less than its limit price.

These discontinuities are difficult for Tâtonnement. (Analogously, many optimization problems struggle on non-differentiable objective functions.) As such, we approximate

the behavior of each offer with a continuous function.

Recall that §B measures one form of approximation error (using the parameter μ) which asks how closely realized offer behavior matches optimal offer behavior. Specifically, SPEEDEX wants to maintain the guarantee that every offer (selling \mathcal{A} for \mathcal{B}) with a limit price below $(1-\mu)\frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$ trades in full, and those with limit prices above $\frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$ trade not at all.

As such, SPEEDEX has the flexibility to specify offer behavior on the gap between $(1-\mu)\frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$ and $\frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$. Instead of a step function, SPEEDEX linearly interpolates across the gap. That is to say, if $\alpha = \frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$, we say that an offer with limit price $(1-\mu)\alpha \leq \beta \leq \alpha$ sells an $\frac{\alpha-\beta}{\mu\alpha}$ fraction of its assets.

Observe that as μ gets increasingly small, this linear interpolation becomes an increasingly close approximation of a step function. This explains some of the behavior in Figure 2, particularly why the price computation problem gets increasingly difficult as μ decreases.

C.3 Periodic Feasibility Queries

Tâtonnement’s linear interpolation simplifies computing each round, but also restricts the range of prices that meet the approximation criteria, as it does not capitalize on the flexibility we have in handling offers within μ of the market price. As a result, Tâtonnement may arrive at adequate prices without recognizing that fact. To identify good valuations, SPEEDEX runs the more expensive linear program every 1,000 iterations of Tâtonnement.

Appendix D Linear Program

Recall that the role of the linear program in SPEEDEX is to compute the maximum amount of trading activity possible at a given set of prices. That is to say, Tâtonnement first computes an approximate set of market clearing prices, and then SPEEDEX runs this linear program taking the output of Tâtonnement as a set of input, constant parameters.

Throughout the following, we denote the price of an asset \mathcal{A} (as output from Tâtonnement) as $p_{\mathcal{A}}$, and the amount of \mathcal{A} sold in exchange for \mathcal{B} as $x_{\mathcal{A},\mathcal{B}}$. We will also denote the two forms of approximation error as ϵ and μ , as defined in §B.

To maintain asset conservation, the linear program must satisfy the following constraint for every asset \mathcal{A} :

$$\sum_{\mathcal{B}} x_{\mathcal{A},\mathcal{B}} \geq \sum_{\mathcal{B}} (1-\epsilon) \frac{p_{\mathcal{B}}}{p_{\mathcal{A}}} x_{\mathcal{B},\mathcal{A}}$$

Define $U_{\mathcal{A},\mathcal{B}}$ to be the upper bound on the amount of \mathcal{A} that is available for sale by all offers with in the money limit prices (i.e., limit prices at or below $\frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$), and define $L_{\mathcal{A},\mathcal{B}}$ to be the lower bound on the amount of \mathcal{A} that must be exchanged for \mathcal{B} if SPEEDEX is to be μ -approximate (i.e., execute all offers with minimum prices at or below $(1-\mu)\frac{p_{\mathcal{A}}}{p_{\mathcal{B}}}$, as described in §B).

Then the linear program must also satisfy the constraint, for every asset pair $(\mathcal{A},\mathcal{B})$,

$$L_{\mathcal{A},\mathcal{B}} \leq x_{\mathcal{A},\mathcal{B}} \leq U_{\mathcal{A},\mathcal{B}}$$

Informally, the goal of our linear program is to maximize the total amount of trading activity. Any measurement of trading activity needs to be invariant to redenominating assets; intuitively, it is the same to trade 1 USD or 100 pennies. As such, the objective of our linear program is:

$$\sum_{\mathcal{A},\mathcal{B}} p_{\mathcal{A}} x_{\mathcal{A},\mathcal{B}}$$

Putting this all together gives the following linear program (let \mathcal{A} be the set of all assets):

$$\max \sum_{\mathcal{A},\mathcal{B}} p_{\mathcal{A}} x_{\mathcal{A},\mathcal{B}} \quad (9)$$

$$s.t. \ p_{\mathcal{A}} L_{\mathcal{A},\mathcal{B}} \leq p_{\mathcal{A}} x_{\mathcal{A},\mathcal{B}} \leq p_{\mathcal{A}} U_{\mathcal{A},\mathcal{B}}(p) \quad \forall \mathcal{A},\mathcal{B} \in \mathcal{A}, (\mathcal{A} \neq \mathcal{B}) \quad (10)$$

$$p_{\mathcal{A}} \sum_{\mathcal{B} \in \mathcal{A}} x_{\mathcal{A},\mathcal{B}} \geq (1-\epsilon) \sum_{\mathcal{B} \in \mathcal{A}} p_{\mathcal{B}} x_{\mathcal{B},\mathcal{A}} \quad \forall \mathcal{A} \in \mathcal{A} \quad (11)$$

From the point of view of the linear program, $p_{\mathcal{A}}$ is a constant (for each asset \mathcal{A}). As such, this optimization problem is in fact a linear program.

It is possible that Tâtonnement could output prices where this linear program is infeasible (this is the case of the Tâtonnement timeout, as discussed in §6). In these cases, we set the lower bound on each $x_{\mathcal{A},\mathcal{B}}$ to be 0 instead of $L_{\mathcal{A},\mathcal{B}}$. This change makes the program always feasible (e.g., an assignment of each variable to 0 satisfies the constraints).

Observe that as written, every instance of the variable $x_{\mathcal{A},\mathcal{B}}$ appears adjacent to $p_{\mathcal{A}}$. We can simplify the program by replacing each occurrence of $p_{\mathcal{A}} x_{\mathcal{A},\mathcal{B}}$ by a new variable $y_{\mathcal{A},\mathcal{B}}$. After solving the program, we can compute $x_{\mathcal{A},\mathcal{B}}$ as $\frac{y_{\mathcal{A},\mathcal{B}}}{p_{\mathcal{A}}}$.

This substitution gives the following linear program:

$$\max \sum_{\mathcal{A},\mathcal{B}} y_{\mathcal{A},\mathcal{B}} \quad (12)$$

$$s.t. \ p_{\mathcal{A}} L_{\mathcal{A},\mathcal{B}} \leq y_{\mathcal{A},\mathcal{B}} \leq p_{\mathcal{A}} U_{\mathcal{A},\mathcal{B}}(p) \quad \forall (\mathcal{A},\mathcal{B}), (\mathcal{A} \neq \mathcal{B}) \quad (13)$$

$$\sum_{\mathcal{B} \in \mathcal{A}} y_{\mathcal{A},\mathcal{B}} \geq (1-\epsilon) \sum_{\mathcal{B} \in \mathcal{A}} y_{\mathcal{B},\mathcal{A}} \quad \forall \mathcal{A} \quad (14)$$

The Stellar implementation charges no transaction commission (i.e., sets ϵ to 0) in its SPEEDEX deployment. This makes the linear program into an instance of the maximum circulation problem (i.e., variable $y_{\mathcal{A},\mathcal{B}}$ denotes the flow from vertex \mathcal{A} to vertex \mathcal{B}). It is well known that the constraint matrices of these problems are totally unimodular (Chapter 19, Example 4 [101]). This means that it always has an integral solution (Theorem 19.1, [101]) and can be solved by specialized algorithms (such as those outlined in [81]). Some of these algorithms run substantially faster than general simplex-based solvers.

Appendix E Market Structure Decomposition

Suppose that the set of goods could be partitioned between a set of numeraires, which might be traded with any other asset, and a set of stocks, which are only traded with one of the pricing assets.

Then SPEEDEX could compute a batch equilibrium by first computing an equilibrium taking into account only trades between pricing assets, then computing an equilibrium exchange rate for every stock between the stock and its pricing asset, and finally combining the results.

More specifically:

Theorem 5. *Let \mathcal{A} be the set of numeraires and \mathcal{S} the set of stocks. A stock $S \in \mathcal{S}$ is traded with asset $a(S) \in \mathcal{A}$.*

Suppose (p, x) is an equilibrium for the restricted market instance considering only the numeraires. For each $S \in \mathcal{S}$, let (r, y) be an equilibrium for the restricted market instance considering only S and $a(S)$.

Then (p', x') is an equilibrium for the entire market instance, where

1. $p'_{\mathcal{A}} = p_{\mathcal{A}}$ for $\mathcal{A} \in \mathcal{A}$
2. $p'_S = (r_S / r_{a(S)}) p_{a(S)}$
3. $x'_{\mathcal{A}, \mathcal{B}} = x_{\mathcal{A}, \mathcal{B}}$ for $\mathcal{A}, \mathcal{B} \in \mathcal{A}$
4. $x'_{S, a(S)} = y_{S, a(S)}$
5. $x' = 0$ otherwise

Proof. More generally, let G be a graph whose vertices are the traded assets and which contains an edge $(\mathcal{A}, \mathcal{B})$ if \mathcal{A} and \mathcal{B} can be traded directly.

Decompose G into an arbitrary set of edge-disjoint subgraphs $\{G_i\}$, such that any two subgraphs G_i, G_j share at most one common vertex. Then define a graph H whose vertices are the subgraphs G_i , and where a subgraph G_i is connected to G_j if G_i and G_j share a common vertex.

If H is acyclic, then an equilibrium can be reconstructed from equilibria computed independently on each G_i .

We reconstruct a unified set of prices iteratively, traversing along H . Given adjacent G_i and G_j sharing common vertex v_{ij} , let (p^i, x^i) and (p^j, x^j) be equilibria on G_i and G_j , respectively, rescale all of the prices p^j by $p^i_{v_{ij}} / p^j_{v_{ij}}$.

This rescaling constructs a new equilibria (p^j, x^j) for G_j that agrees with that of G_i on the price of the shared good. As such, the combined system $(p^i \cup p^j, x^i \cup x^j)$ forms an equilibrium for $G_i \cup G_j$.

This iteration is possible precisely because H is acyclic (a cycle could prevent us from finding a rescaling of some subgraph that satisfied two constraints on the prices of shared vertices). \square

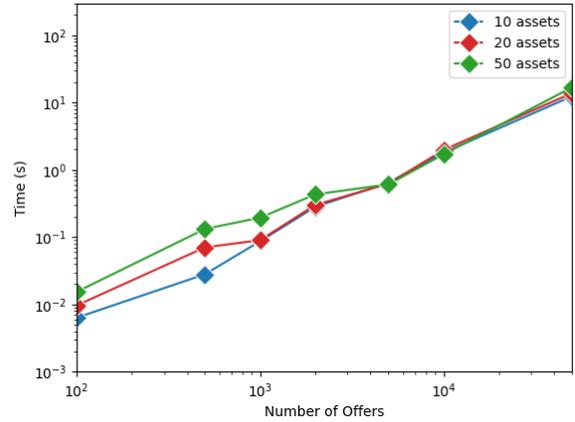

Fig. 8. Time to solve the convex program of Devanur et al. [57] using the CVXPY toolkit [59], varying the number of assets and offers.

Appendix F Alternative Batch Solving Strategies

F.1 Convex Optimization

We implemented the convex program of Devanur et al. [57] directly, using the CVXPY toolkit [59] backed by the ECOS convex solver [61]. Figure 8 plots the runtimes we observed to solve the problem while varying the number of assets and offers.

The runtimes are not directly comparable to those of Tâtonnement—namely, this strategy does not have the potential to shortcircuit operation upon early arrival at an equilibrium (our notions of approximation error also do not directly translate to the notions used internally in the solver), nor is it optimized for our particular class of problems.

The important observation is that the runtime of this strategy scales linearly in the number of trade offers. Instances trading 1000 offers, for example, take roughly 10x as long as instances trading only 100 offers.

This is not a surprising result, given that the number of variables in the convex program scales linearly with the number of trade offers.

The choice of solver strategy does not, of course, change the structure of the input problem instances. The same observation used in §5.1 makes it possible to refactor the convex program so that the number of variables does not depend on the number of open offers, and so that the objective (and its derivatives) can be evaluated in time logarithmic in the number of open offers.

Unfortunately, this transformation makes the objective nondifferentiable. The demand smoothing tactic of §C.2 gives a differentiable but not twice differentiable objective (and presents challenges regarding numerical stability of the derivative). Construction of a convex objective that approximates that of [57] while maintaining sufficient smoothness and numerical stability is an interesting open problem.

F.2 Mixed Integer Programming

Gnosis (Walther, [7]) give several formulations of a batch trading system as mixed-integer programming problems. These formulations track token amounts as integers (instead of as real numbers, as used in Tâtonnement’s underlying mathematical formulation), which enables strict conservation of asset amounts with no rounding error.

However, mixed-integer problems appear to be computationally difficult to solve. Walther [7] finds that the runtime of this approach scales faster than linearly. Instances with more than a few hundred assets appear to be intractable for practical systems.

Appendix G Tâtonnement Preprocessing

We include this section so that this paper can provide a comprehensive reference for anyone to develop their own Tâtonnement implementation.

Every demand query in Tâtonnement requires computing, for every asset pair, the amount of the asset available for sale below the queried exchange rate. As discussed in §9.2, Tâtonnement lays out contiguously in memory all the information it needs to return this result quickly.

For a version of Tâtonnement without the demand smoothing of §C.2, a demand query for exchange rate p (i.e. the ratio of the price of the sold asset to the price of the purchased asset)

$$\sum_{i:mp_i \leq p} E_i \quad (15)$$

where mp_i denotes the minimum price of an offer i and E_i denotes the amount of the asset offered for sale.

We can efficiently answer these queries by computing expression 15 for every price p used as a limit price

Demand smoothing complicates the picture. The result of a demand query (with smoothing parameter μ)

$$\sum_{i:mp_i < p(1-\mu)} E_i + \sum_{i:p(1-\mu) \leq mp_i \leq p} E_i * (p - mp_i) / (p\mu) \quad (16)$$

We can rearrange the second term of the summation into

$$1/(p\mu) \sum_{i:p(1-\mu) \leq mp_i \leq p} (pE_i - E_i mp_i) \quad (17)$$

With this, we can efficiently compute the demand query after precomputing, for every unique price p that is used as a limit price, both expression 15 and

$$\sum_{i:mp_i < p} mp_i E_i \quad (18)$$

The division in equation 16 can be avoided by recognizing that Tâtonnement normalizes all asset amounts by asset valuations (so equation 16 is always multiplied by p).

Appendix H Buy Offers are PPAD-hard

A natural type of trade offer is one that offers to sell any number of units of one good to buy a fixed amount of a good (subject to some minimum price constraint). We call these *limit buy offers*.

Example 2 (Limit Buy Offer). *A user offers to buy 100 USD in exchange for EUR, selling as few EUR as possible and only if one EUR trades for at least 1.1 USD.*

These offers unfortunately do not satisfy a property known as “Weak Gross Substitutability” (WGS, see e.g., [53]). This property captures the core logic of Tâtonnement. If the price of one good rises, the net demand for that good should fall, and the net demand for every other good should rise (or at least, not decrease). Limit sell offers satisfy this property, but limit buy offers do not.

Example 3. *The demand of the offer in of example 2, when $p_{EUR} = 2$ and $p_{USD} = 1$, is $(-50 \text{ EUR}, 100 \text{ USD})$.*

If p_{USD} rises to 1.6, then the demand for the offer is $(-80 \text{ EUR}, 100 \text{ USD})$.

Observe that the price of USD rose and the demand for EUR fell.

Informally speaking, if offers do not satisfy the core logic of Tâtonnement’s price update rule, then Tâtonnement cannot handle them in a mathematically sound manner.

More formally, Chen et al. [48] show through Theorem 7 and Example 2.4 that markets consisting of collections of limit buy offers are PPAD-hard. These theorems are phrased in the language of the Arrow-Debreu exchange market model; see §A for the correspondence between SPEEDEX and this model. In fact, the utility functions used in Example 2.4 to demonstrate an example “non-monotone” (i.e., defying WGS) instance are of the type that would arise by mapping limit buy offers into the Arrow-Debreu exchange market model.

Appendix I Deterministic Filtering Performance

The deterministic transaction batch pruning system works by eliminating the transactions from all of the accounts that could create an unresolvable conflict. To be specific, if the sum of the amount of an asset used (either sent in a payment option or locked to create a offer) by all of an account’s transactions exceeds that account’s balance, then that account’s transactions are removed. If an account sends two transactions with the same sequence number (both of which have valid signatures, and the sequence numbers are higher than the sequence number of the account’s most recent transaction), or two transactions cancel the same offer ID, then that account’s transactions are removed. If two transactions create the same account ID, then both transactions are removed.

We generated batches of 400,000 transactions from the same synthetic transaction model as in §7, and then duplicated 100,000 transactions at random to create a batch of 500,000.

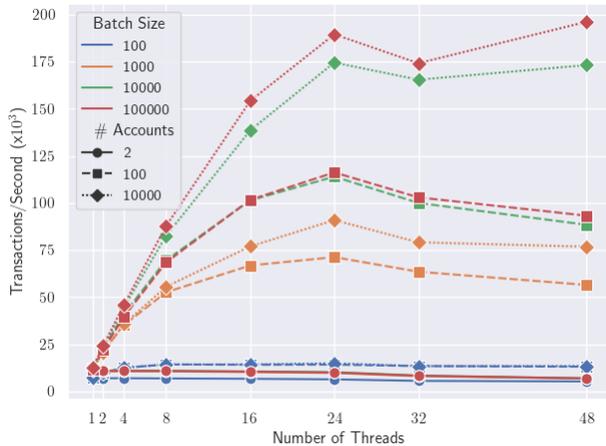

Fig. 9. Throughput of Block-STM on batches of “Aptos p2p” transactions with varying thread counts (average of 100 trials).

A small number of accounts (1000) send transactions with conflicting sequence numbers. We initialize the database (again, 10 million accounts) to give each account a small amount of money, and a small number (one or two hundred) of accounts attempt to overdraw.

This filtering takes 0.13s and 0.07s seconds with 24 and 48 threads, respectively (averaged over 50 trials, after a warmup), giving a $21.0\times$ and $38.4\times$ speedup over the serial benchmark. On a more contested benchmark, with only 10,000 accounts (almost all of which overdraw) the maximum speedup over the single threaded trial is only $5.3\times$, but the overall filtering runtime is still just 0.10s. Our implementation of the filtering is not heavily optimized, but in either parameter setting, the overhead is small.

Appendix J Block-STM Baseline

To provide a baseline for the measurements in Fig. 7, we also ran Block-STM on our hardware (with hyperthreading disabled, as in [70]). Fig. 9 displays the results.

These performance measurements are similar, quantitatively and qualitatively, to those reported in [70] (on different hardware). Note that performance appears to reach a maximum after approximately 16 to 24 threads, and, unlike SPEEDEX, does not effectively use additional hardware beyond this point, even on relatively low-contention workloads.

Appendix K Additional Implementation Details

K.1 Data Organization

Account balances are stored in a Merkle-Patricia trie. However, because a trie is not self-rebalancing, its worst-case adversarial lookup performance can be slow. As such, we store account balances in memory indexed by a red-black tree, with updates pushed to the trie once per block.

For each pair of assets (\mathcal{A} , \mathcal{B}), we build a trie storing offers

selling asset \mathcal{A} in exchange for \mathcal{B} . Finally, in each block, we build a trie logging which accounts were modified.

We store information in hashable tries so that nodes can efficiently compare their database state with another replica’s (to validate consensus and check for errors), and construct short proofs for users about exchange state.

K.2 Data Storage and Persistence

SPEEDEX uses a combination of an in-memory cache and ACID-compliant databases (several LMDB [50] instances). This choice suffices for our experiments, but a database that persists data in epochs, like Silo [106], or is otherwise optimized for batch operation might improve performance.

Our implementation uses one LMDB instance for the set of open offers, one instance for Hotstuff logs, one instance for storing block headers, and 16 instances for storing account states. LMDB is single-threaded, and we find that the throughput of one thread generating database writes does not keep up with SPEEDEX. Accounts are randomly divided between these instances, according to a hash function keyed by a (persistent) secret key (which is different per blockchain node). This key must be kept secret so as to prevent nodes from denial of service attacks.

Processing transactions in a nondeterministic order complicates recovery from a database snapshot where a block has been partially applied. Cancellation transactions, in particular, refund to an account the remainder of an offer’s asset amount. We therefore cannot recover if the snapshot of the orderbooks is more recent than the snapshot of the set of account balances, and our implementation takes care to commit updates to the account LMDB instances before committing updates to the orderbook LMDB.

K.3 Follower Optimizations

A block proposal includes the output of Tâtonnement and the linear program in (the prices and trade amounts, as in §4.2). This permits the nondeterminism in Tâtonnement (§5.2), and lets the other nodes skip the work of running Tâtonnement.

Proposals also include, for every pair of assets, the trie key of the offer with the highest minimum price that trades in that block. When executing a proposal from another node, a follower can compare the trie key of a newly created offer with this marginal key and know immediately whether to make a trade or add the offer to the resting orderbooks. A node also defers all checks that an account balance is not overdrawn to after it has executed all the transactions in a block.

K.4 Replay Prevention

Transactions have per-account sequence numbers to ensure a transaction can execute only once. Many blockchains require sequence numbers from an account to increase strictly sequentially. Our implementation allows small gaps in sequence numbers, but restricts sequence numbers to increase by at most an arbitrary limit (64) in a given block. Allowing

gaps simplifies some clients (such as our open-loop load generator), but more importantly lets validators efficiently track consumed sequence numbers out of order with a fixed-size bitmap and hardware atomics.

The Stellar implementation requires strictly consecutive sequence numbers, mostly for backwards compatibility.

K.5 Fast Offer Sorting

The running times of §6 do not include times to sort or preprocess offers. Naïvely sorting large lists takes a long time. Therefore, we build one trie storing offers per asset pair, and we use an offer’s price, written in big-endian, as the first 6 bytes of the offer’s 22-byte trie key. Constructing the trie thus automatically sorts offers by price.

Additionally, SPEEDEX executes offers with the lowest minimum prices, so a set of offers executed in a round forms a dense (set of) subtree(s), which is trivial to remove.

K.6 Nondeterministic Block Assembly

As discussed in §3, SPEEDEX must assemble blocks of transactions in a manner that guarantees no account is overdrafted after applying all of the transactions in the block. The block proposal system (Fig. 1, 2) manages this by carefully controlling writes to shared state.

The proposal module takes as input a set of unconfirmed transactions (the “mempool”, in typical blockchain parlance) and outputs a proposed block containing a subset of the unconfirmed transactions. For each candidate unconfirmed transaction, a thread reserves the ability to perform all necessary modifications by “locking” all relevant data elements. Once a transaction acquires all of its locks, it performs its necessary state modifications and finally releases the locks. If it cannot acquire all necessary locks, it releases any locks and excludes the transaction from the proposed block.

Conceptually, a transaction offering a trade or sending a payment must lock the number of units of assets that could be debited from the account if the operation succeeds. However, doing this with spinlocks would preclude the scalability displayed in Figure 7. Instead, most reservations are performed with hardware atomics to decrement the number of available units. Crediting an account can never fail because SPEEDEX caps the total amount of any asset issued at `INT64_MAX`. This process is conservative in that it may reject transactions that could have executed safely.

Unique offer IDs ensure that no offer is created twice, and atomic boolean flags ensure an offer cannot be cancelled twice. Sequence numbers can be reserved by atomic bitmaps (as in §K.4). For simplicity, our implementation does use exclusive locks when creating new accounts (which we assume occurs relatively infrequently).

Appendix L Additional Replicas

SPEEDEX invokes a consensus protocol no more than once per second in our experiments. To demonstrate that this overhead

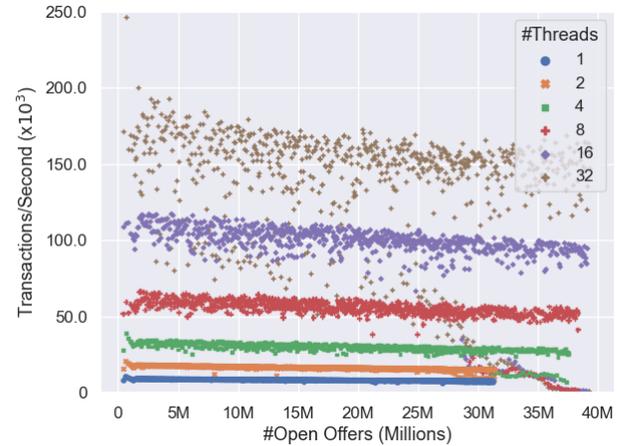

Fig. 10. Transactions per second on SPEEDEX when running with 10 replicas (on weaker hardware than in Fig. 3), plotted over the number of open offers.

is negligible, we ran SPEEDEX with 10 replicas, although with weaker hardware per replica, due to resource limitations. Each replica is one AWS `c5ad.16xlarge` instance, with one AMD EPYC 7R32 processor (48 CPUs @ 2.8Ghz per physical chip, 32 of which are allocated to our instances), 128 GB of memory, and two 1.1TB NVMe drives in a RAID0 configuration. Performance measurements are plotted in Figure 10.

The overall throughput numbers are lower here than in Figure 3 due to the weaker hardware, but the scalability trends are the same. Doubling the thread count increases performance by a factor of between 1.8x and 1.9x, except that the jump from 16 to 32 gives a roughly 1.4x increase due to contention with background tasks (particularly logging to persistent storage).

This graph also highlights how SPEEDEX responds to insufficient hardware resources. As the number of open offers increases, SPEEDEX’s memory requirements increase. Eventually, memory starts to be paged to disk, which dramatically increases disk usage and contends with the logging to persistent storage. SPEEDEX slows down in response, to ensure for safety that data in persistent storage is never too far out of sync.

Boomerang: Metadata-Private Messaging under Hardware Trust

Abstract

In end-to-end encrypted (E2EE) messaging systems, protecting communication metadata, such as who is communicating with whom, at what time, etc., remains a challenging problem. Existing designs mostly fall into the balancing act among security, performance, and trust assumptions: 1) designs with cryptographic security often use hefty operations, incurring performance roadblocks and expensive operational costs for large-scale deployment; 2) more performant systems often follow a weaker security guarantee, like differential privacy, and generally demand more trust from the involved servers. So far, there has been no dominant solution. In this paper, we take a different technical route from prior art, and propose Boomerang, an alternative metadata-private messaging system leveraging the readily available trust assumption on secure enclaves (as those emerging in the cloud). Through a number of carefully tailored oblivious techniques on message shuffling, workload distribution, and proactive patching of the communication pattern, Boomerang brings together low latency, horizontal scalability, and cryptographic security, without prohibitive extra cost. With 32 machines, Boomerang achieves 99th percentile latency of 7.76 seconds for 2²⁰ clients. We hope Boomerang offers attractive alternative options to the current landscape of metadata-private messaging designs.

1 Introduction

In E2EE messaging systems [59], the exposure of privacy-revealing communication metadata, including the identities of the communicating parties, and the timing and volume of the traffic, remains a big concern [26, 39, 61]. Communication metadata can not only be used to target whistleblowers and journalists [37, 70], but also serve as a surveillance means to reveal intimate details of a person’s life [38]. Designing a metadata-private messaging system is a challenging problem, given the powerful attackers that can monitor and actively

interfere with the network traffic [31, 39]. The popular system in practice today that hides communication metadata, namely Tor [34], is not resilient against even passive traffic analysis attacks (e.g., through timing, volume patterns, etc.) [39]. Because of this, academic research systems have been developed recently with well-defined security guarantees for improved metadata privacy [3–6, 8, 11, 15, 16, 27–29, 36, 37, 52, 54, 56–58, 70, 72, 88, 91]. Ideally, such a system must ensure that any pair of connected clients might be communicating from the view of powerful attackers. This implies two necessary requirements: 1) unlinking senders and receivers during any message exchange; and 2) maintaining the same communication pattern across all connected clients, to resist traffic analysis. Roughly speaking, most prior art on metadata-private messaging falls into the balancing act among security, performance, and trust assumptions, while trying to meet these two requirements (more discussions in §7).

Among the diverse landscape of metadata-private messaging designs, there are two commonalities of state-of-the-art systems: 1) leveraging an intermediate “virtual address” to facilitate obfuscated message “drop” and “fetch” between the communicating pairs; and 2) operating in rounds. Designs with cryptographic security follow technical routes of sophisticated cryptographic operations that either obviously “write to (drop)” [5, 27, 37, 52, 54, 70] or obviously “read from (fetch)” the virtual address [4, 8]. The hefty operations, however, often present performance roadblocks and unfavorable operational dollar costs, hindering large-scale voluntary adoptions in practice. More performant systems [11, 56, 87, 88] choose to relax the security guarantee and use random noise to disguise the observable “drop” / “fetch” at the virtual address in the framework of differential privacy. Generally, these systems need to trust a fraction of servers for the claimed security, where the latency would be increased if trusting fewer servers. So far there has yet to be any dominant solution.

Motivations. In this paper we propose Boomerang, an alternative metadata-private messaging system leveraging secure enclaves. Boomerang takes a different technical route from prior art, and is partially motivated by the readily available

*Qian Wang is the corresponding author.

trust assumption on hardware enclaves. As emerging in the cloud [78, 81], secure enclaves provide a convenient and native implementation choice to build secure yet sophisticated systems in practical settings.

Like much prior art [24, 32, 35, 42, 49, 50, 74], Boomerang leverages hardware enclaves for both performance and security. Performance is arguably one of the key reasons for Tor’s wide adoption in practice [39]. Yet, this is what most prior art on metadata-private messaging is still lacking. We believe that using hardware enclaves to improve performance could be the key missing ingredient for wider adoption of metadata-private messaging systems in practice. Under hardware trust, Boomerang hides users’ online communication behaviors with a strong guarantee of metadata privacy and resilience against powerful attackers, while retaining good enough performance.

Besides, we envision that there could be broader options of technical routes for metadata-private messaging, with different trust assumptions, performance, and security guarantees. For whistleblowers [37, 70], their most reasonable choice is to go for designs with a cryptographic guarantee and zero trust in the servers [8, 39], where performance might be much less concerning. For the mass general users who want more than E2EE messaging (e.g., due to concerns about metadata tracking [38, 47]), we hope Boomerang could offer a better option with lowered operational cost and improved performance. These benefits can potentially attract a large user base, which is crucial in private communication systems [33].

Challenges. While trusting the enclaves brings easy-to-see benefits, such as using fewer servers for traffic mixing than prior art for reduced latency, it does not entirely solve the problems in building a scalable metadata-private messaging system. This is because: 1) secure enclaves exhibit their own threat models and attack surfaces, especially the leakage of memory access patterns [32, 90], which demand tailored system structure and oblivious algorithm designs; 2) as acknowledged by prior art [39, 54, 57, 88], even with just one trusted server, dealing with the thorny problems of active attackers that may selectively interfere with traffic, e.g., disconnecting selected clients to gain advantages in identifying targeted communicating pairs, remains hard to address; and 3) as privacy loves company [33], the need to support more clients suggests the necessity of pushing for horizontal scaling designs, which is also a hot topic in recent years [11, 52, 54, 56, 57, 87]. Notably, scalability is not only a usability requirement but also a security demand [33, 39, 54, 56, 87].

Technical overview. For metadata-private messaging, Boomerang draws many insights from the prior art, and is designed to be a performant system with cryptographic security under hardware trust. It operates in rounds for bi-directional conversations, and centers around the paradigm of adopting a private “virtual address” to facilitate obfuscated message exchange that unlinks the sender and receiver. As we overview below, its technical instantiation involves tailored oblivious

algorithms for message shuffling, proactive resistance against active attacks, and horizontal scaling. For ease of presentation, we present a basic single-server Boomerang (§3) and a scalable multi-server Boomerang+ (§4).

1) Basic single-server Boomerang. From a high level, the system operates as follows: Upon proper setup, in each round, each connected client sends a message, tagged with a “private label”, which is randomly derived from a pairwise shared secret with his communicating buddy, to the Boomerang server. The Boomerang server obviously checks all the messages and swaps any pair of messages sharing the same labels for the relevant communicating pair. In this regular case, each label shows up twice each round. But active attackers might block selected clients or control a subset of clients to disrupt this regular pattern, causing each label to show up once or more than twice each round. The problem is quite subtle, because we need to fix these irregular patterns, without giving attackers any advantage in linking the remaining clients.

Boomerang’s key insight is to preserve the same observable receiving pattern for each connected client, no matter how the sending pattern changes. We build oblivious algorithms for enclaves to detect messages with irregular label patterns and proactively patch them (§3.3.2) by returning those messages back to the corresponding senders, like a “boomerang”. In this way, we can contain the influence attempts within the problematic clients themselves, isolated from the remaining clients. Based on a library of basic general-purpose oblivious primitives [2, 71], we design specialized oblivious algorithms (§3.3.2, §3.3.3, §4.2) for all enclave operations in Boomerang, including proactive resistance designs against active attacks and horizontal scaling in Boomerang+.

2) Scalable multi-server Boomerang+. For horizontal scalability, directly replicating the basic single-server Boomerang and letting each server process a subset of communicating pairs would not work, because pairwise clients connecting to one server have a higher possibility to communicate than those across different servers. Introducing a load balancer, known as an entry node in Boomerang+, to obviously distribute batches of messages to a group of Boomerang nodes for message exchange would fulfill the need for “global mixing”, where any pair of connected clients at the entry node might be communicating. But as pointed out by recent art [32, 89], two requirements remain: 1) a centralized proxy [82] can be error-prone and a scalability bottleneck of the underlying system; and 2) any batch structure from a load balancer must be generated using public information, so as to ensure that no sensitive information can be observable from the load balancing.

Note that these requirements are generic for any security-aware scalable system design. Answering them can be quite design specific, especially on setting the bound on batch size without triggering an overflow. Inspired by the balls-into-bins analysis [32], we model the problem of setting the maxi-

mum batch size in Boomerang+ as a weighted balls-into-bins game, where we partition the messages by their private labels and each message’s weight is determined by its label pattern (showing once, twice, or more than twice). We prove an upper bound on the maximum batch size and show its marginal overhead on our horizontal scaling design. Following the oblivious load balancer design [32], we derive tailored oblivious algorithms to generate sub-batches whose distribution across rounds is indistinguishable (§4.2).

2 Threat Model and Security Goals

2.1 Threat Model and Assumptions

We consider the following threats. Attackers can: 1) observe the global network states (including the timing, volume, and link states); 2) actively tamper with the network, such as selectively dropping messages, blocking selected connections, and controlling a subset of clients; and 3) access the server-side components beyond hardware enclaves, such as the memory, files, and networks, as well as the operating system.

Boomerang is built on servers equipped with secure enclaves, where memory access patterns can be observed [32, 49, 62, 66]. Boomerang is designed to work with generic enclaves [18, 30], and we adopt Intel SGX for our implementation. Our oblivious algorithms can deal with side-channel attacks against SGX leveraging memory access patterns to extract secrets, such as the cache attacks [19, 41, 67] and paging-based attacks [20]. We assume a public key infrastructure (PKI) to help manage the public keys of clients. Communications among clients and enclaves are securely established via TLS integrated with remote attestation [1, 46, 51]. In Appendix A, we elaborate in more detail on how a client can establish the trust on a multi-enclave system like Boomerang through remote attestation, following common practices suggested from the prior art [9, 23, 35, 74, 79].

Communication model. Like many previous metadata-private messaging systems [4, 8, 54, 56, 57, 87, 88], Boomerang operates in rounds to ensure the uniformity of communication pattern among clients, and focuses on pairwise messaging among online clients who have coordinated their conversations. Processing message exchanges on round boundaries implies that clients of Boomerang send encrypted messages with a fixed rate and size, independent of their true communication activities, which allows the dealing against traffic analysis attacks. This can be done at Boomerang clients by generating “blank” messages if a user types nothing or too slow, and queuing/splitting messages if a user types too fast or sends a message of large size [88].

Under this communication model, Boomerang does not hide the fact that clients are using the system. Boomerang offers online anonymity by supporting a large scale of clients. The anonymity set includes both active clients in real conversations with their buddies and online idle clients who do not

have a conversation buddy but can voluntarily send “blank” messages to themselves as cover traffic to further enlarge this anonymity set [56, 88]. We suggest the clients always keep online to disguise the real communication actions [33, 39]. Because all clients connected in the system behave the same at each communication round, we can hide the communication metadata with cryptographic security against powerful attackers. We formalize this security notion in Definition 2.1.

Bootstrapping Boomerang. Besides operating in rounds, Boomerang adopts the existing practices of a bootstrapping phase for clients to start conversations [11, 37, 52, 58]. Particularly, clients should run an “add-friend” protocol (where clients can verify each other’s identity and share their secrets) and a “dialing” protocol (where pairwise clients coordinate the time to have the conversation and exchange session keys) [7]. To add a friend, the common practice is to: 1) exchange secrets in person (e.g., by showing a QR code at a coffee shop [7, 37]); or 2) use an online metadata-private add-friend protocol [58]. To dial a friend, the common practice is to adopt an out-of-band metadata-private dialing system, e.g., Alpenhorn [58]. Dialing brings additional costs to clients, which will be amortized over multiple conversation rounds. Note that similar bootstrapping phases have been adopted by prior art [54, 56, 57, 87]. Thus, throughout the paper, we keep our focus on the conversation protocol design, which is where much prior art is differentiated [7], and make simplified assumptions that the bootstrapping phase is properly done. Specifically, upon proper bootstrapping, we will narrow down the problem of metadata-private messaging to how to design an obfuscated message exchange (aka conversation) protocol among pairwise clients under hardware trust.

Attacks out of scope. Similar to other enclave-based systems [32, 35, 49, 75], we don’t consider denial-of-service attacks. The enclave code is assumed to be correct and faithfully fulfilling our oblivious algorithms. Orthogonal countermeasures to recent noteworthy leakage attacks through power consumption channels [25, 68] and transient executions [48, 77] are also beyond the scope of this work. One generic limitation to all metadata-private messaging systems is the long-term intersection threat [14]. Recall that we do not hide whether clients are using the systems or not. Thus, an attacker, who observes the anonymity set of online clients changing across rounds, might infer the linkage of communicating pairs. For example, two clients that simultaneously get online or offline are more likely to be communicating. The common practice to mitigate this concern is to let the clients always stay online [56, 88] or keep the same communication pattern [11] and send enough cover traffic. We also suggest adopting orthogonal mitigation techniques [60, 92] and using more cover traffic, as also noted by Clarion [36].

2.2 Security Goals

Like much prior art, our security goal follows the unobservability concept in anonymous communication [43]. Specifi-

cally, for any two online clients, Alice and Bob, we want to ensure that an attacker cannot distinguish whether they are real buddies in a conversation or not. We want to guarantee this is true even in a malicious setting, where an attacker can control up to $m - 2$ clients for m as the total number of clients connected to the system. We formalize this property below as communication pattern indistinguishability.

Definition 2.1 Let λ be the security parameter and m be the number of connected clients in the system. Define an experiment EXP with an attacker \mathcal{A} who controls $m - 2$ clients:

- The attacker creates a pair of clients in a conversation as $P_0 = (c_0, c_1)$, and a pair of clients not in a conversation as $P_1 = (c'_0, c'_1)$ (e.g., being idle or missing buddies).
- The challenger randomly chooses $b \in \{0, 1\}$ and plays the role of the pair of clients P_b to simulate interactions between them and the server. During this procedure, the challenger needs to simulate the payload (aka contents that can be represented by a random string) for the chosen pair of clients.
- The attacker observes their transcriptions and outputs a bit $b' \in \{0, 1\}$ to guess the challenger's choice.

We define the attacker \mathcal{A} 's advantage with respect to EXP as

$$Adv_{EXP, \mathcal{A}} = |\Pr[b = b'] - \Pr[b \neq b']|.$$

We say that a system is communication pattern indistinguishable if the advantage $Adv_{EXP, \mathcal{A}}$ is negligible in λ for all probabilistic polynomial time (PPT) attackers.

This definition implies that seemingly any pair of connected clients might be communicating with equal chance. We will show this is indeed the case in Boomerang and Boomerang+.

3 Boomerang: Basic Instantiation

3.1 Overview

Boomerang runs in rounds with a single enclave-based server. Following the same practice in previous round-based designs [54, 56, 57, 87, 88], Boomerang requires a coordinator to announce round numbers across the server and clients. In each round, each client sends and receives one message respectively to and from the Boomerang server. To facilitate oblivious message swapping, every message is tagged with a “private label”, which is a pseudorandom string generated from a pairwise session secret between a communicating pair. (See §2 for our system setup assumptions.) Any pair of messages sharing the same private label will be swapped, which indicates a regular case when each private label shows up exactly twice each round. Messages with irregular private label patterns will be detected and looped back (§3.3.2).

Figure 1 shows an overview of our Boomerang design. The Boomerang server first (1) sorts the packets and detects the

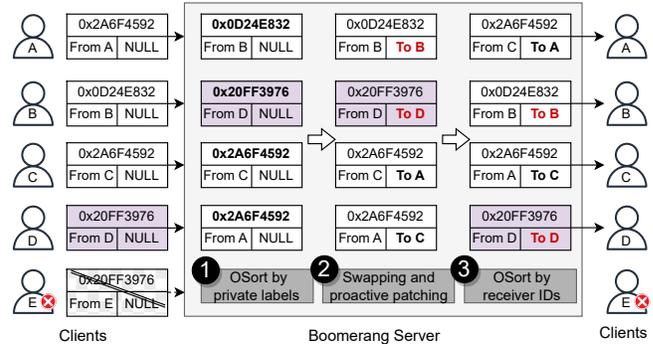

Figure 1: Overview of Boomerang. In this example, A and C are talking. B is idle. D and E are talking, but E is blocked as described at the end of §3.3.2. Boomerang proactively patches the pattern for D and B (Step 2).

irregular pattern of the private labels. Then, (2) it proactively fixes the irregular pattern via the proactive pattern patching algorithm (§3.3.2). Finally, (3) it sorts the messages by receiver IDs and sends them to the clients (§3.3.3).

3.2 Client

Figure 2 shows the pseudocode for client operations. We consider two modes of clients: active clients in conversations with their buddies and idle clients sending dummy cover traffic (as discussed in §2.1). Regardless of being active or idle, each connected client needs to send one message to the Boomerang server in each round.

Packet preparation. A packet Pkt includes the following fields: 1) private label with l bits, $priv_label$; 2) receiver’s identifier, R ; 3) sender’s identifier, S ; 4) round number, $round_num$; and 5) content encrypted by the session key shared with the buddy (Lines 4–6). When preparing the packet, the client fills in all fields except for the receiver’s identifier (e.g., set to $NULL$ by default). If the active client has nothing to deliver to her buddy, she should fill the content anyway, e.g., with a message saying “this is a blank message”. The client then encrypts the packet using the session key shared with the secure enclaves (Line 7). Finally, the client sends the encrypted message to the Boomerang server.

Idle clients. To hide real communication actions, clients need to keep sending messages even if they are not in an active conversation [56, 88]. We let idle clients randomly generate a private label (not shared with others). By design, the server will loop all unpaired messages back to senders.

Exception alert. Normally, after sending the prepared packet to the Boomerang server, the client is expected to receive one packet carrying the message from the buddy/herself every round. Otherwise, the system will raise exceptions for abnormal cases. If there is no message returned by the decryption procedure, it means that the packet to/from the server has been lost. In this case, both active and idle clients should be

```

1 def active_client(round_num, priv_label, my_id,\
2     content, ses_key_encl, ses_key_buddy):
3     # Prepare the packet
4     Pkt pkt; pkt.round_num = round_num
5     pkt.priv_label = priv_label; pkt.S = my_id
6     pkt.enc_content = Encrypt(content, ses_key_buddy)
7     enc_pkt = Encrypt(pkt, ses_key_encl)
8     # Send the packet to the Boomerang server \
9     #     running boomerang_server()
10    send_msg = (my_id, enc_pkt)
11    # Receive the packet from the Boomerang server
12    recv_msg = rpc.request(send_msg)
13    pkt = Decrypt(recv_msg, ses_key_encl)
14    # Exception alert
15    # If there is message loss
16    if pkt == None: raise("Message loss")
17    # If the original message is looped back
18    if pkt.R == my_id: raise("Buddy blocked")
19
20    return Decrypt(pkt.enc_content, ses_key_buddy)
21
22 def idle_client(round_num, my_id, ses_key_encl):
23    # Prepare the packet
24    Pkt pkt; pkt.round_num = round_num
25    pkt.priv_label = random(); pkt.S = my_id
26    pkt.enc_content = ciphertext.random()
27
28    send_msg = (my_id, Encrypt(pkt, ses_key_encl))
29    recv_msg = rpc.request(send_msg)
30
31    if Decrypt(recv_msg, ses_key_encl) == None:
32        raise("Message loss")
33
34    return True

```

Figure 2: Pseudocode for client operations.

alerted about their unreliable network conditions (Lines 13-16 and Lines 31-32). For those successfully decrypted packets, active clients then check whether their messages are from their buddies (Line 18). Note that in Boomerang design, if the receiver ID is the same as the sender ID (indicating that the message is sent back like a “boomerang”), the client should be alerted that his/her buddy has been blocked and can choose to resend the message in the next round or stop the conversation immediately (by changing to idle mode).

3.3 Server

Figure 3 shows the pseudocode for oblivious server operations, including two main functions: 1) oblivious irregular pattern detection and 2) oblivious proactive pattern patching. Below we introduce the background of oblivious primitives and then describe the main ideas of our designs.

3.3.1 Background of Oblivious Primitives

We build Boomerang’s oblivious algorithms over an existing library of general-purpose oblivious primitives developed by XGBoost contributors [2, 55], which is also based on libraries provided in previous noteworthy enclave-based data analytic systems [71, 73]. The library offers basic oblivious functions, including comparisons, assignments, sorting, etc. These oblivious functions are fundamentally built on register-to-register

operators, which are private to the processor and immune to memory access pattern leakages [55, 71, 73].

Oblivious comparisons/assignments. This set of primitives can conditionally assign or compare values on the register level without revealing the results of the comparison or assignment. In this paper, we use `O_Equal(a, b)`, `O_Less(a, b)`, and `O_Choose(cond, a, b)` [2] for comparison and conditional assignment. `O_Equal(a, b)` outputs True if $a = b$ (otherwise outputs False). `O_Less(a, b)` outputs True if $a \leq b$ (otherwise outputs False). `O_Choose(cond, a, b)` chooses from two values given a boolean condition without leaking which value is chosen. If $cond = True$, it outputs value a (otherwise outputs value b).

Oblivious sort (`O_Sort(key, array)`). An oblivious sort algorithm outputs ordered data without revealing any information (e.g., the original order) about the input data [10]. In our instantiation, we choose bitonic sort [12], which is highly parallelizable with $O(n \log^2 n)$ computational complexity. Bitonic sort compares and swaps the items in a fixed and data-independent order, and thus is oblivious by design.

3.3.2 Oblivious Proactive Pattern Patching

Detecting irregular pattern. When receiving a batch, the server first needs to identify all the regular and irregular messages for subsequent processing. The server first obviously sorts the batch by `priv_label` (Step 2 in Figure 3, Line 12). This step is to map the messages of the same label (which implies a communicating pair) together for further pattern detection. Before introducing the detection algorithm, we first show the possible label patterns after sorting. Since the private label is a l -bit pseudorandom string shared between the pair, the possibility that attackers can guess it and forge messages is negligible if l is sufficiently large (e.g., 256 bits). Therefore, a communicating pattern indicates a double-accessed label, which we regard as a regular pattern. Otherwise, the pattern is regarded as irregular. There are three possible label patterns after `O_Sort`, as shown below

- double: messages from communicating pairs;
- single: messages from idle clients or incomplete pairs (caused by client churn or malicious blocking);
- more-than-two: multiple messages with repeating labels controlled by an attacker.

To detect irregular patterns, the server linearly scans the ordered packets using oblivious comparison primitives to identify the above three patterns. Basically, we can achieve this by scanning the messages with a sliding window of three each time, as shown in Step 3.1 in Figure 3. For each message, we compare its private label with its previous, next, and next next messages, respectively (Lines 17-22). This will give us the relationship of the packets in the sliding window.

We first clarify how to determine more-than-two cases. If the label of a message is the same as its two subsequent messages (`is_next2_same = True`), this implies that this private

```

1 def boomerang_server(round_num, recv_msgs, session_keys):
2     pkts = [], R_list = [] # Receiver IDs
3     recv_msgs = Dedup(recv_msgs)
4     # Step 1: decrypt the messages
5     for (S, enc_pkt) in recv_msgs:
6         pkt = Decrypt(enc_pkt, session_keys[S])
7         # Filter out messages not in this round
8         if pkt.round_num != round_num:
9             continue
10        pkts.append(pkt)
11    # Step 2: Pair the private labels
12    pkts.O_Sort(key=pkt.priv_label)
13    # Step 3: Oblivious proactive pattern patching
14    is_mtt = False # mtt: more_than_two
15    for pkt in pkts:
16        # Step 3.1: Detect irregular pattern
17        is_prev_same = O_Equal(pkt.priv_label, \
18                               Prev(pkt).priv_label)
19        is_next_same = O_Equal(pkt.priv_label, \
20                               Next(pkt).priv_label)
21        is_next2_same = O_Equal(pkt.priv_label, \
22                                Next(Next(pkt)).priv_label)
23        # Detect more-than-two (mtt) pattern
24        is_mtt = is_mtt and is_prev_same or is_next2_same
25        # Detect and patch single patterns in Lines 27-28
26        # Step 3.2: Swapping and patching
27        pkt.R = O_Choose(is_next_same, Next(pkt).S, pkt.S)
28        pkt.R = O_Choose(is_prev_same, Prev(pkt).S, pkt.R)
29        pkt.R = O_Choose(is_mtt, pkt.S, pkt.R)
30    # Step 4: Re-order messages by receiver IDs
31    pkts.O_Sort(key=pkt.R)
32    # Step 5: Encrypt and send the messages
33    send_msgs = {}
34    for pkt in pkts:
35        enc_pkt = Encrypt(pkt, session_keys[pkt.R])
36        send_msgs[pkt.R] = enc_pkt
37        R_list.append(R)
38    rpc.response(R_list, send_msgs)

```

Figure 3: Pseudocode for server operations.

label must occur at least three times. Then, we can identify this message as a more-than-two case (by setting the flag `is_mtt = True`). Another observation is that, if a message’s label repeats as a detected more-than-two case, this message must belong to the same case. We identify this by checking whether a message’s previous neighbor belongs to a more-than-two case (based on the flag `is_mtt` as set in the previous iteration), and whether the message’s label repeats that of its previous neighbor (based on the flag `is_prev_same`).

To determine single cases, we check both the message’s previous and next neighbors. If inequality holds for both neighbors (`is_prev_same = False` and `is_next_same = False`), this message belongs to the single case. To save operational costs, we integrate this logic with the swapping process in Step 3.2 (Lines 27-28). This finishes the identification part. In this step, the server has obtained information about the relationship of the private labels in an ordered sequence and determined whether the label pattern falls into an irregular case. Next, the Boomerang server will swap the regular messages and patch the irregular ones.

Swapping and patching. For regular patterns, the server swaps the sender IDs of the two messages and assigns their values to the receiver ID fields (Lines 27-28). Specifically, if the current label is the same as that of the previous (next)

packet, we assign its receiver ID field to have the value of the sender ID of its previous (next) packet. The oblivious choose function helps us conditionally assign the sender ID values to the right packets. It ensures that the server will not learn which part is actually copied to the receiver ID field.

For irregular patterns, Boomerang proactively patches them by looping back such “single” and “more-than-two” messages to its sender (like a boomerang), i.e., setting `pkt.R = pkt.S`, where `R` and `S` denote the identifiers of the receiver and sender, respectively. For single cases, the server obviously assigns `pkt.R` to have the value of `pkt.S`, if the conditions of `is_next_same` and `is_prev_same` are both `False` (Lines 27-28). Finally, for more-than-two cases, where `is_mtt = True`, the server also loops back the packet (Line 29). Note that the original messages do not explicitly carry the information of the receivers. This makes sure that only expected “collisions” on private labels can push forward message delivery. In other words, the server will not obtain the receiver IDs from messages with irregular label patterns.

This step patches the receiving pattern of idle clients, active clients with blocked buddies, and clients controlled by an attacker. With Boomerang, messages with irregular label patterns will not influence their receiver’s receiving pattern. For the example in Figure 1, the message from `E` to `D` is blocked, in which case `D` would not receive any message if there were no pattern patching. The Boomerang server loops back `D`’s message by setting `D` as the receiver (as shown in Step 2), defeating active attacks.

3.3.3 Oblivious Re-order

After the proactive patching, Boomerang needs to re-order the label-ordered sequence. This step is necessary, because adjacent messages in the label-ordered sequence will imply a high possibility that they share the same private label, indicating that the receivers are talking to each other. Hence, we choose to use `osort` with the order of receiver identifiers (IDs) to obviously re-order the sequence.

Sorting the outgoing messages by receiver IDs would reveal the set of receiver IDs (along with their order), which are essential fields to be reported to the server for message transmission anyway. Recall that in the proactive patching step, the server carefully assigns the values of sender IDs to receiver IDs via swapping and patching. This ensures that the receiver set is exactly the same as the sender set (publicly observable to attackers), and each receiver will receive exactly one message. Therefore, sorting the messages by receiver IDs, which reveals the ordered receiver ID list, would not reveal additional information about the conversation metadata.

Remark. This completes our round-based oblivious message exchange in Boomerang design. Note that at the beginning of each round, we can further employ a textbook deduplication procedure in enclaves to filter repeated packets, just in case a malicious host might try to cause an exchange failure

(DoS attack) by injecting replicated packets from the network stack to let the packets' private labels appear more than twice. Similar treatment has also been done in prior art [32, 56, 57].

4 Boomerang+: Horizontal Scalability

4.1 Overview

As noted in §1, for horizontal scalability, directly replicating the single-server Boomerang, with each server processing a subset of clients, would not work because it immediately implies that clients connecting to different servers are not able to talk to each other. To address the problem, one direct idea is to employ an entry node as a load balancer to obliviously distribute batches of messages from all clients to a group of Boomerang nodes for message exchange. Here, the oblivious design is supposed to hide the mapping between the messages and the Boomerang nodes from an attacker. While this opens up a possible pathway to scale Boomerang, subtle issues remain: how to set up the batch structure?

Recent studies on distributed oblivious data stores [32, 89] have pushed forward the understanding on security-aware scaling designs. Particularly, an oblivious load balancer must set up the batch structure only using public information, independent of the input distribution. In this way, an attacker would not observe any sensitive information from the load balancing. We note that these requirements for setting up an oblivious load balancer are generic to any security-aware scalable system designs. Yet, answering them can be quite design specific. Indeed, a batch structure of data requests generated by an oblivious balancer for a distributed data store, where data partitions are fixed at each server across all rounds [32], would be ill-suited for obliviously distributing batches of messages in Boomerang+, where messages might be mapped to different Boomerang nodes each round.

Setting a batch size for Boomerang+. This has motivated us to search for solutions specific to our Boomerang+ design. In our context, the public information at an entry node is the m messages from m connected clients, and n Boomerang nodes (the back-end nodes for message exchange). Functionally-wise, we need to partition the messages by their private labels, which are random (§4.1), to facilitate the exchange of messages sharing the same labels at the same servers. For security, we need to ensure that the batch structures reveal nothing about the input distribution. For performance, we must set the batch size B as small as possible, but without triggering the overflow (otherwise, there will be dropped messages).

Inspired by the balls-into-bins analysis [32], our problem of finding the bound on batch size B in distributing m messages by their random labels (balls) to n servers (bins) can be translated to: what is the maximum load of balls into any bin? In §3.3.2, we have shown each message's label pattern as single, double, or more-than-two. This suggests that each message carries a different weight in the distribution, and

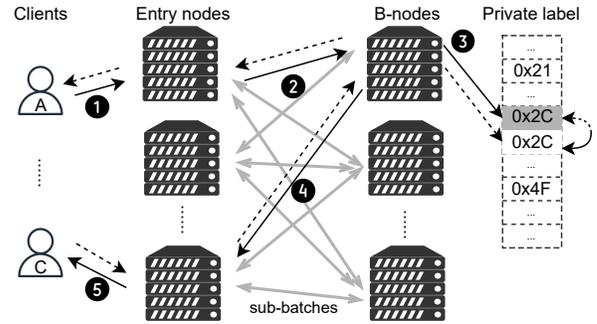

Figure 4: Overview of the scalable Boomerang+ instantiation.

thus we need to answer the question in a *weighted* balls-into-bins game. In Appendix B, we show the complete analysis and proofs to derive the maximum batch size in Boomerang+ (results listed below for easy reference), by applying classic results [13, 76] from the balls-into-bins literature to our problem context.

Theorem 4.1 For any set of m messages, n Boomerang nodes, and a security parameter λ , satisfying $m \gg n(\ln n)^3$ and $\lambda/\log_2 n > 1$, let $B(m, n)$ be a function that outputs the maximum batch size B for each node in Boomerang+. Then the probability of overflow is negligible in λ if we choose

$$B = \left\lceil \frac{m}{n} + 4 \sqrt{\frac{m \ln n}{3n} \left(1 - \frac{1}{\lambda} \frac{\ln \ln n}{2 \ln 2} \right)} \right\rceil.$$

Based on the formula, the maximum batch size will be dominated by m/n , with the extra padding size per batch varying with different choices of messages m and Boomerang nodes n . Note that $\lambda/\log_2 n > 1$ can always hold in practice because n is always smaller than 2^λ for any reasonable security parameter λ . As shown in Appendix B, Figure 13, with $\lambda = 128$ and $m = 2^{16}$, when we scale the number of Boomerang nodes n from 4 to 28, the ratio of extra paddings over real messages ranges from 2% to 8%. With the maximum batch size settled, we will describe our oblivious “load balancers” (entry nodes) and the architecture of Boomerang+ next.

Architecture. Figure 4 shows Boomerang+. We leverage the classic two-layer architecture, consisting of entry nodes and Boomerang nodes (B-node for short) to share traffic and computation workload. The message transmission flow is summarized as follows. (1) Each client connects to one entry node. (2) Entry nodes generate oblivious sub-batches for B-nodes (§4.2). (3) Each B-node merges the sub-batches from entry nodes and processes messages like a single Boomerang server (e.g., proactive irregular pattern detection and patching, §3), except for one additional step to swap the entry node identifiers of the pairs (§4.3). (4) Upon done with the processing, B-node sends the swapped messages back to entry nodes. (5) Finally, entry nodes merge the sub-batches, pad for possible lost messages, and send them back to receivers.

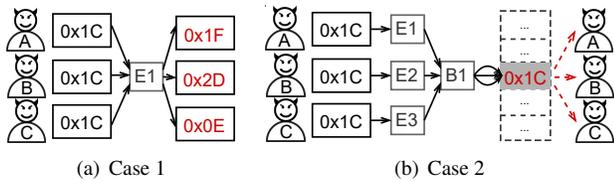

Figure 5: An illustration of more-than-two label patterns on (a) entry nodes and (b) B-nodes. The red dotted arrows in (b) imply that the messages to “0x1C” will be looped back to the malicious clients ultimately.

4.2 Entry Nodes

4.2.1 Irregular Pattern Patching

Similar to the basic single-server Boomerang, when receiving a batch, the entry nodes first decrypt and obviously sort the batch by `priv_label`, and then detect and patch irregular label patterns. But different from the proactive pattern patching algorithm at the basic Boomerang (§3.3.2), here the entry nodes only need to handle the more-than-two cases and leave the single ones to B-nodes.

Patching the more-than-two cases on entry nodes, in case of multiple clients controlled by an attacker sending multiple messages carrying the same private label, is essential. Because such a threat will cause workload skew [32] and potentially influence the non-overflow guarantee of our weighted balls-into-bins algorithm. To eliminate the skew, we let the entry node replace the redundant private labels with new random labels. To detect the more-than-two label patterns, entry nodes adopt the detection algorithm in Boomerang (Step 3.1 in Figure 3, Lines 17–25). Next, instead of looping the irregular messages back, the entry node reassigns new random private labels to them, as shown in Figure 5(a). To set it obviously, we assign `pkt.priv_label` to have the value of `0_Choose(is_mtt, random(), pkt.priv_label)`.

Since the fresh private label is randomly chosen with negligible possibility of collision, the irregular messages will be regarded as a single pattern to be looped back in subsequent processes on the Boomerang node. In this way, we can eliminate workload skew without revealing the number of malicious messages or changing the communication pattern.

4.2.2 One-time Message Assignment

The message assignment function has two main goals:

- (function goal) assigning the messages with the same private labels to the same B-node, no matter which entry nodes the clients are connecting to, and
- (security goal) ensuring the assignment is (pseudo)random, and the distribution of the sub-batches across rounds will not leak the communication pattern.

For the function goal, the intuition is to derive B-node ID

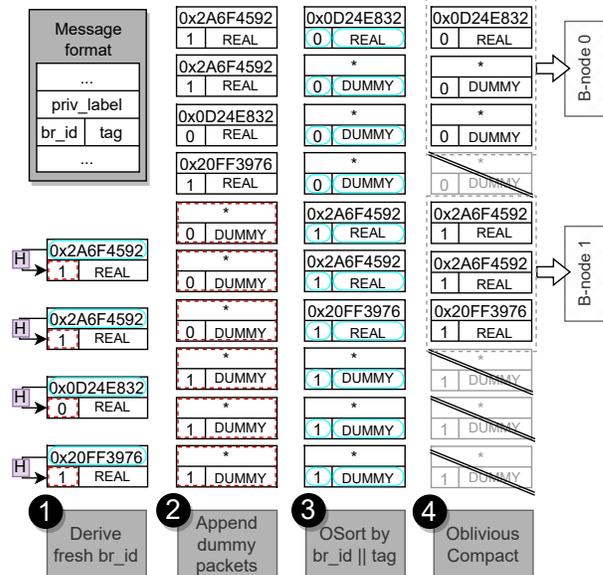

Figure 6: An example of entry node operations. “H” in Step 1 refers to the mapping function (Eq. (1)). B is set to 3. The blue box with rounded corners refers to read operations, and the red box with dotted lines refers to write operations.

(denoted as `br_id`) from the private label using the same deterministic function across all entry nodes. For example, we can simply compute the identifier from the private label modulo the number of B-nodes: $br_id = priv_label \% n$, where n refers to the number of B-nodes. For the security goal, we make the mapping function change across rounds.

Specifically, we use a keyed hash function $H_k(\cdot)$ to derive a fresh string from the private label, round number, and a secret key k shared among the enclaves of all entry nodes. We apply the modulo function to the fresh string and the number of B-nodes. The assigned B-node is:

$$br_id = H_k(priv_label || round_num) \% n. \quad (1)$$

The keyed hash function provides a fresh mapping from the private label to the B-node every round, so attackers cannot predict any future assignments in new rounds.

4.2.3 Oblivious Sub-batch Padding

Although the distribution is fresh across rounds, the true size of each sub-batch is revealed, which brings security concerns in long-term communications [32, 52, 87]. Based on our derived maximum batch size in §4.1, we opt to pad the sub-batches to equal size B , which is calculated from public information, namely m messages and n B-nodes, and will not carry any private information about the content.

The remaining step is to obviously pad the sub-batches without leaking the original sizes. We here follow the oblivious padding algorithm in Snoopy [32]. The padding steps are

shown in Figure 6 and described as follows. Firstly (❷), the entry node appends B dummy messages (with `tag = DUMMY`) for each sub-batch to the message sequence. The private labels in dummy messages are randomly generated. Secondly (❸), it obviously sorts the message sequence by `br_id||tag`. After the sorting, we can get a group of sub-batches, each of which is formed of real messages followed by B dummy messages. Finally (❹), it squeezes extra dummy messages using oblivious compaction. An oblivious compaction algorithm [40] (`O_Compact(flag, array)`) can remove the items in an array with certain flags without leaking which items are removed. The complexity is $O(n \log n)$.

To decide which messages to send or remove obviously (that is, to set the `flag` for each message), the entry node linearly scans the sorted batch and keeps a counter (c) to record the relative position of the message in a sub-batch. If the message is among the first B messages in its sub-batch ($c \leq B$), the message should be sent (`flag = True`). Otherwise, the flag should be set to `False`. We next introduce how to obviously iterate c and assign `flag`. The counter is initially set to 1. When iterating through the batch, the node accumulates the counter ($c + 1$) if the current `br_id` repeats its previous one. Otherwise, set the counter to 1, meaning that the node has finished processing the current sub-batch and encounters the first message for a new sub-batch. With the right counter c , the node can obviously assign `flag` accordingly. The pseudocode for the above step is as follows.

```

is_br_same = 0_Equal(pkt.br_id, Prev(pkt).br_id)
c = 0_Choose(is_br_same, c + 1, 1)
flag = 0_Less(c, B)

```

B is the upper bound calculated from our weighted balls-into-bins algorithm, which guarantees that real messages assigned to the same B-node will not exceed size B (except with negligible probability). Therefore, all real messages will be marked with `flag = True` and not be dropped. Finally, the node uses oblivious compaction to remove extra dummy messages (those marked with `flag = False`).

With the steps above, the size of the sub-batch for each group is exactly B , and the attacker cannot differentiate the dummy messages from the real ones. The entry nodes then send sub-batches to B-nodes for further processing.

4.3 Boomerang Node

Like the basic Boomerang, B-nodes also need to: 1) detect irregular access patterns and patch them (i.e., the patching algorithm in §3.3.2); and 2) swap the messages carrying the same private label. Figure 7 shows operations on B-nodes, among which most operations are the same as Boomerang.

Similarly, there are two types of irregular label patterns on B-nodes: 1) single pattern and 2) more-than-two pattern. Besides idle clients and incomplete pairs as discussed before, single patterns may also come from the irregular messages

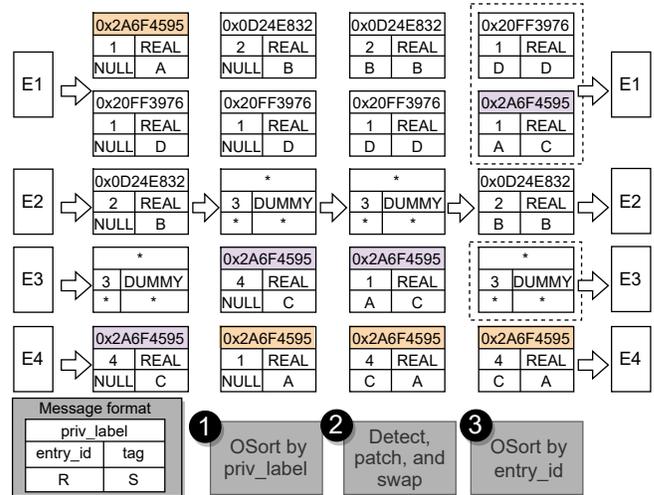

Figure 7: An example of B-node operations. In this example, A and C are talking to each other, B talks to herself (idle client), and the message from someone to D is blocked.

with private labels reassigned by entry nodes. Interestingly, although entry nodes have eliminated workload skew, more-than-two patterns might still appear on B-nodes. As shown in Figure 5(b), malicious clients could send messages with the same private label through multiple entry nodes, with only one message to each entry node, evading the irregular pattern detection. Ultimately, these messages will end at some B-node and appear as more-than-two patterns. To detect such irregular patterns, B-nodes follow the same detection and patching algorithm as Boomerang (Steps 2 and 3 in Figure 3).

Different from Boomerang, B-nodes cannot directly send the processed messages to clients, because this reveals the identities of clients connecting to the same B-node, indicating they are more likely to be talking. Instead, we let B-nodes send each message back to the entry node first, and then let the entry node send the message back to the receiver connecting to it. The entry node ID of the receiver can be obtained from the paired message (if any) with which it was swapped. Hence, (❷) the B-node can swap entry node IDs (`entry_id`) of the paired messages during the linear scan. Similar to the receiver ID swapping step in Boomerang, the B-node swaps (or loops back) both the entry node IDs and receiver IDs using oblivious choose. Finally (❸), the B-node obviously sorts the sequence by entry node IDs (to group the batch for each entry node together) and sends the messages back to the corresponding entry nodes.

In Boomerang, the last step is to re-order messages. We accordingly move this step to entry nodes. When receiving the sub-batches from B-nodes, entry nodes merge the sub-batches, sort the batch by receiver IDs, pad for possible missing messages (as we will discuss in §4.4), remove extra dummy messages, and send the messages to receivers.

4.4 Server Churn

So far, we have introduced our mechanisms (e.g., one-time message assignment and oblivious sub-batch padding) to make the communication pattern among servers oblivious to attackers. However, such mechanisms only consider the “accidents” from clients. For completeness, here we discuss some possible accidents that may happen to servers and introduce Boomerang+’s enhancing strategies.

B-node churn. B-nodes can be blocked (e.g., under DoS attacks) or accidentally go offline without sending back the messages, leading to missing patterns on the clients whose messages are processed on the corresponding B-node. This gives an attacker a chance to link the clients with certain B-nodes. Towards this threat, we let the entry node proactively patch the dropping pattern due to the lost connection with some B-nodes. The patching algorithm is very similar to the oblivious sub-batch padding algorithm in §4.2.3. Firstly, the entry node appends one dummy message for each client connecting to itself. This is feasible because the node can record the list of connecting clients when it processes the incoming messages in the very beginning. Secondly, the entry node obliviously sorts the batch by receiver identifiers. Finally, it linearly scans the sequence, marks which messages to send, and obliviously compacts the batch. After the patching, we can ensure that all clients connecting to the entry node will receive one message in each round, no matter whether there is any B-node churn or not. For efficiency, we only trigger this patching algorithm when a connection loss occurs. Once a B-node goes offline, entry nodes will ignore this node and not assign messages to it in the next round (according to the instructions from the coordinator). In this way, we make sure that B-node churn will not cause severe service denial.

Entry node churn. This case is similar to the case where the clients are blocked, but on a larger scale. The direct impact is that the buddies of clients connected to this entry node will fail to form a paired private label, and thus their messages will be looped back (by other entry nodes). In this case, attackers observe nothing but a predictable situation where a set of clients cannot link to the churned entry node.

5 Analysis

We now show Boomerang and Boomerang+ achieve communication pattern indistinguishability as we claimed in §2. Thanks to the oblivious designs, we ensure that all connected clients behave the same in every round, either exchanging messages with a buddy or sending messages to themselves.

Theorem 5.1 *Given oblivious comparison/assignment operations, an oblivious sort algorithm, and an oblivious patching and swapping algorithm, Boomerang achieves communication pattern indistinguishability presented in Definition 2.1.*

Proof sketch. We focus on the setting defined in Definition 2.1, where $m - 2$ clients are compromised by the attacker. As

Boomerang operates in rounds, in view of the attacker, the only way to distinguish the communication pattern of two given clients is from the observation of memory access patterns during the “obfuscated” message exchange procedure. Thus, the security of Boomerang hinges on the oblivious algorithms designed for proactive pattern patching and re-order (in §3.3.2 and §3.3.3). As the re-order algorithm is essentially the oblivious sorting [10], we mainly pay attention to proving the obliviousness of proactive pattern patching, captured by Lemma C.1 in Appendix C.1. When all involved algorithms are oblivious, it is easy to derive that the attacker cannot identify whether two clients are communicating or not within each round, except with negligible probability. For the fixed system configuration, it follows that the attacker’s view will remain the same across rounds. The full proof of the Theorem 5.1 can be seen in Appendix C.1.

We next show that Boomerang+ achieves the same communication pattern indistinguishability as Boomerang, even though multiple servers are introduced.

Theorem 5.2 *Given a cryptographic hash function, oblivious comparison/assignment operations, an oblivious sort algorithm, an oblivious patching and swapping algorithm, an oblivious sub-batch padding algorithm, and an oblivious compaction algorithm, Boomerang+ achieves communication pattern indistinguishability presented in Definition 2.1.*

Proof sketch. Following the proof sketch in Theorem 5.1, here we also focus on the settings where $m - 2$ clients are controlled by the attacker. With multiple entry nodes and B-nodes deployed, we will first show that Boomerang+ assigns a message to each B-node uniformly due to the deployment of the cryptographic hash function and our security-aware load-balancing design. Then, we show that for the two targeted clients, whether they are communicating or not, the probabilities that their messages are assigned to one single B-node are always equal. Thus, combined with Theorem 5.1, we have that an attacker cannot identify whether two clients are communicating or not in Boomerang+. The detailed analysis can be seen in Appendix C.2.

It is intuitive to see that Boomerang+ is horizontally scalable. See Appendix B for the scalability analysis.

6 Implementation and Evaluation

We implement Boomerang and Boomerang+ in about 4000 lines of C++ code. We build secure enclaves using the framework of Intel SGX v2.16 on Intel SGX DCAP Driver v1.14 and use Intel’s AVX-512 SIMD instructions for basic oblivious primitives. We build our oblivious algorithms using the oblivious library from XGBoost [2]. Clients and Boomerang(+) servers communicate using gRPC v1.35 on asynchronous RPC mode over TLS. The Boomerang(+) prototype is available online at <https://github.com/CongGroup/boomerang>.

6.1 Evaluation Overview

We experimentally answer the following questions: 1) How fast are Boomerang and Boomerang+? 2) Can Boomerang+ scale by adding servers? We highlight some results below:

- Boomerang achieves 99th percentile latency of 1.41 second for 2^{16} clients on one 16-core server. For space, we present the results in Appendix D.
- Boomerang+ achieves 99th percentile latency of 615 ms for 2^{16} on 16 servers and 7.76 second latency for 2^{20} clients on 32 servers, respectively.

Experiment setup. We evaluate Boomerang(+) on Tencent Cloud M6ce VMs [83], with Intel Xeon Ice Lake processors with Intel SGX support [45]. For Boomerang, we use one M6ce.4XLARGE128 instance (16 vCPU, 128 GB of memory, and 13 Gbps of network bandwidth). For Boomerang+, we assign 12 M6ce.4XLARGE128 instances as entry nodes and 4 M6ce.4XLARGE128 instances as B-nodes by default. For completeness, we also evaluate three metadata-private communication systems: Pung (XPIR) [8], XRD [54] and Addra [4]. According to Azure pricing [65], instances with TEEs are roughly twice as expensive as those without TEEs at the same level of computing power. Therefore, to compensate for the machine cost of the trusted hardware Boomerang uses, we allocate twice the number of machines (or total CPU cores) for these systems. For XRD, we use 32 M6.4XLARGE128 instances (16 vCPU, 128 GB of memory, and 13 Gbps of network bandwidth) to construct the chain-based architecture. For Pung, we use one M6.4XLARGE128 instance and run 1/32 total traffic over it, following the setting in XRD [54]. Since Pung is directly parallelizable, letting one server share 1/N of the total traffic is the best performance it can possibly achieve. For Addra, we use one S4.8XLARGE128 instance (32 vCPU, 128 GB of memory, and 11 Gbps of network bandwidth) as the master and 30 M6.4XLARGE128 instances as the workers. For clients in the four systems, we use one C5.26XLARGE368 instance (104 vCPU, 368 GB of memory, 36 Gbps of network bandwidth) to run simulated clients, each sending/receiving one RPC request at a time. We run instances in the same data center to save bandwidth and simulate client-server round trip latency of 100 ms by using Linux tc command. Results are averaged 20 times for each experiment.

Parameters. We set the message size to 256 Bytes and the private label to 256 bits. We set the conversation round to 12 seconds, according to the latency results from our experiment on Boomerang+ dealing with 2^{20} messages. We set the batch size B according to Theorem 4.1, with the security parameter $\lambda = 128$. For XRD, we construct 32 chains, each of which consists of 30 machines. The length ensures that the probability of the existence of a group of malicious servers is less than 2^{-64} if 20% of the servers are malicious. We let each client send 8 messages to 8 chains, following XRD’s recommendations. For Pung, we use recursion with a depth of 2 and set the bucket size to 64.

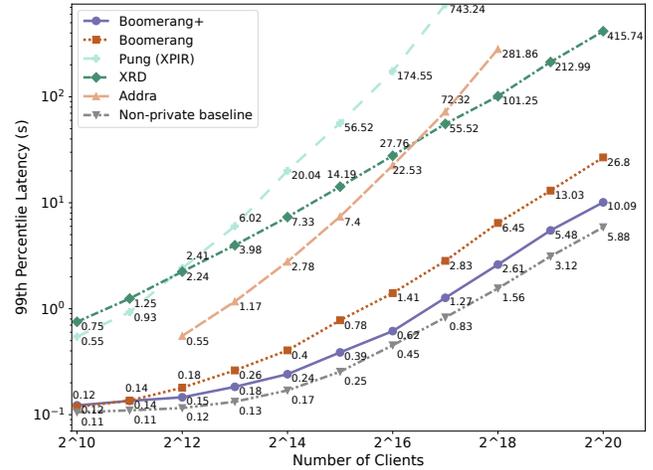

Figure 8: 99th percentile latency of Boomerang, Boomerang+, and other baselines with a varying number of clients.

6.2 Boomerang+ Performance

Latency and throughput. Figure 8 depicts the latency of Boomerang, Boomerang+, Pung (XPIR) [8], XRD [54], Addra [4], and a non-private baseline. Pung, XRD, and Addra are the latest work achieving pairwise metadata-private communication under cryptographic security, but with different trust assumptions. XRD operates on fractional trusted servers, and Addra and Pung operate on fully untrusted servers. We notice that the latency results of Addra and XRD are higher than those reported in their papers. This is perhaps because we used fewer and less powerful machines. Besides, we only ran Addra over up to 2^{18} clients, as our testbed (one 32-core master and 30 16-core workers) could not afford a workload for clients more than 2^{18} .

Boomerang+ achieves 615 ms latency for 2^{16} clients and 10.09 second latency for 2^{20} clients. The throughput of Boomerang+ reaches 85.4K messages per second under 16 machines. Compared to the prior systems based on cryptographic primitives, Boomerang+ is significantly more efficient thanks to leveraging the trusted hardware. For example, for 2^{16} clients, Boomerang+ is 36× faster than Addra and 45× faster than XRD. We also evaluate a non-private version of Boomerang+ to show the cost of non-oblivious operations (most of which is from the network operation cost). In this baseline, we keep the same round-based design and traffic transmission flow (i.e., the same two-layer network architecture) but remove all security-enhancing operations in enclaves (e.g., oblivious sort, padding, patching, etc.). Results (the grey dotted line in Figure 8) indicate that the computational overhead of the oblivious operations for metadata hiding over that of other basic operations is small. Interestingly, compared to Boomerang (the basic instantiation), Boomerang+ does not have an overwhelming advantage when the clients are less than 2^{15} . This is because Boomerang+ involves more oblivious

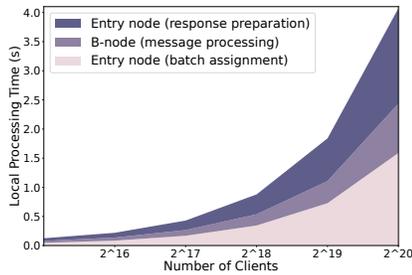

Figure 9: Breakdown of Boomerang+ operational costs.

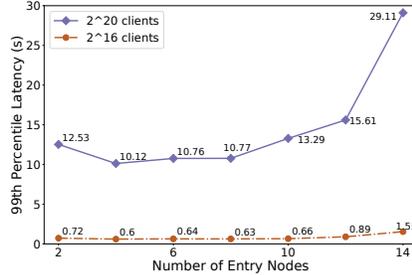

Figure 10: Latency with varying numbers of entry and B-nodes (sum fixed to 16).

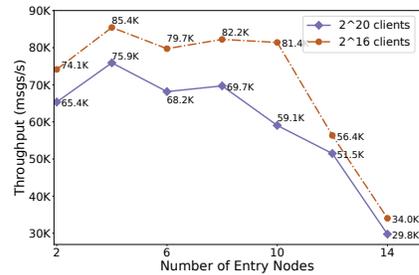

Figure 11: Throughput with varying numbers of entry nodes and B-nodes.

ious operations (e.g., the padding, oblivious sort, and compaction on the entry nodes) to take care of potential threats due to the scalable design. When the clients scale to 2^{20} , the benefits of horizontal scaling gradually show up: Boomerang+ runs $2.66\times$ faster than Boomerang. In §6.3, we will further show the horizontal scalability of Boomerang+; that is, it can achieve lower latency by adding more servers.

Bandwidth cost. Boomerang+ requires one message per round for both active and idle clients. On the server side, Boomerang+ involves dummy paddings, and the overhead is relatively small. According to our calculation, for a workload of 2^{15} messages on one entry node to four B-nodes, dummy messages account for less than 4% of all messages (details about the padding overhead in Figures 13 and 14 in Appendix B). Luckily, on Azure Cloud and many other clouds, data transfer within one VNet is free [63].

6.3 Microbenchmarks

Breakdown of Boomerang+ operational cost. To evaluate the computational cost on entry nodes and B-nodes, we break down Boomerang+ latency into three parts: 1) entry node batch assignment, 2) B-node message processing, and 3) entry node response preparation. Figure 9 shows the processing time for 8 entry nodes plus 8 B-nodes, each of which handles (almost) an equivalent volume of messages. Besides, we only record the local processing time on each node and eliminate the network cost (e.g., RPC request and response with clients) here. In this way, we can clearly see the computational overhead at each stage. Note that the total operation latency is smaller than the end-to-end latency presented in Figure 8. This is because processing RPC requests is time-consuming in our implementation, especially under a large number of requests. Generally, facing the same volume, the entry nodes (both the first and third stages) operate longer than B-nodes. We conjecture that assigning a few more machines as entry nodes than B-nodes with a fixed total number of machines may save latency, as shown below.

Resource allocation on entry nodes and B-nodes. As discussed before, resource allocation can be important for Boomerang+'s overall performance. We have tested the la-

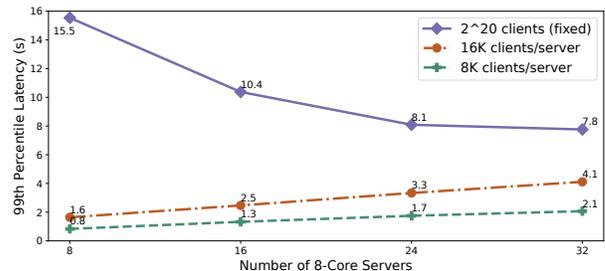

Figure 12: Latency with a varying number of servers.

tency and throughput under different allocations on entry nodes and B-nodes using 16 machines in total, as shown in Figures 10 and 11, respectively. We find that Boomerang+ performs the best over 12 entry nodes and 4 B-nodes. This is because the operational cost is higher on entry nodes, and assigning more entry nodes reduces the average workload on each entry node. This observation is consistent with the breakdown results, where processing on entry nodes takes longer than that on B-nodes. We also report the performance of different allocations given different total numbers of servers in Appendix E.

Scaling by adding servers. With horizontal scalability, Boomerang+ should, ideally, achieve the same level of latency by adding more servers when handling more clients. In this experiment, we adopt 32 8-core M6ce.2XLARGE64 instances to test the scalability of Boomerang+ over more servers.

We first set a fixed total number of clients to 2^{20} and gradually increase the number of servers from 8 to 32 to see how the latency can be reduced by adding servers. We then evaluate the scalability by proportionally adding servers and clients, by keeping a fixed number of clients on one server group. Specifically, we let every 8 servers handle 2^{17} and 2^{16} clients (amortized to about 16K and 8K clients per server, respectively). For different numbers of servers, we choose the best ratio of entry nodes to B-nodes according to the supplementary resource allocation experiment (Appendix E). The ratio is 5:3 for 8 servers and 3:1 for 16, 24, and 32 servers. As reported in Figure 12, the latency reduces from 15.5 seconds to 7.8 seconds when Boomerang+ scales from 8 to 32 servers. Adding more servers to decrease the amortized workload helps re-

duce latency when client size scales, but this also increases the system dollar cost (as discussed in Appendix F). This is a trade-off between performance and cost. For example, with the same total number of clients, supporting an average of 8K clients per server doubles the machine cost of supporting 16K clients per server, while gaining a $2\times$ speed-up. Fortunately, the host cost for a 16-core SGX instance on Azure cloud is only 1121 USD/month, which we believe is affordable when amortized to 8K clients (0.14 USD/month per client).

7 Related Work

Mix-nets and follow-up enhancements. There has been significant progress in metadata-private communication designs recently. One category of results follows the concept of mix networks (mix-nets) [21]. Based on that, recent results [15, 16, 52–54, 56–58, 72, 87, 88] have proposed a number of noteworthy security and privacy enhancement strategies to deal with powerful attackers, including: 1) batch processing of messages from all clients in synchronous rounds to mitigate traffic analysis threats [31, 39]; 2) carefully structuring protocols to reveal less observable variables (and thus exposing reduced useful information) to attackers, with representative examples of adopting private virtual addresses for obfuscated message exchanges [54, 56, 87, 88]; 3) generating cover traffic with calibrated parameters to obscure the communication patterns among users (as well as users) [56, 87, 88]; 4) adding verifiability to the message shuffling to defeat misbehaving servers among the mix-nets [54, 56, 87]; and 5) designing proactive self-recovering schemes (usually relying on the assumption of honest servers) in the face of inadvertent user disconnections or even active network disruptions [54, 57]. One latest effort has tried to shift the online burden of clients [11] through oblivious delegation to untrusted proxy servers.

Boomerang’s design draws insights from these strategies but differs from them on instantiations with hardware enclaves. Trusting the enclaves enables Boomerang to use fewer servers for traffic mixing with reduced latency. But the unique enclave security context demands Boomerang to bring together tailored oblivious designs for message shuffling, horizontal scaling, and proactive patching against active attacks.

Metadata-private messaging via cryptographic designs.

There have been cryptographic designs to facilitate metadata-private communications. One category of results follows the dining cryptographers network (DC-net) [22], which demands broadcasting data linear to the size of the participating clients in the anonymous communication at a high level [28]. Later systems [3, 29, 91] propose scalability improvement and resilience designs against unreliable clients and untrusted servers. Another category of cryptographic designs utilizes private information retrieval [4, 6, 8], MPC [5] and distributed point function techniques [3, 27, 37, 70] to facilitate oblivious read / write to a database with private mailboxes, based on which metadata-private messaging (and broadcast) system can

be constructed. Recently, Clarion [36] gives an MPC-based shuffling design for anonymous communication.

Despite providing cryptographic security (sometimes even under fully untrusted server [4, 8]), these systems do not easily scale to more than hundreds of thousands of users while maintaining low latency and high throughput. The inherent cryptographic operations also present unfavorable operational dollar cost, which might yet be attractive for voluntary adoptions in practice.

Security-aware scaling of oblivious data stores. Recent results have studied how to scale the oblivious data access systems without leaking information about the data requests [32, 89]. The key is an oblivious load balancer design that distributes access batches independent of the input distribution (with security-aware paddings) and sets the batch size using only public information. The entry-node design in Boomerang+ is inspired by these generic observations. Yet, with context-specific modeling and analysis, we have derived the bound of the maximum batch size that best suits our metadata-private messaging system, through a weighted balls-into-bins game.

Enclave-based network systems. While enclave-based network applications are many, e.g., SGX-Tor [49, 50], SGX-middleboxes [35, 42, 74], to our best knowledge, usage of enclaves is rarely attempted for metadata-private communications, except for one recent work DAEnet [80]. The focus of DAEnet is different from Boomerang, as it tends to hide the conversation route through a peer-to-peer infrastructure, where each peer as a personal computer is assumed to be equipped with an enclave. Unfortunately, this assumption seems no longer in line with the industry movement [44].

8 Conclusion

We have presented Boomerang, a metadata-private messaging system that leverages the readily available trust assumption on hardware enclaves. Boomerang draws many insights from the prior art and achieves efficient pairwise communication with cryptographic security. Its technical instantiation involves tailored oblivious algorithms for message shuffling, horizontal scaling, and proactive resistance against active attacks. We hope Boomerang’s comparably high efficiency and low operational cost could make metadata-private messaging systems one step closer to mass adoption in practice.

A Discussion and Limitations

Establishing trust on Boomerang. Boomerang relies on the trust assumption on secure enclaves, which provide confidentiality and integrity for data and codes. While trusting a single enclave node can be done through the standard remote attestation, like the one from Intel SGX [46], trusting multiple-enclave applications would additionally involve mutual attestation, which is necessary among interacting enclaves to establish a trust relationship [23, 79]. One common practice is to rely on a trusted third party (TTP) to facilitate mutual attestation [9]. The TTP can perform remote attestation with each enclave individually and serve as a trusted anchor to bootstrap the mutual trust among those enclaves. In the case of Boomerang, we suggest following the above common practice for any client connecting to the system to establish trust on Boomerang. The TTP that all clients need to rely on can be the trusted developer of Boomerang or his/her delegated server in a trusted domain [9, 23]. A very recent work has proposed a new way for mutual attestation among enclaves without relying on a TTP [23], which can be beneficial to the trust establishment in the Boomerang system. In the future, to mitigate the concern on the centralized trust of a single enclave vendor (e.g., Intel), we can further consider employing a mix of enclaves from different vendors, e.g., Intel SGX, ARM

TrustZone, AMD SEV, etc., to distribute the trust, which is also a trendy subject in recent literature [23].

Reduce client online burden. Metadata-private messaging systems usually assume clients should always keep online and send messages at regular rates to hide the real communication behavior [4, 33, 39, 54, 57, 87, 88]. To simplify the problem statement, Boomerang’s security analysis also follows this assumption. Although Boomerang achieves acceptable bandwidth cost, we acknowledge that this “always-online” requirement may be a barrier to the practical use of Boomerang. The latest work Groove [11] studied this issue and proposed an oblivious delegation mechanism to reduce client online burden, by introducing proxies between clients and mixnets. To improve Boomerang’s client flexibility, a feasible way is to integrate the oblivious delegation mechanism and the proxy design with Boomerang, considering that Boomerang can be an alternative to mixnets for message shuffling. We believe our Boomerang can serve as a performant and secure backend for metadata-private message shuffling.

B Balls into Bins

To analyze the overflow probability in Boomerang+, we introduce the balls-into-bins game to estimate the probability that a message may be dropped during batch distributions.

Balls-into-bins studies the allocation problem that throws m balls into n bins by placing each ball into a bin chosen independently and uniformly at random [76]. One natural question in this area is to ask for the maximum number of balls in any bin. According to prior art [13, 76], an interesting result about the maximum number of balls in any bin problem is introduced below, which will be used to estimate the maximum load bound of Boomerang+.

Lemma B.1 (Maximum load [76]) *Let ℓ be the random variable that counts the maximum number of balls in any bin, if we throw m balls independently and uniformly at random into n bins and $m \gg n(\ln n)^3$. Then we have*

$$\Pr[\ell > \frac{m}{n} + \sqrt{\frac{2m \ln n}{n} \left(1 - \frac{1}{\alpha} \frac{\ln \ln n}{2 \ln n}\right)}] = 1 - \frac{1}{n^\alpha},$$

where α is a positive constant larger than 1.

Here α serves a role to ensure the tightness of the bound of the maximum load [13, 76]. Next, we prove Theorem 4.1 below.

Theorem 4.1 *For any set of m messages, n Boomerang nodes, and a security parameter λ , satisfying $m \gg n(\ln n)^3$ and $\lambda / \log_2 n > 1$, let $B(m, n)$ be a function that outputs the maximum batch size B for each node in Boomerang+. Then the probability of overflow is negligible in λ if we choose*

$$B = \left\lceil \frac{m}{n} + 4 \sqrt{\frac{m \ln n}{3n} \left(1 - \frac{1}{\lambda} \frac{\ln \ln n}{2 \ln 2}\right)} \right\rceil.$$

Proof. Like most existing works, allocating a set of m messages to a given number of servers can be formalized as a balls-into-bins game. But a bit different from their works, the balls are weighted in Boomerang+ because messages with the same private labels will be allocated to the same servers. Suppose m_1 is the number of messages with single-pattern private labels (see §3.3.2 for possible causes), and m_2 is the number of messages with double-pattern private labels (i.e., regular messages from communicating pairs). Since assigning messages with single-pattern private labels and assigning messages with regular private labels are independent, the task of allocating m messages can be separated as two subtasks: 1) allocating m_1 messages with single-pattern private labels; and 2) allocating m_2 messages with double-pattern private labels. It’s clear that $m_1 + m_2 = m$.

For the task of allocating m_1 messages to n B-nodes, it can be formalized as the game throwing m_1 balls into n bins. For the task of allocating m_2 messages, a pair of messages with the same regular private labels will be allocated to the same B-node. Thus, we can tie m_2 balls together in pairs (by their double-pattern labels), and throw $m_2/2$ times. Namely, it is a $m_2/2$ -balls-into- n -bins problem. Let ℓ_1 and ℓ_2 be two random variables that count the maximum messages assigned in any B-node in the above two tasks, respectively. Let

$$B_{m_1} = \frac{m_1}{n} + \sqrt{\frac{2m_1 \ln n}{n} \left(1 - \frac{1}{\alpha} \frac{\ln \ln n}{2 \ln n}\right)}$$

and

$$B_{m_2} = \frac{m_2}{n} + 2 \sqrt{\frac{m_2 \ln n}{n} \left(1 - \frac{1}{\alpha} \frac{\ln \ln n}{2 \ln n}\right)}.$$

According to Lemma B.1, we have

$$\Pr[\ell_1 > B_{m_1}] = 1 - \frac{1}{n^\alpha} \text{ and } \Pr[\ell_2 > B_{m_2}] = 1 - \frac{1}{n^\alpha}.$$

To prevent overflow, the probability of a message being dropped should be confined to a negligible function in the security parameter λ . Thus we have

$$1 - \frac{1}{n^\alpha} = 1 - \frac{1}{2^\lambda} \Rightarrow \alpha = \frac{\lambda}{\log_2 n}.$$

Let $B' = B_{m_1} + B_{m_2}$, then

$$B' = \frac{m}{n} + \left(\sqrt{m_1} + \sqrt{2m_2}\right) \sqrt{\frac{2 \ln n}{n} \left(1 - \frac{1}{\lambda} \frac{\ln \ln n}{2 \ln 2}\right)}. \quad (2)$$

With the arithmetic-geometric mean inequality, we have that

$$\left(\sqrt{m_1} + \sqrt{2m_2}\right) \leq \sqrt{2(\sqrt{m_1})^2 + 2(\sqrt{2m_2})^2},$$

which attains its equality if and only if $\sqrt{m_1} = \sqrt{2m_2}$.

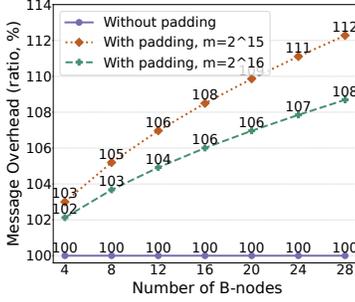

Figure 13: Message overhead (ratio), which describes the ratio of overall padded messages to real messages, i.e., nB/m .

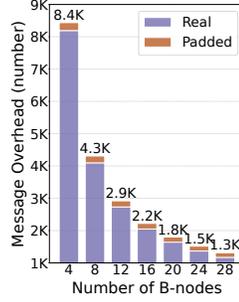

Figure 14: Message overhead (number) under 2^{15} real messages concretely.

Combined with the condition $m_1 + m_2 = m$, we can solve for $m_1 = 2m/3$ and $m_2 = m/3$. Then

$$(\sqrt{m_1} + 2\sqrt{m_2}) \leq \sqrt{2 \left[\left(\sqrt{\frac{2m}{3}} \right)^2 + \left(\sqrt{\frac{2m}{3}} \right)^2 \right]} \leq 2\sqrt{\frac{2m}{3}}. \quad (3)$$

Applying Eq. (3) to Eq. (2), it is easy to get

$$B' \leq \frac{m}{n} + 4\sqrt{\frac{m \ln n}{3n} \left(1 - \frac{1}{\lambda} \frac{\ln \ln n}{2 \ln 2} \right)} \leq B.$$

Finally, we compute the probability that a message is dropped on a server. It equals the probability that the maximum number of messages allocated to a node is larger than the maximum load. As mentioned, the above two subtasks are independent, and thus we have

$$\begin{aligned} \Pr[\ell > B] &\leq \Pr[\ell > B'] = \Pr[\ell > B_{m_1} + B_{m_2}] \\ &\leq 1 - \Pr[\ell \leq B_{m_1} + B_{m_2}] \\ &\leq 1 - \Pr[\ell_1 \leq B_{m_1} \wedge \ell_2 \leq B_{m_2}] \\ &\leq 1 - (1 - \Pr[\ell_1 > B_{m_1}])(1 - \Pr[\ell_2 > B_{m_2}]) \\ &\leq \frac{2}{n^\alpha} - \frac{1}{n^{2\alpha}} = \frac{2}{2^\lambda} - \frac{1}{2^{2\lambda}}. \end{aligned}$$

That is to say, the probability that a message is dropped (aka overflow) is negligible in λ . This completes the proof.

In practice, we usually round the above bound up to an integer that is greater but nearest to it. Figures 13 and 14 have demonstrated that our maximum batch size only incurs marginal overhead (with extra paddings) on our horizontal scaling design.

Scalability Analysis. We borrow the idea from XRD [54] to define the scalability of the designed system. Specifically, we say that a system is scalable if the number of requests that one server needs to handle trends to zero when the number of deployed servers increases to infinite. Without loss of generality, we start with (one entry node that obliviously distributes

the incoming messages to a set of B-nodes in Boomerang+. Let m and n denote the number of messages and deployed B-nodes, respectively. According to Theorem 4.1, we know that the upper bound of the number of messages sent to a B-node server is $\frac{m}{n} + 4\sqrt{\frac{m \ln n}{3n} \left(1 - \frac{1}{\lambda} \frac{\ln \ln n}{2 \ln 2} \right)}$. It is clear that

$$\lim_{n \rightarrow \infty} \frac{m}{n} + 4\sqrt{\frac{m \ln n}{3n} \left(1 - \frac{1}{\lambda} \frac{\ln \ln n}{2 \ln 2} \right)} = 0.$$

Now let us consider having more entry nodes in the system. It is intuitive to see that in Boomerang+ each entry node can run independently and in parallel, which effectively eliminates a potential bottleneck at a single entry node. Similar to the observations in Snoopy [32], in Boomerang+, adding more entry-nodes is not entirely free, because it would increase the total amount of messages sent to each B-node server. Suppose we have v entry-nodes, n B-nodes, and each entry-node has m incoming messages (out of the total $v \times m$ messages) for oblivious distribution. The upper bound of the total amount of messages from v entry-nodes sent to a B-node server is $v \times \left(\frac{m}{n} + 4\sqrt{\frac{m \ln n}{3n} \left(1 - \frac{1}{\lambda} \frac{\ln \ln n}{2 \ln 2} \right)} \right)$, which would still approach 0 when $n \rightarrow \infty$. Thus, Boomerang+ can scale with more clients and messages by adding more entry nodes and more B-nodes.

Our analysis mainly focuses on the heavy load cases, where $m \gg n(\ln n)^3$ generally holds. For example, for those deployments in practice with good anonymity, m at each entry node can easily reach at least in the order of 10^5 , while the overall workload can largely be handled with no more than $n = 100$ B-nodes. If in the extreme cases where m becomes small, we have some fallback options: 1) setting the maximum load $B = m$; or 2) adaptively falling back to single-server Boomerang mode. We leave this adaptive switching design as our future work.

Note that our scalability analysis does not give specific configuration guidelines on how to add entry-nodes and B-nodes, because this would be highly dependent on specific requirements on performance, e.g., latency, throughput, etc., and cost, e.g., expenses of adding respective nodes, bandwidth, etc. We would resort to the abstract configuration planner in Snoopy [32] as a good starting point when we push Boomerang+ to a more practical realm in the future.

C Security Analysis

C.1 Proof of Theorem 5.1

As mentioned, due to the deployment of secure enclaves and a round-based communication model in Boomerang, the only thing left is to prove that memory access patterns in the obfuscated message exchange are oblivious. From the description in §3, Boomerang is designed by combining several oblivious algorithms. Here we prove the indistinguishability of memory access patterns in Boomerang in a modular way. First, we demonstrate that our proactive pattern patching (denoted

```

    pkt.R = Sim_0_Choose(pkt.S, pkt.R)
end for

```

Figure 15: Real and ideal experiments for an oblivious proactive pattern patching algorithm

as PPP) algorithm built on existing oblivious algorithms is oblivious according to Definition C.1 below. Then we prove that our Boomerang system protects metadata privacy when built on the oblivious PPP. We first give the definition of a secure PPP algorithm.

Definition C.1 *The proactive pattern patching algorithm PPP is secure if for any PPT attacker, there exists a PPT simulator such that*

$$|\Pr[\text{Real}_{\text{PPP}}(\lambda) = 1] - \Pr[\text{Ideal}_{\text{PPP}}(\lambda) = 1]| \leq \text{negl}(\lambda), \quad (4)$$

where λ is the security parameter, Real_{PPP} and $\text{Ideal}_{\text{PPP}}$ are experiments defined in Figure 15.

Below we show that our PPP algorithm satisfies the above definition by proving the Real_{PPP} and $\text{Ideal}_{\text{PPP}}$ experiments are indistinguishable.

Lemma C.1 *Given the oblivious primitives for comparison and assignments 0_Choose and 0_Equal , the proactive pattern patching protocol described in §3 and formally defined in Figure 15 is also an oblivious algorithm.*

Proof. To simplify the proof and our description of the simulator, we assume that the packets (aka encrypted messages) received by the server are indistinguishable by size and traffic patterns, which the attacker cannot exploit to distinguish the

memory access patterns. Then we need to demonstrate that the memory accesses of the simulated experiment $\text{Ideal}_{\text{PPP}}$ that takes public information as input are indistinguishable from those of the real experiment Real_{PPP} . As shown in Figure 15, we leverage the following oblivious building blocks in the Real_{PPP} experiment.

- $0_Choose(\text{cond}, a, b)$: If $\text{cond} = \text{True}$, it outputs value a . Otherwise, it outputs value b .
- $0_Equal(a, b)$: Obviously assigns True to the output if a equals b . Otherwise, it outputs False .

The simulated experiment $\text{Ideal}_{\text{PPP}}$ is built on top of simulations of the above oblivious building blocks.

- $\text{Sim}_0_Choose(a, b)$: Simulates choosing from (a, b) as the output, given a hidden bit.
- $\text{Sim}_0_Equal(a, b)$: Simulates testing whether a equals b and outputs True if they are equal.

With these building blocks, we show that the memory access patterns in the real and ideal experiments defined in Figure 15 are indistinguishable. Specifically, if an attacker can distinguish the $\text{Ideal}_{\text{PPP}}$ and Real_{PPP} , then the distinguishability must occur in at least one of the steps. But this happens only with negligible probability because: 1) the simulator uses the public information to simulate indistinguishable

dummy input from real input (i.e., the number of packets m and the packet size), and accordingly follows the same for loop structure as the `RealPPP`; 2) for each iteration inside the for loop structure, the security of oblivious building blocks `O_Choose` and `O_Equal` ensures that the corresponding simulations `Sim_O_Choose` and `Sim_O_Equal` produce indistinguishable memory access patterns; and 3) the operations on direct assignment to `is_mtt` in both `IdealPPP` and `RealPPP` are also indistinguishable. This completes the proof of Lemma C.1.

Proof of Theorem 5.1. Based on the fact that the proactive pattern patching (PPP) algorithm is oblivious, we continue to prove Theorem 5.1 under the security notion defined in Definition 2.1. Let b and b' be the choices of the challenger and the attacker \mathcal{A} , respectively, in the experiment EXP defined in Definition 2.1.

From the attacker’s view, as all messages are encrypted, the only way to distinguish the communication patterns of two given clients is by observing memory access patterns during the “obfuscated” message exchange procedure. We assume all involved oblivious algorithms are computationally indistinguishable, except with negligible probability in λ (aka $\text{negl}(\lambda)$). As seen, Boomerang leverages an oblivious proactive pattern patching algorithm (as shown in Lemma C.1) and an oblivious sorting algorithm [10]. Let “M fails” denote the event that the memory access patterns of at least one of the algorithms mentioned above fail to achieve obliviousness, which happens only with negligible probability in λ . Thus, we have

$$\begin{aligned} \text{Adv}_{\text{EXP}, \mathcal{A}} &= |\Pr[b = b'] - \Pr[b \neq b']| \\ &\leq \max\{\Pr[b = b', \text{M fails}], \Pr[b \neq b', \text{M fails}]\} \\ &= \max\{\Pr[b = b' | \text{M fails}], \Pr[b \neq b' | \text{M fails}]\} \cdot \Pr[\text{M fails}] \\ &\leq \Pr[\text{M fails}] = \text{negl}(\lambda). \end{aligned}$$

The above shows that the attacker cannot identify whether two clients are communicating or not within each round, except with negligible probability. For the fixed system configuration across rounds, it is easy to see that the attacker’s view will remain the same across rounds. This completes the proof of Theorem 5.1.

C.2 Proof of Theorem 5.2

The proof of Theorem 5.2 is analogous to that of Theorem 5.1. The only difference between Boomerang and Boomerang+ is that Boomerang+ employs entry nodes as load balancers to distribute batches of messages from all clients to a group of B-nodes for message exchange. Thus, the key is to show that this distribution procedure is oblivious.

We assume that the system configuration is fixed across rounds, including the number of entry nodes, B-nodes, and connected clients to each entry node. First, we show that Boomerang+ assigns a message to each B-node uniformly.

Note that Boomerang+ assigns a message to each B-node by computing $\text{br_id} = H_k(\text{priv_label} || \text{round_num}) \% n$, where H is a keyed cryptographic hash function, and n refers to the number of B-nodes. According to the classical simulation-based security definition of a keyed hash function [17], the result of a hash function and a random value is computationally indistinguishable. It implies that the distribution of `br_id` is uniform, and further confirms that allocating messages to different B-nodes can indeed be formulated as a random balls-to-bins assignment. Therefore, we can apply the batch size derived from Theorem 4.1 to set up the batch structure without overflow. Moreover, the batch size is determined by the public information (as shown in §4.2.3) only, independent of the input.

Based on the above initial result, it follows that the probability that a message is assigned to any individual B-node is always equal. Without loss of generality, we assume that the number of deployed entry nodes is v . Let c be an encrypted message sent by a client and e be its refreshed copy by the entry node. The probability for the message assigned to the t -th B-node is

$$\Pr[c \rightarrow \mathbb{B}_t] = \sum_{j=1}^v \Pr[c \rightarrow \mathbb{E}_j] \cdot \Pr[e \rightarrow \mathbb{B}_t] = \frac{1}{n},$$

where \mathbb{B}_t denotes the t -th B-node, \mathbb{E}_j denotes the j -th entry node, and $c \rightarrow \mathbb{B}_t$ denotes that message c is assigned to \mathbb{B}_t finally. This result holds as long as no empty B-node exists during one communication round, which is guaranteed by our uniform message assignment and oblivious sub-batch padding algorithms. Our oblivious sub-batch padding algorithm is largely based on existing building blocks, including the oblivious padding algorithm in Snoopy [32]. Thus, we omit the proofs for its obliviousness here. With the above results, we can obtain that messages from any two clients i and j , whether they are communicating or not, are assigned to the same B-node t with the same probability $1/n^2$. In other words, whether the two clients are communicating or not, their message assignment from entry node(s) to a single B-node is indistinguishable from the attacker.

Now let’s focus on messages assigned to each individual B-node. According to Theorem 5.1, an attacker cannot identify whether any pair of clients are communicating or not at a single-server Boomerang. Thus, it follows that at each individual B-node in Boomerang+, an attacker cannot identify whether any pair of messages are from two communicating clients or not. It holds in any single round. As the assignment mapping (through the keyed hash function H) is refreshed for every round, it is easy to see that the attacker’s view will remain the same across rounds, with a fixed system configuration. It ensures the indistinguishability of whether two clients communicate or not in Boomerang+.

Finally, we need to prove that the memory access patterns in Boomerang+ are oblivious. To achieve such obliviousness, we build Boomerang+ on top of a group of oblivious primitives

Table 1: Latency with varying numbers of entry nodes (#E) and B-nodes (#B). The best ratios with the lowest latency are marked in bold.

	#E	#B	Latency	#E	#B	Latency	#E	#B	Latency	#E	#B	Latency
8 Servers	7	1	20.10	6	2	16.08	5	3	15.54	4	4	16.19

	6	26	12.47	4	28	16.49	2	30	28.46			

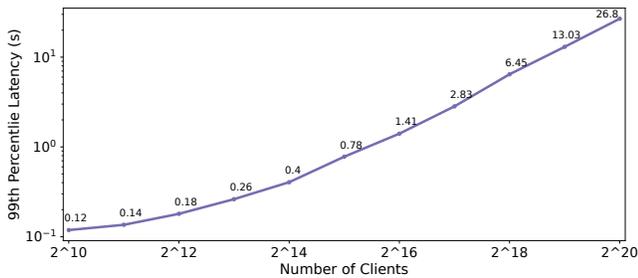

Figure 16: 99th percentile latency of Boomerang.

including oblivious comparisons, assignments, compaction, and sorting functions. Based on these oblivious primitives, we develop the oblivious batch generation and distribution procedures, and those based on the oblivious PPP algorithm with slight modifications in Boomerang+, just like the way we develop Boomerang. Thus, we do not spend more space repeating that their algorithms are oblivious. By the above two derivations, we show that Boomerang+ is secure according to Definition 2.1. This completes the proof.

D Boomerang Performance

Latency. We evaluate Boomerang on one 16-core server and test the latency over up to 2^{20} clients. Figure 16 shows the 99th percentile latency of Boomerang with a varying number of clients. For 2^{15} clients, the latency is 778 ms, which is also enough for VoIP communication. Notably, Boomerang achieves 1.41 second latency for 2^{16} clients using only one server. We can observe that the latency increases (almost) linearly with the number of clients (messages). There are mainly two factors: 1) with the increasing of clients, the server needs to handle more RPC requests; and 2) the most expensive computation in enclaves is oblivious sort (twice), which is of

$O(n(\log n)^2)$ complexity. When the client number increases to 2^{20} , the latency reaches 26.8 seconds, which is no longer suitable for latency-sensitive applications. The increased latency also shows the need for horizontal scalability.

Bandwidth cost. Boomerang requires each client to send a message of 256 Bytes every round. It occupies 512 Bps bandwidth for each client if we set a 500 ms round. If the client keeps online on Boomerang for one month, the bandwidth cost is 2.47 GB (including sending and receiving data), which we believe is affordable for ordinary users.

E Supplementary Experiments for Resource Allocation

Recall that in §6.3 we show the best resource allocation for entry nodes and B-nodes with 16 servers that can achieve the lowest latency. This section further reports the best allocation with 8, 16, 24, and 32 servers. We have exhaustively tried different combinations of entry nodes and B-nodes for each set of servers and let them handle 2^{20} messages. The results are reported in Table 1. The best allocation for entry nodes and B-nodes for 8, 16, 24, and 32 servers are 5:3, 12:4, 18:6, and 24:8, respectively. Note that this is a brute-force way to get the best ratio. A possibly more efficient way to configure the system is to design a configuration planner [32], which we will leave as our future work.

F System Dollar Cost

We here report the estimated cost in US dollars of running Boomerang+ servers. Leaving human-operation costs aside, we calculate the total cost for hosting Boomerang+ servers and data egress costs and show how much each user would (at least) pay for joining Boomerang+ for one month.

Server cost. Since the Tencent Cloud machines we use did not announce the international pricing for M6ce.4XLARGE124 [85], we alternatively choose Standard_Dc16s_v3 instances from Azure Cloud for price estimation, which have the same properties as M6ce.4XLARGE128. According to the prices for Azure Cloud VMs [65], the host (machine) cost is 1121 USD/month. The cost varies with different performance goals. For example, running 16 instances for 2^{16} clients achieves 615 ms latency, which results in \$0.274 amortized monthly cost per client. In the scaling experiment, Boomerang+ runs 32 8-core instances for 2^{20} clients, resulting in \$0.017 amortized cost and 7.76 second latency based on the price for the alternative instance Standard_Dc8s_v3 (560 USD/month). Ideally, adding more servers will further reduce the latency, but it will also increase the overall server cost.

Bandwidth cost. We assume that each client sends a 256 Byte message every 500 ms, adding up to 1.24 GB data ingress to (or egress from) the server if the client stays online for one month. To save data transfer costs, we can set the servers in the same availability zone, within which the transferred data is free of charge. If the clients and servers transfer data between different continents, the price is at most 0.16 USD/GB [63]. Then, the server-side bandwidth cost is 0.198 USD/month for each client. Overall, we believe Boomerang+ is affordable for clients while maintaining good privacy and high-performance services. Its promising cost is comparable to non-private cloud-based IM services today [64, 69, 84, 86].

Hamilton: A High-Performance Transaction Processor for Central Bank Digital Currencies

Abstract

Over 80% of central banks around the world are investigating central bank digital currency (CBDC), a digital form of central bank money that would be made available to the public for payments. We present Hamilton, a transaction processor for CBDC that provides high throughput, low latency, and fault tolerance, and that minimizes data stored in the transaction processor and provides flexibility for multiple types of programmability and a variety of roles for financial intermediaries. Hamilton does so by decoupling the steps of transaction validation so only the validating layer needs to see the details of a transaction, and by co-designing the transaction format with a simple version of a two-phase-commit protocol, which efficiently applies state updates in parallel. An evaluation shows Hamilton achieves 1.7M transactions per second in a geo-distributed setting.

1 Introduction

Central banks are increasingly investigating general-purpose central bank digital currency (CBDC), a digital currency that would be broadly available to users making retail payments, could provide interoperability and programmability depending on how it is designed, and, because it would be a direct liability of the central bank, reduces risk [7, 8, 14, 15, 19, 22, 23, 24, 37, 47, 65].

Figure 1 summarizes the different properties of a CBDC as compared to other forms of payment instruments [9]. A CBDC could help address public policy objectives such as ensuring public access to central bank money, fostering payment competitiveness and resilience, supporting financial inclusion, and offering privacy-preserving digital payments [3, 7, 15, 42, 70].

Technical designs for CBDC vary depending on specific policy requirements and goals. For example, a CBDC could provide low value payments in an anonymous, peer-to-peer fashion, or be distributed and accessed only

through accounts at approved financial institutions. To better inform policy discussions, central banks are recognizing the importance of technical experimentation in understanding the implications and trade-offs of different CBDC models and other policy choices. Importantly, the feasibility, operating performance and impact of different CBDC policy choices are dependent upon the technical design of the underlying transaction processor.

This paper presents a collaboration with a major central bank in the design of Hamilton, a high-performance transaction processing system flexible enough to support experimentation with different choices around data storage, programmability, and intermediation. Hamilton processes payments from users (or financial institutions) who address and sign transactions using cryptographic keys stored in digital *wallets*. Wallets submit transactions to the Hamilton transaction processor to move *unspent funds*—a representation of money containing an amount and the rules required to spend it (in our case, a public key indicating ownership). Our initial goals (set by the central bank) were a centralized transaction processor for CBDC with high performance and geo-replicated resiliency. Three additional goals emerged within the collaboration:

Intermediary and custody flexibility. An open question in CBDC design is that of the role of the central bank and other intermediaries, and determining how (if at all) CBDC access can be moderated. These roles will likely vary by jurisdiction, due to policymaker decisions and consumer preferences. Currently, people who want to digitally store funds and make payments must open accounts with financial institutions or payment service providers which are linked to the identity of the owner and are responsible for processing transactions on behalf of their customers, interfacing with payment networks, and safeguarding customer funds. In contrast, cash can be held directly by the public and used to conduct transactions without the need for a financial institution to process the payment on their behalf. A CBDC could be designed to offer similar functionality to cash and provide users the ability to spend their own funds without the need for an account provider or custodian to generate transactions, it could be designed more like existing digital payment

The views expressed in this paper are those of the authors and do not necessarily reflect the views of the Federal Reserve Bank of Boston or the Federal Reserve System.

systems, or it could even support a combination of the two models [17].

Interoperability and programmability. Many payment processor systems provide high throughput and low latency, but unfortunately, they generally provide limited application programming interfaces (APIs) and do not natively *interoperate*. For example, if a Venmo user wants to pay a user who only has Square Cash, they would need to transfer their funds outside the application into bank accounts and send the money via traditional banking rails (inside the United States using ACH or FedWire; across borders, even in the same currency, using SWIFT and correspondent banking), which incurs bank and application fees and could take days to complete. Central bank Real-Time Gross Settlement Systems (RTGS), or instant payment systems, help reduce interoperability latency but do not preclude the requirement for multi-step transfers between applications and bank accounts (where fees are charged) or provide interoperability and programmability, especially between payment applications. Contrast these systems with cryptocurrencies which do not scale well but natively provide interoperability and programmability.

Preserving privacy and minimizing data retention. There is strong user demand for financial privacy [37] and central banks would prefer not to collect and store user-identifying information or sensitive transaction details.

Challenges. Building Hamilton to achieve these goals required addressing the following challenges. First, we had to build a flexible platform that could support multiple designs without explicit policy requirements or well-defined tradeoffs. For example, it is unclear what balance to target between end-user privacy and data storage requirements for users at the central transaction processor. We take a layered approach with a design where additional functionality can be built outside the core transaction processor. Our design supports a range of intermediary roles including one where users custody their own funds. Hamilton does not store personally identifiable information (PII), transaction addresses or amounts in the core of the system.

The second challenge is in providing strong consistency, geographic fault tolerance, high throughput, and low latency, all with a workload that consists of 100% read/write, multi-server transactions. Since Hamilton is unaware of the mapping between users and unspent funds, we cannot rely on user locality for partitioning, which is often exploited by traditional database systems to make workloads predominantly single-partition transactions.

Key ideas. We address these challenges in Hamilton by carefully co-designing the transaction format, data model, and distributed transaction commitment protocol to achieve the above goals while getting good performance. This involves three parts: First, we decouple transaction validation from fund existence checks; only user wallets and a *validating layer* see transaction details. Hamilton only ever stores funds as opaque 32 byte hashes, in an *Unspent funds Hash Set*, or UHS [41] (§3.3). This hides details about the funds (like amounts and addresses) from the UHS storage, reduces storage requirements, and creates opportunities to improve performance, described below.

Next, we next create a UHS-designed transaction format (§3.4), which is extensible and secure against double spends, inflation attacks, replay attacks, and malleability, and also has the benefit of supporting future layer 2 designs for even higher throughput in the future. It borrows from Bitcoin’s transaction format but is designed to be validated without looking up data from the UHS, which we term *transaction-local validation*.

Our design choices let us exploit payment application semantics to create a streamlined commit protocol for distributed transactions. In particular, our transaction format guarantees that Hamilton knows the read and write sets for every valid transaction *before* its execution; similarly, our cryptographically-generated UHS identifiers (hashes) are globally unique. These two properties guarantee that Hamilton does not need any reads or locks before commit time, and that valid transactions (those that do not try to spend the same funds twice) will never conflict.

Our evaluation shows that co-design achieves improved performance over more general, commercial databases. We measured Hamilton’s throughput at 1.7M txns/sec, 26× that of PostgreSQL on the same workload, though with higher latency (§6). We also compare against Rolis [64], a replicated in-memory database, and show that Hamilton achieves close performance, even though it stores data on disk for whole system crash recovery.

The UHS design, in combination with our transaction format, also affords us substantial flexibility. We believe that the abstractions our system provides and the assumptions it makes are compatible with most ideas underlying certain types of programmability and cryptographic privacy-preserving designs [10, 52, 69, 71]. In addition, we can upgrade the scripting language or add a cryptographic privacy-preserving protocol (even supporting multiple concurrent designs), as long as they are com-

patible with 32-byte hash storage, without needing any changes to the backing UHS, making it possible to defer decisions on specific programmability features. However, our design choices have implications on what data users or intermediaries need to store in their wallets and what messages are required to confirm a payment (§3.7).

In summary, the contributions of this paper are the following:

- Hamilton, a flexible transaction processor design that supports a range of models for a CBDC and minimizes data storage in the core transaction processor while supporting self-custody or custody provided by intermediaries
- A transaction format and implementation for a UHS which together support modularity and extensibility
- An implementation and evaluation which shows good performance in comparison to centralized databases. Hamilton and the benchmarks are available at <https://github.com/mit-dci/openbdc-tx>.

2 System model and security goals

This section describes the actors in Hamilton, their roles, and the security properties we want Hamilton to satisfy. In our description, we make the simplifying assumption that users directly custody their money without help of an intermediary. Hamilton supports intermediaries, and adding an intermediary would not change the core security properties of the transaction processor.

2.1 Actors

We distinguish three types of actors: the *transaction processor*, the *issuer*, and *users*. The transaction processor keeps track of *funds* which are owned by different users. Funds are a representation of money and as such refer to an amount of money (such as dollars) and a condition that must be satisfied to move this amount (say, to another user or users). The funds enter and exit the system through acts of the *issuer* who can *mint* and *redeem* funds to add and remove them from the transaction processor, respectively. Users can execute *transfer* operations (transactions or payments) that atomically change the ownership of funds, with the requirement that the total amount of funds stored in the transaction processor has not changed. A user does so by submitting their transaction to the transaction processor over the Internet, which the processor then validates and executes. Figure 2 shows the high-level system model and potential communication channels between users and the transaction processor. Users run *wallet* software (e.g. on mobile phones or specialized hardware in smart cards) to manage cryptographic keys, track funds, and facilitate transactions. An important piece of future work is preventing spam and denial of service attacks.

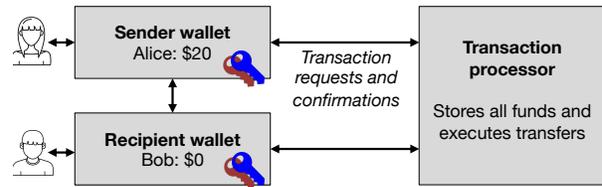

Figure 2: Data flows between all participants in a transaction.

2.2 Threat model

Our goal is that each user’s funds and the integrity of the monetary system are safe from interference of an external actor. We assume that the transaction processor is faithfully executing our design, that users’ wallets are able to maintain secret keys, and that the users are able to use a secure channel to communicate with the transaction processor. Our design is a cryptographic system so we assume the security of standard cryptographic primitives such as hash functions and digital signatures.

We aim to protect against an adversary who can freely interact with the system as a regular user, and as such make no additional assumptions about an adversary’s capabilities or behavior. For example, the adversary is free to create arbitrarily many identities and wallets, receive funds from other users, and engage in elaborate transaction patterns. Our designs are multi-server systems and the adversary is free to attempt concurrent attacks against all externally-exposed parts of the system.

2.3 Data representation

The two most common ways to represent funds are the account balance model and the UTXO model.

Account model. Traditional payment systems and several cryptocurrencies, like Ethereum [73] use an account model where the system stores unspent funds as balances associated with unique account identifiers. Users make payments by issuing requests to the transaction processor to move balance to another identifier (decrementing their balance and incrementing another identifier’s balance).

UTXO model. Another choice is to track discrete pieces of outstanding funds without explicitly consolidating them in a single balance. For example, Bitcoin maintains an append-only ledger of accounting entries (sometimes called “coins”) each of which records a value and conditions to spend the funds. Furthermore, each entry is either marked as “spent” or “unspent”. Users make payments by issuing transactions that mark some entries (*inputs*) as spent, and appends new unspent entries (*outputs*) to the ledger. In Bitcoin these are called *UTXOs* or Unspent Transaction Outputs. Importantly, UTXOs are never modified and must be spent in their entirety. Therefore, Alice wishing to use a \$10.00 UTXO to send \$4.99 to Bob

will create a transaction with two outputs: a \$4.99 output meant for Bob and a \$5.01 *change output* meant for herself.

We derive Hamilton's data model from the UTXO model for two reasons: First, because it offers greater transaction execution parallelism; inputs can only be spent once, and so in the common case there should never be conflicting transactions, unlike concurrent transactions against a popular account. We leverage this in our data storage design (§3.4). Second, UTXOs are the leading choice for privacy designs [10, 16, 26, 45, 48, 69, 71] (including for those deployed on top of account-based currencies [61, 72]). UTXOs can be less intuitive to the user, but note that the transaction processor's internal data representation is distinct from the user interface; wallets can still present a user account balance on top of the UTXO data representation.

2.4 System operations

Logically, Hamilton maintains a record of all unspent funds in existence and in order to spend funds, they must be present in the set of unspent funds. Our system supports three kinds of operations: Mint, Redeem, and Transfer, all of which are atomic and serialized.

Minting and redeeming. The Mint operation creates new unspent funds and adds these to the set of unspent funds, whereas the Redeem operation removes unspent funds from the system, making them unspendable. These operations also have semantics outside Hamilton: minting would normally correspond to funds in other forms of central bank money being set aside for use in Hamilton, whereas redeeming would make them available again.

Value transfers. The Transfer operation both consumes unspent funds and creates new unspent funds. This transaction is specified by a list of funds to be spent (inputs), a list of new funds to be created (outputs), and a list of witnesses (i.e., digital signatures) authorizing spends of each input. A successful Transfer completely consumes its inputs; these are removed from the system and cannot be used again, whereas the new outputs are available to be used as inputs to other Transfer or Redeem operations.

No editing of unspent funds. The set of unspent funds can only be modified via the above three operations, and funds tracked in the system cannot be modified to change their ownership or value.

Payment discovery. In public blockchains users can search the publicly available history of transactions to see if they have received payment. Transaction history in Hamilton is not public, and the sender must give the recipient the information about newly created unspent funds so that the recipient can further spend them. To ensure users know a Transfer is complete and has been applied, the transaction processor is also responsible for responding to user queries about the existence of unspent funds.

2.5 Security properties

In brief, the system must faithfully execute transactions, ensuring that each was authorized by the owner of the input funds, and safeguard that transactions do not disturb the overall balance of funds (outside of minting and redemption). Hamilton's transaction processor ensures this by satisfying the following four security properties.

Authorization. Hamilton only accepts and executes Mint and Redeem operations authorized by the issuer, i.e., only the issuer can mint and redeem funds. We use digital signature authorization for these. Similarly, we require that each Transfer transaction is signed by owners of all inputs the transaction attempts to spend.

Authenticity. The set of unspent funds tracked in Hamilton only contains *authentic* funds, as we now define. Define unspent funds created by authorized Mint operations to be *authentic*. Moreover, define unspent funds created by Transfer operations to also be authentic if and only if all inputs consumed by the transaction were authentic and the transaction preserves balance. Note that the recursive authenticity property depends on both the contents of the transaction itself, as well as the set of unspent funds when Transfer is applied.

Durability. Mint, Redeem, and Transfer are the only operations in Hamilton that change the set of unspent funds.

As a consequence of the three integrity properties defined above the set of unspent funds always remains authentic and transactions in Hamilton cannot be reverted. We further require that the transaction processor makes the following availability guarantee and always makes progress:

Availability. The transaction processor will always accept an authorized transaction spending authentic funds.

3 Transaction design and processing

This section first reviews Bitcoin's UTXO model in more detail and explains the challenges associated with using this data model in our setting. It then describes the UTXO hash set (UHS), a different idea that we choose as a basis for Hamilton's data model and the motivation behind our choice. Finally, it introduces Hamilton's transaction format, describes how to securely create and process transactions in this model, and discusses implications on future functionality.

3.1 Bitcoin's UTXO model

Bitcoin uses the UTXO model, where each output *utxo* has a value and an encumbrance: The value v is an integer multiple of the smallest subdivision of Bitcoin and an encumbrance is a *script*, an executable program which evaluates the conditions for a valid spend. An encumbrance expresses a predicate P taking two arguments: a transaction tx seeking to spend this *utxo*, and a witness wit . A

transaction is a list of references to input UTXOs to be consumed together with a list of corresponding witnesses, and lists of values and encumbrances for new UTXOs to be created. Each encumbrance predicate returns true if and only if its corresponding witness signifies that this spending transaction should be authorized.

A common encumbrance is that of digital signature authorization, known as pay-to-pubkey (P2PK). Here the predicate P hard-codes a public key pk and $P(tx, wit)$ checks that wit consists of a valid signature under the public key pk where the message is the serialized spending transaction tx . To spend such a $utxo$, the user creates a transaction tx having the $utxo$ as an input and signs tx with the corresponding secret key sk .

3.2 UTXO model challenges

Adopting Bitcoin’s design in our setting comes with a number of challenges. First, Bitcoin’s UTXO model requires maintaining a copy of the entire UTXO set in full detail. This has unwanted implications for privacy as Bitcoin node operators are both privy to values and encumbrances (i.e., users’ public keys), as well as for data storage, especially when using complex or post-quantum secure encumbrances, which might be large. Second, in Bitcoin, transactions only refer to their inputs by specifying a hash $txid$ of a prior transaction together with a particular output index idx of that transaction. Thus, to validate a transaction a node has to look up the input encumbrances and values in its local UTXO set, and only trivial validation checks can be done statelessly. This is reasonable when the UTXO set is small and nodes store it locally, but becomes more challenging when it must be partitioned across many machines to achieve higher performance, while still being accessed consistently.

3.3 UTXO hash set

A key observation in the design of Hamilton is that we can divide transaction validation checks into two parts – *transaction-local validation*, which does not require access to shared state, and *existence validation*, which does. We can then scale these two tasks independently. This is useful because they have different scalability profiles, with transaction-local validation requiring mostly compute resources (i.e., verifying digital signatures used in spend authorization) and existence validation requiring mostly persistent storage I/O.

By doing this, we can go even further and observe that after transaction-local validation, instead of processing and storing the entire UTXO, we can operate on cryptographic *commitments* to the UTXOs. In Hamilton we replace the UTXO set with a *UTXO hash set* (UHS), extending an idea first proposed as a Bitcoin storage and scalability improvement [41]. That is, our transaction processor stores unspent funds as a set of opaque 32-byte cryptographic hashes of UTXOs, not UTXOs themselves.

We refer to hashes of UTXOs as UHS IDs or simply hashes. Instead of looking up the transaction input data (which we do not have), we ask the (untrusted) user to provide full input UTXOs in a transaction. However, a malicious user might lie and claim to have more funds to spend than they actually do. To catch this, we reduce the problem of checking UTXO correctness to *UHS commitment existence*—Do the funds the user is claiming they can spend actually exist? As we’ll see in §4, this affords us the opportunity to piggyback existence validation with actual execution inside the distributed transaction commit protocol.

UTXOs must be stored in the user wallets and are supplied as part of transactions. We also note that while in Bitcoin the UTXO set is derived by processing the Bitcoin blockchain and keeping the set of unspent UTXOs, Hamilton’s backend is a transactional database that maintains the UHS without operating a ledger.

Using a UHS has a number of benefits. First, as described above, a UHS-based transaction format lets us decouple transaction validation from funds existence checks and affords us opportunities for performance improvement in the backend. Second, it lowers storage requirements, as the transaction processor only stores a 32-byte hash per UTXO, independent of a UTXO’s size. Third, it increases flexibility, as the UHS abstraction makes no assumptions about what hashes represent: it is easy to adapt a high-performance system maintaining a UHS, like Hamilton, to a different transaction formats or scripting languages without needing to change the core execution engine. Fourth, it improves privacy as the transaction processor does not store balances or account information.

However, a UHS design also presents some challenges, stemming from its data minimization. The UHS, as described above, does not contain enough information to audit the total amount of unspent funds (the “full” UTXOs only reside in user wallets). However, UHS hashes could be augmented to store a value alongside hashes (making supply auditing trivial, at some privacy cost), or by converting UHS IDs to homomorphic commitments that can be maintained and tallied using additional cryptographic techniques [54, 60]. The sender also has to provide the recipient with the UHS ID preimage to further spend their funds, as described in §3.7. Finally, decoupling transaction-local validation and access to shared state means that future transaction programmability is restricted to only referencing transaction-local data.

3.4 Transaction format

To build Hamilton we designed a new, extensible transaction format in the UHS model. As we will see later, Hamilton’s transactions can be split into transaction-local validation and existence checks.

Unspent funds. We represent unspent funds as triples

$utxo := (v, P, sn)$. Here v and P are value and encumbrance. Currently we only support encumbrances of public keys, and thus represent predicate P by the 32-byte public key pk itself. Our model supports future encumbrances, such as requiring a subset of signatures from multiple public keys.

The third component, sn is a globally unique *serial number*. The serial number, enables us to reference and distinguish funds that share the same encumbrance and value (e.g., Alice having received same \$5.00 value in two different transactions encumbered with the same public key pk_{Alice}); it also implies that UHS is a set, not a multi-set. Our transaction format will ensure that serial numbers do not repeat across time: a serial number associated with a spent UTXO cannot “reappear” as a serial number for a new unspent UTXO. Global uniqueness of serial numbers is not a mere technicality: they express the intent of singling out a particular UTXO and prevent *replay attacks* (see §3.6 for discussion).

UTXO hash set. Instead of storing a set of entire UTXOs $utxo = (v, P, sn)$, we store cryptographic commitments $h := \mathcal{H}(v, P, sn)$ to UTXOs. In Hamilton we set \mathcal{H} to be SHA-256 to derive these hash commitments.

Mint transactions. New funds enter the system by system operator creating new $utxo$ ’s and adding their hashes to the UHS. The issuer must choose unique serial numbers for newly minted UTXOs. It suffices to set these as uniformly random nonces.

Transfer transactions. A k -input, l -output Transfer transaction seeks to fully consume k UTXOs currently present in the system, and create l new UTXOs specified by encumbrances and values. Such a transaction $tx_{Transfer} = (utxo_{inp}, \vec{v}_{out}, \vec{P}_{out}, wit)$ is comprised of (a) a size- k list $utxo_{inp}$ of input UTXOs to be spent; (b) two size- l lists \vec{v}_{out} and \vec{P}_{out} of output values and encumbrances specifying output UTXOs to be created; and (c) a size- k list of witnesses wit , one for each input.

Such $tx_{Transfer}$ creates l UTXOs with value/encumbrance pairs $(v_{out,i}, P_{out,i})$. We make UTXOs unique by deriving the serial numbers sn as pairs $sn := (txid, idx)$ as follows. The first component, $txid$ is the unique transaction identifier, the cryptographic hash of the transaction that created this UTXO. This hash covers all input UTXOs, output encumbrances and values: $txid(tx_{Transfer}) := \mathcal{H}((utxo_{inp}, \vec{v}_{out}, \vec{P}_{out}))$. The second component, idx , is the particular output index, i.e., first, second, etc, output of the transaction.

Note that our transaction format includes input UTXOs in the Transfer itself. In contrast, a Bitcoin transaction does not: it references UTXOs via $txid$ and idx instead, and requires UTXO look-ups in transaction processing.

Transaction creation. To create a Transfer transaction, users digitally sign $txid$ with private keys corresponding to

inputs they are spending. Each of these signatures serves as the witness authorizing the transaction to spend the given input. Witnesses are not included in the transaction identifier so signing can be deferred by the sender to after the transaction has been shared with the recipient. This is useful to support future smart contract functionality where unsigned transactions could be shared between parties to be signed and broadcast later under certain conditions. Recall that encumbrances are applied to individual outputs rather than whole transactions, and transactions can have multiple inputs, which means that funds can be spent atomically from multiple public keys in a single transaction. Once a transaction is finalized, the users will deterministically derive serial numbers of each of the output UTXOs from the transaction contents. Users store this outpoint information in their wallets.

3.5 Transaction execution

Processing a Transfer transaction involves confirming that it is valid and then applying it to the state. Validation involves checking the following:

1. *Syntactical correctness.* Check that the transaction has at least one input and output, and that the transaction supplies exactly one witness per input.
2. *Balance.* Check that transaction’s input values tally up to exactly the same value as outputs to be created.
3. *Authorization.* Check that each input UTXO is accompanied by a valid signature, relative to the input’s public key, on a message comprised of the transaction’s identifier $txid$.
4. *Authenticity.* Check that transaction’s input hashes exist in the UHS.

To apply a valid transaction to the UHS we atomically remove the spent input hashes and create the new output hashes under the control of the recipient(s); this in combination with the other checks provides durability.

Performing local-validation. Hamilton has dedicated components, which we call *sentinels*, that receive transactions from users and perform transaction-local validation. This local validation performs the above syntactical correctness, balance, and authorization checks.

Compaction. We further observe that while the transaction-local validation does not reference any data from the state and only uses transaction-local data, the UHS, in turn, does not reference a transaction’s contents and only operates on the hash values. Thus, once locally validated, a transaction is *compacted*. First, the sentinel derives the output UTXO serial numbers; together with output encumbrances and values they fully specify output UTXOs to be created. Next, the sentinel hashes the input and output UTXOs and obtains two lists of hashes which we call a *compact transaction*. Finally, sentinels forward

compact transactions to the execution engine, which maintains the UHS, for existence checks and to update the UHS state.

Checking existence, execution and the *swap* abstraction. Now, given a compact transaction, our system does the following: First, check if all input hashes exist in the UHS; if so (a) remove the input hashes from the UHS and (b) add the output hashes of newly created UTXOs to the UHS. We call this UHS primitive *swap*. Processing Hamilton transactions at scale reduces to the challenge of implementing a fast, scalable, and durable backend for executing *swap*, which we describe in §4. Such a backend abstraction maintains a set of hashes, and exposes *swap* as the only operation. The inputs to *swap* are two lists of hashes: one for existence checks and removal (called input hashes), and one for insertion (called output hashes). To execute a *swap*, the system atomically checks that all input hashes are present. If an input hash is missing, *swap* aborts. Otherwise, it obtains an updated set of hashes by erasing all input hashes and inserting all output hashes. All other hashes in the set remain unchanged.

We note that separating transaction-local validation and execution means that *swap* supports multiple transaction formats concurrently without affecting UHS performance.

3.6 Transaction format security

Using our transaction format Hamilton maintains an authentic, authorized and durable set of unspent funds (§2.5), eliminates the possibility of double spends, and also achieves additional security goals related to its use. In particular, transactions in Hamilton are not *replayable* and digital signature authorizations are not *reusable*.

These properties are a consequence of the fact that each UTXO created by a Mint or Transfer transaction is unique and guaranteed to not equal any other UTXO in the past or in the future, as we now explain. In Hamilton, each Transfer’s UHS IDs are derived by hashing all the corresponding transaction’s inputs, as well as details pertinent to the particular output itself (see §3.4). In particular, *sn* references previous unique serial numbers and recursively incorporates the entire transaction history up to distinct (due to presence of the uniformly random nonce) Mint’s. Collision resistance of \mathcal{H} guarantees that these serial numbers are unique. Because UHS hashes commit to the same UTXO data which must be provided in the transaction, an attacker can not fit a different UTXO preimage into the same UHS hash without violating the collision-resistance of \mathcal{H} .

No double-spends. Transfer operations permanently delete input hashes from the UHS. Therefore, as serial numbers are unique, no UHS ID can be spent more than once or recreated after having been spent.

No replay attacks. In a basic replay attack the victim has signed a single transaction to authorize a single value

transfer. The attacker, however, submits this transaction twice in the hope of effectuating two value transfers. For example, Alice, who has two unspent \$5.00 “bills”, might give Bob a transaction that spends one of her \$5.00 bills to pay for ice cream, which Bob then submits twice to take possession of both.

Hamilton’s transaction format prevents replay attacks as each transaction references globally unique input hashes, and each signature covers the entire transaction, including all its inputs and outputs. Thus, signatures are not valid for spending any other UHS ID, including those created in the future, and it is not possible to copy a Hamilton transaction and apply it multiple times to spend additional funds.

Transactions are non-malleable. In a system with malleable transactions, an attacker can change some details about the transaction (e.g., the witnesses used to satisfy input encumbrances or output UTXO serial numbers) without otherwise changing the input UTXOs or modifying output UTXO values or encumbrances. For example, if the transaction format included an auxiliary field not covered by the signatures but used in serial number computation, an attacker could change this field. This would change output UTXO serial numbers and make it unsafe to accept a chain of unconfirmed transactions, thus preventing certain higher level protocols like the Lightning Network. In 2014, the largest Bitcoin exchange Mt. Gox closed after claiming to be a victim of malleability attacks [32]. In our implementation, we require signatures to cover all fields of uniquely-encoded transaction and derive UTXO serial numbers from the same fields (plus, output indexes).

3.7 Transaction protocol

Our choice of transaction data model and format directly impacts potential transaction protocols. For example, transaction compaction for the UHS adds a new communication step requirement between sender and recipient. The recipient should not consider a payment “complete” until they have received both a confirmation from the transaction processor *and* the full preimage data for their new outputs. If the recipient does not receive these, the sender has essentially destroyed the funds.

In theory, cryptocurrencies in which the recipient’s address is obfuscated also have this problem. In practice, because the entire blockchain is public and standard address formats are used, recipients can scan *every* transaction to detect if they have been paid and, if so, construct new transactions to spend those funds. Even if the UHS were public, recipients would still not be able to unilaterally detect payments. The hash preimage for a UHS ID depends on data from the transaction that creates the UTXO which is unavailable to the recipient. As there is no public ledger, recipients must rely on the transaction processor to learn about the status of outstanding transactions.

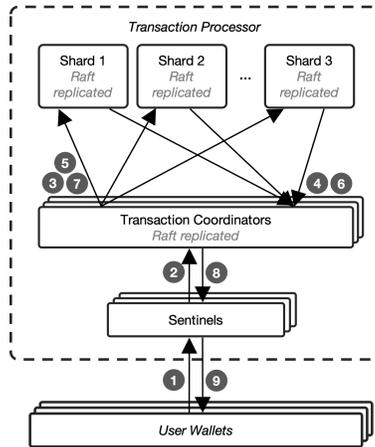

Figure 3: System diagram for the 2PC architecture and inter-component data flow

4 Processing transactions at scale

As described in §3, transaction processing can be split into transaction-local validation, existence validation, and execution, which creates opportunities for improving performance. To process more transactions, we *partition* the set of unspent funds across multiple computers. Transactions might reference unspent funds stored on different machines, requiring a coordination protocol to check existence of inputs and execute transactions atomically.

One way to achieve this is to first explicitly order all valid transactions and subsequently apply them to the partitioned state in the same order, if the inputs exist and have not already been spent. We investigated this architecture and found performance was limited by the ordering server (§4.3). However, we note that payment semantics do not *require* materializing a linear transaction history. Thus, we also built an architecture which executes transactions in parallel to achieve high performance, described next.

4.1 Applying transactions to the UHS

We use variants of two-phase commit and conservative two-phase locking[36, 44] to atomically apply transactions to the UHS, partitioned across *shards* which are each responsible for a subset of the UHS IDs which are unspent within the system.

Figure 3 shows a diagram of the components in the 2PC architecture and the data flow between components. As described in §3.5, a wallet submits a transaction to a sentinel (1), which validates everything *except* the existence of inputs. Upon success, sentinels convert transactions to compact transactions and send compact transactions to a *transaction coordinator* (2).

Each coordinator has a thread pool to execute transactions in parallel, and adds incoming compact transactions from sentinels to a queue. Once a thread from the pool becomes available, it drains the queue and creates a new

distributed transaction (*dtxn*) containing the pending compact transactions (up to a maximum size). The thread then performs the 2PC protocol to commit the *dtxn*. If a thread is available, it will begin a new *dtxn* even if there is only one compact transaction waiting in the queue, it will not wait for the queue to grow. Due to application choices described in §3, we know the read/write sets ahead of time and can execute the *dtxn* entirely inside the 2PC protocol, without any extra roundtrips. This is the same technique introduced in Sinfonia [1].

There are three steps to commit a *dtxn*:

1. **Prepare (3).** The coordinator contacts each shard responsible for a UHS ID included in the *dtxn* and requests that it durably lock the input UHS IDs (a *prepare* request). (Note that by design of our transaction format (see §3.4), valid output UHS IDs are guaranteed to be unique across transactions, so reserving outputs is not necessary.) Each shard responds to the *prepare* request indicating which compact transactions in the *dtxn* had their IDs successfully locked, and which no longer exist, or were already locked by a different *dtxn* (4).
2. **Commit (5).** The coordinator uses the shards' responses to determine which compact transactions in the *dtxn* can be completed, and which cannot complete because some of the inputs are unavailable or already locked. The coordinator makes this decision durable and then contacts each shard again to indicate which compact transactions in the *dtxn* to complete and which to cancel (a *commit* request). Each shard then atomically unlocks the input UHS IDs belonging to a canceled transaction, deletes input UHS IDs and creates the output UHS IDs for successful transactions, and updates local *dtxn* state about the status of the *dtxn*. The shard then responds to the coordinator to indicate that the *commit* was successful (6).
3. **Discard (7).** The coordinator issues a *discard* to each shard informing them that the *dtxn* is now complete and it can forget the relevant *dtxn* state.

Once every shard participating in the *dtxn* has completed the *commit*, the coordinator informs each sentinel whether its transactions were successfully executed or rejected by the shards (8). The sentinels in turn forward these responses to the users who submitted the transactions (9).

It is possible that if two concurrent transactions by different transaction coordinators spend the same inputs, neither will succeed, because both will be canceled due to observing the other's lock conflicts. This means that at least one will need to be retried, which is left to the user's wallet. An adversary could try to continually conflict a user's transaction by spending the same input. However,

this requires the adversary to have the authorization to spend the input in order to pass sentinel validation. Investigating methods to fairly resolve concurrency conflicts is left to future work.

Combining many compact transactions into a larger distributed transaction amortizes the costs of messaging and making the result of each phase of the protocol durable on each shard, whether by flushing to persistent storage or replicating as part of a distributed state machine. Because our application semantics are constrained, this is slightly different from traditional two-phase commit in that dtxn always complete successfully, and individual compact transactions are executed (or not) deterministically: if all of a compact transaction's input UHS IDs are locked and output UHS IDs are reserved, the compact transaction will succeed. The transaction coordinator always completes both phases of dtxn, even if some of the compact transactions within do not succeed. General 2PC designs need to support transaction coordinators that might make arbitrary decisions about whether to commit or abort transactions.

4.2 Fault Tolerance

Each transaction coordinator and shard is made fault tolerant using Raft [58], a distributed consensus algorithm. Sentinels only maintain state during the duration of the user wallet request to return transaction status to the user; if one fails, the user's wallet will need to retry its transaction or ask about its status with another sentinel.

Only the leader node in the transaction coordinator Raft cluster actively processes dtxn; followers simply replicate the inputs to each phase of the dtxn. This is a technique used in deterministic scalable database systems [68]. Before initiating each phase of the distributed transaction, the coordinator replicates the inputs to both the *prepare* and *commit* requests to each shard. Shards remember which phase each dtxn has last executed and the response to the coordinator. If the coordinator leader changes mid-dtxn, the new leader reads the list of active dtxn from the coordinator state machine and continues each dtxn from the start of its most recent phase. Shards that have already completed the requests will return the stored response to the new coordinator leader. To ensure proper completion of the *commit* across all shards, shards will remember the response for the *commit* until the coordinator has received responses from all shards in the dtxn and issued a *discard* to inform shards the dtxn is complete and can be forgotten. Note that these can be applied lazily and the transaction coordinators can inform the sentinels the transactions were successful before issuing *discard*.

Similar to coordinators, in each shard cluster only the leader processes dtxn and responds to sentinels. Although followers do not handle RPCs, they maintain the same UHS as the shard leader, so they are prepared to

take over processing RPCs if the leader fails without a specific recovery procedure beyond that provided by Raft. Once a dtxn has entered the *prepare* phase and has been replicated by the coordinator cluster, the dtxn will always run to completion. If a shard leader fails mid-transaction, the coordinator leader will retry requests until a new shard leader processes and responds to the request.

4.3 Comparison to blockchain architectures

Many have suggested using blockchain technology to design a central bank digital currency. We found that using a blockchain-based system in its entirety was not a good match for our requirements. First, there was no requirement to distribute governance amongst a set of distrusting participants. The transaction processing platform is controlled and governed by a central administrator. Blockchains use relatively new distributed consensus protocols which are designed to operate in a permissionless, adversarial environment. This introduces software and operational complexity as well as new cryptographic assumptions. A CBDC should rely on the simplest, most well-understood, well-tested protocols to achieve its goals.

Second, we anticipated the complexity of a blockchain architecture would limit performance. To evaluate this we implemented a streamlined permissioned-blockchain-inspired design, the *atomizer*. Instead of using transaction coordinators and two-phase commit, the atomizer orders compact transactions into blocks through a replicated state machine. To reduce load on this ordering server, the design outsources storage of the UHS to shards, which hold the partitioned UHS ID state as in the 2PC design. However, a shard's UHS ID state is only correct up to a specific block height. Sentinels send compact transactions to shards, and shards then pass attestations for input IDs that exist to the atomizer, which collects complete compact transactions into blocks. The atomizer broadcasts confirmed blocks so shards can update their state, deleting spent UHS IDs and creating new ones. Shards do not require consensus or even primary/backup for correctness, they are merely replicated. For the specifics of the atomizer design see a related technical report [51]. As might be anticipated, we found the atomizer architecture's throughput is limited by the resource constraints (network bandwidth and CPU) of a single server, the atomizer leader, and cannot benefit beyond a limited point from additional shard resources (§6).

OmniLedger [49] is a sharded blockchain design which, like Hamilton, operates in the UTXO model, but uses a client-driven commit protocol to commit cross-shard transactions without going through a single server. Based on reported results, OmniLedger can achieve much higher performance than our atomizer prototype (with a replication factor of four per shard and 1% adversarial power, approximately 400K txns/sec). However, in Hamilton we

did not want to rely on clients, which might fail or disappear, to complete transactions. Hamilton instead uses replicated transaction coordinators, so incomplete transactions will never result in stuck or frozen funds.

5 Implementation

We implemented Hamilton in C++17, released at [https://github.com/mit-dci/openbcdb-tx], and tested on Linux and macOS, though it should be portable to any UNIX-like system. The primary dependence on a UNIX-compatible API is our use of UNIX sockets for network communication. Clients communicate via a custom serialization protocol, via single, short-lived TCP connections.

We use LevelDB [43], NuRaft [35], libsecp256k1 [13] and vendored components from Bitcoin Core [12]. We use BIP-340 compatible Schnorr signatures [76] as our digital signature scheme. We also use the cryptography components of Bitcoin Core to provide optimized implementations of SHA256 [56], used as our cryptographic hash function, SipHash [4] used for hashmaps and bech32 [74, 75] used for error-correcting public key encoding.

6 Evaluation

Our evaluation answers the following questions:

- How does Hamilton’s performance compare to other database and blockchain-based designs?
- How does Hamilton perform with multiple regional failures?
- How well does Hamilton tolerate different transactional workloads, whether with larger transactions or double spends?

Setup. Unless otherwise specified, for benchmarking we deployed on Amazon Web Services (AWS) using EC2 virtual servers running Ubuntu 20.04 (c5n.2xlarge instances with 8 vCPUs and 21GB RAM). We ran the system components across three regions within the United States: Virginia, Ohio and Oregon. Round-trip time between Virginia and Ohio was ≈ 12 ms, Virginia to Oregon ≈ 62 ms and Ohio to Oregon ≈ 51 ms. Unless otherwise stated, there were 1B outputs, 8 logical shards, and shard and coordinator clusters were replicated by a factor of three. In particular, each shard and each coordinator has a Raft node in each of these three regions. Non-replicated components such as sentinels and load generators were distributed between regions to simulate load from across the United States. Load generators (c5n.large instances with 2 vCPUs and 5.25GB RAM) were simulated wallets that produced valid, signed transactions with two inputs and two outputs unless otherwise stated. We limited dtxns to a maximum size of 2000 compact transactions, and each coordinator had a thread pool containing 75 threads.

We do not consider data from a benchmark for a configuration if any Raft cluster was unable to reliably replicate

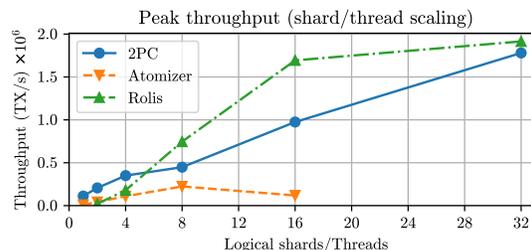

Figure 4: Compares the peak throughput of 2PC, the atomizer, and Rolis, when varying logical shard count (2PC and atomizer) or the number of threads (Rolis).

data between *all* regions during the experiment. Take, for example, a three node cluster: if one follower is reliably lagging behind due to data replication issues, though the leader and other follower still form a quorum, this configuration can’t tolerate an additional failure of either node without potentially suffering a delay and throughput reduction. We took this to imply the system was oversaturated.

6.1 Comparison

Figure 4 shows the peak throughput for Hamilton and the atomizer when varying the number of load generators for different shard counts. Our 2PC architecture scales linearly as the number of logical shards increases, up to 1.7M txns/sec with less than one second 99% tail latency and under 500ms 50% latency, though we expect peak throughput would continue to increase with more shards and this would not negatively affect latency. Additionally, if a lower tail latency is desired for a particular transaction throughput, increasing the number of shards can decrease tail latency for the same offered load. This makes sense because, in the worst case, each transaction requires the participation of a subset of shards equal to the number of inputs and outputs in the transaction. Since transactions in the test load have an upper bounded number of inputs and outputs, increasing the number of shards results in each transaction requiring the participation of a smaller proportion of the total shards in the system.

The atomizer achieves 170K txns/sec with under two seconds 99% tail latency and 700ms 50% latency, the bottleneck being network bandwidth limitations between the replicas in different regions. In other experiments we found if bandwidth constraints are relaxed, computation in the lead atomizer replica to manage Raft replication and execute the state machine becomes the bottleneck.

We compare Hamilton’s performance to three centralized databases: PostgreSQL, Rolis [64], and CockroachDB. In all cases the workload was the *swap* function with 2-in/2-out compact transactions; we did not run sentinels or do signature checking, which improved latency for these measurements.

PostgreSQL. We chose to compare against PostgreSQL

since it is a widely used, fully-featured commercial database. We ran PostgreSQL on c5a.8xlarge EC2 instances, using benchmarking recommendations [50] and implementing `swap` as a stored function. We were able to obtain a max throughput on PostgreSQL v13.8 of 63.4K txns/sec and an average throughput over a 45 second run of 61K txns/sec, with average and 99% latency (as measured on the client) of 10ms, using hundreds of load generating clients. The database had 38.4M UHS IDs. Our experiments indicated that PostgreSQL is limited by throughput to the write-ahead log. Note that this was a single-machine benchmark with no replication.

Rolis. Rolis is a very high-performance in-memory research database. To evaluate Rolis we implemented the `swap` function in the benchmarking experiment software that accompanies Rolis. We used three replicas in the regions specified above and, as Rolis uses significant amount of RAM, used c5n.18xlarge instances (72 vCPUs, 192 GB RAM), largest among the c5n family of instances that we used to evaluate Hamilton. We did our experiments using Ubuntu 18.04.

We used a database containing 200M UHS IDs, unlike the 1B used for benchmarking Hamilton as 250M and larger data base sizes reliably ran out of memory. Figure 4 shows the performance as we increase the number of threads; the thread count there includes the additional thread [64, §6.1] that Rolis uses to advance the watermark and perform leader election tasks. To maximize Rolis’s performance, we (a) implemented load generators inside each Rolis thread (so unlike when evaluating Hamilton, PostgreSQL, or CockroachDB, the load generators were not networked) and (b) used sequential UHS IDs. The latter avoids calling a hash function to generate UHS IDs in the critical path of the load generator, which halved the throughput when we tried it, but would be parallelizable in a different load generator implementation.

Rolis achieves a max throughput of 1.91M txns/sec on our workload. When replicating the YCSB++ benchmark on the same EC2 instances, the max throughput using 32 threads was 10.2M txns/sec, comparable to 10.3M reported in the Rolis paper. Our keys are 32 bytes instead of 8 bytes, and unlike YCSB++, which is 50% read-only, our workload is 100% read/modify/write, thus it requires more logic per transaction and more bandwidth for replication.

The almost-linear scalability when using 1, 2, 4, 8, and 16 threads did not continue when thread count increased from 16 to 31. We attribute this to hyper-threading: Rolis’s implementation only supports a single socket (as it uses `rdtscp` counters for time-stamping), whereas our 72 vCPU instance had 16 cores (32 hyper-threads) per socket. This made our 31 thread benchmarks use hyper-threading and we would expect Rolis to perform better with an increased number of dedicated cores.

When comparing performance, it is important to note

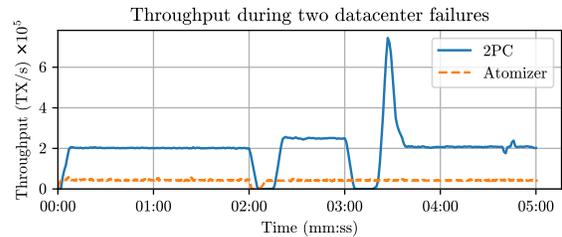

Figure 5: Throughput over time where the number of supported failures for both architectures was 2 and 2 whole data center failures were triggered at 120s and 180s. 5 sample moving average.

that Hamilton durably commits every transaction to disk, whereas Rolis runs wholly in-memory persisting nothing to disk. As our setting calls for ability to cold-start a system after potentially correlated failures, we see the excellent Rolis in-memory performance as establishing an upper, rather than a lower, bound for a backend.

CockroachDB. We ran limited experiments against CockroachDB v22.1.9, a feature-complete scalable distributed database. CockroachDB automatically manages data partition assignments. We ran with a replication factor of three in the regions specified above, using c5d.4xlarge instances. We had to implement the `swap` function through client queries, requiring two roundtrips to commit a transaction, as CockroachDB does not yet support stored procedures or functions. It achieved throughput of 3.4K, 5.7K, and 11K txns/sec partitioning data across 1, 2, and 4 logical shards, respectively. CockroachDB is slower because it implements many more features than Hamilton, whereas implementing `swap` as a primitive in our distributed backend reduces the number of roundtrips and transferred data required to commit.

In summary, Hamilton achieves higher throughput than PostgreSQL and CockroachDB by co-designing the application with the data model, and pushing the `swap` primitive into the commit protocol. It approaches the performance of Rolis, a very fast in-memory replicated database. Rolis might be a better choice for a backend if in-memory replication is sufficient for durability; in our application it was important to have data on disk to have a path to recovery from simultaneous crashes. Another reasonable choice is to use an existing commercial database if performance is not as much of a concern.

6.2 Fault Tolerance

We evaluate how our system handles up to two regional data center failures, and its scalability as the number of supported faults increases.

Figure 5 shows the overall system throughput over time when shards and coordinators have a replication factor of five (supporting up to two failures per cluster). To test continued system availability when up to two data centers fail

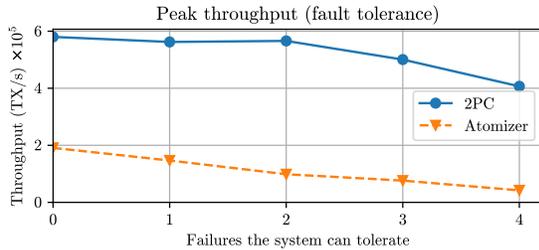

Figure 6: Peak throughput versus the number of tolerated failures per replicated service. Atomizer used 100M UHS IDs, 2PC used 1B.

completely, the Raft leaders for coordinators and shards were killed at 120 seconds into the test, and a subsequent set of nodes for each cluster were killed at 180 seconds into the test. The second group of nodes contained a mixture of leaders and followers depending on the result of the leader election from the previous failure. The plot shows that our system is successfully able to recover from the failure of two entire data centers with minimal downtime and no loss of system performance. For each failure, throughput was temporarily reduced for less than fifteen seconds, before automatically recovering to the baseline. There is no data loss and the system is not left in an inconsistent state as the replacement coordinators complete any distributed transactions that were in progress at the time of each failure.

Figure 6 compares how peak throughput is affected by the number of supported system failures between architectures by increasing the number of tolerated failures from 0 through 4. The plot shows that as replication factor increases, peak throughput for a given system configuration decreases. Since the performance of our Raft replicated services is limited by bandwidth constraints between the leader and follower nodes, more replicas require more leader bandwidth to provide the same throughput. In 2PC, we believe a higher replication factor can be supported without a loss in performance by increasing the number of shard and coordinator clusters. The atomizer architecture could not scale in this way, as the system throughput is limited by a single Raft service which provides the global order of transactions.

6.3 Workload Variability

We varied the proportion of transactions with a high number of inputs and outputs, and the proportion of double-spending transactions to see how Hamilton performs under different workloads from users.

Figure 7 shows how the proportion of double-spending transactions, or those with a large number of inputs and outputs affects peak throughput. In this test, the proportion of invalid or non-2-in-2-out transactions in the workload was varied from 0% through 30%. The load generators sent double-spending transactions by storing previously

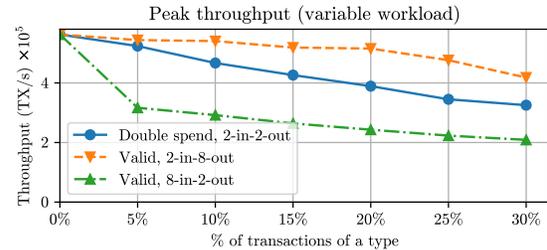

Figure 7: Peak throughput varying the proportion of valid, 2-in-2-out transactions.

confirmed transactions and re-issuing them at a later time. We only plot the throughput of valid transactions because double-spending transactions never complete.

As the proportion of large or double-spending transactions increases, the peak throughput decreases. This behavior is similar to increasing the overall number of 2-in-2-out transactions. The system is limited by the overall number of UHS IDs being processed, regardless of how they are grouped into transactions. Shards and coordinators replicate all transactions, so double-spends exert the same load as valid transactions. Thus, increasing the number of shards and coordinators could absorb an increased proportion of large or double-spending transactions while executing the same number of valid transactions. Transactions with a large number of inputs most negatively affect peak throughput because the sentinels have to validate more signatures per transaction. This could be solved by increasing the number of sentinels per load generator.

7 Related Work

Central banks are experimenting with or launching CBDCs. Some [22, 23, 34, 65] use DLT [57, 63], but according to their reports do not achieve as high performance as Hamilton. Other CBDC work uses a parallelized architecture; China's e-CNY is currently in public trials [24, 46, 62] and is a scalable system based on the UTXO model, but does not support self-custody. The Eurosystem has tested a CBDC design based on tracking groups of bills using a set of parallelized blockchains [38]. While it achieves linear scalability, transactions involving multiple bills require external coordination. The Regulated Liability Network [29] presents a design which claims to achieve 1M transactions per second with multiple coordinated blockchains. However, they do not discuss deployment across multiple geographic regions which is vital for resiliency or provide latency measurements.

Chaumian eCash [26] and designs based on it [18, 20, 21] operate with a central trusted intermediary, but either require maintaining an ever-growing list of all spent coins for double spend prevention, or require users to manage expiring coins, which has significant policy implications. The Swiss National Bank [27] expands upon the Chau-

mian ecash model using this technique.

Several central banks already support real-time gross settlement (RTGS) and fast payment systems [5]. These systems are designed to settle transactions between only eligible financial institutions. In practice, these systems do not handle a volume of traffic representative of a national retail payment system, do not provide programmability, nor provide access to the general public [6, 39, 40, 59].

Contrary to decentralized cryptocurrencies [53, 73] or stablecoins [11, 25, 33, 67], Hamilton is designed to be administered directly by the central bank or a related entity, and transacts in central bank liabilities. However, Hamilton borrows ideas from cryptocurrency designs; it uses the UTXO transaction model, but only stores 32-byte hashes [41]. Users cannot verify transaction execution themselves since they cannot access the ledger or state of the system. Techniques like authenticated datastructures [66] or cryptographic proofs of transaction inclusion [55] might be able to help with this.

Newer consensus algorithms [30] achieve higher throughput for agreement on ordering, and Hamilton could benefit from these as a replacement for Raft. However, faster consensus does not address the scalability bottleneck of state machine execution and validation in non-sharded blockchain-based architectures. Our 2PC architecture outperforms both our straw-man sharded blockchain as well as existing sharded blockchains which aim to operate in a decentralized setting, and thus cannot rely on a trusted coordinator to drive the cross-shard commit protocol to completion [2, 31, 49, 77]. However, some of these blockchains provide more features than Hamilton, like general smart contracts.

Via careful choices in application transaction design and format, Hamilton is able to avoid the need for reads or any other transaction execution before commit time, and can apply good ideas in traditional distributed transaction commit protocols [1, 28, 68] in a simplified backend that does not need to handle general transactions.

8 Conclusion

This work presents a high-performance, resilient transaction processor for CBDCs. We support a range of potential policy choices and can minimize data stored in the transaction processor while supporting a variety of custodial models. Our experiments show that a blockchain-based design for CBDC has serious scalability limitations, but by validating transactions in parallel we can achieve millions of transactions per second.

Abstract

Continuous learning has recently shown promising results for video analytics by adapting a lightweight “expert” DNN model for each specific video scene to cope with the data drift in real time. However, current adaptation approaches either rely on periodic retraining and suffer its delay and significant compute costs or rely on selecting historical models and incur accuracy loss by not fully leveraging the potential of persistent retraining. Without dynamically optimizing the resource sharing among model selection and retraining, both approaches have a diminishing return at scale. RECL is a new video-analytics framework that carefully integrates model reusing and online model retraining, allowing it to quickly adapt the expert model given any video frame samples. To do this, RECL (i) shares across edge devices a (potentially growing) “model zoo” that comprises expert models previously trained for all edge devices, enabling history model reuse across video sessions, (ii) uses a fast procedure to online select a highly accurate expert model from this shared model zoo, and (iii) dynamically optimizes GPU allocation among model retraining, model selection, and timely updates of the model zoo. Our evaluation of RECL over 70 hours of real-world videos across two vision tasks (object detection and classification) shows substantial performance gains compared to prior work, further amplifying over the system lifetime.

1 Introduction

Video analytics with deep neural networks (DNNs) is a promising technology adopted in a wide range of applications such as enterprise security, retail, traffic management, and transportation [1, 2]. Across these applications, it is often imperative to run analytics tasks directly on edge devices (e.g., using on-premises edge servers [3, 4]) to ensure that the system can deliver real-time results with low latency and in compliance with data privacy constraints [5–8]. However, the edge has limited compute resources, which cannot match the unrelenting growth of video analytics workloads, DNN models, and video streams [9, 10]. Even for applications that can be deployed in resourceful environments such as public clouds, the cost of running video analytics remains exorbitant despite recent advancements in DNN resource efficiency [11–13]. For example, a high-end NVIDIA V100 GPU can only support two video streams running the state-of-the-art YOLOv5-L model [13] at 30 FPS, which translates to a steep cost of \$1,100/month/stream on public clouds [14].

One common approach to reducing the resource requirements for video analytics is to use specialized and compressed

DNNs [15–18]. However, owing to their inherent limits on the number of object appearances and scenes they can learn in their condensed structures, such specialized DNNs require *continuous retraining* to cope with dynamic scenes (data drifts) in order to maintain high inference accuracy. Recent work in the computer vision and systems communities [19–21] has shown the effectiveness of this approach for edge video analytics, delivering both high resource efficiency and accuracy in results.

Though promising, continuous retraining and deploying specialized DNNs has two fundamental limitations. First, continuous retraining consumes the vast majority of *compute resources* in these video analytics systems (70%–90% in our study) [20, 21], making model retraining the key bottleneck in scaling video analytics to more video streams with limited compute resources. Our study (Fig. 2) shows that accuracy drops sharply (by 40% in object detection) as 4× more cameras share the GPU cycles to retrain their models (§2.2). Second, it takes *time* to retrain specialized DNNs, and abrupt video scene changes inevitably lead to drastic accuracy drops until the retraining is completed (see Fig. 3 for an example). Hence, it is fundamentally challenging to uphold the accuracy lower tail during the retraining.

Our goal in this work is to address the above two fundamental limitations so that video analytics are scalable with more consistent accuracy. As retraining specialized DNNs requires resources and takes time, we aim to minimize the necessity of retraining by judiciously *reusing* historical specialized DNNs that are trained with past video segments. The intuition behind our approach is that video streams typically exhibit spatio-temporal correlations (e.g., a car drives back on the same street or another car has been on the same street before) [22]. Thus, it is likely that the current video segment bears some resemblance to historical video segments, and the corresponding historical specialized DNNs can be *reused* for the current scene. Indeed, our study in §2 shows that an idealized model reusing scheme can consistently deliver high accuracy (35% mAP) with limited compute resources. In comparison, existing continuous retraining systems (e.g., [20]) cannot keep up with the compute demand of more cameras, with their accuracy dropping to a low 24% mAP.

Technical challenges: Harnessing the potential of model reuse for video analytics faces two challenges. First, we need to quickly and accurately find the specialized DNN that works well for the current video segment so that we can reuse the DNN in real-time. This is difficult because it is unclear how to compare the similarity of high-dimensional and unstructured data such as video segments [23], and comparing the current

video segment with all the historical video segments is not practically feasible. Second, we need to keep the cost of enabling model reuse much lower than the cost of model retraining. This is challenging as the cost of seeking through historical models grows with the size of history, while model retraining only requires fixed expenditure for each video segment. Recent video analytics solutions that reuse historical models (e.g., ODIN [23]) cannot address these challenges because they are not designed for resource efficiency.

Solution: We present RECL, a new video analytics solution that leverages historical specialized DNNs to improve scalability, responsiveness, and accuracy consistency in a resource-constrained environment. RECL is the first end-to-end system that integrates model reusing with model retraining for resource-efficient video analytics, entailing three main ideas:

- We design a *fast and robust model selection* procedure to quickly select a suitable model from the *model zoo*, a large collection of historical specialized models (§3.1). Our model selector is inspired by sparse gating networks in the mixture of experts (MoEs) approach [24–26], and we make it resource-efficient by decoupling the training of the gating network from the training of underlying experts. This allows RECL to select a model based on the characteristic of video analytic tasks and video scenes (e.g., detecting cars on a sunny day), which is superior to existing solutions that only consider the similarity of video frames (e.g., rainy or sunny days) [23].
- RECL *shares* the model zoo across different edge devices to enable more *model reusing* and dynamically adds new experts to the model zoo with a lightweight process to update the model selector (§3.3).
- RECL shares GPU resources across the retraining jobs using an *iterative training scheduler* that dynamically prioritizes retraining jobs that progress faster (§3.2). As a result, it spends little retraining resources on expert models that are already a good match with the current video segments.

We implement and evaluate RECL on two computer vision tasks: object detection and object classification. We compare RECL against three state-of-the-art video analytics systems (Ekya [21], AMS [20], and ODIN [23]) over a total of 71 hours of driving videos. Given the same compute resource, our evaluation shows that RECL improves the object detection mAP and image classification accuracy over the state-of-the-art solutions by up to 9.0% and 7.4%, respectively. To put these accuracy gains in perspective, the state-of-the-art mAP score for the object detection task on the PASCAL dataset has only improved by less than 8 percent in the past 6 years [27]. Moreover, the baseline systems need at least $3.2\times$ more compute resources to match RECL’s accuracy. Our ablation study shows that RECL’s superior performance mostly comes from effective integration of model reuse in our design. Compared to Ekya as a prior continuous training approach, RECL achieves the same accuracy up to 91 seconds faster on average. We also show that the compute overhead of RECL declines gracefully over time as more expert models are learned and added to the model zoo.

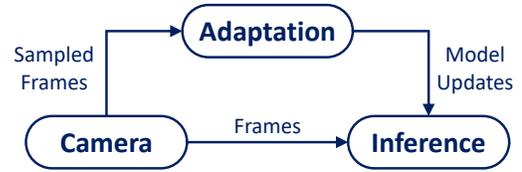

Figure 1: Overview of a video analytics system utilizing continuous learning. A typical adaptation module continuously retrains expert models or selects them from an existing collection of models trained in the past.

2 Background and Motivation

We first introduce the background of continuous retraining and deploying specialized DNNs for video analytics (§2.1). We then discuss the fundamental limitations of this approach and how reusing historical specialized DNNs can address these limitations effectively (§2.2).

2.1 Continuous Retraining for Video Analytics

State-of-the-art generic DNNs are often too expensive to run for video analytics all the time in resource-constrained environments such as a mobile edge computing (MEC) network [28]. A common approach is to deploy specialized and compressed DNNs (or “expert” models) that are trained using the knowledge of the generic and expensive DNNs (or the “teacher” model). The idea is to use knowledge distillation [29] to transfer the knowledge from a large teacher model to a small expert model for a specific video segment or video stream. On a matching video segment, an expert model can save compute resources by orders of magnitude while achieving similar model accuracy as the large teacher model [15, 16, 30]. This approach has been widely adopted in modern systems such as Microsoft’s Rocket [17] and Google’s Learn2Compress [18].

As an expert model only recognizes a limited set of object appearances and video scenes, a static expert model cannot achieve high accuracy on dynamic live videos where objects and scenes inevitably change over time (e.g., different locations, lighting conditions, object classes, etc.) [21]. A promising approach to employing expert models on dynamic live videos is to *continuously retrain* the expert model with the most recent video frames. Recent work [19–21, 31] has established that continuous retraining and deploying small expert models can simultaneously achieve high accuracy and resource efficiency on dynamic video content. Furthermore, continuous retraining has shown superior performance compared to running the large teacher model on a subset of frames and interpolating the labels (e.g., using optical flow tracking methods) [20].

Fig. 1 can be used to illustrate the high-level components of a video analytics system that continuously retrains and deploys expert models. They include: (i) *camera service*: periodically sends new sample video frames to the adaptation service; (ii) *adaptation service*: uses the recently sampled frames to fine-tune (a copy of) the camera’s expert model to mimic a larger teacher model for the current scene, and sends (or “streams”) the updated expert model to the inference service; and (iii) *in-*

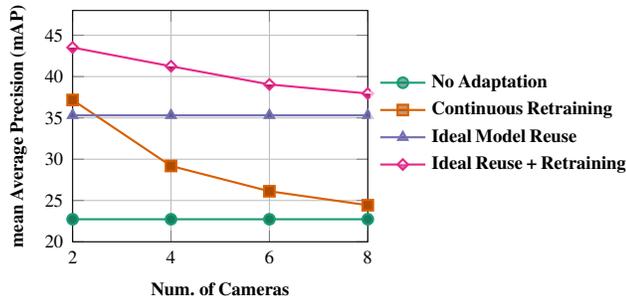

Figure 2: Object detection accuracy (mAP) of different designs under different numbers of cameras. Model reuse has the potential to significantly improve the accuracy in resource-constrained regimes (4, 6, and 8 cameras), and when combining model reuse and model retraining, performance *could* be greatly improved.

ference service: uses the received lightweight expert model for real-time inference on video frames from the camera service.

This paper focuses on the adaptation service. As retraining an expert model takes significant compute resources and time (§1), the adaptation service becomes a key bottleneck in resource efficiency and accuracy consistency. We observe that these systems [20, 21] need to spend 70%–90% of the overall compute resource on retraining their expert models. This is because model training is much more expensive than model inference. Besides, knowledge distillation needs to run the large teacher model to generate data labels on the sampled frames. In order to address this fundamental challenge, we need an effective approach to minimize the necessity of invoking expert retraining.

2.2 The Case of Reusing Historical Expert Models

It is well known that a video deployment usually exhibits temporally and spatially recurrent patterns [22, 23, 32]. Similar video scenes reoccur on the same camera at a similar time of day (e.g., morning or night), weather (e.g., sunny or raining), and location (e.g., a drone revisits the same street). More importantly, a video scene from one camera can also appear on *other* cameras, especially those in the same geographical vicinity, such as a self-driving car visiting a place that other cars in the same fleet have seen. These temporal and spatial correlations imply that some expert models trained on video scenes in the past could perform reasonably well on the current video scene, and we can potentially leverage these historical expert models to minimize the necessity of retraining.

To empirically show the potential of reusing historical expert models, we use a total of 71 hours of driving videos collected from YouTube (more details in §5.1). The large teacher model is a state-of-the-art object detector DNN, YOLOX-X (282 GFLOPs), and the expert model is a much smaller variant YOLOX-Nano (1 GFLOPs) [13]. Similar to existing continuous retraining solutions, we train one expert model for each 30-second video segment. We create a model zoo using all the expert models trained on the first 30 hours of the videos ("training data"), and we use the remaining 41 hours of the

videos ("test data") to report the object detection accuracy.

We evaluate four designs:

1. **No Adaptation**: trains a single expert model based on all training data and deploys this expert on the test data.
2. **Continuous Retraining**: periodically retrains an expert model for each camera using the most recent video segments. This serves as a reference point of recent model-retraining systems, such as AMS [20] and Ekya [21].
3. **Ideal Model Reuse**: deploys the *best* expert model from a given model zoo created based on video segments in the first 30 hours (ignoring the model-selection overhead). This can be seen as a strictly better version of ODIN [23], recent model reusing baseline.
4. **Ideal Reuse with Retraining**: combines 2 & 3 (retraining the reused model selected by 3.) This shows how much an ideal model reusing scheme can improve in a continuous retraining framework.

All designs are given the same amount of GPU resources to continuously retrain expert models, while No Adaptation (Design 1) and Ideal Model Reuse (Design 3) do not use this resource for retraining.

Benefits in resource efficiency: Fig. 2 shows the mean Average Precision (mAP) score on the test data while varying the number of cameras. The observations are two-fold.

First, model reuse is a promising direction in minimizing retraining. The benefits of model reuse become more evident when the compute resource is not enough to retrain the expert models for more cameras (4, 6, and 8 cameras). Even when the compute resource *is* enough for model retraining (2 cameras), Ideal Model Reuse can still achieve a similar mAP as Continuous Retraining. This observation is encouraging because reusing history models does not require the resources (not shown here) to retrain any new expert models, and at the same time, the best expert model in the past already achieves comparable accuracy with the expert models trained on the most recent video data.

Second, model reuse has a promising synergy with continuous retraining—Ideal Reuse with Retraining achieves the highest mAP across the board. This is because the reused model provides a strong starting point for retraining, which reduces the compute resource needed by retraining (i.e., faster convergence) *and* improves the inference accuracy of the resultant expert models.

Benefits in accuracy consistency: Another key benefit of model reuse is that we do not need to wait for an expert model to finish retraining. This is particularly important when a camera has experienced a sudden scene change and is in urgent need of a new model. For example, when a car drives into a tunnel, we can select and change the expert model quickly without the latency of training a new expert (Fig. 3 shows a concrete example). We demonstrate this benefit with the CDF of mAP across all video segments for the 8 camera setting (Fig. 4). As the figure shows, Ideal Model Reuse has a much better

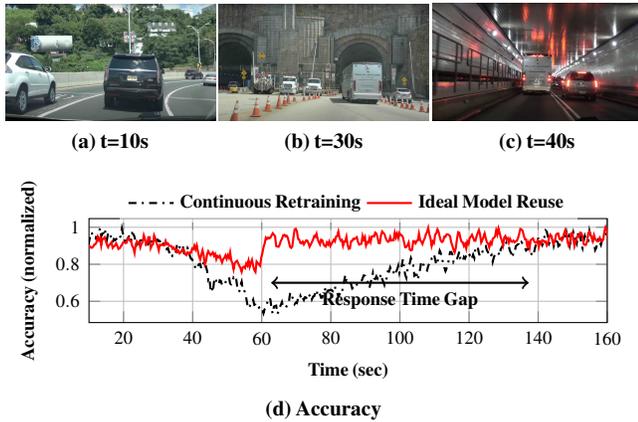

Figure 3: Example of a scene change when a car camera enters a tunnel and how fast Ideal Model Reuse and Continuous Retraining respond: Model updates arrive every 30 seconds. At $t=60$ sec, both schemes can access sample frames from the tunnel scene. Ideal Model Reuse switches to a good model for the new scene immediately at $t = 60$ sec, whereas Continuous Retraining takes about 80 sec to retrain the model till the accuracy bounces back.

tail mAP than Continuous Retraining. For instance, at the 1st percentile, Ideal Model Reuse retains 24% mAP while Continuous Retraining drops to an unacceptable 7% mAP. Fig. 3 illustrates a concrete example. As the car drives into the tunnel ($t = 40s$), Ideal Model Reuse switches to a matching expert much faster ($t = 60s$) than Continuous Retraining ($t = 120s$), which leads to a much more moderate drop in model accuracy.

Challenges of model reuse: Several technical challenges need to be addressed to fully realize the benefits of model reuse. Ideal Model Reuse assumes that it always selects the best expert model with no compute cost or delay in searching through all experts in the model zoo, which is not practical. Recent model reuse solutions in the database community (e.g., ODIN [23]) cannot address these challenges either, because they are not designed for resource efficiency, when sharing the compute resource among the functions of model selection and model retraining for many edge devices. To unleash the potential of model reuse in practice, we need a mechanism to find the best expert model quickly and accurately. We also need to rein in the cost and latency of model selection, so that it does not grow indefinitely with the number of videos or cameras.

In summary, reusing historical expert models is a promising complement to model retraining, and when used jointly, it leads to better resource efficiency and more stable and accurate model adaptation. That said, to make model reuse practical, several technical challenges remain, which we will tackle in the next section.

3 Design of RECL

This paper presents RECL, a new end-to-end design of model adaptation for continuous learning on edge devices. At a high level, RECL is given an accurate-yet-expensive model (the “teacher”) and a set of edge devices, and it automatically adapts

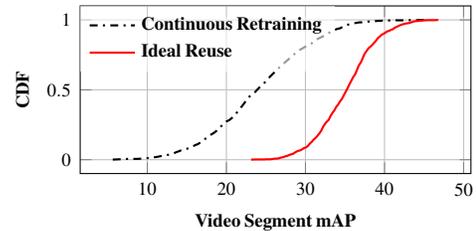

Figure 4: Ideal Reuse improves both average and tail accuracy (mAP) across video segments.

the deployed lightweight (“expert”) models, each dynamically tailored to an edge device’s particular distribution of video frames at any point in time, allowing each edge device to obtain results similar to running the teacher model.

Overall architecture (Fig. 5): RECL launches a *model-adaptation controller* on a server machine (e.g., in the cloud, edge compute cluster, etc.), which manages a set of daemons running on edge devices. The controller selects and deploys lightweight models on edge devices, which run local fast inference using the lightweight model. This work focuses on the adaptation controller, and the optimizations inside the edge devices or on the communication between the controller and the edge device are orthogonal to RECL. Furthermore, we assume the interactions between the server and edge do not interfere with any other processes running on the edge device (including the local inference).

In each model-update window (by default, every 30 seconds),¹ each edge device sends sampled frames to the controller to query if a new model should be used. (Note that the RECL controller only updates models for edge devices, which then use models to run inference on video streams.) The frame sampling rate is set dynamically based on the extent of scene change (similar to the technique used in AMS [20]). AMS takes the drift rate of the labels measured at the server as a signal for setting the frame sampling rate. As labels are usually in a lower dimension than input images, their variation rate is a less noisy proxy for detecting the scene change pace.

Based on the sampled frames, the controller performs two basic functions—*model selection* (§3.1), which selects a suitable expert model from a collection of history expert models to quickly respond to the edge device’s query, and *model retraining* (§3.2), which fine-tunes the selected model based on the sampled frames and manages GPU resources to many edge devices to retrain their models. Furthermore, retrained models are periodically added to the model zoo shared with other edge devices (§3.3). The rest of the section will present their designs and rationales.

¹We use fixed update windows, similar to Ekya [21]. Dynamic window size is orthogonal to RECL. In general, an update window can be triggered by an edge device when it detects substantial changes in its video stream, and there are several prior efforts on scene change detection.

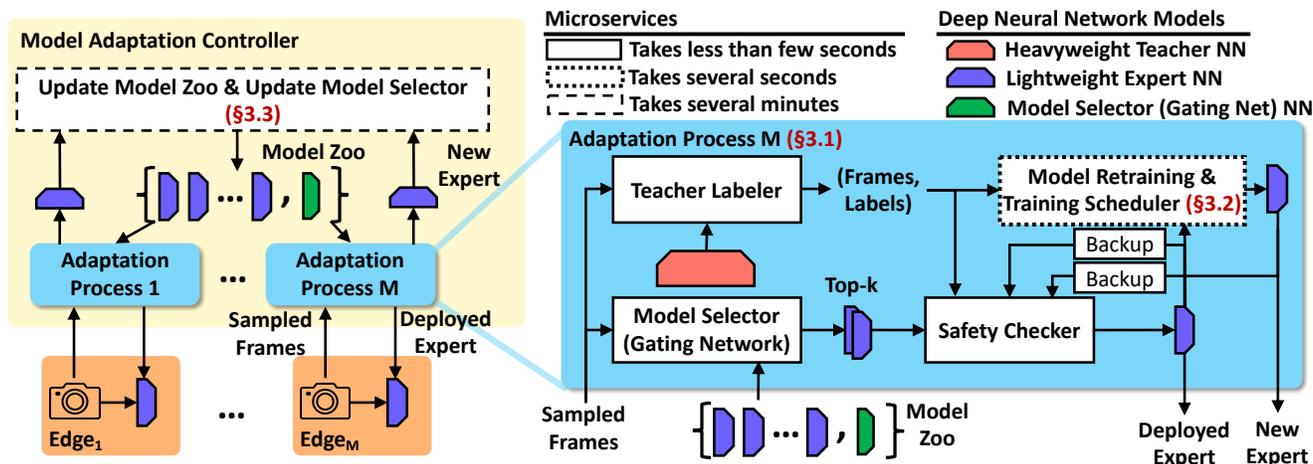

Figure 5: RECL system architecture. Edge devices (cameras) run real-time inference using lightweight models, and the model-adaptation controller manages a model zoo of expert models trained on history frames from edge devices (cameras) and, on receiving a model-update query, quickly selects a suitable model from the model zoo and recently trained models (the light-blue box). New models are also continuously retrained (optimized by a custom training scheduler) and then incrementally added to the model zoo over time. (The figure does not show optimizations to speedup inference on edge devices or the controller-device communication, as they are orthogonal to RECL.)

3.1 Model Selection

RECL’s model selection module, on receiving a query from an edge device, should *quickly* select a high-quality (accuracy) expert model from a collection of models. RECL achieves this goal by: (i) maintaining a large (potentially growing) *model zoo* of history expert models that are previously trained for any edge device; and (ii) using a fast and robust selection procedure to navigate the large model zoo.

Sharing model zoo across video sessions: RECL’s model zoo consists of a set of lightweight expert models, each trained for a specific scene distribution previously seen by some edge device managed by the controller. For example, if the controller manages several driving video sensors in an area, the model zoo might contain experts for different streets/neighborhoods, different weather conditions, etc. It is crucial to note that RECL does *not* directly rely on any priors about the features (e.g., weather conditions) of video content as a signal for creating new models; rather, an expert model is created based on frames of an edge device in an update time window, and then added to the model zoo if it improves performance (see §3.3).

An important design choice of RECL is that rather than caching the history models of different devices separately, RECL *shares* the model zoo and its gating network across devices, enabling model *reuse* across similar video sessions of different devices that might share similar temporal-spatial correlations (e.g., in the same geographical vicinity) [33]. This reduces the need for online model retraining and improves system responsiveness when an edge device experiences a sudden scene change for which a previously trained model (probably of another device) with good accuracy is available. For example, cars in the same city would observe the same scenery over time, even though the frames observed

throughout one driving session may vary significantly. In such an application, the model zoo would eventually include an expert for most scene distributions encountered, significantly reducing the need for per-session model training.

Fast, robust online model selection: Figure 5 (right-hand side) describes RECL’s online procedure to select a model from the model zoo. One strawman solution to the model selection problem is running an exhaustive search over all experts in the zoo. However, the number of models in the zoo can grow large over time, and it would become prohibitively expensive to select models by testing all of them on the sampled frames in each update window. To scale model selection to a large model zoo, RECL uses a *gating network* [26] to directly infer which models in the zoo better fit a given video content. The gating network is a lightweight DNN that given an image, assigns a score to each model in the model zoo. Logically, the gating network is similar to an image classifier, except that the labels are not object classes but models in the model zoo. A higher score indicates the model likely has higher accuracy on the image. (§3.3 will explain how to update the gating network to handle the changing model zoo.)

An alternative approach [23,34] to model selection is to map video content to an embedding space (via an autoencoder), partition the embedding space, and map each partition to a specific expert model. We found that this approach works poorly in practice (§5.2). The intuitive reason is that auto-encoders are trained to learn the distributions of only *input* data (e.g., which video frames look similar), rather than simply learning which frames can share a good expert model. The former task is too generic, and therefore, it is significantly hard to learn an efficient embedder to deploy in practice. We refer readers to [35] for further details. In contrast, RECL’s gating network directly predicts the quality (accuracy) of each

expert model and avoids the need to have a good auto-encoder.

That said, it is hard to train a gating network that always picks the best model from the model zoo. Instead, RECL runs the gating network on the edge device’s latest sampled frames and selects the top- K models (e.g., $K = 10$) with the highest average scores. The intuition is that the performance of the best of the top- K models improves quickly with larger K (see §5.3). In short, the top- K filtering approach strikes a decent balance between leveraging a large model zoo and fast model selection.

The *safety checker* then tests the accuracy of these top K models, along with the current model of the edge device and the last model retrained on video frames from the same edge device (explained in §3.2). The testing is based on the sampled frames and their “ground truth” labeled by the more accurate and more expensive “teacher” model. Finally, among these models (top- K from the model zoo, current model, and the last retrained model), RECL selects the one with the highest empirical accuracy on the labeled images and sends it to the device. This online model selection process is fully automatic and has a low compute cost. For the object detection task, for example, we use YOLOX-nano for the lightweight experts and ResNet18 as the gating network. These two models have a close inference cost per sample (1.1 vs. 1.8 GFLOPs). However, the gating network only runs on a significantly smaller subset of frames (e.g., 1/30th of frames).

3.2 Model Retraining

So far, we discussed how to reuse the previously trained models. Like other continuous learning frameworks [20, 21, 23], RECL also retrains models online for each edge device. The edge device periodically queries the controller in every model-update window. For each query, RECL will initiate a retraining job using the sampled frames sent by the device (similar to [21]), after the model selection process described above is finished.

However, to scale to more edge devices, many of which need new models, RECL must carefully allocate its GPU resource to model retraining jobs. The basic idea of RECL is to closely monitor how accuracy improves on each training job and dynamically share more GPU resources to the jobs that benefit more from additional GPU cycles.

RECL time-shares the GPU among multiple retraining jobs by micro-windows—in a micro-window, we let one of the retraining jobs use all GPU cycles and may switch to a different job at the boundary of micro-windows based on the logic described next. Each micro-window is long enough for one retraining job to complete one epoch (i.e., going through all sampled frames once). A typical micro-window size is about one second. (We will explain the reason for timesharing GPU shortly.)

Retraining scheduling algorithm: Targeting a fixed maximum accuracy gap with the teacher model for each video scene can become quickly intractable as it can be pretty challenging for the student model to track the same target performance for all real-world scenes. However, as our results show later, we

Algorithm 1 RECL GPU Sharing Algorithm

```

1: Input: training requests  $\mathcal{R}$ , micro-window number of
   seconds  $\mu$ , window size of  $T$  sec
2:  $budget \leftarrow T$  ▷ Total time budget
3: procedure PROCESSREQUEST( $r$ )
4:    $acc_i \leftarrow r.EVAL()$ 
5:   Train the model for request  $r$  for  $\mu$  seconds
6:    $acc_f \leftarrow r.EVAL()$ 
7:    $budget \leftarrow budget - \mu$ 
8:   return  $(acc_f - acc_i)/\mu$  ▷ Returns the accuracy gain
9: end procedure
10: for  $r$  in  $\mathcal{R}$  do ▷ Initialize the gain estimates
11:    $gain[r] \leftarrow PROCESSREQUEST(r)$ 
12: end for
13: while  $budget > \mu$  do ▷ Schedule the most promising
14:    $r \leftarrow \operatorname{argmax} gain$  ▷ Find the request with max gain
15:    $gain[r] \leftarrow PROCESSREQUEST(r)$ 
16: end while

```

can still target a fixed maximum gap on the average accuracy. Hence, having a system that uses the resources efficiently, we can always add more resources as the number of cameras grows till we are happy with the overall accuracy.

Consider C concurrent training jobs (one for each edge device). We define $I_c(\tau)$ as the improvement achieved from training the model corresponding to camera c for τ seconds. Our objective is:

$$\begin{aligned} \max_{\tau_1, \tau_2, \dots, \tau_C} \sum_{c=1}^C I_c(\tau_c) \\ \text{s.t. } \sum_{c=1}^C \tau_c = T \end{aligned} \quad (1)$$

That is, given a time budget T (e.g., the update window duration), we want to time-share GPU resources to maximize the total improvement of accuracy across all models.

To solve this optimization problem, RECL uses the following *iterative scheduler* (Algorithm 1). At the beginning of each update window of size T , the scheduler receives a set of training requests, \mathcal{R} . Each training request corresponds to a set of labeled frames (already labeled by the teacher model as part of safety checking), and an expert model checkpoint (selected by the safety checker at the beginning of the window). In each micro-window of μ seconds, the PROCESSREQUEST procedure (Lines 3-9) takes one of the requests r as input and evaluates *how much its accuracy improves between before and after a micro-window*. Notes that the cost of these accuracy evaluations is ignored as they only require a lightweight forward pass on the test subset of the data.

The main loop of the algorithm first spends one micro-window to process each request and initialize its accuracy improvement (Lines 10-12). Then it iteratively picks the

training request with the largest accuracy improvement as our next model to train till we run out of time (Lines 13-16).

Since DNN training curves $I_c(\tau)$ are usually concave (i.e., accuracy improves quickly and then slows down), then this iterative algorithm effectively minimizes the maximum speed of these models' training curves ($\frac{\partial I_c}{\partial \tau_i}$). It can be shown that this iterative process converges to a near-optimal partition of the total time budget that maximizes the total accuracy improvement across the training jobs [36].

Design choices: We highlight two design choices behind the retraining scheduler.

To find the best GPU allocation, both Ekya and RECL predict each retraining job's training speed (accuracy improvement vs. epochs) but with different approaches. Ekya periodically runs extra ("out-of-band") micro-profiling on each camera: running a few epochs of training on a subset of history images to build a profile of the training curve of each camera. Such upfront micro-profiling has extra compute overhead and fails when the training curve changes over time. In other words, they inherently trade off between the profile accuracy and their overhead. In contrast, RECL uses an "in-band" profiler—it measures the *actual* learning progress (accuracy improvement) of each job on the fly and dynamically determines which one progresses faster. This scheme avoids the micro-profiling overhead of Ekya without losing accuracy. Note that RECL requires fast switching between models, which will be discussed next. Our scheduler's iterative algorithm is similar to [37] which is designed to achieve fairness among the cluster-level training jobs which compete at a significantly longer time scale.

Instead of splitting GPU cycles spatially across concurrent training jobs, RECL time-shares the GPU cycles by switching among concurrent retraining jobs every micro-window. While it is logically equivalent to spatially sharing, RECL's GPU timesharing is based on three practical considerations. (1) The delay to context switch between GPU-loaded models (usually less than tens of milliseconds) is negligible compared to a micro-window. Since a lightweight model in RECL has a small memory footprint, we can load it to GPU memory and not swap it out (even when switching between retraining jobs) until the model retraining completes. (2) Unlike Ekya, RECL does not have to finish model training very quickly (it responds to each edge device by first selecting a good model from the model zoo or the most recently trained model has been good enough). (3) It does not rely on any GPU library to dynamically reallocate GPU across different jobs.

3.3 Updating the Model Zoo & Selector

Admission of new models to model zoo: RECL does not add every retrained model to the model zoo. A recently trained model is considered *promising* if the safety checker finds this retrained model's accuracy is α higher than the rest of the candidate models (the top- K experts selected by gating network and edge device's current model). These promising models are put in a queue. When the promising model's queue

grows larger than a fixed threshold, γ , we empty the queue by adding them to the model zoo and update the gating network (explained next) to consider the recently added models. Hence, α and γ control the frequency of model selector updates. We later study the impact of the zoo admission rate on the system performance (§5.3).

Incrementally update of gating network: Recall that the gating network predicts the accuracy of each expert in the model zoo on the input frame. Hence, when updating the gating network to handle new expert models, we need to first label the accuracy of all experts on both the new frames that were used to train the new expert models as well as a sub-sampled set of history frames (those used to update gating network before). To this end, we label the new samples with existing experts in the zoo and label the existing samples with the new experts added to the zoo. This way, we track the performance of all experts on a sampled set of frames so far. Note that when we create the training frame set of the gating network, we sub-sample frames used before and mix them with the new frames in order to keep the same training size over time.

As the zoo size increases, the output size of our gating network must change as well. Since the accuracy prediction logic does not change for most of the models in the zoo, we only need to add corresponding neurons for the new models to the final layer without changing the connectivity weights for existing expert models. This way, we transfer as much knowledge as possible from one gating network to the next. To further speed up the training of the gating network, we use the mean and variance of the most recent model selector in order to initialize the connectivity weights corresponding to the new experts in the final layer.

Pruning the model zoo: Though updating the gating network is usually fast, the overhead of retraining for updating the gating network grows proportionally with the size of the model zoo. To prevent the model zoo to grow indefinitely, we deem an expert in the zoo ineffective if other experts always have a preferred accuracy. In particular, we remove the experts that are chosen less than η times in the last q model selection calls. We set $q = 3000$, which is about one day's worth of video streaming in our system and study the impact of the η parameter later in §5.2.

4 Implementation

We have implemented RECL in Python and used Pytorch [38] for inference and training of ML tasks. For communication between the services, we use the gRPC [39] framework for remote procedure calls.

Microservices: We implement several microservices to prototype RECL. These microservices are designed to generalize to different continuous adaptation design choices in prior work. RECL runs a camera streaming service on each camera device to send the subsampled video frames to the teacher labeler service running on the adaptation server. We use TensorRT [40] and half-precision computation to further

speed up the inference processes. One runner microservice manages the coordination of different components across all video streams that share resources in the server.

Hooks: Each microservice can register a hook in other microservices. These hooks are specific functions to run at predefined time events in the system. Our time events are a combination of before/after, window/microwindow, and first/last time. For example, if a model zoo update strategy requires to have information about the training gain of each model at the microwindow level, it registers accuracy evaluation hooks in the training scheduler before and after each window.

Adaptation state: There is an adaptation state shared across all microservices that register to the same runner. All microservices have read and write access to the adaptation state to optimize their decisions, possibly share the hooks results, and keep track of possible global events like the beginning of a new window.

Training strategy: Our training scheduler service relies on a sharing strategy abstraction. Each strategy has access to the adaptation state, can register or subscribe to a hook, and has a run method to decide which camera model should train next in each microwindow. If an adaptation scheme is not microwindow-based, it only has to register hooks for the first and last microwindow.

Performance monitoring: For tracking the system performance metrics, we implement logging hooks to track system-level metrics like compute times and resource utilization in addition to RECL-specific performance metrics like zoo admission rate and model reuse rates.

5 Evaluations

Finally, we evaluate RECL on two video-analytics tasks using real-world driving videos. Our key findings include:

- Given the same compute resource, RECL improves the object detection mAP and image classification accuracy over state-of-the-art baselines by up to 9.0% and 7.4%, respectively. The baselines need to use at least $3.2\times$ more compute resources to match RECL’s accuracy.
- The superior performance of RECL comes primarily from our distinctive design of model reuse. RECL’s fast gating network and safety checker outperform the state-of-the-art model selection mechanism in terms of accuracy and efficiency by a large margin.
- RECL is highly responsive to a model-update request. On average, the time RECL needs to adapt models to the same accuracy is 11–91 seconds faster than that of the baselines, with the gap growing both at the tail of the distribution (by almost $2\times$) and with the total number of cameras.
- RECL’s retaining scheduler also makes better use of GPU. In contrast to round-robin and out-of-band profiling used in several recent continuous learning systems, RECL’s in-band profiling provides a 2.0% higher mAP at up to $6.1\times$ lower overhead.
- Compute overhead of RECL decreases gracefully over time

Model	Params	FLOPs	Throughput (FPS)
MobileNetV2	3.5M	0.32G	1.5K
ResNet50	25.6M	4.12G	153
YOLOX-Nano	0.91M	1.1G	312
YOLO-X	99.1M	282G	58
ShuffleNetV2	2.28M	0.15G	3.7K
ResNet18	11.7M	1.8G	490

Table 1: Specifications of the models used for the evaluation. Throughputs are reported for NVIDIA V100 GPU with a batch size of 1.

as more models are trained and added to the zoo.

5.1 Methodology & Setup

Dataset: We evaluate RECL on two computer-vision tasks—image classification and object detection—using 151 driving videos collected from YouTube. Since we would like our video sessions to include meaningful data drifts, we adopt videos that have a length of at least a few minutes (up to a couple of hours)² with a total length of 71 hours. Furthermore, our dataset covers a wide range of cities and driving situations in North America, including weather conditions, time of day, and driving speed. Note that in each experiment, we do *not* play the exact same video segment twice on *any* edge devices, since it might artificially amplify the gain from model reusing. Driving video is a remarkably challenging workload for evaluating our system as the scenes change more widely and frequently. This workload brings a variety of situations where exact matching is impossible and requires more than a few models to cover the wide range of possible scenarios. Responsiveness is also more challenging for driving cameras compared to fixed cameras. For example, traffic light cameras mostly need only to update every few hours when the lighting/weather change, significantly stressing the compute power at the adaptation server.

Models: For object detection, we use YOLOX-Nano and YOLOX-X [13] for the student and teacher models, respectively. For image classification, we use MobileNetV2 [42] and ResNet50 [43] for the student and teacher models. Details of these models are shown in Table 1. Our models are pre-trained on ImageNet [44] and COCO [45] datasets for classification and detection, respectively. For fast model selection, we use ResNet18 as the gating network architecture by default, unless otherwise stated.

Metrics: To evaluate the accuracy of different schemes, we compare the inference results on the edge device with labels extracted for the same video frames using the teacher model (similar to prior work [20, 21]). We use *mean Average Precision (mAP)* for the detection task, while for classification, we report *accuracy* by the proportion of correct predictions (both true positives and true negatives) among the total number of cases examined. We calculate these metrics across *all* 80 and 1000 classes of MS COCO and ImageNet datasets for

²Video sessions in other similar video datasets like Berkeley Driving Dataset (BDD) [41] were not long enough for our purpose. For example, each driving episode in BDD is only 40 seconds.

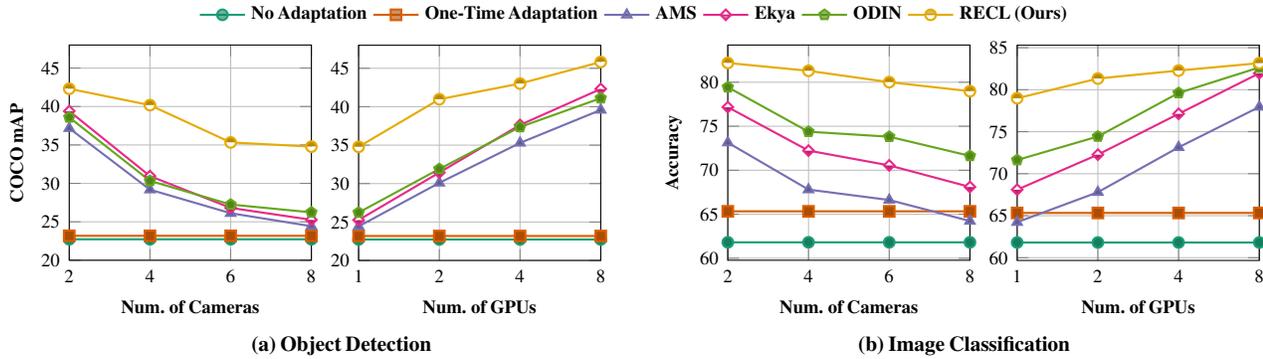

Figure 6: End-to-end scaling of the average accuracy across different schemes for two typical vision tasks.

detection and classification, respectively.

Setup: In our setting, model selection and training of the adaptation controller happen in the cloud, and each edge device only runs inference by the lightweight expert model on the local video stream. All experts can run at a real-time inference speed (30 frames-per-second) even on lower compute power edge devices such as NVIDIA Jetson Nano [46] and Coral Edge TPU [47], and we do not evaluate any optimization on the edge device, as it is orthogonal to RECL. We use NVIDIA V100 GPUs for the adaptation server. The adaptation processes of different edge devices share the same pool of GPU resources.

Baselines. We compare RECL against the following continuous learning methods:

- **No Adaptation:** We run the pre-trained model on the edge device without any adaptation.
- **One-Time Adaptation:** We fine-tune the entire model on the first half of the videos and test on the rest. This adaptation happens only once. Comparing RECL with this scheme will show the benefit of having a continuous adaptation system in place.
- **AMS:** We implement Adaptive Model Streaming (AMS) as in [20], which uses a remote server to continually adapt lightweight expert models running on edge devices. As the update intervals are longer and our lightweight models are smaller than AMS, network bandwidth consumption is less of a concern in our setup. As such, we relax the bandwidth constraint of AMS and allow for full model parameter updates in this scheme. AMS uses a simple round-robin mechanism for GPU sharing. Comparison with AMS mainly highlights the gains of model reuse and optimized GPU sharing. As AMS reasonably outperforms Just-In-Time [19] and remote server inference in prior work [20], we no longer compare with these schemes.
- **Ekya:** Ekya enables both retraining and inference to co-exist on the edge node without any model reuse. Since RECL shares the server GPU resource only among model retraining and selection jobs (inference is on edge devices), for a fair comparison, we compare RECL with applying Ekya’s microprofiler and thief scheduler (released in Ekya [21]) to model retraining jobs. Despite the more

sophisticated resource-sharing mechanisms compared to AMS, Ekya, however, incurs the out-of-band profiling overhead and cannot reuse models compared to RECL. Moreover, since Ekya shows how continuous retraining significantly outperforms naive model reuse methods (e.g., reuse models from the same time of the day) [21, §6.4], we do not compare RECL with these naive reuse heuristics.

- **ODIN:** ODIN [23] is a video analytics system that can detect and recover from data drift by building expert models based on the similarity of video scenes. We use the autoencoder-based method proposed in ODIN for model selection. Specifically, the average of embedding vectors of the sampled frames in a window is used as the embedding vector of that window. Also, each trained expert is assigned an embedding vector the same as its training data. We use the L2 distance between the embedding vector of a window and the models in the zoo as a measure of similarity, and the model selector returns the model with the least distance from the samples in each window as in the ODIN paper [23].

5.2 Results

End-to-end performance: We first compare the end-to-end accuracy of RECL with the baselines over a range of provisioned GPUs and a varying number of concurrent cameras replaying videos from our dataset. Whenever a video ends, we continue with another video from our dataset. Note that we never repeat the same video twice as it favorably impacts the accuracy gain of model reuse. We use NVIDIA V100 GPU as the adaptation server. In measuring the impact of the number of cameras on the accuracy, we fix the number of GPUs to 1. For the varying number of GPUs experiment, we run a workload consisting of 8 cameras. As shown in Fig. 6:

1. Continuous adaptation significantly improves mAP and accuracy. Gains from continuous learning grow with more resources provisioned per camera.
2. Overall, RECL outperforms all baselines by a large margin. In object detection, for instance, RECL improves mAP by up to 9.0% (8 cameras, 1 GPU) compared to the second best approach. In terms of resource consumption, RECL supports $2.6\times$ more cameras on one GPU, and requires

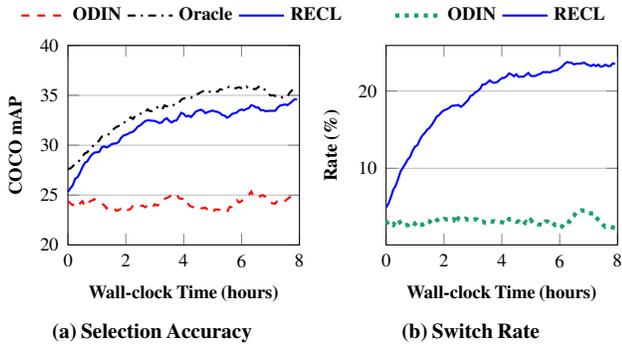

Figure 7: An example of RECL model selection performance over time. As the model zoo grows, (a) accuracy of the RECL-selected models gradually improves, and (b) the model selected by RECL’s gating network has higher accuracy than models selected by ODIN (as evidenced by the fact that the safety checker would more frequently pick the model by the gating network than it would pick the model selected by ODIN).

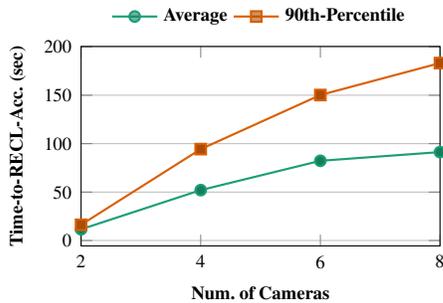

Figure 8: Model reuse impact on improving the response time.

- 3.2× fewer GPU cycles to maintain an mAP of 35%.
- 3. mAP/accuracy improvements from model reuse are significant. Compared with Ekya and AMS which do not reuse historical models, RECL brings up to 9.8% and 10.7% improvement in mAP and accuracy for object detection and image classification, respectively.
- 4. Without model reuse, RECL’s scheduler provides about 1.5% mAP improvement compared to Ekya.
- 5. In image classification, ODIN performs the best among the baselines due to its model reuse and specialization design. Nonetheless, ODIN’s auto-encoder-based model selector (and the lack of optimized resource sharing) performs poorly on relatively complicated tasks like object detection. In contrast, we see better performance of RECL across all settings in both tasks due to our unique model selector and retraining scheduler design.

Model selection performance: To directly examine the model selector performance, in Fig. 7a, we plot the accuracy of the selected models vs. the system’s wall-clock for 8 GPUs, i.e., within each hour on the wall-clock, the system ingests 8 hours of video. In the figure, we also include the performance of ODIN (a recent model selector) over the same zoo created by RECL, as well as the accuracy of an oracle model that exhaustively searches over all models in the zoo at each point in time (while ignoring the oracle’s compute overhead). It

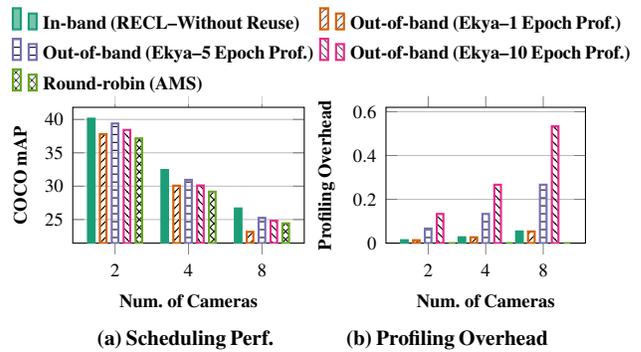

Figure 9: Impact of profiling on retraining performance: RECL’s retraining scheduler (which uses a low-overhead in-band profiling) outperforms Ekya (which relies on out-of-band profiling on each job) and AMS (which uses a round-robin scheduler).

is not surprising that the accuracy of the model selected by RECL improves over time as more models are being added to the zoo. Furthermore, we observe that RECL performs closely to the oracle selector, while ODIN struggles to select a good model from the same zoo. Notice that the cost of running the oracle model is prohibitively expensive as, after a couple of hours, it requires testing the accuracy of thousands of experts in the zoo for each sample frame. On the contrary, RECL uses ResNet18 as the underlying gating architecture that runs at 490 frames per second (see Table 1).

We further notice that, in Fig. 7a, the model zoo roughly converges to a desirable accuracy after four hours, totaling 32 hours of video stream ingestion. This observation shows an opportunity to reduce model zoo update frequency (and thus its cost) after enough representative experts are collected in the system. With the growing model zoo, model reuse becomes more favorable over time as well. Fig. 7b depicts the percentage of the time that the safety checker prefers the selected model over the rest (e.g., a recently trained model). For a fair comparison of the effectiveness of model reuse, we run RECL and ODIN end-to-end independently (i.e., they are not sharing the same model zoo). As can be seen in Fig. 7b, RECL’s model hit ratio increases with a larger zoo, making our system both more accurate and efficient than ODIN. Moreover, notice that the safety checker picks the offered historical model 25% of the time in the case that the most recent trained model is also coming from RECL. To better understand the model reuse impact here, we design the following experiment.

Impact of model reuse on responsiveness: Model reuse improves the response time of the adaptation server by not needing to retrain a new expert model first. To directly evaluate this effect, we first profile the accuracy of 102 models generated in Ekya (in a video of 51 minutes long) against 2 minutes of offline training on a single V100 GPU. Using these profiles, we then measure the time it would take Ekya, as a continuous retraining approach, to adapt each model to the same accuracy level of the RECL’s selected model for reuse on the same window. We refer to this metric as Time-to-RECL-Accuracy. Figure 8 shows the

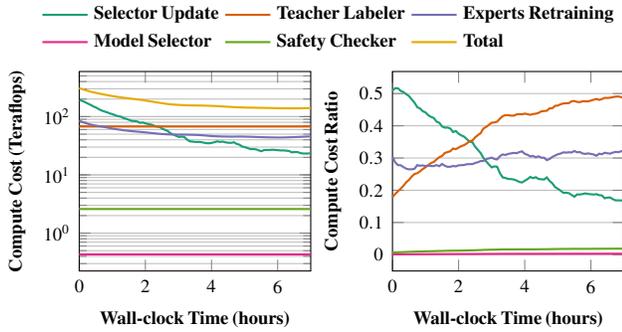

Figure 10: Breakdown of compute cost by the components of RECL controller. The total cost drops over time as the extra-cost of maintaining the model zoo significantly reduces, allowing RECL to enjoy the benefit of model reuse without much additional overhead.

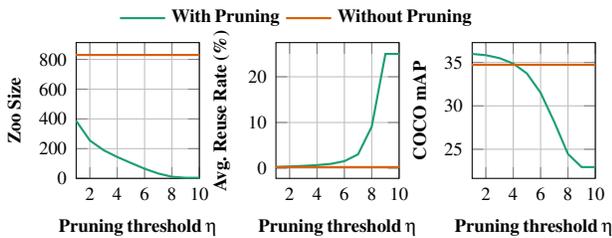

Figure 11: Pruning policy impact on RECL accuracy.

mean and 90th percentile of the Time-to-RECL-Accuracy for the object detection task across a varying number of cameras sharing one GPU. We observe that Ekya takes up to 90 seconds longer than RECL, on average, to achieve the same level of accuracy. More importantly, this gap grows significantly large with increasing the number of cameras and at the tail scenarios.

Scheduler performance: We now evaluate RECL’s retraining scheduler with its “in-band” profiling (§3.2) and compare its performance with Ekya’s out-of-band micro-profiler and AMS’s round-robin scheduling method. For a fair comparison between Ekya and RECL, we turn off RECL’s model reuse and let Ekya adapt its early stop parameter, which has a similar effect to the micro-window-based scheduling in RECL. To run Ekya’s profiler, we set its early stop parameter to 1, 5, and 10 epochs. Fig. 9 compares the accuracy and profiling overhead (ratio of the time spent on profiling in each window) of these schedulers vs. the number of cameras. We observe that Ekya’s out-of-band profilings are either too costly to run (e.g., Ekya with an early stop of 10 epochs), or too noisy to identify a good early stop parameter, which results in low accuracy. For example, an early stop at 1 epoch has the same cost as RECL’s in-band method but performs worse than round-robin when resource allocation becomes more challenging with 8 cameras.

Breakdown of compute cost: Fig. 10 shows the cost of different components in RECL over the course of 7 hours. Initially, model selector update has the dominant cost in the system. However, as the zoo grows over time, the need for updating the model zoo (and consequently the selector) reduces to the extent that after a while, the teacher labeler and training scheduler

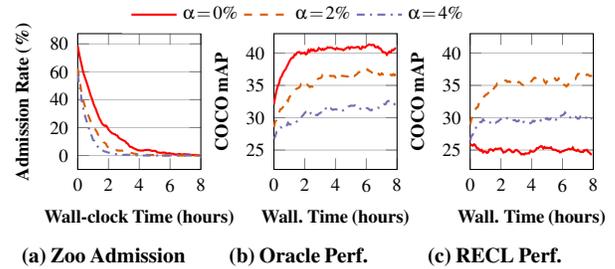

Figure 12: Impact of changing the admission rate through the α -promise threshold on RECL model selection performance.

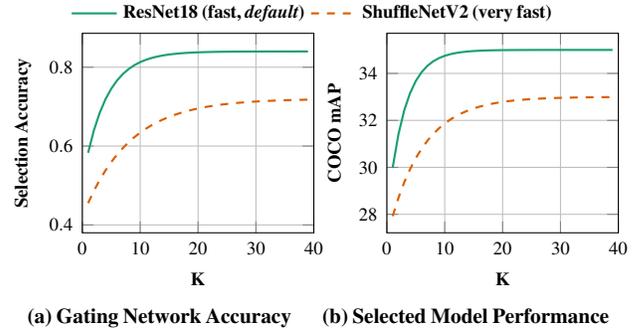

Figure 13: Impact of using top-k models suggested by the gating network for the default gating network and a faster gating network model.

become the dominant cost of the system, but these “base cost” is the same as a typical continuous retraining system (such as Ekya and AMS). In short, the extra overhead for RECL to enable model reusing (model selector and maintaining a growing model zoo) significantly reduces over time.

5.3 Ablation Studies

Model zoo pruning: In Fig. 11, we compare RECL accuracy across various levels of pruning intensity over the course of nearly 60 hours. Naturally, reducing the value of η leads to a significant drop in model zoo size without much accuracy sacrifice. For instance, a balanced choice of the pruning threshold, $\eta = 4$ provides the same accuracy despite efficiently shrinking the size of the model zoo by a factor of $5.6\times$, from 830 down to about 150 experts.

Zoo admission rate impact (α -promise margin): In order to evaluate the impact of the admission rate, we turn off the zoo pruning mechanism and measure the selected model accuracy. Fig. 12 shows this accuracy for three levels of α for both the ideal oracle selector and RECL’s selector. As decreasing α allows for admitting more models to the zoo, the oracle-based scheme can choose among more models. However, it gets harder for the gating network model to select from an arbitrarily large model zoo. Hence, we observe a diminishing return in increasing the admission rate beyond $\alpha = 2\%$, which seems to be a good balance between the zoo size and the model selection complexity.

It should be noticed that the exact values of these parameters (η, α) largely depend on the dynamics of video content. The

message from Fig. 12 and 11 is that there are sweet spots for them that, on a large set of videos, strike a desirable tradeoff between the cost of maintaining a reasonably sized model zoo and the quality (accuracy) of the selected models. The parameter γ controls the gating network update frequency (i.e., cost). As the Selector Update cost in Fig. 10 shows, this cost diminishes over time as the system collects a comprehensive set of experts. Therefore, RECL’s performance in steady state is not as sensitive to γ as it is to α and η .

Model selector top-k: As discussed in §3.1, we pass the top- k selected model to the safety checker (instead of 1) in order to find a better model for reuse. In Fig. 13, we show the accuracy of model selection and the performance of the selected model for our default and a faster gating network model (see Table 1 for speed comparison). Given this observation, we find $K = 10$ is a good default operating point for RECL. Notice that while a higher K increases the cost of the safety checker, as shown in Fig. 10, our safety checker still has a negligible overhead compared to the other components in the system.

6 Discussion

Safety-critical applications: Predicting the feasibility of minimum accuracy thresholds is not a trivial problem in non-convex ML training tasks. Therefore, as we cannot guarantee a minimum accuracy level using continuous adaptation for safety critical problems, the solution might come at the cost of provisioning enough resources to run the large state-of-the-art model for inference. However, if the problem is not safety-critical, one solution might be to set minimum accuracy thresholds with timeouts to achieve them, which we leave to future work.

Data residency: RECL requires sharing training samples with the adaptation server. While there are recent solutions in computation over encrypted data for secure AI [48], our current evaluation has been based on having access to the actual video frames. Depending on the data residency policies, such data sharing may constrain how far the adaptation server can be taken from the cameras.

7 Related work

Optimization of video-analytics systems: To maintain high inference accuracy with low resource usage and fast response, video-analytics systems have explored many approaches, including model distillation [16, 20, 21], model architecture pruning [49, 50], configuration adaptation [32, 51], frame selection [52, 53], and DNN feature reusing [54, 55]. The closest to RECL is model distillation—creating lightweight models (i.e., experts in RECL) that are small and fast yet accurate on a specific video scene [16, 56]. The challenge is that as the video scene evolves, the system must create new expert models on the fly to fit new video content. Existing solutions rely on either of two approaches—model retraining techniques train the lightweight models on the latest video frames [19–21] or on the most relevant images from the training set [31], and model selection techniques maintain, and

then select a model from, a collection of history models [23] or a cascade of models with increasing capacities [31, 57].

In contrast, RECL uses both techniques—model retraining and model selection—as building blocks in an end-to-end framework. In particular, when an edge device queries for a model update, RECL can respond faster than Ekya [21] and AMS [20] by selecting a model from a large collection of history models used by all edge devices which might have seen a similar scene and object distribution. RECL also shares GPU cycles to enable more concurrent model retraining jobs, refreshing new models for more edge devices.

Model selection under data drifts: In the ML literature, model selection in a collection of expert models, or Mixture-of-Experts (MoE), has attracted much attention, especially after Shazeer et al. [26] demonstrated that using a sparsely gating network with an MoE of many expert models can drastically reduce the compute cost of DNNs. Recent work has obtained accuracy comparable to state-of-the-art expensive models with a fraction of compute cost [58]. One key distinction between RECL and MoE applications is that in MoE, all or a subset of the experts work together on each input. However, in RECL, there only works one expert on each input. For example, the recent MoE approach [58] operating on *tokenized* images requires access to 768 experts for inference on each input image. To implement such an approach, one must either load all experts in the accelerator’s memory or quickly swap the experts on the accelerator per patch per image, introducing significant challenges for even more resourceful settings such as entirely cloud-based applications [59]. That said, many techniques in MoE also assume that the MoE consists of a static set of models. To handle MoEs that gradually incorporate new models (as in RECL), the gating network or the model selector must be retrained over time [60, 61]. To avoid retraining model selectors or saving training data, recent works leverage an autoencoder that projects input data to a latent space and map new models to a region in the latent space [23, 34].

RECL’s model selection strategy (§3.1) builds on the literature on gating networks [26], but reduces the delay and compute overhead when adding new expert models. Instead of jointly training the new experts and the gating network [26], RECL freezes the new expert models already trained to fit the edge devices’ recent videos and only reshapes and fine-tunes the last layer of the gating network. Compared to recent autoencoder-based model selectors [23], RECL’s gating network enjoys better algorithmic intuition (see §3.1) and better empirical performance (§5.2).

Resource allocation for DNNs: Resource sharing for DNN-related jobs has been extensively studied in the systems literature, including sharing of GPU and network resources among multiple concurrent DNN training jobs (e.g., [37, 62]), inference tasks of video analytics (e.g., [51, 63]), and between inference and training jobs [21]. The common challenge facing these settings is to predict how much each job’s accuracy can improve with the same amount of compute/network resources.

This is usually profiled offline [51], periodically [21], or by reusing compute data [37].

RECL is a custom design of GPU sharing for continuous learning across many edge devices. Compared to Ekya [21], the most recent related work on edge continuous learning, RECL avoids profiling the training curve of each model; instead, it tracks the actual training progress of each retraining job on the fly, similar to SLAQ's quality-driven scheduler [37] proposed for large-scale DL clusters.

8 Conclusion

Resource efficiency is one of the most important problems in modern video analytics applications, and continuous retraining and deploying expert models is a promising direction. We show that reusing historical expert models has a large potential to improve resource efficiency and response time for continuous retraining, but this approach comes with its own challenges. We present RECL, the first end-to-end system that integrates model reusing with model retraining for resource-efficient video analytics. We show that RECL achieves significantly better resource efficiency and higher accuracy simultaneously than state-of-the-art baselines with (i) a fast and robust model selection procedure, (ii) a model zoo that shares across multiple edge devices, and (iii) an iterative training scheduler. We hope that our findings and designs can stimulate further research in unleashing the full potential of the synergy between model reusing and model retraining.

Boggart: Towards General-Purpose Acceleration of Retrospective Video Analytics

Neil Agarwal, Ravi Netravali
Princeton University

Abstract

Commercial retrospective video analytics platforms have increasingly adopted general interfaces to support the custom queries and convolutional neural networks (CNNs) that different applications require. However, existing optimizations were designed for settings where CNNs were platform- (not user-) determined, and fail to meet at least one of the following key platform goals when that condition is violated: reliable accuracy, low latency, and minimal wasted work.

We present Boggart, a system that simultaneously meets all three goals while supporting the generality that today's platforms seek. Prior to queries being issued, Boggart carefully employs traditional computer vision algorithms to generate indices that are imprecise, but are fundamentally comprehensive across different CNNs/queries. For each issued query, Boggart employs new techniques to quickly characterize the imprecision of its index, and sparingly run CNNs (and propagate results to other frames) in a way that bounds accuracy drops. Our results highlight that Boggart's improved generality comes at low cost, with speedups that match (and most often, exceed) prior, model-specific approaches.

1 INTRODUCTION

Video cameras are prevalent in our society, with massive deployments across major cities and organizations [4, 10, 11, 22, 32, 47]. These cameras continually collect video data that is queried *retrospectively* to guide traffic/city planning, business or sports analytics, healthcare, crime investigation, and many other applications [5, 14, 23, 26, 31, 33–35, 37, 61, 69, 122]. Queries typically involve running convolutional neural network (CNN) models that locate and characterize particular objects in scenes [53, 99, 104, 106, 125]. Applications tailor the architectures and weights of those CNNs to their unique requirements (e.g., accuracy, latency, and resource cost) and target tasks, e.g., via specialization to scenes or object types [8, 13, 116], proprietary training datasets [7, 27, 28].

To support these diverse applications, commercial video analytics platforms (e.g., Microsoft Rocket [41, 44, 45], Amazon Rekognition [39], Google AI [70], IBM Maximo [83]) have steadily transitioned away from exposing only predetermined video processing results, towards being platforms that allow users/applications to register custom, large-scale video analytics jobs without worrying about infrastructural details [55, 116, 118]. To register a query, users typically provide (1) a CNN model of arbitrary architecture and weights, (2) a target set of videos (e.g., feeds, time periods), and (3) an accuracy target indicating how closely the provided results must match those from running the CNN on every

frame. Higher accuracy targets typically warrant more inference (and thus, slower responses and higher costs).

From a platform perspective, there exist three main goals for each registered query. First and foremost, provided results should *reliably* meet the specified accuracy target (usually above 80% [80, 92, 105, 116]). Subject to that constraint, the platform should aim to consume as few computational resources as possible (i.e., minimize unnecessary work) and deliver responses as quickly as possible. The main difficulty in achieving these goals stems from the potentially massive number of video frames to consider, and the high compute costs associated with running a CNN on each one. For example, recent object detectors would require 500 GPU-hours to process a week of 30-fps video from just one camera [77, 82].

Unfortunately, despite significant effort in optimizing retrospective video analytics [42, 48, 80, 81, 93–95], no existing solution is able to simultaneously meet the above goals for the general interfaces that commercial platforms now offer. Most notably, recent optimizations perform ahead-of-time processing of video data to build indices that can accelerate downstream queries [48, 80, 95]. However, these optimizations were designed for settings where models were known *a priori* (i.e., not provided by users), and thus deeply integrate knowledge of the specific CNN into their ahead of time processing. Porting these approaches to today's bring-your-own-model platforms fundamentally results in unacceptable accuracy violations and resource overheads. The underlying reason is that models with even minor discrepancies (in architecture or weights) can deliver wildly different results for the same tasks and frames. Consequently, using different models for ahead-of-time processing and user queries can yield accuracy drops of up to 94% (§2.3). Building an index for all potential models is unrealistic given the massive space of CNNs [102, 107, 114, 149], and the inherent risk of wasted resources since queries may never be issued [80, 137].

In this paper, we ask “*can retrospective video analytics platforms operate more like general-purpose accelerators to achieve their goals for the heterogeneous queries+models provided by users?*” We argue that they can, but doing so requires an end-to-end rethink of the way queries are executed, from the ahead-of-time processing used to develop indices, to the execution that occurs only once a user provides a model and accuracy target. We examine the challenges associated with each phase, and present **Boggart**, a complete video analytics platform that addresses those challenges.

Ahead-of-time processing (indexing). To support our goals, an index must meet the following criteria: (1) comprehensive with respect to data of interest for different models/queries – any information loss would result in unpredictable accuracy

drops, (2) links information across frames so CNN inference results – the most expensive part of query execution [80, 94] – can be propagated from one frame to another at low cost, and (3) cheap to construct since queries may never come in.

We show with Boggart that, if applied in a *conservative* manner, traditional computer vision (CV) algorithms [52, 88, 100, 127] can be repurposed to generate such an index per video. Along these lines, Boggart’s ahead-of-time processing extracts a comprehensive set of *potential* objects (or blobs) in each frame as areas of motion relative to the background scene. Trajectories linking blobs across frames are then computed by tracking low-level, model-agnostic video features, e.g., SIFT keypoints [110]. Crucially, Boggart’s trajectories are computed once per video (not per video/model/query tuple) using cheap CV tasks that require only CPUs, and are generated 58% faster than prior model-specific indices constructed using compressed CNNs and GPUs (§6.3).

Query execution. Once a user registers a query and CNN, the main question is how to use the comprehensive index to quickly generate results that meet the accuracy target, i.e., running inference on as few frames as possible, and aggressively propagating results along Boggart’s trajectories. The challenge is that Boggart’s index is extremely coarse and imprecise relative to CNN results. For instance, blob bounding boxes may be far larger than those generated by CNNs, and may include multiple objects that move in tandem. Worse, the imprecision of Boggart’s index varies with respect to different models and queries; prior systems avoid this issue by using indices that directly approximate specific models.

To handle this, Boggart introduces a new execution paradigm that first selects frames for CNN inference in a manner that sufficiently bounds the potential propagation error from index imprecision and unavoidable inconsistencies in CNN results [97]. The core idea is that such errors are largely determined by model-agnostic features about the video (e.g., scene dynamics), and can be discerned via inference on only a small set of representative frames. CNN results are then propagated using a custom set of accuracy-aware techniques that are specific to each query type (e.g., detection, classification) and robustly handle (and dynamically correct) imprecisions in Boggart’s trajectories.

Results. We evaluated Boggart using 96 hours of video from 8 diverse scenes, a variety of CNNs, accuracy targets, and objects of interest, and 3 widely-used query types: binary classification, counting, and detection. Across these scenarios, Boggart consistently meets accuracy targets while running CNNs on only 3-54% of frames. Perhaps more surprisingly given its focus on generality and model-agnostic indices, Boggart outperforms existing systems that (1) rely solely on optimizations at query execution time (NoScope [94]) by 19-97%, and (2) use model-specific indices (Focus [80]) running with knowledge of the exact CNN) by -5-58%.

Taken together, our results affirmatively answer the question above, showing that Boggart can support the general in-

terfaces and diverse user models that commercial platforms face, while delivering reliable accuracy and comparable (typically larger) speedups than prior, model-specific optimizations. The source code and experimental data for Boggart are available at <https://github.com/neilsagarwal/boggart>.

2 BACKGROUND AND MOTIVATION

In this section, we first present an overview of retrospective video analytics pipelines and their use cases (§2.1). We then describe existing optimizations (§2.2), and present measurements highlighting their inability to generalize to the different models and queries that users register (§2.3). Additional related work can be found in §7.

2.1 Primer on Retrospective Video Analytics

Numerous applications leverage (and are guided by) insights gleaned from analyzing the large amount of video data previously captured in different environments. For example, sports analytics tools leverage video analytics on previous game film to detect players on a field; these detections are fed into tracking algorithms to determine the efficacy of various strategies and to evaluate player performance [16, 29]. Similarly, retail analysts use video analytics to locate customers in indoor environments with high accuracy, in order to understand customer-product interaction and, ultimately, to improve store layout designs and product placement [31, 34]. City planners and traffic engineers employ video analytics to extract trends from historical footage, e.g., identifying points of congestion or opportunities for expansion [3, 20, 33, 35].

Despite their diverse use cases, retrospective video analytics generally share two main properties that characterize their computational requirements. First, they typically process video frames using convolutional neural networks (CNNs), a class of deep neural networks that have become the norm for automated vision processing due to their success in extracting spatial dependencies within images [53, 99, 104, 106, 125]. CNNs incorporate 3 kinds of layers: convolutional (responsible for recognizing pixel-level features), pooling (responsible for making these features more abstract), and fully-connected (responsible for using acquired features for prediction). In a CNN, each successive layer learns a more complex feature representation. Earlier layers focus on simple features such as colors and edges, while later layers aim to recognize specific objects. We refer the reader to prior reports [80, 94, 103] for more details.

Second, retrospective video analytics applications typically use CNNs to perform *object-centric* queries, e.g., to locate, characterize, and label different types of objects in frames. Indeed, the output of a CNN is a set of bounding boxes that localize all identified objects in a given frame, with each box being accompanied by a probability distribution characterizing its potential labels (or types). Such object-centric queries subsume those reported by both recent academic literature [55, 64, 92, 94, 105] and industrial organizations that run video analytics platforms [36, 80, 87, 111,

116, 140]. Concretely, in this paper, we consider the following query types (and accuracy metrics):

- **binary classification:** return a binary decision as to whether a specific object or type of object appears in each frame. Accuracy is measured as the fraction of frames tagged with the correct binary value.
- **counting:** return the number of objects of a given type that appear in each frame. Per-frame accuracy is set to the percent difference between the returned and correct counts.
- **bounding box detection:** return the coordinates for the bounding boxes that encapsulate each instance of a specific object or object type. Per-frame accuracy is measured as the mAP score [67], which considers the overlap (IOU) of each returned bounding box with the correct one.

The heterogeneity in use cases also brings important differences between manifestations of retrospective video analytics applications. Most notably, applications often apply *specialized* CNNs that cater to their specific target environments, object(s) of interest, required accuracy, task complexity, and available computational resources [75, 80, 94, 113]. Recent analyses of production video analytics workloads have shown that applications carry out such specialization by (1) selecting an existing reference model architecture from a popular family (e.g., ResNet, YOLO) and (2) training that model using custom and/or proprietary datasets that yield desirable weights for the target use case [116].

2.2 Existing Acceleration Approaches

Query-time strategies. Systems such as NoScope [94] and Tahoma [42] only operate once a user issues a query. To accelerate response generation, they first train cascades of cheaper binary classification CNNs that are specialized to the user-provided CNN, object of interest, and target video. The specific cascade to use is selected with the goal of meeting the accuracy target while minimizing computation and data loading costs. If confidence is lacking with regards to meeting the accuracy target, the user’s CNN is incrementally run on frames until sufficient confidence is achieved.

Ahead-of-time (preprocessing) strategies. Other systems provide speedups by performing some computation ahead of time, i.e., before a query is issued; for ease of exposition, we refer to such computations as *preprocessing* in the rest of the paper. For example, Focus [80] speeds up binary classification queries by building an approximate, high-recall index of object occurrences using a specialized and compressed CNN that roughly matches the full CNN on the target video. Objects are then clustered based on the features extracted by the compressed model such that, during query execution, the full CNN only runs on the centroid of each cluster, with labels being propagated to all other objects in the same cluster.

BlazeIt [93] and TASTI [95] accelerate aggregate versions of certain query types, e.g., total counts across all frames. Preprocessing for both systems involves generating sampled

results using the full CNN. TASTI uses the sampled results to train a cheap embedding CNN that runs on all frames and clusters those that are similar from the model’s perspective. During query execution, the full CNN is run only on select frames in each cluster, with the results propagated to the rest. In contrast, BlazeIt uses the sampled results to train specialized CNNs that act as control variates for the remaining frames: the specialized CNNs run on all frames, and the results are correlated with sampled results from the full CNN to provide guarantees in statistical confidence. OTIF [48] follows a similar strategy, but uses proxy models (trained using the sampled results) to extract tracks about model-specific objects that are later used to accelerate tracking queries.

Videozilla [81] aims to extend such indexing optimizations across multiple video streams. More specifically, it identifies and exploits semantic similarities across streams that are based on the features extracted by the full CNN.

2.3 The Problem: Model-Specific Preprocessing

As confirmed by prior work [80, 93, 95] and our results in §6.3, preprocessing (intuitively) reduces the amount of computation required during query execution, and is crucial to enabling fast responses. However, *all* existing solutions suffer from the same fundamental issue: they deeply integrate a specific CNN into their preprocessing computations (e.g., to generate sampled results for training the compressed models used to build indices or group similarly-perceived frames), and assume that all future queries will use that same exact CNN. While such an approach was compatible with prior platforms that exposed only predetermined results from platform-selected CNN(s), it is no longer feasible with the bring-your-own-model interfaces that are now commonplace on commercial platforms. To make matters worse, consider that queries can be made at any point in the future and the space of potential CNNs is immense and rapidly evolving [102, 107, 114, 149], with variations in architecture (e.g., # of layers) or weights (e.g., different training datasets). In fact, building an index for even today’s reference models would quickly present intractable resource challenges at the scale of retrospective video datasets: there exist tens of popular model families, each with multiple architecture options, e.g., the ResNet family alone has 8 architectures.

To quantify the issues when this assumption is violated, we ran experiments asking: how would accuracy be affected if the CNN provided by users during query execution (i.e., *query CNN*) was different than the CNN used during preprocessing (i.e., *preprocessing CNN*)? We consider the three query types above, videos and objects described in §6.1, and a wide range of CNNs: Faster RCNN, YOLOv3, and SSD, each trained on two datasets (COCO and VOC Pascal).

For each possible pair of preprocessing and query CNNs, we ran both CNNs on the video to obtain a list of object bounding boxes per frame. In line with Focus’ observation that classification results from two CNNs may not identically match but should intersect for the top-*k* results [80], we ig-

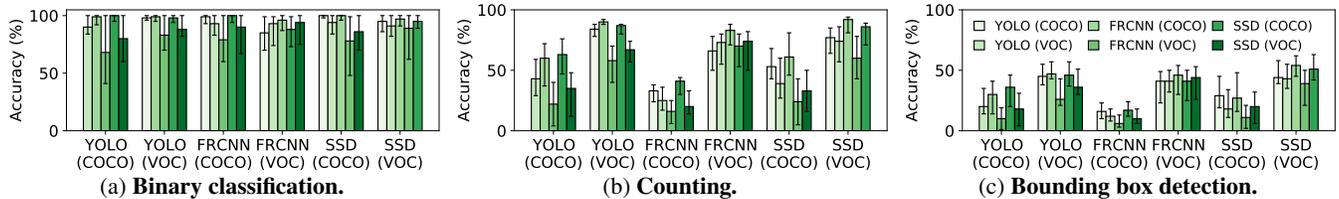

Figure 1: Query accuracies when *different* CNNs are used for preprocessing (bar types) and query execution (X axes). Bars show results for the median video, and error bars span the 25-75th percentiles. Models are listed as ‘architecture (training dataset)’.

nore the classifications from each CNN. Instead, we consider all bounding boxes from the preprocessing CNN that have an IOU of ≥ 0.5 with some box generated by the query CNN; results were largely unchanged for other IOU thresholds. This presents the *best scenario* (accuracy-wise) for existing preprocessing strategies. Finally, we compute query results separately using only the remaining preprocessing CNN’s boxes or all of the query CNN’s boxes, and compare them.

Figure 1 shows that discrepancies between preprocessing and query CNNs can lead to significant accuracy degradations, with the errors growing as query precision increases. For example, median degradations were 0-32% for binary classifications, but jump to 8-84% and 46-94% for counting and detections. Note that degradations for binary classification and counting are by definition due to the preprocessing CNN entirely missing objects relative to the query CNN. Parsed differently, median degradations across query types were 0-84%, 2-94%, and 1-90% when the preprocessing and query CNNs diverged in terms of only architecture, only weights, or both. Figure 2 shows that these degradations persist even for variants in the same family of CNNs.

Takeaway. Ultimately, when run on the general interfaces of today’s commercial video analytics platforms where users can provide CNNs, all existing optimizations would sacrifice at least one key platform goal:

- *reliable accuracy*: running preprocessing optimizations as is (using platform-determined CNNs) would yield unpredictable and substantial (up to 94%) accuracy hits;
- *minimal wasted work*: performing preprocessing for all potential user CNNs is not only unrealistic given the sheer number of possibilities, but would also result in substantial wasted work since queries may never be issued;
- *low-latency responses*: optimizing only once a query is issued will yield higher than necessary response times.

3 OVERVIEW OF BOGGART

This section describes the overall workflow that Boggart uses to simultaneously meet all three platform goals for general, user-provided CNNs (Figure 3). §4 and §5 detail its preprocessing and query execution phases, and the project repository includes end-to-end visualizations of its operation [9].

Preprocessing. The main goal of Boggart’s preprocessing phase is to perform cheap computations over a video dataset such that the outputs (an index) can accelerate query exe-

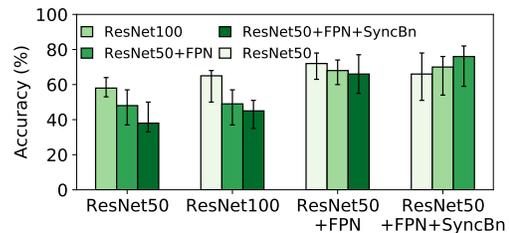

Figure 2: Accuracies when CNNs for preprocessing (bar types) and query execution (X axis) are FasterRCNN+COCO with different ResNet backbones. Results are for counting queries; bars list medians with error bars for 25-75th percentiles.

cution for diverse user CNNs, without sacrificing accuracy. Crucially, to avoid the pitfalls of prior work (§2.3), Boggart’s preprocessing does not incorporate *any* knowledge of the specific CNN(s) that will be used during query execution. Instead, our insight is that traditional computer vision (CV) algorithms [88, 100, 124, 127] are well-suited for such preprocessing, as they extract information purely about video data, rather than how a specific model or query would parse that data. Using generic CV algorithms enables Boggart to generate a single index per video, rather than per video/query/model tuple. Further, those CV algorithms are computationally cheaper than (even compressed) CNNs, and rely on CPUs (not GPUs), keeping monetary costs low (§6.3). Both aspects drastically reduce the potential for wasted work.

However, in contrast to their intended use cases, for our purposes, CV algorithms must be *conservatively* tuned to ensure that accuracy during query execution is not sacrificed. Namely, Boggart’s index must *comprehensively* include all information that may influence or be incorporated in a query result (across CNNs), regardless of how coarse or imprecise that information is. Whereas coarse or imprecise results can be corrected or filtered out during query execution, missing information would result in unpredictable accuracy drops.

Accordingly, Boggart carefully uses a combination of motion extraction and low-level feature tracking techniques to identify all potential objects as areas of motion (or *blobs*) relative to a background estimate, and record their *trajectories* across frames by tracking each blob’s defining pixels (or keypoints). For the former task, only high-confidence pixels are marked as being part of the background, ensuring that even minor motion is treated as a potential object; note that static objects are definitively discovered during query execution via CNN sampling on the frames across which the ob-

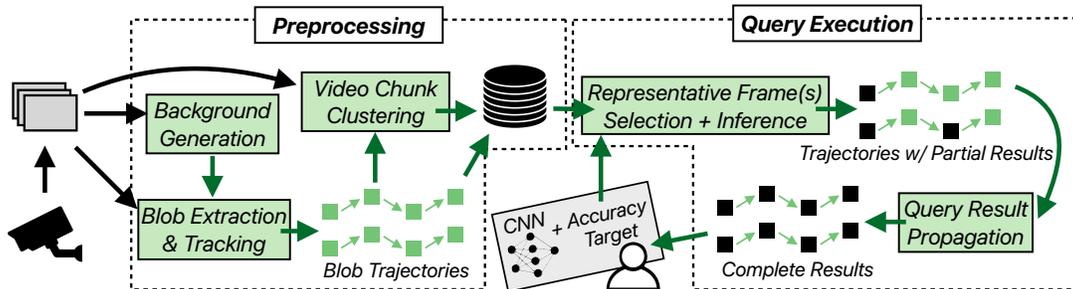

Figure 3: Overview of Boggart.

jects are static. For the latter task, any uncertainty in trajectory continuity (e.g., tracking ambiguities) is handled by simply starting a new trajectory; this ensures that results are not mistakenly propagated across different objects during query execution, albeit at the cost of additional inference. Overall, we did not observe *any* missed moving objects in Boggart’s indices across our broad evaluation scenarios (§6.1).

Trajectories are a fundamental shift from the clustering strategies that prior systems use to group frames or objects based on how they are perceived by a specific CNN (§2.2). In contrast, trajectories are computed in a model-agnostic manner, but still provide a mechanism through which to propagate CNN results across frames during query execution – the primary source of speedups. Such generality does, however, come at a cost. Whereas prior efforts cluster on frames or object classes, Boggart’s trajectories group frames on a per-object basis. This discrepancy lets Boggart defer the determination of how a user’s CNN perceives each object to query execution, but it limits potential propagation, i.e., Boggart propagates the result for an object across the frames in which it appears, while prior approaches can propagate results across appearances of different objects. Note that this discrepancy does not apply to detection queries that require precise object locations (not just labels) to be propagated.

A natural question is: why not cluster objects on the features extracted by traditional CV algorithms to enable more result propagation? The issue is that, if performed without knowledge of the user-provided CNN, such clustering could lead to unsafe result propagation. More specifically, objects that are similar on some set of features but are perceived differently by the user’s CNN could end up in the same cluster.

Query Execution. Once a user registers a query (providing a CNN, accuracy target, and video to consider), Boggart’s goal is to generate a full set of per-frame results as quickly as possible, while reliably meeting the target accuracy. This translates to using the index from preprocessing (i.e., blobs and trajectories) to run the CNN on a small sample of frames, and efficiently propagate those results to the remaining frames.

The main challenge is that, owing to their general-purpose nature (relative to different models/queries) and closeness to noisy image signals, the CV algorithms used during preprocessing typically produce results that fail to precisely align with those from a user’s CNN [55, 105]. Consequently, in

being comprehensive, Boggart’s index is coarse and imprecise relative to the target results from a user’s CNN, e.g., with misaligned bounding boxes or extraneous objects that are not of interest to the query. Worse, the degree of imprecision is specific to the user CNN, and can lead to cascading errors (and accuracy drops) as results are propagated along Boggart’s trajectories. All prior efforts avoid these issues by tuning indices to specific CNNs at the cost of generality.

To bound accuracy degradations (and reliably meet the specified target) while avoiding substantial inference, Boggart introduces a new query execution approach with two main components. First, to quickly and judiciously select the frames to run CNN inference on, our key observation is that errors from index imprecision and result propagation are largely dictated by model-agnostic features about the video, e.g., scene dynamics or trajectory lengths. Accordingly, Boggart clusters chunks of video in the dataset based on those features, and runs the user’s CNN only on cluster centroids to determine the best frame selection strategy per cluster for the query at hand, i.e., the lowest frequency of CNN inference that meets the user-specified target accuracy. We note that, since clustering is based on model-agnostic features, it can be performed during preprocessing; CNN inference on centroids, however, only occurs once a user registers a query.

Second, to further limit inference overheads, Boggart introduces a new set of result propagation techniques that are specific to each query type and bolster propagation distances in spite of imprecisions in the index. For instance, for bounding box detections, Boggart leverages our empirical observation that the relative position between an object’s keypoints (from preprocessing) and its bounding box edges remain stable over time. Building on this, Boggart propagates an object’s CNN-produced bounding box to subsequent frames in its trajectory by efficiently searching for the coordinates that maximally preserve these spatial relationships.

Query model and assumptions. Boggart currently supports the large body of object-centric queries whose results are reported at the granularity of individual objects (e.g., labeling or locating them) and whose CNNs are run on a per-frame basis. Thus, currently handled queries include classifications, counting, and detections, as well as queries that build atop those primitives such as tracking and activity recognition. Such queries dominate the workloads reported

by commercial platforms [36, 80, 87, 116, 140], and subsume those supported by prior work (§2.2). We note that Boggart’s approach is general enough to also accelerate less common, finer-grained queries, e.g., semantic segmentation [109]. For such queries, the keypoints (and their matches across frames) recorded in Boggart’s index can be used to propagate groups of pixel labels; we leave implementing this to future work.

Boggart does not make any assumptions about or require any knowledge of the object type(s) that a query targets. Instead, as described above, Boggart relies on generic background estimation and motion extraction to identify potential objects. The intuition is that a moving object of any kind will involve (spatially correlated) moving pixels that can be identified purely based on the scene. Boggart leaves it to the user’s CNN to determine whether those potential objects are of interest during query execution. We stress-test Boggart’s robustness to different object types in §6.4.

Boggart’s preprocessing operates on videos from static cameras that capture a single scene. Boggart currently does not support preprocessing for videos with changing backgrounds, e.g., CGI-generated films or videos from moving cameras. We note, however, that the CV community has actively been extending the core techniques that Boggart builds atop to deliver improved robustness in the face of moving cameras [65, 128, 135, 142]. We leave an exploration of integrating these efforts into Boggart to future work.

Reliance on Heuristics. Despite its focus on reliably meeting accuracy targets, Boggart’s operation does involve multiple heuristics, i.e., tracking algorithms (§4), preset video chunk sizes (§4), thresholds for blob extraction (§4), and clustering parameters (§5.2). The upcoming sections and results in §6.4 elaborate on Boggart’s sensitivity to each parameter. More generally, Boggart’s approach to ensure sufficient accuracy is shared: each heuristic is conservatively configured to err on capturing too much data (resulting in unnecessary processing) rather than missing important data, i.e., prioritizing accuracy over efficiency. Examples include returning blobs for unlikely (but possible) objects, splitting trajectories upon uncertainty in object tracking, etc. §6 shows that this approach enables Boggart to consistently and efficiently deliver accurate query responses for diverse camera feeds, queries, models, objects, and accuracy targets.

4 BOGGART’S PREPROCESSING

Boggart’s target output from preprocessing is a set of blobs and their trajectories. To efficiently extract this information and enable parallel processing over the dataset, Boggart operates independently on video chunks (i.e., groups of contiguous frames); the default chunk size is 1 min (profiled in §6.4), and trajectories are bound to individual chunks to eliminate any cross-chunk state sharing. The rest of this section describes the analysis that Boggart performs per chunk.

Background estimation. Extracting blobs inherently requires a point of reference against which to discern areas of

motion. Thus, Boggart’s first task is to generate an estimate of the background scene for the current chunk. However, existing background estimation approaches [46, 101] are ill-suited for Boggart as they are primarily concerned with generating a single, coherent background image despite scene dynamics (e.g., motion) that complicate perfect foreground-background separation. In contrast, Boggart’s focus is on navigating the following tradeoff between accuracy and efficiency, not coherence. On one hand, placing truly background pixels in the foreground will lead to spurious trajectories (and query execution inefficiencies). On the other hand, incorrectly placing a temporarily static object in the background can result in accuracy degradations. Indeed, unlike entirely static objects that will surely be detected via CNN sampling and propagated to all frames in a chunk (during query execution), temporarily static objects may be missed and should only be propagated to select frames.

Boggart addresses the above tradeoff in a manner that favors accuracy. More specifically, Boggart only marks content as pertaining to the background scene when it has high confidence; all other content is conservatively marked as part of the foreground and is resolved during query execution. To realize this approach, Boggart eschews recent background estimation approaches in favor of a custom, lightweight strategy.

In its most basic form, background estimation involves recording the distribution of values assigned to each pixel (or region) across all frames in the chunk, and then marking the most frequently occurring value(s) (i.e., the peaks in the probability density function) as the background [124, 127]. This works well in scenarios where there is a clear peak in the distribution that accounts for most of the values, e.g., if objects do not pass through the pixel or do so with continuous motion, or if an object is entirely static and can thus be safely marked as the background. However, complications arise in settings with multiple peaks. For instance, consider a pixel with two peaks. Any combination of peaks could pertain to the background: a tree could sway back and forth (both), a single car could temporarily stop at a traffic light (one), or multiple cars could serially stop and go at the light (none).

To distinguish between these multi-modal cases and identify peaks that definitely pertain to the background for a chunk, Boggart extends (into the next chunk) the duration over which the distribution of pixel values is computed. The idea is that motion amongst background components should persist with more video, while cases with temporarily static objects should steadily transform into uni-modal distributions favoring either the background scene or the object (if it remains static). To distinguish between the object and background in the latter case, Boggart further extends the distribution of pixel values to incorporate video from the previous chunk. If the same peak continues to rise, it must pertain to the background since we know that the object was not static throughout the entire chunk. Otherwise, Boggart conservatively assigns an empty background for that pixel.

Figure 4: Example screenshots from the Auburn video (Table 1). CNN (YOLOv3+COCO) detections are shown in white, while each of Boggart’s trajectories (and their constituent blobs) is shown in a different color.

Blob Extraction. Using the background estimate, Boggart takes a second pass through the chunk in order to extract areas of motion (blobs) on each frame. More specifically, Boggart segments each frame into a binary image whereby each pixel is annotated with a marker specifying whether it is in the foreground or background. Our implementation deems a pixel whose value falls within 5% of its counterpart(s) in the background estimate as a background pixel, but we find our results to be largely insensitive to this parameter. Given the noise in low-level pixel values [105], Boggart further refines the binary image using a series of morphological operations [115], e.g., to convert outliers in regions that are predominantly either background or foreground. Lastly, Boggart derives blobs by identifying components of connected foreground pixels [71], and assigning a bounding box using the top left and bottom right coordinates of each component.

Computing Trajectories. Boggart’s final preprocessing task is to convert the set of per-frame blobs into trajectories that track each blob across the video chunk. At first glance, it may appear that sophisticated multi-object trackers (e.g., Kalman Filters) [50, 91, 134, 138] could directly perform this task. However, most existing trackers rely on pristine object detections as input. Blobs do not meet this criteria, and instead are far coarser and imprecise (Figure 4). At any time, a single blob may contain multiple objects, e.g., two people walking together. Blobs may split or merge as their constituent objects move and intersect. Lastly, the dimensions of a given object’s blob bounding boxes can drastically fluctuate across frames based on interactions with the estimated background.

To handle these issues, we turn to tracking algorithms that incorporate low-level feature keypoints (SIFT [110] in particular) [88, 89], or pixels of potential interest in an image, e.g., the corners that *may* pertain to a car windshield. Associated with each keypoint is a descriptor that incorporates information about its surrounding region, and thus enables the keypoint (and its associated content) to be matched across images. Boggart conservatively applies this functionality to generate correspondences between blobs across frames.

For each pair of consecutive frames, Boggart pairs the constituent keypoints of each blob. This may yield any form of an $N \rightarrow N$ correspondence depending on the underlying tracking event, e.g., blobs entering/leaving a scene, fusion or splitting of blobs. For instance, if the keypoints in a blob on frame f_i match with keypoints in N different blobs on frame

f_{i+1} , there is a $1 \rightarrow N$ correspondence. To generate trajectories, Boggart makes a series of forwards and backwards scans through the chunk. For each correspondence that is not $1 \rightarrow 1$, Boggart propagates that information backwards to account for the observed merging or splitting. For example, for a $1 \rightarrow N$ correspondence between frames f_i and f_{i+1} , Boggart would split f_i ’s blob into N components using the relative positions of the matched keypoints on f_{i+1} as a guide.

Index Storage. Preprocessing outputs are stored in MongoDB [1]; overheads are profiled in §6.4. Matched keypoints are stored with the corresponding frame IDs: row = [$\langle(x,y)$ -coordinates, frame # \rangle]. Blob coordinates (and their trajectory IDs) are stored per frame to facilitate the matching of CNN results and blobs on sampled frames during query execution (§5.1): row = [$\langle(x,y)$ -coordinates of top left corner, (x,y) -coordinates of bottom right corner, trajectory ID \rangle].

5 FAST, ACCURATE QUERY EXECUTION

During query execution, Boggart’s sole goal is to judiciously use the user-provided CNN and the index from preprocessing to quickly generate a complete set of results that meet the specified accuracy target. Doing so involves answering two questions: (1) what sampled (or *representative*) frames should the CNN be run on such that we can sufficiently adapt to the registered query (i.e., CNN, query type, and accuracy target) and bound errors from index imprecisions?, and (2) how can we use preprocessing outputs to accurately propagate sampled CNN results across frames for different query types? For ease of exposition, we describe (2) first, assuming CNN results on representative frames are already collected.

5.1 Propagating CNN Results

Regardless of the query type, Boggart’s first task is to pair the CNN’s bounding box detections on representative frames with the blobs on those same frames; this, in turn, associates detections with trajectories, and enables cross-frame result propagation. To do this, we pair each detection bounding box with the blob that exhibits the maximum, non-zero intersection. Trajectories that are not assigned to any detection are deemed spurious and are discarded. Further, detections with no matching blobs are marked as ‘entirely static objects’ and are handled after all other result propagation (described below). Note that, with this approach and in spite of the trajectory corrections from §4, multiple detections could be associated to a single blob, i.e., when objects move together and

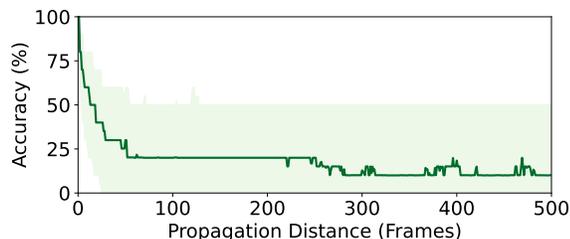

Figure 5: Accuracy (mAP) degradations when CNN bounding boxes are propagated by computing the blob-to-detection coordinate transformation on a representative frame, and applying it to all other blobs in the trajectory. Line represents median detections, with ribbons spanning 25-75th percentiles.

never separate. Using these associations, Boggart propagates CNN results via techniques specific to the target query type.

Binary classification and counting. To support both query types, each trajectory is labeled with an object count according to the number of detections associated with it on representative frames. If a trajectory passes through multiple representative frames, Boggart partitions the trajectory into segments, and assigns each segment a count based on the associations from the closest representative frame. Lastly, Boggart sums the counts across the trajectories that pass through each frame, and returns either the raw count (for counting), or a boolean indicating if count > 0 (for binary classification).

Bounding box detections. Whereas binary classification and count queries simply require propagating coarse information about object presence, bounding box queries require precise positional information to be shared across frames. However, as noted in §4, blobs and trajectories are inherently imprecise and fail to perfectly align with detections. A natural approach to addressing such discrepancies is to compute coordinate transformations between paired detections and blobs on representative frames, and apply those transformations to the remainder of each blob’s trajectory; equivalently, one could compute transformations for a blob across its own trajectory, and apply them to add detections to non-representative frames. Unfortunately, Figure 5 shows that detection accuracy rapidly degrades with this approach, e.g., median degradations are 30% when propagating a box over 30 frames. The reason is that blobs and their paired detections move/resize differently across frames, resulting in median errors of 84% between the Euclidean distances of blob-blob and detection-detection coordinate transformations.

To fill the void of stable propagation mechanisms, Boggart leverages our finding that the relative positions between an object’s constituent keypoints (i.e., those extracted and tracked during preprocessing) and its detection bounding box edges remain largely unchanged over short durations; we refer to these relative positions as *anchor ratios* since they ‘anchor’ an object’s content to a relative position within the bounding box. This stability is illustrated in Figure 6, and is intuitive: objects tend to remain rigid over short time scales, implying that the points they are composed of move in much

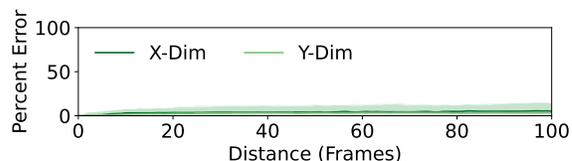

Figure 6: Percent difference in anchor ratios for each object’s keypoints across its trajectory. Lines show medians, with ribbons spanning 25-75th percentiles.

the same way as the entire object does (including as the object scales in size). Building on this, Boggart propagates detections by using matching keypoints along the trajectories to which they have been associated, and efficiently solving an optimization problem in search of bounding box coordinates that maximally preserve the anchor ratios for each keypoint.

More formally, for each detection on each representative frame, Boggart considers the set of keypoints K that fall in the intersection with the associated blob. Each keypoint k in K has coordinates (x_k, y_k) . Further, let the coordinates of the detection bounding box be (x_1, y_1, x_2, y_2) , where (x_1, y_1) and (x_2, y_2) refer to the top left and bottom right corners. The anchor ratios (ax_k, ay_k) for keypoint k are computed as:

$$(ax_k, ay_k) = \left(\frac{x_2 - x_k}{x_2 - x_1}, \frac{y_2 - y_k}{y_2 - y_1} \right) \quad (1)$$

For each subsequent non-representative frame (until the next representative frame) that includes the same trajectory, Boggart finds the set of keypoints that match with those in K ; denote the set of matching keypoints as K' , where each k' in K' matches with keypoint k in K . Finally, to place the bounding box on the subsequent frame, Boggart solves for the corresponding coordinates (x_1, y_1, x_2, y_2) by minimizing the following function to maximally preserve anchor ratios:

$$\sum_{k'}^{K'} \left[\left(\frac{x_2 - x_{k'}}{x_2 - x_1} - ax_k \right)^2 + \left(\frac{y_2 - y_{k'}}{y_2 - y_1} - ay_k \right)^2 \right] \quad (2)$$

Note that this optimization (which takes 1 ms for the median detection) can be performed in parallel across frames and across detections on the same frame. Further, Boggart initializes each search with the coordinates of the corresponding detection box on the representative frame, thereby reducing the number of steps to reach a minima.

Propagating entirely static objects. Thus far, we have only discussed how to propagate detection bounding boxes that map to a blob/trajectory, i.e., moving objects. However, recall from §4 that certain objects which are entirely static will be folded into the background. These objects are discovered by the CNN on representative frames, but they will not be paired with any blob. Instead, Boggart broadcasts these objects to nearby frames (until the next representative frame) in a query-specific manner: such objects add to the per-frame counts used for classification and count queries, and their boxes are statically added into frames for detection queries.

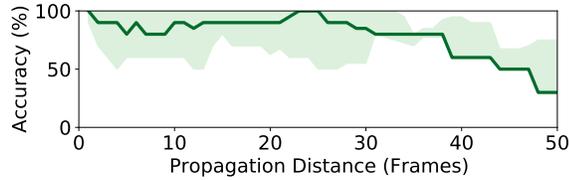

Figure 7: Accuracy (mAP) degradations grow as Boggart propagates detection bounding boxes over longer durations. Results consider all object trajectories in the median video. Line represents medians, with ribbons spanning 25-75th percentiles.

5.2 Selecting Representative Frames

To use the result propagation techniques from §5.1, we must determine the set of sampled, representative frames to collect CNN results on. Because CNN execution is the largest contributor to query execution delays (§6.4), we aim to select the smallest set of representative frames such that Boggart can sufficiently discern the relationship between its index and the CNN results, and generate a complete set of accurate results.

A natural strategy for selecting representative frames is to pick the smallest set of frames such that every trajectory appears at least once. In theory, executing the CNN on this set of frames should be sufficient to generate a result (e.g., object label, bounding box) for each trajectory, and propagate that result to all of the trajectory’s frames. However, this straightforward approach falls short for two reasons:

1. CNNs can be inconsistent and occasionally produce different results for the same object across frames, e.g., a car in frame i may be ignored in frame $i + 1$ [97, 98]. In line with prior analyses, we mostly observe this behavior for small or distant objects, e.g., YOLOv3 mAP scores are 18% and 42% for the small and large objects in the COCO dataset [120]. The consequence is that, if such an inconsistent result appears on a representative frame, Boggart would propagate it to all other frames in the trajectory, thereby spreading the error.
2. Even for consistent CNN results, propagation errors inherently grow with longer trajectories (i.e., as a given result is propagated to more frames). For instance, median accuracies are 90% and 30% when Boggart propagates bounding boxes over 10 and 50 frames (Figure 7).

These issues are more pronounced in busy/dynamic scenes with significant object occlusions/overlap [79, 132]. Moreover, the implication of both is that solely ensuring that the set of representative frames covers each trajectory is insufficient and can result in unacceptable accuracy degradations. To address this, Boggart introduces an additional constraint to the selection of representative frames: any blob in a trajectory must be within $max_distance$ frames of a representative frame that contains the same trajectory. This, in turn, bounds both the duration over which inconsistent CNN results can be propagated, as well as the magnitude of propagation errors.

Tying back to our original goal, we seek the largest $max_distance$ (and thus, fewest representative frames) that

allows Boggart to meet the accuracy target. However, the appropriate $max_distance$ depends on how the above issues manifest with the current query, CNN, and video. Digging deeper, we require an understanding of how Boggart’s propagation techniques (for the query type at hand) and the user’s CNN interact with each frame and trajectory, i.e., how accurate are Boggart’s propagated results compared to the CNN’s results. Though important for ensuring sufficient accuracy, collecting this data (particularly CNN results) for each frame during query execution would forego Boggart’s speedups.

To achieve both accuracy and efficiency, Boggart clusters video chunks based on properties of the video and its index that characterize the aforementioned issues. The idea is that the chunks in each resulting cluster should exhibit similar interactions with the CNN and Boggart’s result propagation, and thus should require similar $max_distance$ values. Accordingly, Boggart could determine the appropriate $max_distance$ for all chunks in a cluster by running the CNN and result propagation only on the cluster’s centroid chunk.

To realize this approach, for each chunk, Boggart extracts distributions of the following features: object sizes (i.e., pixel area per blob), trajectory lengths (i.e., number of frames), and busyness (i.e., number of blobs per frame and trajectory intersections). These match our observations above: CNN inconsistencies are most abundant in frames with small objects, the potential for propagation errors is largest with long trajectories, and both issues are exacerbated in busy scenes.

With these features, Boggart clusters chunks using the K-means algorithm. We find that setting the number of target clusters to ensure that the centroids cover 2% of video strikes the best balance between CNN overheads and robustness to diverse and rapidly-changing video chunks; we profile this parameter in §6.4. Note that since clustering is based on model-agnostic features (from the extracted trajectories), it can be performed during preprocessing. Then, during query-execution, for each resulting cluster, Boggart runs the CNN on all frames in the centroid chunk. Using the collected results, Boggart runs its result propagation for a range of possible $max_distance$ values, and computes an achieved accuracy for each one relative to the ground truth CNN results. More precisely, for each $max_distance$, Boggart selects the set of representative frames by greedily adding frames until our criteria is met, i.e., all blobs are within $max_distance$ of the closest representative frame containing the same trajectory. From there, Boggart selects the largest $max_distance$ that meets the specified accuracy goal, and applies it to pick representative frames for all other chunks in the same cluster.

Figure 8 highlights the effectiveness of Boggart’s clustering strategy in terms of (quickly) adapting to different query types, accuracy targets, objects of interest, and CNNs. As shown in Figure 8(top), the median discrepancy between each chunk’s ideal $max_distance$ value and that of the corresponding cluster centroid is only 0-8 frames; this jumps to 45-898 frames when comparing chunks with the centroid

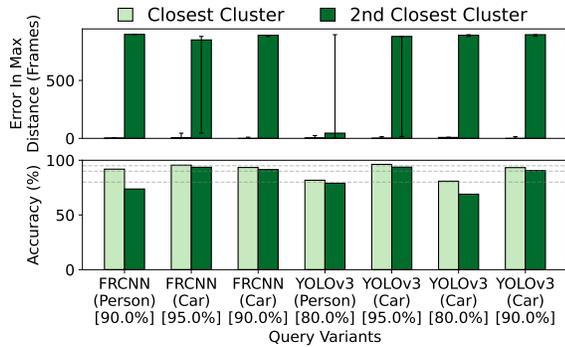

Figure 8: Effectiveness of Boggart’s clustering with different CNNs, (object types), and [accuracy targets]. Results are for the median video, and compare the ideal *max_distance* value for each chunk with those of the centroids in its cluster and the nearest neighboring cluster. The top graph measures the discrepancies in per-chunk *max_distance* (bars list medians, with error bars for 25-75th percentile); the bottom graph evaluates the corresponding hits on average accuracy (for detections).

of the closest neighboring cluster. Figure 8(bottom) illustrates the importance of shrinking these discrepancies. More specifically, applying each centroid’s ideal *max_distance* to all chunks in the corresponding cluster (i.e., Boggart’s approach) yields average accuracies that are consistently above the targets. The same is not true when using the ideal *max_distance* values from the nearest neighboring cluster.

In summary, Boggart meets accuracy targets through co-analysis of the video content and specified query, i.e., object of interest, model, and query type. Boggart performs query/model-specific profiling of representative video chunks (where representative is defined by video content/dynamics) to identify the frame inference strategy that most efficiently meets the accuracy target, and then executes this strategy for the remaining video chunks within each cluster.

6 EVALUATION

We evaluated Boggart on a wide range of queries, CNNs, accuracy targets, and videos. Our key findings are:

- Boggart consistently meets accuracy targets while running the CNN on only 3-54% of frames, highlighting its comprehensive (model-agnostic) index and effective adaptation during query execution.
- Despite its goal of generality, Boggart’s response times are 19-97% lower than NoScope’s. Compared to Focus (which requires a priori knowledge of the CNN that will be used during query execution), Boggart’s response times are 33% and 52% lower on counting and detection queries, and only 5% higher on classifications.
- Boggart’s preprocessing (and index construction) runs 58% faster than Focus’, while also generalizing to different CNNs/queries and requiring only CPUs (not GPUs).
- Boggart’s preprocessing and query execution tasks speed up nearly linearly with increasing compute resources.

Table 1: Summary of our main video dataset.

6.1 Methodology

Videos. Table 1 summarizes the primary video sources used to evaluate Boggart. Video content across the cameras exhibits diversity in setting, resolution, and camera orientation (relative to the scene). From each camera, we scraped 12 hours of continuous video (at 30 fps) in order to capture varying levels of lighting and object densities (i.e., busyness). We consider additional videos and scene types in §6.4.

Queries. We consider the three query types (and their corresponding accuracy definitions) described in §2, i.e., binary classification, counting, and bounding box detection. For each type, we ran the query across our entire video dataset, and considered two objects of interest, people and cars, that cover drastically different size, motion, and rigidity properties; §6.4 presents results for additional object types. We evaluated Boggart with three accuracy targets – 80%, 90%, and 95% – and report accuracies as averages for each video. Accuracies are computed relative to running the model directly on all frames; as in prior systems and commercial platforms [41, 64, 80, 87, 105], Boggart does not aim to improve the accuracy of the provided model, and instead targets the same per-frame results at lower resource costs and delays.

CNN models. We consider three popular architectures: (1) SSD with a ResNet-50 backbone, (2) Faster RCNN with a ResNet-50 backbone, and (3) YOLOv3 with a Darknet53 backbone. For each, we used one version trained on the COCO dataset, and another trained on VOC Pascal. Trends for any results shown on a subset of CNNs (due to space constraints) hold for all considered models.

Hardware. Experiments used a server with an NVIDIA GTX 1080 GPU (8 GB RAM) and 18-core Intel Xeon 5220 CPU (2.20 GHz; 125 GB RAM), running Ubuntu 18.04.3.

Metrics. In addition to accuracy, we evaluate query execution performance of all considered systems (Boggart, Focus [80], and NoScope [94]) in terms of the number of GPU-hours required to generate results. We report GPU-hours for two reasons: (1) CNN execution (on GPUs) accounts for almost all response generation delays with all three systems, and (2) it is directly applicable to all of the systems, e.g., it incorporates NoScope’s specialized CNNs. For preprocessing, we report both GPU- and CPU-hours since Boggart only requires the latter. As in prior work [80, 94], we exclude the video decoding costs shared by all considered systems.

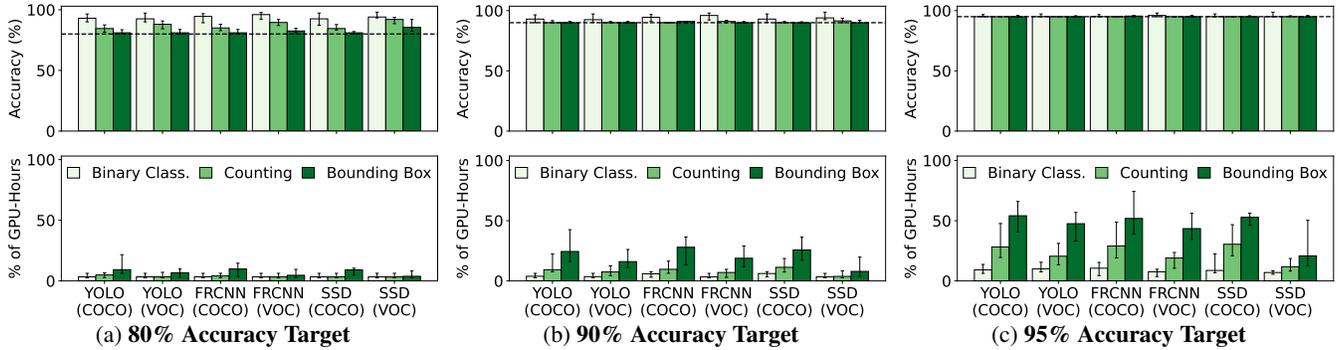

Figure 9: **Boggart’s query execution performance across CNNs, query types, and accuracy targets; results are aggregated across object types.** Bars summarize the distributions of per-video average result accuracy (top) and percentage of GPU-hours required to generate results relative to running the CNN on all frames (bottom). Bars list medians with error bars spanning 25-75th percentiles.

Object Type →	People		Cars	
Query Type ↓	Acc.	% GPU-hrs	Acc.	% GPU-hrs
Binary Classif.	92%	6%	98%	3%
Counting	90%	11%	90%	7%
Bounding Box	91%	27%	90%	16%

Table 2: **Average accuracy and percentage of GPU-hours (relative to the naive baseline) for different query types and objects of interest.** Results list median per-video values across all CNNs.

6.2 Query Execution Speedups

Figure 9 evaluates Boggart’s query response times relative to a naive baseline that runs the CNN on all frames. Boggart always used the same, model-agnostic index per video.

There are three points to take away from Figure 9. First, across all of the conditions, Boggart *consistently* meets the specified accuracy targets. Second, the percentage of GPU-hours required to meet each accuracy target with Boggart grows as we move from coarse classification and counting queries to finer-grained bounding box detections. For example, with a target accuracy of 90%, the median percentage of GPU-hours across all models was 3-6%, 4-11%, and 8-28% for the three query types, respectively. Third, the percentage of GPU-hours also grows as the target accuracy increases for each query type. For instance, for counting queries, the percentage (across all CNNs) was 3-5% when the target accuracy was 80%; this jumps to 12-30% when the target accuracy grows to 95%. The reason is intuitive: higher accuracy targets imply that Boggart must more tightly bound the duration over which results are propagated (to limit propagation errors) by running the CNN on more frames.

Different object types. Table 2 reports the results from Figure 9 separately per object type. As shown, the high-level trends from above persist for each. However, for a given query type, the percentage of required GPU-hours is consistently lower when considering cars versus people. The reason is twofold. First, inconsistencies in CNN results are more prevalent for people since they appear as smaller objects in our scenes (§5.2). Second, cars are inherently more rigid than people, and thus deliver more stability in the anchor ratios that Boggart relies on for bounding box propagation (§5.1);

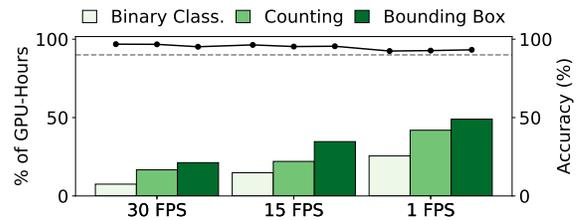

Figure 10: **Average accuracy (line) and percentage of GPU hours (relative to the naive baseline) for different video sampling rates.** Results are listed for the median video, and consider YOLOv3+COCO and a 90% accuracy target.

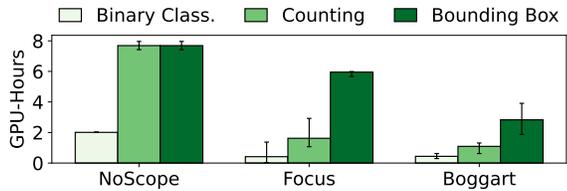

consequently, propagation errors for bounding box queries grow more quickly with people. Boggart handles both issues by running the CNN on more representative frames.

Downsampled video. Users may issue queries on sampled versions of each video [80]. We evaluated Boggart with three different sample rates: {30, 15, 1} fps. Although the number of considered frames drops, Figure 10 shows that Boggart’s query execution speedups persist when operating over downsampled videos. For instance, with 1-fps video, Boggart requires only 25-49% of the GPU-hours that the naive baseline would need across all query types. Figure 10 also shows that Boggart’s ability to consistently meet accuracy targets holds across sampling rates. We find that Boggart can hit accuracy targets without resorting to running the CNN on all frames because object keypoints – the primitive that Boggart tracks across frames during both trajectory construction (preprocessing) and detection propagation (query execution) – typically persist across frames even at these sample rates. For instance, Boggart matches 85% of the median object’s keypoints across the 29-frame gap induced by the 1-fps rate.

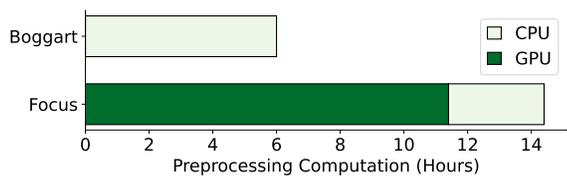

6.3 Comparison to State-of-the-Art

We compared Boggart with two recent retrospective video analytics systems: (1) NoScope [94], which only employs optimizations during query execution, and (2) Focus [80], which performs model-specific preprocessing by assuming a priori knowledge of user CNNs. §2.2 details each system.

For these experiments, we set the user-provided CNN to be YOLOv3+COCO, and the accuracy target to be 90%. Our

(a) Query execution efficiency. Bars list values for the median video, with error bars spanning 25-75th percentiles.

(b) Preprocessing efficiency. Bars list GPU/CPU-hours for the median video. Note that NoScope does not perform preprocessing.

Figure 11: Comparing Boggart, Focus [80], and NoScope [94]. Results use YOLOv3+COCO and a target accuracy of 90%.

Focus implementation used Tiny YOLO [120] as the specialized/compressed model (i.e., we ran Focus as if it knew the user CNN a priori), while NoScope used all of its open-source models. Following the training methodology used in both papers, we train the specialized/compressed models on 1-fps versions of the first half (i.e., 6 hours) of each video in our dataset, and run queries on the second half of each video.

Query Execution. Figure 11a compares the query response times of all three systems. As shown, Focus requires 5% fewer median GPU-hours than Boggart for binary classification queries. The main reason is that Focus' model-specific preprocessing (i.e., clustering of objects) enables more result propagation than Boggart's general, model-agnostic trajectories, i.e., Focus can propagate labels across objects, whereas Boggart can propagate labels only along a given object's trajectory (§3). Median propagation distances for results from the full CNN are 58 and 44 frames with Focus and Boggart.

Summing Focus' classifications to generate per-frame counts was insufficient for our 90% target. Thus, for counting queries, we performed favorable sampling until Focus hit 90% in each video: we greedily select a set of contiguous frames with constant count errors, run the CNN on a single frame, and correct errors on the remaining ones in the set. Even with such favorable sampling, Boggart required 33% fewer GPU-hours than Focus for counting queries.

Bounding box detections paint a starker contrast, with Boggart needing 52% fewer GPU-hours than Focus. Unlike with classification labels, Focus cannot propagate bounding boxes across frames. Instead, to accelerate these queries, Focus relies on binary classification, and runs the full CNN on all frames with an object of interest (to obtain their bounding boxes); for our videos, this translates to running the full CNN on 63-100% of frames. In contrast, Boggart propagates bounding boxes along each trajectory (median propagation distance of 23 frames) and reduces CNN tasks accordingly.

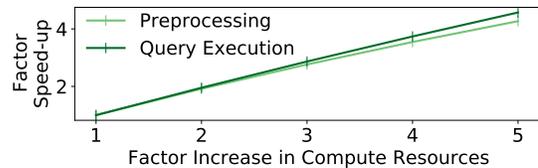

Figure 12: Boggart's performance with increasing compute resources. Resource factors are multiples of the 18-core CPU and single GPU listed in §6.1. Results consider YOLOv3+COCO, a 90% accuracy target, and the median video.

Compared to NoScope, Boggart's query execution tasks consume 19-97% fewer GPU-hours across query types. Boggart's speedups are largely due to three limitations with NoScope. First, NoScope does not perform preprocessing, and instead must train and run inference with its specialized and compressed CNNs during query execution. Second, results are not propagated across frames. Third, bounding box detections are sped up only via binary classification; note that NoScope performs binary classification on each frame (not object, like Focus), so we cannot simply sum the classification results to answer a counting query, and instead must execute counting queries as bounding box queries.

Preprocessing. Figure 11b shows that Boggart's preprocessing tasks take 58% fewer computation hours than Focus'. The discrepancy is from the training and inference costs that Focus incurs by using a specialized/compressed model. Note that *all* of Boggart's preprocessing is CPU-based, while Focus' costs are dominated (79%) by GPU operations. Further, Boggart's preprocessing runs once per video to support all future CNNs. To avoid accuracy drops (§2.3), Focus would have to run preprocessing for each CNN it wishes to support, leading to higher costs and potential for wasted work.

6.4 Profiling Boggart

Dissecting Boggart's performance. Boggart's preprocessing delays are dominated (83% on the median video) by the extraction of SIFT keypoints across frames; background estimation, trajectory construction, and clustering together account for only 17% of the time. Query execution profiles are similar, with CNN inference on centroid chunks and representative frames contributing 7% and 91% of runtime; result propagation (mostly for detections) takes the remaining 2%.

Resource scaling. Figure 12 shows that Boggart's preprocessing and query execution performance scale nearly linearly with increasing CPU and GPU resources, respectively. The reason is that feature extraction and CNN inference, the tasks that dominate delays in the two phases, inherently operate on a per-frame basis and can thus naturally be parallelized across frames. Note that these results only consider parallel processing within each chunk; Boggart can also parallelize across chunks since trajectories are bound to single chunks, i.e., there is no cross-chunk state sharing (§5).

Storage costs. Boggart's preprocessing generates, on average, 306 MB of data per 1 hour of video. For context, (1) the

average video in our dataset consumes 1 GB when encoded with H.264, and (2) Focus' preprocessing generates 70 MB of data for the same video. Recall that NoScope does not involve video preprocessing, and thus does not incur storage costs for indices. Note that 98% of Boggart's storage overheads are for keypoints used to propagate bounding boxes; blobs and trajectories consume only 2%.

Sensitivity to parameters. Boggart includes parameters for video chunk size (default: 1 min) and target number of clusters (default: centroids cover 2% of video). On average, we find that Boggart's performance is largely insensitive to both: varying chunk sizes from 0.2-10 min and the videos covered by centroids from 0.5-5% altered Boggart's performance by less than 5% (note that accuracy never dropped below the targets). However, the effects of each parameter are more pronounced on short amounts of video and are dependent on the content being considered. More specifically, smaller chunk sizes reduce the potential result propagation, but also shrink cluster centroids and increase the potential for parallel processing. Similarly, more clusters implies fewer suboptimalities in the selection of representative frames, but also additional centroids on which to run the CNN.

Generalizability. To further evaluate Boggart's ability to generalize, we ran experiments with three additional videos (3 hours each) and new object types specific to those scenes: birds in nature [19], boats in a canal [30], and people, cups, chairs, and tables in a restaurant [6]. For these experiments, we ran Boggart in the same way as above, i.e., it is not tuned in any way to the video or objects of interest. We also ran experiments considering different object types (trucks and bicycles) in the traffic videos from Table 1; these experiments used the same indices as in our main evaluation. All results exhibit similar trends as above, with Boggart always meeting accuracy targets (80%, 90%, 95%) and running CNNs on only 11.7-34.2%, 11.7-53.4%, and 12.6-56.7% of frames for binary classification, counting, and detection.

7 ADDITIONAL RELATED WORK

Live video analytics. Multiple systems accelerate queries on live video, with optimizations along the following axes: (1) profiling pipeline knobs to identify cheaper (but accurate) configurations [87, 140], (2) integrating on-camera or edge server resources for partial inference, frame filtering, or reusing results from prior frames [43, 54, 58, 63, 66, 73, 74, 105, 129, 136, 141, 148], (3) content/model-aware encoding to reduce data transfers [64, 133], and (4) spatiotemporal coordination for efficient multi-camera queries [86, 111]. These systems target an entirely different computational model (stream processing vs. "after-the-fact" querying) and thus face a different set of goals, optimization knobs, and constraints, e.g., by not having the entire dataset up front, live analytics can only propagate results to later frames.

Accelerating GPU tasks. One line of work optimizes DNNs for accelerated inference via distillation [78], quantization [60, 84, 144], or pruning [51, 108]. Another direction

targets faster inference for a model, either through better scheduling of GPU resources across inference tasks [85, 123, 126], or hardware acceleration [38, 68, 90, 117]. These works are complementary to Boggart, which focuses on reducing the number of frames on which inference must be performed.

Video Object Detection. In addition to those in §4, Boggart builds on a line of work in the CV community that leverages the spatiotemporal aspect of video to accelerate detection and classification tasks. These techniques swap inference on sampled frames with optical flow networks that extend results from earlier frames [49, 56, 57, 59, 62, 72, 76, 98, 112, 130, 131, 145–147], and are thus similar in spirit to Boggart's result propagation strategy. However, unlike Boggart, these approaches are model-specific, in that the networks used for propagation must be trained according to the specific CNN (e.g., its feature extractor) used in the target query.

Video storage and indexing. Many systems balance video storage and lookup costs for specific query types [121, 139, 143] or CNNs [40, 96, 119, 137]. Boggart is complementary to these works in that its focus is on performing generalizable preprocessing and accelerating response generation after video frames are loaded into memory.

8 CONCLUSION

This paper described Boggart, a system for retrospective video analytics that supports the general "bring your own model" interfaces that are now commonplace in commercial platforms. To meet the core accuracy, speed, and efficiency goals of those platforms, Boggart holistically rethinks the query execution process, introducing cheap techniques to generate comprehensive (but imprecise) indices during preprocessing, and later use those indices to limit costly inference while bounding accuracy drops from imprecisions. Our results show that such generality can come at low cost, as Boggart outperforms prior, model-specific approaches.

Ethics. The focus of this work is on making the ethical processing of videos (public or private, according to the law) more efficient. We do not advocate for the processing of video for illicit purposes, unlawful tracking, etc. Moreover, Boggart is developed to improve the resource efficiency of existing retrospective video analytics platforms in a manner that does not change the interfaces they expose, i.e., the videos, models/queries, and customers they handle remain unchanged. In sum, Boggart does not alter the set of information exposed to applications – the videos that an application can query and the queries that the application can run on those videos are unchanged, and Boggart's internal state (e.g., preprocessing results) is not exposed.

Abstract

Packet loss degrades the quality of experience (QoE) of videoconferencing. The standard approach to recovering lost packets for long-distance communication where retransmission takes too long is forward error correction (FEC). Conventional approaches for FEC for real-time applications are inefficient at protecting against bursts of losses. Yet such bursts frequently arise in practice and can be better tamed with a new class of theoretical FEC schemes, called “streaming codes,” that require significantly less redundancy to recover bursts. However, existing streaming codes do not address the needs of videoconferencing, and their potential to improve the QoE for videoconferencing is largely untested. *Tambur* is a new streaming-codes-based approach to videoconferencing that overcomes the aforementioned limitations. We first evaluate *Tambur* in simulation over a large corpus of traces from Microsoft Teams. *Tambur* reduces the frequency of decoding failures for video frames by 26% and the bandwidth used for redundancy by 35% compared to the baseline. We implement *Tambur* in C++, integrate it with a videoconferencing application, and evaluate end-to-end QoE metrics over an emulated network showcasing substantial benefits for several key metrics. For example, *Tambur* reduces the frequency and cumulative duration of freezes by 26% and 29%, respectively.

1 Introduction

The quality of videoconferencing calls dictates the effectiveness of remote meetings [17] which are now ubiquitous. Videoconferencing calls can be one-on-one [27] or multi-party [39]. Our work focuses on one-on-one calls. Video quality depends on several key performance indicators, such as freeze, bandwidth, packet loss, and latency [14, 28, 41].

Recovering lost packets is crucial for providing high-quality videoconferencing [33, 48]. Losing even a single packet may prevent rendering a video frame. It may also prohibit rendering multiple future frames (i.e., causing the video to freeze) due to inter-frame dependencies of compressed video. Due to this, it is common for videoconferencing applications to handle packet losses at the application level. The two broad viable solutions are retransmissions and forward error correction (FEC). Both approaches transmit redundant data. Consequently, there is a trade-off between bandwidth allocated for redundancy and transmitting original data. Furthermore, videoconferencing applications must recover lost packets within a strict latency—preferably less than

150 ms [33]—to meet the real-time playback requirement.

Retransmission involves minimal redundant data since it resends only the lost packets. Hence, it is preferred whenever possible [64]. However, retransmission is suitable only for scenarios with short round trip times due to the strict real-time latency requirement of videoconferencing applications. For all other cases, videoconferencing applications rely on FEC to recover lost packets within an acceptable latency.

Block codes are the most common form of FEC employed in production systems today. Under a block code, k “data packets” are used to create r redundant packets—called “parity packets.” When some of these $(k + r)$ packets are lost, the k data packets can still be recovered. There are r extra parity packets, so the bandwidth overhead is $(r/k) \times 100\%$. One main objective in designing FEC schemes is to minimize the bandwidth overhead. Common examples of block codes include Reed-Solomon (RS) block codes [55] and fountain (i.e., rateless) codes [40]. Many of the codes, e.g., RS codes, are optimal for *random losses* in which packets are lost independently. For instance, in the above example, if RS codes are used, any k packets suffice for recovery. Hence, block codes are popular for production videoconferencing applications. For example, Microsoft Teams uses RS codes.

Videoconferencing applications send data from compressed video frames over multiple packets. We refer to losing several packets over one or more consecutive frames as a “burst” loss. Burst losses can occur for various reasons, including persistent Wi-Fi interference and network congestion (when applications overflow router buffers and cause correlated losses [29]). Our analysis of packet traces from thousands of video calls from Teams (§3.3) shows that real-world losses faced by videoconferencing applications are indeed bursty.

Block codes are highly inefficient in their bandwidth consumption when recovering from burst losses under real-time latency requirements. In contrast, a relatively new theoretical FEC framework, known as “streaming codes” [5, 42, 43], handle burst losses along with strict latency constraints efficiently. At a high level, streaming codes recover packets lost in a burst sequentially by their respective playback deadlines, whereas block codes recover all the lost packets simultaneously by the earliest playback deadline. Using block codes for loss recovery wastes later parity packets sent before the deadline of the final lost packet. Most prior work on streaming codes is theoretical [5, 20, 22, 26, 35, 36, 42, 43, 59–61], studying bounds and code constructions. A few existing works [6, 25] explore the practical applicability of streaming codes but only

for VoIP (i.e., audio, but not video).

Given the dual importance of bandwidth and loss recovery, streaming codes are appealing to videoconferencing applications. However, there are two main challenges. First, there are gaps between existing streaming codes and videoconferencing applications. Most practical variants of streaming codes [6, 25] are limited to settings in which the sizes of the input data are a fixed constant over time. In contrast, in videoconferencing, the sizes of compressed video frames are variable. The only streaming codes that accommodate such variability [59–61] pessimistically assume that a frame is entirely lost or received because the framework involves sending each frame in a single packet. This is seldom true in videoconferencing applications. Existing streaming codes also require that every burst is followed by a *guard space* where all packets are received. But this assumption often does not hold in practice (as we show in §3.2). Also, existing streaming codes set the amount of redundancy with a parameter of a theoretical channel model that is unknown in practice. Second, streaming codes’ effectiveness for improving the QoE for real-world videoconferencing applications is untested on real-world data.

This work addresses the aforementioned challenges. We present *Tambur*, a new communication scheme for bandwidth-efficient loss recovery for videoconferencing.¹ *Tambur* comprises two components. First, a new streaming code that builds upon a prior theoretical framework [61] while overcoming its limitations with respect to real-world videoconferencing applications. Specifically, *Tambur* allows for specifying a bandwidth overhead for each frame. Furthermore, for any given bandwidth overhead, *Tambur* creates data packets and parity packets in a manner that (a) is not overly pessimistic by facilitating recovery from bursts where only some packets are lost per frame and (b) is robust to losses in the guard space. Second, the streaming code is integrated with a machine learning (ML) model to take a predictive decision on the bandwidth allocated to streaming codes. Specifically, a lightweight approach is employed, which uses only a simple model and a single bit of additional feedback.

We analyze packet traces collected from thousands of video calls from Teams and present three key observations in §3: (a) Bursts of packet losses frequently arise. (b) Losses are often, but not always, followed by a guard space of several frames with no losses. (c) Codes employed in production (RS codes) use a significant bandwidth overhead to recover lost packets in real time, depleting the bandwidth for the original data.

We first evaluate *Tambur* in simulation over a large corpus of traces from Teams (§5.2). We compare *Tambur* with Teams’s FEC (“Block-Within,” a block code within a frame; §5.1) and show that *Tambur* recovers 26.5% more frames with 35.1% less bandwidth overhead.

We also implement and integrate *Tambur*, several baselines (Block-Within and “Block-Multi,” a block code across

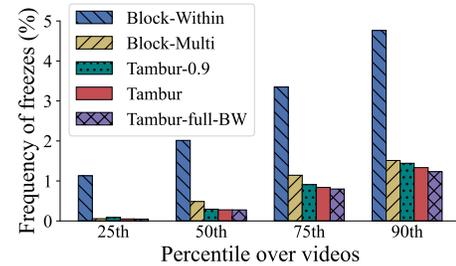

Figure 1: *Tambur* reduces the ratio of frozen frames to total frames per-video by 78% and 26% compared to Block-Within and Block-Multi, respectively, at a lower bandwidth overhead.

multiple frames) and several variants of *Tambur* (“*Tambur*-full-BW,” which matches the bandwidth overhead of Block-Within and “*Tambur*-0.9,” which reduces the bandwidth overhead more at the cost of recovering fewer frames) with a videoconferencing benchmark platform that we developed. We then evaluate the schemes over an emulated network to assess the impact on the QoE (§5.4). *Tambur*, *Tambur*-full-BW, and *Tambur*-0.9 reduce the average frequency of video freezes by 26%, 29%, and 17%, respectively, compared with the better of Block-Within and Block-Multi. Fig. 1 shows that these benefits hold across many percentiles. These benefits highlight that *Tambur* improves the QoE, as it has been shown [44, 53, 66] that video freezes have a detrimental effect on user engagement.

In summary, our main contributions are to:

- Analyze thousands of packet loss logs for video calls taken from a large commercial videoconferencing application, and characterize their suitability for using streaming codes. To the best of our knowledge, this is the first work to evaluate the potential of streaming codes using large-scale, real-world traces.
- Present *Tambur*, which bridges the gap between the theory behind streaming codes and videoconferencing applications by (a) designing a new streaming code that is well-suited to videoconferencing and (b) integrating it with a lightweight ML model to take a predictive decision on the bandwidth allocated to streaming codes.
- Implement a new benchmark platform to enable research on videoconferencing with an easy-to-use interface to integrate and assess new FEC schemes. In addition, implement *Tambur*, Block-Within, and Block-Multi in C++ and incorporate them into the benchmark platform using the interface.
- Evaluate *Tambur* over a large corpus of production traces through simulation, and show that it simultaneously reduces the frequency of non-recoverable frames and bandwidth overhead by 26.5% and 35.1%, respectively.
- Evaluate *Tambur* over emulated networks and show significant improvements over key metrics pertaining to end-to-end QoE (e.g., reducing the frequency of freezes

¹Named to convey *Taming burst* losses.

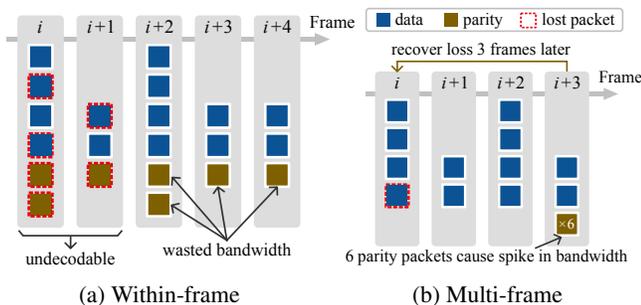

Figure 2: Two approaches for employing block codes: (a) within each frame and (b) across multiple frames.

by 26% and the cumulative duration of freezes by 29%).

Overall, to the best of our knowledge, this work is the first to establish that streaming codes can improve key metrics relating to the QoE for videoconferencing. This work also showcases the potential of a new form of FEC, streaming codes along with learning-based bandwidth allocation, for bandwidth-efficient loss recovery in videoconferencing. This work poses no ethical issues.

2 Background and motivation

2.1 Conventional FEC and its challenges in videoconferencing

Block codes. One of the most commonly used FECs is the so-called “block codes.” The idea of block codes is to encode k data packets, $\langle D[1], \dots, D[k] \rangle$ to r parity packets into $\langle D[1], \dots, D[k], P[1], \dots, P[r] \rangle$, so that the k data packets can be recovered using a subset of the $(k+r)$ packets. When any k of the $(k+r)$ packets suffice for recovery, the block code is termed “maximally distance separable (MDS).” One of the best known examples of MDS codes is the Reed-Solomon (RS) block codes [55]. Other examples of block codes include fountain (i.e., rateless) codes [40], or two-dimensional block codes [67].

Traditionally, FEC applies to packets, but videoconferencing involves transmitting multiple packets for each video frame. One natural solution is to apply a block code to the data packets *within each frame* (Fig. 2a). The parity packets are sent immediately after the final data packet of a frame. A second approach is to apply a block code across the data packets of *multiple frames* (Fig. 2b) by sending all parity packets after the final data packet of the last frame in the block. Our analysis of the production packet loss traces (§3) from Teams shows that the packet losses are bursty. Both approaches have significant limitations for burst losses.

Limitations of block codes for videoconferencing. When packet losses occur as bursts, the within-frame approach wastes the redundancy sent in frames immediately following a burst because it is useless for recovering the lost frames.

Although the multi-frame approach overcomes this problem, it has two main drawbacks. First, the latency of recovering losses is high due to waiting for the parity packets, which are sent after the final frame in the block, to recover any packets. The length of the block code must be short lest the latency exceeds the real time deadline to play a frame, leading to an increased bandwidth overhead and reduced robustness to burst losses. Second, packets sent in rapid succession may be lost if a router buffer is full. When a full router buffer coincides with the final frame of a block, no lost packets are recovered.

The bandwidth consumed by parity packets of FEC can be substantially higher than retransmission, even for modest packet loss rates. Unlike retransmission, which only resends lost packets, even an “optimal” FEC scheme does not know which packets will be lost. Hence, it must send far more parity packets than lost packets. For example, to prevent a video freeze, at least one parity packet must be sent every ≈ 150 ms to cover the scenario of losing a data packet. However, this parity packet is not used if there are no losses.

2.2 Streaming codes

A class of codes, known as “streaming codes” [5, 42, 43, 59–61], specifically addresses burst losses and sequential communication between a sender and a receiver. At a high level, streaming codes avoid the limitations of within-frame and multi-frame by (a) sending parity packets with each frame and (b) using all parity packets received by the playback deadline of the *final* frame of a burst for recovering losses. We describe the theoretical framework of streaming codes in detail, provide an illustrative example, and then discuss how it is a promising option for videoconferencing applications impeded by a large gap between the framework and practice.

The streaming codes framework consists of the following.

- (1) A sender that generates data packets sequentially at regular intervals and transmits packets sequentially to a receiver.
- (2) An adversarial packet loss channel that introduces burst losses of length b followed by guard spaces of packet receptions.
- (3) A requirement that the receiver recovers lost data packets within a specified time. The data packet that arrives at the time index i must be recovered by time index $(i + \tau)$. We call the parameter τ the “latency deadline.” After a burst, the guard space must be at least τ packets (but longer guard spaces are not needed since bursts are to be recovered within τ packets).

Sequential encoding. The sequential nature of encoding in streaming codes is well suited for videoconferencing, wherein a sequence of compressed frames are to be transmitted periodically (e.g., one every 33.3 ms for a video showing 30 frames per second). We will denote the symbols sent for the i th video frame as $D[i]$, where each symbol can be thought of as a vector of bits.² These symbols are distributed over

²More formally, a symbol is an element of a mathematical entity called a finite field, and all operations are performed over finite fields using modular arithmetic. For simplicity, readers can just assume the usual arithmetic.

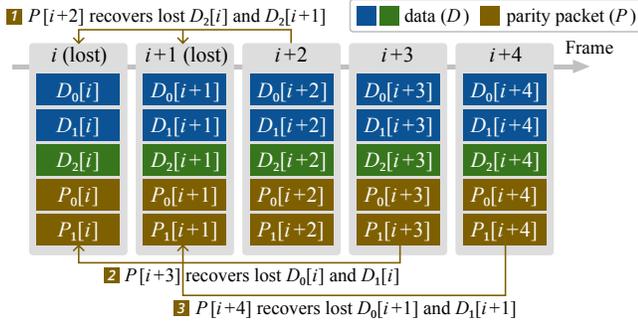

Figure 3: Recovering $b = 2$ lost frames starting in frame i within a latency deadline of $\tau = 3$ using a streaming code. For each frame in the burst, all parity symbols sent τ packets later recover its lost symbols.

one or more packets to be sent to the receiver. In addition, some parity symbols, denoted as $P[i]$, are transmitted in one or more packets. These parity symbols are a function (linear combinations) of the data symbols of the past few frames.

Sequential recovery. Under the streaming codes model, the latency deadline parameter τ determines the delay in recovering a lost packet: if $D[j]$ is lost, it must be recovered using symbols from parity packets until $P[j + \tau]$. Each video frame must be recovered within a strict latency to be rendered in real time. The latency deadline parameter τ is set according to the frame rate and one-way delay to induce a suitable maximum latency to recover lost frames. For example, if the maximum tolerable latency is 150 ms (a standard value for real-time video communication [33]), the one-way propagation delay is 50 ms, and a frame is encoded every 33.3 ms (i.e., at 30 fps), τ could be set as 3 ($= (150 - 50)/33.3$).

An example of sequential loss recovery of a burst of length 2 starting in frame i within a latency deadline of $\tau = 3$ using existing streaming codes (e.g., [5, 42, 43]) is shown in Fig. 3. Each frame comprises the same amount of data. First, the parity symbols of the packet sent immediately after the burst recovers one-third of the missing data symbols of each lost frame (i.e., $D_2[i]$ and $D_2[i+1]$). Second, the remaining lost data symbols of frames i and $(i+1)$ (i.e., $(D_0[i], D_1[i])$ and $(D_0[i+1], D_1[i+1])$, respectively) are recovered with the parity symbols sent in frames $(i+3)$ and $(i+4)$, respectively.

Streaming codes recover a burst loss by *sequentially recovering* each frame in the burst within its deadline. For a burst loss that encompasses b consecutive frames $\{i, \dots, i+b-1\}$, a data packet $D[j]$ in the burst is recovered using the parity symbols of $P[i+b], \dots, P[j+\tau]$. This sequential nature of the recovery of streaming codes allows them to use *all* parity symbols that are received within the deadline. For example, $P[j+\tau]$ is used to recover $D[j]$ *after* the latency deadline of $D[i]$ for $i < j$. In contrast, block codes recover all lost packets together. Hence, the recovery occurs by the first lost frame's deadline (i.e., by the time the symbols of $P[i+\tau]$ are received),

wasting the parity symbols sent subsequently. This key difference enables streaming codes to attain significantly lower bandwidth overhead; the longer the burst, the greater the benefits of streaming codes. However, it also requires a guard space of at least τ frames after the burst lest some frame not be recovered with the latency deadline.

2.3 Challenges of using streaming codes for videoconferencing

There are two main challenges in using streaming codes for videoconferencing. First, significant gaps between the theoretical models and practical systems render existing streaming codes incompatible with videoconferencing applications. Second, streaming codes's effectiveness for videoconferencing is untested on large-scale real-world traces. Hence, the potential of streaming codes improving QoE of videoconferencing applications is yet unknown. These challenges are discussed in more detail below.

Gaps between the existing model and videoconferencing applications. The existing practical work on streaming codes [6, 25], like the theoretical work they build upon [5, 42], is limited to settings where the amount of data to be transmitted at each time instant is a fixed constant. However, videoconferencing involves sending compressed video frames whose sizes vary. Only a few streaming code constructions [59–61] can handle this variability. However, as discussed in §2.2, existing streaming codes, including those in [59–61], consider an *adversarial* loss model that imposes bursts of length b . When applied for videoconferencing, the parameter b translates into the number of consecutive frames for which *all* packets are lost. However, videoconferencing applications frequently send multiple packets per frame, and often only some of these packets are lost, as we show in greater detail in §3 for packet loss traces from production. Existing streaming codes are overly pessimistic because they can recover from losing all packets for multiple consecutive frames. This requirement imposes a significant bandwidth penalty, negating the potential bandwidth savings of streaming codes. Streaming codes are also vulnerable to recovery failures if there are *any* losses in the guard space after a burst. But, in practice, many bursts are not followed by such guard spaces (see §3.2).

Applicability of streaming codes in the wild. The benefits of streaming codes for VoIP applications have been studied using simulated losses under theoretical loss models, such as the Gilbert-Elliott channel [23] and over traces [6, 25], wherein each frame is sent in one packet and all frames/packets are of a fixed constant size. However, these results do not apply to videoconferencing applications, which send (a) multiple packets for each frame and (b) varying amounts of data per frame. Streaming codes perform best when each burst occurs across multiple frames and is followed by a guard space of several frames without losses. A natural question is whether

such losses arise in videoconferencing and if they can be exploited via streaming codes. To the best of our knowledge, no study of large-scale real-world packet losses establishes the applicability of streaming codes in the wild. Furthermore, establishing that streaming codes are viable to improve the QoE hinges on improving several metrics relating to the QoE. Yet an analysis of streaming codes’ impact on such metrics is similarly lacking in the existing literature. Finally, the effect of inter-frame dependencies on the benefits of streaming codes has yet to be assessed, even though inter-frame dependencies are prevalent in videoconferencing.

3 Packet loss in the wild

Logs (specifically, packet loss traces) from Microsoft Teams were collected from a random sample of calls over two weeks. One week’s traces were held out as a test set for the evaluation.

Teams uses FEC only after a packet loss occurs, which is fairly standard in the industry [64] to avoid wasting bandwidth for the many calls that do not experience any loss. We limit our study to traces with at least two instances of loss since our focus is on improving scenarios *after* FEC is activated (i.e., FEC is turned on after the first loss and then used to recover the second). Our analysis involves approximately 9700 traces, which constitute 16% of all the traces. Studying these traces sheds light on the tail performance, which is crucial for real-world commercial applications. Each trace corresponds to one call and contains the size, sequence number, and send/receive timestamps for each received packet, as well as whether it is a parity packet or data packet; lost packets are identified via missing sequence numbers. Due to the application’s data collection method, the traces are limited to the final one minute of the call. Although the logs are for packets, we approximate frame-level information by combining the logs with Teams’s packetization logic and have corroborated with the Teams engineers that this approximation is good.

3.1 FEC metrics

Teams employs an RS block code within each frame and varies the bandwidth overhead based on infrequent feedback from the receiver on packet losses. We will denote the FEC scheme used by the application simply as “Block-Within.”

We evaluate three metrics over the traces. First, the percent of video frames using FEC for each videoconferencing call (Fig. 4a). The 25th, 50th, and 75th percentile for the percent of video frames over each trace using FEC are 13%, 48.8%, and 70% of calls respectively, indicating that FEC is applied to a significant portion of the frames. Second, the percent of decoding failures for video frames over all frames for each videoconferencing call (Fig. 4b). The 25th, 50th, and 75th percentile for the percent of decoding failures of frames are 0.6%, 1.8%, and 6.1% of calls. Note that the decoding failures should be kept below around 1% to provide high QoE [33].

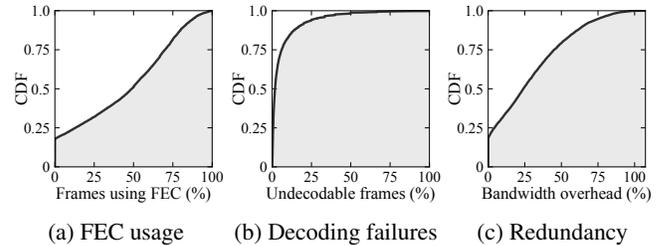

Figure 4: CDFs over the traces from Teams of (a) how often FEC is used to encode frames to protect against packet loss, (b) how often the lost packets are not decoded, and (c) the bandwidth overhead of parity packets.

As such, decoding failures are prevalent enough to tangibly negatively impact the QoE, prompting the need for a more effective FEC mechanism. Third, the bandwidth overhead for each call (Fig. 4c). The 25th, 50th, and 75th percentile for the bandwidth overhead are 4.2%, 24%, and 45% of calls. Thus, reducing the bandwidth overhead will free a significant portion of the bandwidth for these calls.

3.2 Network quality

We analyze the packet losses to assess streaming codes’ suitability for real-world videoconferencing applications. To the best of our knowledge, this is the first work to analyze large-scale real-world packet loss traces from this perspective. We analyze three key metrics of losses in Fig. 5. (1) The packet loss rate for each trace (Fig. 5a). (2) The distribution of lengths of bursts of packets measured over all of the calls (Fig. 5b). (3) The distribution of the lengths of bursts of frames (i.e., the number of consecutive frames with at least one packet lost) measured over all of the calls (Fig. 5c). This metric indicates streaming codes’ suitability, as they are most effective when bursts of lost packets encompass multiple frames (see § 2.2).

The mean percent of packets lost over the traces is 7%. It is higher than the packet loss in the FCC report [15] since we focus on the traces where FEC is employed. If the other traces from Teams are also considered, the mean packet loss over all traces is 1.7%, which is comparable to the FCC measurement. In earlier studies of end-to-end Internet packet loss, loss rates tended to vary over time and between ISPs and access network technology [8, 18, 24, 54], with ISP queue management policies impacting the loss patterns seen by applications. As discussed in [24], in home broadband networks, loss rates are often less than 1% for long periods, with infrequent periods of very bursty packet loss. Similar patterns are seen in mobile networks, where loss rates tend to increase during handovers [8], and much longer packet loss bursts are seen. Our traces from Teams, described in this section, show similar behavior, with a large number showing very low loss rates, with a long-tail of traces showing extremely bursty packet loss. Specifically, 38.1% of the instances of packet loss in-

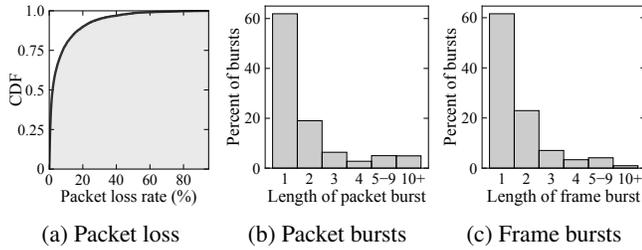

Figure 5: Packet loss is prominent (e.g., Fig 5a shows 1 – 10% packet loss for most traces) and often occurs as bursts across consecutive packets (Fig 5b) or frames (Fig 5c).

volve at least two consecutive packets being lost (Fig. 5b), and 38.4% of instances of packet loss encompass more than one video frame. Such loss patterns can be efficiently recovered by streaming codes (§3.3).

There is also a trade-off between the bandwidth overhead (i.e., the bandwidth used for parity packets) and the probability of decoding failure. The bandwidth overhead cannot be prohibitively high lest there be insufficient bandwidth for the original data. Consequently, the frequency of decoding failures for frames is non-negligible despite using FEC.

3.3 Potential of streaming codes

Recall from §2.3 that streaming codes are most effective when (a) packet loss occurs as a burst across multiple consecutive frames and (b) the burst loss is followed by a guard space of multiple consecutive frames with no losses. We formalize two metrics to capture these conditions. We then show that the packet losses in the traces exhibit these features.

Measuring bursts. The bandwidth overhead needed to decode a burst depends on the fraction of the packets being lost when losses occur across multiple frames. We introduce a new metric to formalize this notion.

Definition 1 (Multi-frame burstiness) *Suppose a burst occurs across two or more frames, i through j , over which s packets are sent. If l of the s packets are lost, the **multi-frame burstiness** is defined as l/s .*

For example, suppose Tambur sends packets $(D_0[i], D_1[i], D_2[i])$ and $(D_0[i+1], D_1[i+1])$ over frames i and $(i+1)$, respectively. Suppose $D_1[i], D_2[i]$, and $D_0[i+1]$ are lost. Then the multi-frame burstiness is $3/5$. The multi-frame burstiness is always positive since at least one packet is lost for each frame in the burst. The maximum value of 1 occurs when all packets are lost for all frames in the burst. High values correspond to situations of a high percentage of the packets being lost for multiple consecutive frames. The value of the multi-frame burstiness directly relates to the minimum bandwidth overhead needed for any code to decode lossy frames in real time.

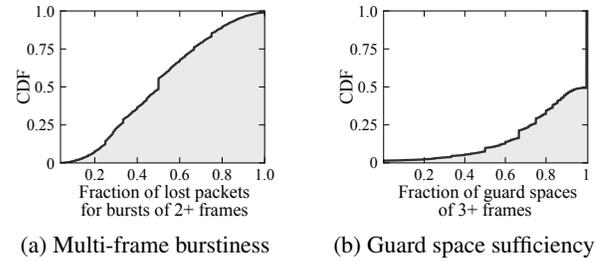

Figure 6: The CDFs over the traces of the (a) the multi-frame burstiness (for traces with at least one burst over 2+ frames), and (b) the guard space sufficiency.

Measuring guard spaces. Streaming codes can reduce bandwidth overhead for scenarios where a burst of packet losses is followed by a guard space of at least τ frames that experience reliable transmission, where τ is the latency deadline parameter (§2). We now introduce a new metric to measure the extent to which the guard spaces exhibit this property.

Definition 2 (Guard space sufficiency) *The τ -guard space sufficiency is the fraction of instances in which one or more frames with packet loss are followed by at least τ consecutive frames which experience lossless transmission.*

The value of the guard space sufficiency varies from 0 to 1. It is *negatively* related to the bandwidth overhead needed when using streaming codes. High values for the guard space sufficiency indicate that the bandwidth overhead can be reduced.

Suitability of streaming codes. The multi-frame burstiness and 3-guard space sufficiency is evaluated over the traces in Fig. 6.³ In Fig. 6a, the value of the multi-frame burstiness is shown to vary over the range 0 to 1, with values at the 25th, 50th, and 75th percentiles of 0.32, 0.5, and 0.67 respectively. This indicates that the bandwidth overhead needed when using streaming codes varies over the traces, as expected. For higher values, more bandwidth must be allocated to redundancy to decode the losses. For lower values, it is possible to make do with less bandwidth used for redundancy. The guard space sufficiency is evaluated over the traces in Fig. 6b, and its values at the 25th, 50th, and 75th percentiles are 0.73, 1.0, and 1.0 respectively. These values imply that *streaming codes are often suitable*. For example, for the traces with a value of 1.0, every single time a burst occurs across multiple frames, streaming codes could have been used to decode the losses with the optimal amount of bandwidth overhead. Yet, the low values indicate insufficient guard spaces for using existing streaming codes to reduce the bandwidth overhead, as they are vulnerable to losses in the guard space.

³Recall from § 2.2 that $\tau = 3$ applies for a realistic choice of parameters, in which case a guard space of length 3 is beneficial for loss recovery with streaming codes.

3.4 Key findings

Bursts of packet losses followed by guard spaces arise frequently and are conducive to streaming codes. However, this is not always the case. Bursts are sometimes followed by short guard spaces or involve significant packet loss, in which case the bandwidth overhead cannot be reduced via streaming codes. Hence, integrating streaming codes into real-world applications *requires* (a) *predicting whether the bandwidth overhead can be reduced without incurring decoding failures*, (b) *leveraging partial losses in a frame (i.e., losses of only some packets per frame rather than all packets)* and (c) *adding robustness to losses in the guard space*.

4 Tambur

We present Tambur, which exploits the potential discussed in §3.3 and addresses the challenges discussed in §2.3 by (1) using an ML model to take predictive decisions on the bandwidth overhead, and (2) designing a new streaming code suitable for videoconferencing given any setting for the bandwidth overhead.⁴ First, an ML model makes a predictive decision on the number of parity symbols to allocate for each frame. This helps to set the bandwidth overhead to match the network conditions. Second, the parity symbols are defined to provide (a) sequential recovery of bursts over multiple frames while exploiting partial losses, (b) recovery of occasional losses within a single frame immediately, and (c) robustness to a small amount of loss in the guard space after a burst. Third, a new methodology is employed to distribute each frame’s data and parity symbols over multiple packets. The design of the parity symbols and their distribution across packets constitute Tambur’s streaming code. During loss recovery, Tambur uses the received packets from the frames involved in a burst (i.e., partial losses), which allows for a lower bandwidth overhead than is possible for existing streaming codes that ignore such packets.

Fig. 7 shows how Tambur fits into the stack of a videoconferencing application. The *streaming encoder* encodes data from compressed frames into data packets and parity packets. A *Bandwidth Overhead Predictor* periodically selects bandwidth overhead for each frame using a predictive (ML) model based on the losses observed at the decoder and sends the value to the encoder. The *streaming decoder* uses parity packets to recover lost data packets. We will now describe these components in detail.

4.1 Tambur’s streaming code

We present the code in two parts: encoding and decoding.

Encoding. We illustrate how Tambur encodes the i th frame. Fig. 8 shows an example of encoding for $\tau = 3$. The data

⁴The new streaming code builds upon recently developed theoretical streaming codes [60, 61] while overcoming the limitations discussed in §2.3.

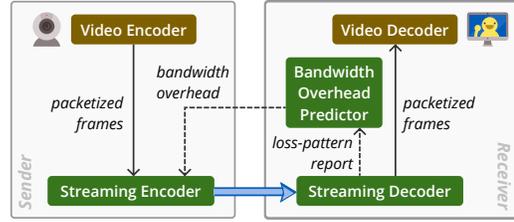

Figure 7: Overview of Tambur. The components in green are specific to Tambur.

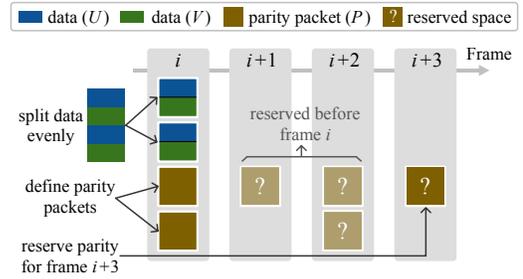

Figure 8: Encoding for $\tau = 3$. Tambur splits frame i evenly into $(V[i], U[i])$ and sends them over data packets. Also, Tambur sends parity packets for recovering $V[i-3], \dots, V[i], U[i]$ and $U[i-3]$ and reserves space for parity symbols of frame $(i+3)$.

symbols of this frame, $D[i]$, are sent in data packets, and the parity symbols, $P[i]$, are sent in parity packets. The sizes of the packets are maximized subject to (a) not exceeding an MTU (for example, 1500 bytes in our experiments) to be equal. The previous value of the Bandwidth Overhead Predictor determines how many parity symbols are allocated for frame i . These parity symbols will be sent τ frames later (see “reserved space” in Fig. 8). The number of parity symbols sent for frame i was determined by the size of frame $(i - \tau)$.

Next, we describe how parity symbols are formed. The symbols of $P[i]$ are linear combinations of the symbols of the $(\tau + 1)$ frames, $\{D[i], \dots, D[i - \tau]\}$. To define the parity symbols, it helps to view the data symbols of the associated $(\tau + 1)$ frames as being divided evenly into two parts as $D[j] = (V[j], U[j])$, for $j \in \{i, \dots, i - \tau\}$. Fig. 8 shows these components in blue and green, respectively.

The symbols of $P[i]$ are carefully designed linear combinations of the symbols of $V[i], \dots, V[i - \tau], U[i]$, and $U[i - \tau]$. Specifically, $P[i]$ is sum of three quantities: $P[i] := P_1[i] + P_2[i] + P_3[i]$. The symbols of $P_1[i]$ are linear combinations of the symbols of $V[i - \tau], \dots, V[i - 1]$. The symbols of $P_2[i]$ are linear combinations of the symbols of $U[i - \tau]$. The symbols of $P_3[i]$ are linear combinations of the symbols of $U[i]$ and $V[i]$. All linear combinations are carefully chosen to be *linearly independent* linear equations.⁵

Decoding. We describe the decoding process in two parts:

⁵It suffices to take linear equations from three different Cauchy matrices.

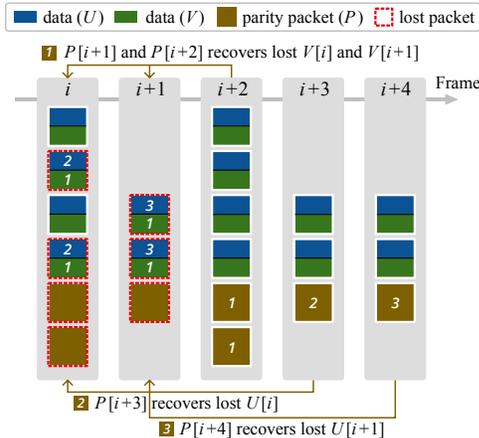

Figure 9: Decoding a burst across 2 frames within $\tau = 3$ frames delay using Tambur’s streaming code. Data symbols labeled 1, 2, and 3 are decoded using the parity packets with the same label.

(1) occasional packet losses and (2) burst of packet losses. Let all frames before the loss be decoded. First, suppose that packet loss is rare, and the size of $P[i]$ exceeds the number of symbols lost for frame i . Then $P[i]$ suffices to decode the i th frame (specifically, by solving a system of linear equations).

Second, consider a burst of packet losses across two consecutive frames for $\tau = 3$, as is shown in Fig. 9. Packet losses (red-dashed border) span frames i and $(i + 1)$. For each frame i , the blue, green, and brown parts represent $U[i]$, $V[i]$, and $P[i]$, respectively. First, $V[i]$ and $V[i + 1]$ are both decoded using $P[i + 2]$, which consists of independent linear combinations of (a) the symbols of $V[i]$ and $V[i + 1]$, and (b) the (received) symbols of $V[i - 1]$, $U[i - 1]$, $U[i + 2]$, and $V[i + 2]$. Second, for $j \in \{i, i + 1\}$, $U[j]$ is decoded using $P[j + 3]$, which consists of independent linear combinations of (a) the symbols of $U[j]$, and (b) the (available) symbols of $V[j - 3], \dots, V[j]$, and $U[j]$. The key to this methodology is that $U[i + 1]$ is *not* recovered by the latency deadline of $D[i]$ (i.e., $(i + 3)$). This enables using extra parity symbols (i.e., $P[i + 4]$) to recover $U[i + 1]$ while still decoding each data packet within $\tau = 3$ frames. Appendix A presents the general case. If decoding fails, the receiver queries the sender to generate a new keyframe (i.e., a self-sufficient frame) to handle inter-frame dependencies.

There are three key differences from existing streaming codes for videoconferencing: (1) The data symbols and parity symbols of a frame are sent over multiple packets instead of a single packet. (2) Each frame’s parity packets are designed such that they are useful in recovering its lost data packets (in addition to being useful in recovering previously sent frames). (3) The code is flexible enough to allow per-frame bandwidth overhead to be set using the Bandwidth Overhead Predictor.

4.2 Bandwidth overhead predictor

At a high level, Tambur makes use of a predictive model to determine the bandwidth overhead employed by its streaming code (i.e., the amount of “reserved space” in Fig. 8). This predictive model takes as input a feature vector computed by the receiver periodically (e.g., every two seconds), dubbed a *loss-pattern report*. The predictive model’s output is then sent to the sender to set the bandwidth overhead for each frame for Tambur’s streaming code until the next loss-pattern report is received. For example, a bandwidth overhead of 50% means that if frame i comprises 1000 bytes, 500 bytes of parity symbols are allocated.

Loss-pattern report. Let P be the bitmap of packet losses since the last loss-pattern report, where 1 denotes a loss and 0 is a reception. Let F be a bitmap over all frames since the last loss-pattern report of whether at least one of the frame’s packets was lost. The loss-pattern report consists of the following 13 quantities, all of which can be computed in linear time with a single sequential pass over F and P .

- Multi-frame burstiness and guard space sufficiency (§3).
- Fraction of losses for P and F .
- Mean number of consecutive losses for P and F .
- Mean length of guard spaces for P and F .
- Burst density [12] and gap density [12] for P and F ⁶.
- A score employed by Teams to choose its bandwidth overhead, which is based on the observed fraction of packet losses and lengths of bursts.

Bandwidth overhead prediction via weighted classification. Tambur uses an ML model to determine the bandwidth overhead allocated per frame based on the recent loss conditions. As discussed above in § 4.1, Tambur’s streaming code enables such an approach by allowing fine-grained tuning of the bandwidth overhead. To keep the model simple, we select two options for the bandwidth overhead. This approach easily generalizes to more than two values for bandwidth overhead by using a multiclass classifier to enable tuning the bandwidth overhead used by Tambur. In our implementation, we use a small neural network (discussed further in §4.3), although any methodology could be substituted.⁷

The ML model is trained with different *weights* for the two classes based on prioritization of bandwidth savings versus minimizing decoding failures. Essentially, the higher the weight for the class corresponding to the higher bandwidth overhead, the greater the frequency of decoding frames, but the lower the reduction in bandwidth overhead. Videoconferencing service operators can use these weights as a knob to prioritize reducing decoding failures or bandwidth overhead.

Neural network details. Binary classification is conducted using a small fully connected neural network with one hidden layer. The input is the values of the 13 metrics for the

⁶The parameter $gMin$ [12] is set to be 1 and τ for P and F respectively.

⁷We found ML models to outperform heuristics empirically.

previous 3 loss-pattern reports. The cross-entropy loss is applied, and by default the weights for mistakenly reducing the bandwidth overhead (i.e., causing a decoding failure) and not reducing the bandwidth overhead by half (i.e., failing to save bandwidth) are 0.999 and 0.001, respectively. We tested various number of hidden neurons (e.g., 100, 1000, and 10000) and selected 1000 as the smallest option to reach the point of diminishing returns. The model is implemented and trained in PyTorch offline using the traces based on the optimal decision for reducing the bandwidth overhead without causing decoding failures. During inference, it is instantiated in C++.

4.3 Implementation

We implemented Tambur in C++ as part of a new independent library called Tambur that any videoconferencing application can use.⁸ At the sender, Tambur takes successive compressed frames as input and outputs data packets and parity packets. At the receiver, Tambur decodes lost packets by solving a system of linear equations using the symbols of the received packets. When packets are lost, we combine properties of streaming codes with an open-source min-cut/max-flow algorithm [11] to determine which data symbols can be decoded using which parity symbols in negligible time (see Appendix B). Data is then decoded by solving the smallest full-rank systems of linear equations.

We use a small header to provide frame-level information needed for decoding. This includes sequence numbers for packets and frames and relative positions of a packet within a frame and amongst parity packets. The streaming decoder also needs the size of the lost frame in order to decode it (even when all packets corresponding to the frame are lost); hence, we encode the sequence of frame sizes using a streaming code and send one parity symbol of this code in each packet.

The library provides an interface for rapidly prototyping new FEC schemes. We used this interface to implement the baselines from §1 (i.e., Block-Within and Block-Multi).

The core arithmetic of linear encoding and solving a system of linear equations for decoding is done using Jerasure 2.0 [52], an open-source library in C/C++ with modules for key operations of erasure coding. Jerasure 2.0 is built on top of the GF-Complete library [51], which uses Intel SIMD instructions to perform Galois Field arithmetic quickly. Tambur involves encoding data into “coding blocks” of 256 bytes, each of which uses the same linear equations. Extending Tambur to use hardware offload to encode and decode frames is a potential avenue of future work.

Integration with videoconferencing. To validate Tambur’s effectiveness in the real world, we integrate it with *Ringmaster*⁹, a new videoconferencing platform that emulates one-on-one video calls for benchmarking FEC schemes. Ringmaster

is implemented in ~4000 lines of C++. Its video sender reads raw frames from an input Y4M video file on disk at a precise frame rate (e.g., 30 fps) and compresses them with the VP9 encoder in the `libvpx` [1] library using similar codec configuration as in WebRTC [2]. A user-provided FEC scheme provides parity data for the encoded frames, which is sent over UDP after packetization to the video receiver. Upon receiving the frames, the video receiver applies the FEC decoder and VP9 decoder sequentially to decode and render the original video frames. In addition, Ringmaster allows for requesting new keyframes, e.g., when the receiver fails to recover a video frame due to excessive loss of packets and thus requests the sender to encode a new keyframe so as to resume the video. At the end of the automated call, QoE metrics are computed by aggregating logs from both endpoints, which record the timestamps when each frame is encoded or decoded, along with its frame ID, size, FEC bandwidth overhead, etc.

Ringmaster provides clean and modular interfaces that we use to integrate it into Tambur. Combining Ringmaster with Tambur enables benchmarks of FEC schemes’ performance featuring QoE metrics, e.g., video freezes, per-frame delay, rendered frame rate, for FEC schemes implemented via Tambur’s interface. Furthermore, Ringmaster also allows researchers to isolate the impact of FEC and disable modules that interfere with FEC, such as bandwidth estimation [13] and packet retransmission.

5 Evaluation

To assess whether Tambur can improve the QoE, we ask:

- Can Tambur provide significant benefits for metrics relating to FEC on real-world losses?
- Do the benefits of Tambur lead to a higher QoE?

5.1 Experimental methodology and highlights

Videoconferencing application parameters. In our experiments, we aim for a maximum tolerable latency of 150 ms to meet industry recommendations [33], which is a fairly standard value for interactive video. The frame rate is taken to be 30 fps, which is a typical value in videoconferencing. The inter-frame arrival time for 30 fps is 33.3ms. Allowing for a one-way frame delay of 50 ms leaves room for a decoding delay of around 100ms. Thus, the parameter τ can be at most 3 (frames) for the end-to-end latency (i.e., $33.3\tau + 50$) to be at most ≈ 150 ms. The two options for the bandwidth overhead of Tambur are to match or use half of the bandwidth overhead of the baseline coding scheme, Block-Within, which is introduced next.

Coding schemes. We evaluate six coding schemes. (1) **Block-Within** (Fig. 2a), which applies RS codes within a frame. This scheme is employed in production by Teams. (2) **Block-Multi** (Fig. 2b) which applies RS codes across $(\tau + 1) = 4$

⁸<https://github.com/Thesys-lab/tambur>

⁹<https://github.com/microsoft/ringmaster>

frames. RS codes are *optimal* block codes, and hence the above two baselines outperform other block codes such as fountain or rateless codes in recovering losses and bandwidth overhead. (3) **Tambur-full-BW**, which is a variant of Tambur that matches Block-Within’s bandwidth overhead. (4) **Tambur-0.9**, which is Tambur with the neural network trained to prioritize bandwidth savings more by decreasing the weight of misclassification from 0.999 to 0.9 in the loss function. Thus, Tambur-0.9 prioritizes reducing the bandwidth overhead more than Tambur. (5) **Tambur-low-BW**, which is a variant of Tambur that uses 50% of the bandwidth overhead of Block-Within. (6) **Oracle**, which optimally selects between Tambur-full-BW, Tambur-low-BW, or Block-Within. Each time the sender obtains feedback from the receiver, the Oracle selects the scheme with the smallest bandwidth overhead among the scheme(s) that recover the most frames. This choice never causes a non-recoverable loss. Consequently, the Oracle always recovers at least as many frames as Block-Within, Tambur, and Tambur-full-BW. The bandwidth overhead of Block-Within and Block-Multi is never reduced to ensure a fair comparison of Tambur’s loss recovery capabilities and because both baselines already perform worse than Tambur despite using the full bandwidth overhead. Like Tambur, Block-Within and Block-Multi send feedback to the sender once FEC decoding has failed to trigger a new keyframe as a fallback mechanism to handle inter-frame dependencies.

Metrics. We evaluate the following metrics: (1) Percent of non-recoverable frames, which is the percentage of compressed frames that are not recovered. (2) Bandwidth overhead for FEC. (3) Percent of non-rendered frames, which is the percent of frames that are not played by the receiver—this includes non-recovered frames and recovered frames that depend on non-recovered frames. (4) Latency, which is the duration between a frame being created and rendered. (5) Frequency of freezes, which is the number of times the receiver’s video is frozen. (6) Duration of freezes, which is the cumulative length of time where the receiver’s video is frozen.¹⁰ We calculate these metrics only for the frames where FEC is applied (i.e., where FEC affects the quality). We compute one value per call (e.g., median duration of freezes, bandwidth overhead, etc.) and then consider the percentiles over these values. For latency, we consider all frames over all calls.

QoE is difficult to measure precisely with so-called “QoE models” [68] because it depends on video-specific properties (e.g., in sports, video quality during gameplay matters more than during timeouts). But several works [7, 21, 37] have shown that key metrics for QoE (e.g., frequency of freezes, duration of freezes, bandwidth, etc.) impact the mean opinion score—the gold standard measure of QoE. These metrics also affect user interactions (e.g., users watch more video when there are fewer freezes). In fact, [19] showed that cumulative

¹⁰We use the definition of freezes and duration of freezes from the most recent (unofficial) draft of identifiers for WebRTC’s statistics [10].

freeze duration is crucial for QoE, as well as the importance of bitrate and frequency of video freezes for live video.

Offline evaluation. We evaluate the performance of Block-Within, Tambur, Tambur-full-BW, Tambur-0.9, Tambur-low-BW, and Oracle over the test set of traces from Teams described in §3, which was held out from the previous analyses. The packet logs provide the performance of Block-Within. We make two safe assumptions to evaluate the remaining schemes over the traces: (a) modifying the payload of a packet, but not its size, would not change whether it is lost or received; (b) reducing the size of a packet’s payloads would not incur any new packet losses. Each data packet is sent identically as in the trace, the payloads for the parity packets are changed, the sizes of the parity packets are sometimes reduced, and the bitmap of packet losses from the trace is used. To satisfy the assumptions, we must force Tambur to send the number of parity symbols allocated for each frame within the frame (rather than delayed by τ frames), which we expect to *degrade Tambur’s performance*. This enforcement alters the number of parity packets sent under Tambur but not how their symbols are defined. Block-Multi is excluded because it sends all parity packets after the final data packet of the final frame of the block, so its performance cannot be fairly simulated using the production traces.

Online evaluation. We evaluate prototype implementations of Block-Within, Block-Multi, Tambur, Tambur-full-BW, and Tambur-0.9 integrated with Ringmaster (the videoconferencing benchmark platform described in §4.3) via network emulation using Mahimahi [46] while simulating a Gilbert-Elliott (GE) [23] loss model over a dataset of 80 videos. Specifically, we evaluate 20 video calls from [16, 47] at four constant bitrates each (namely, 500, 1000, 1500, and 2000 kbps) to isolate the effect of FEC. The bandwidth overhead is set to 50% for Block-Within (likewise, for Block-Multi and Tambur-full-BW).¹¹ The GE loss model is a standard loss model which is a Markov model with two states: “good” and “bad,” each with an associated probability of packet loss. For a fair and realistic comparison, different coding schemes must experience the same distribution of burst losses at the frame level even though they send differing numbers of packets per frame. Therefore, we consider transitions between the states occurring once at the start of every frame (i.e., once every 33.3 ms) rather than a transition between states every packet, which is commonly used in the literature when only one packet is sent per frame. Packets within each frame are lost independently with the same probability. The modified GE channel can be viewed as a buffer overflowing for a short period, as can arise from on/off characteristics of traffic [49]. Appendix C details how we set the parameters of the GE model based on the losses from the traces.

Result highlights.

¹¹The bandwidth overhead is sometimes slightly higher for *all* schemes due to rounding and ensuring at least one parity packet is sent per frame.

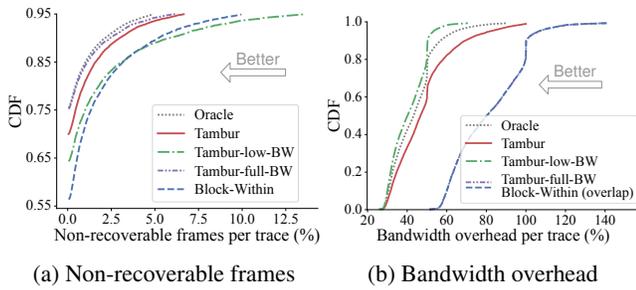

Figure 10: CDFs for the percent of non-recoverable frames for the 55th through 95th percentiles and the bandwidth overhead for the offline evaluation.

- In offline evaluation, Tambur reduces the frequency of non-recoverable frames by 26.5% while using 35.1% less bandwidth overhead.
- In online evaluation, Tambur reduces frequency of non-rendered frames, frequency of freezes, and duration of freezes by 28%, 26%, and 29%, respectively compared to Block-Multi, and by 73%, 78%, and 77% compared to those of Block-Within. Block-Multi has a significantly higher latency than Block-Within (see Fig. 13b).
- Modest memory overhead and median encoding and decoding times of 575 KB, 1.7ms, and 3.4ms, respectively.

5.2 Offline evaluation

We assess only the frequency of non-recoverable frames and the bandwidth overhead for offline traces because the remaining metrics are unavailable. Fig. 10a shows the CDF of the percent of non-recoverable frames from 55th to 95th percentiles over the traces. These percentiles correspond roughly to the 92nd to 99th percentile over all traces. The Oracle reduces the total number of non-recoverable frames by 44.2% compared to Block-Within and reflects an upper bound on performance. Tambur-full-BW reduces the frequency of non-recoverable frames by 33% compared to Block-Within, indicating the potential improvements of using streaming codes. In contrast, Tambur-low-BW *increases* the frequency of non-recoverable frames by 34.7% compared to Block-Within, indicating the need for more sophisticated methods to reduce the bandwidth overhead without incurring a significant penalty in non-recoverable frames. By using a predictive model to determine the bandwidth overhead, Tambur reduces the bandwidth overhead by 35% while simultaneously reducing the number of non-recoverable frames by 26.5% compared to Block-Within (Fig. 10b). §5.3 summarizes the spectrum of bandwidth savings versus recovering frames for Tambur based on tuning the associated weight parameter.

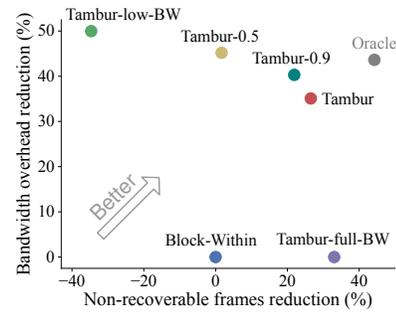

Figure 11: Sensitivity analysis of the weights for the classes used in the predictive model for the frequency of non-recoverable frames and bandwidth overhead over all of the frames where FEC is used in the traces.

5.3 Sensitivity analysis

There is an inherent trade-off in performance between the non-recoverable frames and bandwidth overhead metrics. The ML model for Tambur is trained using a loss function with a weight of 0.999 on avoiding recovery failures and the remaining weight (i.e., 0.001) on saving bandwidth overhead (§4.3). Fig. 11 shows the impact of this parameter on the frame recovery performance of Tambur with the weight set to 0.9 (i.e., Tambur-0.9) and to 0.5. The improvement in non-recoverable frames for the two schemes are respectively 21.9% and 1.7%. The reduction in the bandwidth overhead is respectively 40.3% and 45.2%. By contrast, recall that Tambur leads to a 26.5% improvement in non-recoverable frames and reduces the bandwidth overhead by 35.1%. Reducing the value of the parameter reduces the frequency of recovering frames and increases the reduction in the bandwidth overhead. Videoconferencing service operators can use these weights as a knob to prioritize one metric over another.

5.4 Online evaluation

Next, we establish Tambur’s potential to improve the QoE. To facilitate an easy comparison with the offline evaluation, we show the frequency of non-recoverable losses and the bandwidth overhead (as in §5.2) in Fig. 12. On average, Tambur reduces the number of non-recoverable frames by 69% compared to Block-Within and 34% compared to Block-Multi. Tambur-0.9 reduces the number of non-recoverable frames by 65% compared to Block-Within and 26% compared to Block-Multi despite Block-Multi’s much higher latency (Fig. 13b). The results differ slightly from the offline evaluation at the lower percentiles because of setting the parameters of the channel based on average loss statistics over all the traces. This significantly reduced the frequency of calls with low loss rates where any coding scheme suffices to recover nearly all frames (i.e., sophisticated FEC schemes are unnecessary).

Tambur—which is conservative in risking recovery failures to save bandwidth—reduces the bandwidth overhead by 3%

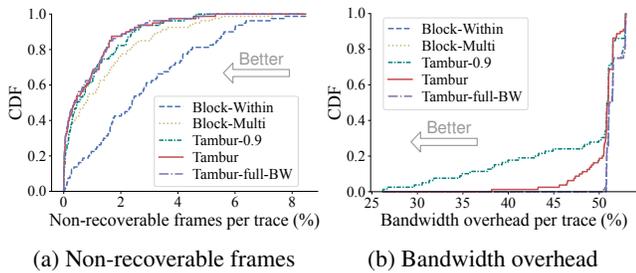

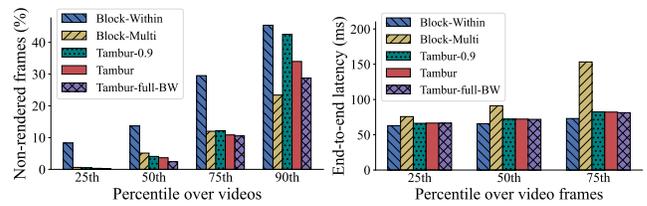

Figure 12: CDFs for the percent of non-recoverable frames and the bandwidth overhead for the online evaluation.

on average of the calls. In contrast, Tambur-0.9 reduces the bandwidth overhead by an average of over 8%. These results reflect both schemes reducing the bandwidth overhead significantly on some calls but only negligibly on many others, which is expected given the loss rates of most calls. Tambur-0.9’s bandwidth savings are especially pronounced at the lower percentiles (e.g., 31% at the 10th percentile and 15% at the 20th percentile). Tambur-0.9 provides a win-win by both recovering more frames and saving bandwidth despite the online evaluation reflecting out-of-sample performance for its neural network, which was trained offline over the production traces. The results further validate the trade-off between the bandwidth overhead and recovering frames discussed in §5.3.

Next, we examine the percent of non-rendered frames in Fig. 13a; recall that fewer frames are rendered than recovered due to inter-frame dependencies. Tambur reduces the frequency of failing to render frames compared to Block-Multi and Block-Within by an average of 28% and 73%, respectively. Tambur does worse than Block-Multi at the tail, but this only occurs after all schemes have a failure rate above 23%. Thus, all schemes should employ more redundancy. Tambur-0.9 decreases the frequency of failing to render frames by an average of 70% and 20% compared to Block-Within and Block-Multi, respectively. Tambur-0.9 modestly increases the frequency by 1% at the 75th percentile compared to Block-Multi. Overall, the rate of rendering frames can be improved while simultaneously reducing the bandwidth overhead for most calls. The results are the first to establish the benefits of streaming codes when there are inter-frame dependencies.

Fig. 13b shows that the end-to-end latency is within the upper limit of approximately 150ms for all schemes. Block-Within’s latency is slightly lower due to a shorter encode/decode time and always recovering rendered frames using the parity of the same frame (see Fig. 15 and Fig. 16 in Appendix D); Tambur decodes 87% of frames without extra frames versus 88% for Block-Within, so the extra latency from the waiting for extra frames should really be compared to Block-Within failing to decode at all. We argue that Tambur’s small cost (e.g., an extra 1.7ms to encode and 3.4ms to decode at the median) is worthwhile due to substantial improvements across the remaining QoE metrics. We also note that our implementation of Tambur’s streaming code is not yet optimized

(a) Frequency of non-rendered frames (b) Latency of rendered frames

Figure 13: Tambur renders significantly more frames than Block-Multi and with lower latency. Tambur’s modestly higher latency than Block-Within is more than offset by the improvement in rendering frames.¹²

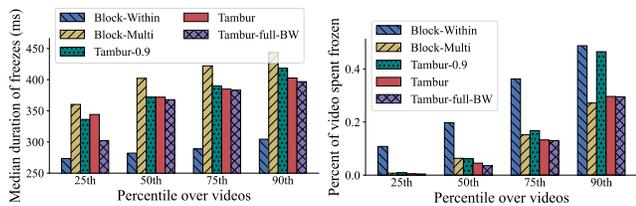

for fast encoding/decoding; hence, we believe it can be significantly faster. Our goal is to establish that Tambur’s streaming code is practical enough for videoconferencing applications.

Recall from Fig. 1 that Tambur reduces the frequency of freezes by 78% and 26% compared to Block-Within and Block-Multi, respectively, and Tambur-0.9 reduces the frequency of freezes by 75% and 17% compared to the two respective baselines. Fig. 14a shows that Tambur and Tambur-0.9 each reduce the median duration of freezes compared to Block-Multi by 30ms on average. Tambur and Tambur-0.9 each have a 90ms longer median duration of freezes than the Block-Within because Block-Within has over 300% more freezes than Tambur does. Many of the extra freezes are short, reducing Block-Within’s median value to below Tambur’s.

Tambur-0.9 reduces the cumulative duration of freezes by an average of 69% compared to Block-Within. The cumulative duration of freezes is 17% lower for Block-Multi than for Tambur-0.9 despite Tambur-0.9 having on average 11% shorter median durations of freezes and 17% fewer freezes. While the combined effect of the frequency and duration of freezes on the QoE for Block-Multi and Tambur-0.9 are similar, recall that Tambur-0.9 also improves the bandwidth overhead and renders more frames for most traces. As such, we expect Tambur-0.9 to provide an overall higher QoE. Tambur has an average of 77% and 28% shorter cumulative durations of freezes than Block-Within and Block-Multi, respectively, which is a clear win. Tambur, Tambur-0.9, and Tambur-full-BW exhibit higher cumulative durations of freezes at the tail than Block-Multi. We argue that this matters less because the tail QoE is already bad, indicating that all schemes needed more bandwidth overhead. Appendix E explains how this phenomenon is an artifact of the implementation and includes our proposed a solution.

The benefits across QoE metrics of Tambur, Tambur-full-BW, and Tambur-0.9 suggest a markedly improved QoE compared to Block-Within and Block-Multi. Without using ML to reduce the bandwidth overhead, Tambur-full-BW offers a substantial improvement over the two baselines. Tambur and

¹²We omit the 90th percentile since over 10% of frames are not rendered.

(a) Median duration of freezes (b) Percent of video spent frozen

Figure 14: Tambur has a higher median duration of freezes than Block-Within but a significantly smaller cumulative duration of freezes because Tambur has 78% fewer freezes than Block-Within (Fig. 1). Tambur has a lower cumulative and median duration of freezes than Block-Multi.

Tambur-0.9 progressively trade off improvements in loss recovery with bandwidth overhead. Overall, the results illustrate a Pareto frontier of the benefits of streaming codes across the QoE metrics that could be studied further in future work.

6 Related work

FEC for videoconferencing. From the early days of VoIP and Internet-based audio and videoconferencing, FEC has played a key role in recovering lost packets (e.g., [50]). As standards for real-time media and conferencing developed, RTP payload formats for various FEC schemes were defined (e.g., [62]). Later, the FECFRAME working group of the IETF [58] documented traditional FEC schemes such as parity codes [9] and RS codes [57], as well as LDPC [56] and Raptor codes [65]. As the WebRTC project developed based on these standards, it also incorporated the use of FEC to protect media streams [32, 64]. All these codes are block codes. As such, RS codes (i.e., the main baselines against which Tambur was evaluated) have the best loss recovery capabilities of any of them, including fountain [40] and raptor codes [63]. FEC has also been used for rate adaptation. For example, a proposed rate adaptation algorithm for WebRTC, known as FBRA [45], uses extra FEC packets to probe for additional bandwidth, with the benefit that some of the packet losses due to self-induced congestion can be recovered by the FEC.

Streaming codes. In addition to the prior work discussed in §2 and §4, streaming codes have also been studied under various other theoretical models, such as multiplexing with two different decoding delays [4] and multiple burst losses [38]. However, these settings are not directly relevant to our focus on videoconferencing applications.

Alternatives to FEC. Prior work has explored avoiding lossy paths using overlay networks (e.g., Via [34] and J-QoS [31]). While these can be effective in some circumstances, there are two drawbacks to relying only on such approaches. Firstly, these assume that a suitable alternative path *exists* (i.e., that the lossy portion of the path is on a transit network that can

be avoided, rather than on the user’s home network or last-mile to the ISP, and that there is available interconnectivity with the provider’s overlay network); in the current era of hybrid work, enterprises cannot completely eliminate loss through traditional QoS approaches. Secondly, when overlay networks are a feasible solution, there needs to be a careful analysis of when to apply this approach since there is a high financial cost to relaying traffic and fixed capacity on provider networks. Another alternative to FEC is using retransmission to recover losses (e.g., [30]), provided the end-to-end latency is tolerable. However, when there is both high latency and loss (e.g., in cases of acute congestion), retransmission is not always feasible [3]. Tambur provides a flexible end-to-end solution within the application that adapts to any path and is orthogonal to these other approaches.

7 Conclusion

This work introduces Tambur—a new communication scheme for bandwidth-efficient loss recovery for videoconferencing comprising two components. First, a new streaming code that bridges the gap between theoretical streaming codes and videoconferencing applications, which takes as input any given bandwidth overhead. Second, a learning-based predictive model to set the bandwidth overhead. Tambur simultaneously reduces the frequency of non-recoverable frames and the bandwidth overhead by 26.5% and 35.1%, respectively, in our evaluation over large-scale real-world traces from a commercial videoconferencing application. We also design the first videoconferencing framework for implementing and evaluating FEC schemes. The framework enables easy evaluation of the QoE benefits of new communication schemes by providing a simple interface to incorporate (a) new FEC schemes and (b) new learning-based predictive models. Using the framework, we evaluate Tambur and show improvements in QoE metrics, including 26% fewer freezes and 28% fewer non-rendered frames. The benefits establish streaming codes as a viable solution to recovering lost packets for videoconferencing applications. The results thus also show the promise of streaming codes for other live-streaming applications such as cloud gaming.

Acknowledgments

This work was funded in part by an NSF grant (CCF-1910813). We thank our anonymous reviewers for their comments and Nandita Dukkipati for shepherding this work. We also thank Sasikanth Bendapudi, Sivakumar Ananthakrishnan, Nelson Pinto, Jiannan Zheng, and Ross Cutler from Microsoft for their helpful discussions and supporting the project.

Appendices

A Recovering a burst with Tambur’s streaming code

Consider a burst of length b starting in frames i and delay constraint τ . Suppose all frames before the burst have been decoded. First, the received symbols of $P[i], \dots, P[i + b - 1]$ as well as $P[i + b], \dots, P[i + \tau]$ are used to decode the lost symbols of $V[i], \dots, V[i + b - 1]$. Second, each $U[j]$ for $j \in \{i, \dots, i + b\}$ is decoded using $P[j + \tau]$. In both steps, decoding follows from solving a system of linear equations.

B Tambur’s streaming code’s flow network

The graph of the flow network at a high level represents each $P[i]$ that may be used in decoding with a node with an edge into nodes corresponding to each of $U[i], U[i - \tau], V[i], \dots, V[i - \tau]$, where one unit of flow represents decoding one symbol. The flow network is small (i.e., at most $(5\tau + 3)$ vertices and $(2\tau^2 + 11\tau + 5)$ edges for $\tau = 3$). Therefore, the time to solve it is negligible compared to solving the system of linear equations.

C Parameters of the GE channel

To set the parameters of the GE channel for the offline evaluation, we first identify settings that match several aggregate statistics of the production traces as follows. The probability of transitioning from the bad state to the good state (respectively, vice versa) is the mean over traces of one divided by the mean length of bursts (respectively, guard spaces) in frames. The probability of loss in the bad state equals the mean over traces of the multi-frame burstiness. The probability of loss in the good state is then set so that the expected loss rate

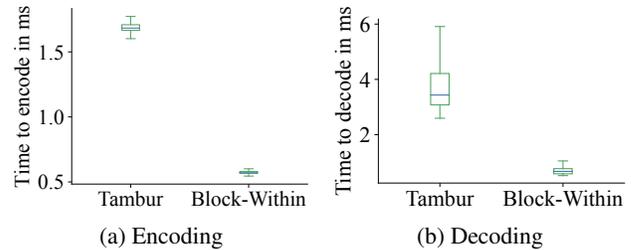

Figure 15: The encoding and decoding times are modest.

matches the mean loss rate over traces given the other three parameters. To ensure our results hold for varying network conditions, we then draw the values for each of the four parameters uniformly at random from intervals around these values (rounded to increments of 0.05) as follows. The probability of transitioning from the good state to the bad state and vice versa are distributed as $\text{Uniform}(0, 0.05)$ and $\text{Uniform}(.75, .9)$, respectively. The probability of loss in the good and bad states are distributed as $\text{Uniform}(0, 0.05)$ and $\text{Uniform}(0.05, 1)$, respectively.¹³

D Encoding and decoding overheads

We compare the encoding and decoding time for Tambur with that of Block-Within, which is the fastest of all the baselines (Fig. 15). As seen in Fig. 15, the time to encode and decode is comparable to Block-Within and is only a small fraction of the end-to-end latency budget of 150 ms. The median times for encoding are 1.7ms and .6ms for Tambur and Block-Within, respectively, whereas decoding takes 3.4ms and .7ms for Tambur and Block-Within, respectively. Because Tambur operates over multiple frames of varying sizes, encoding and decoding times are slightly longer and more variable. Our implementation of Tambur requires a fixed amount of memory of approximately 575 KB during encoding and decoding.

But times for encoding and decoding are just a small component of the end-to-end latency. The 50ms one-way delay and the number of extra frames used in decoding (see Fig. 16) have more pronounced effects. Recall that each additional frame used in adds approximately 33 ms to the end-to-end latency, so using fewer extra frames is faster. Tambur does not decode within the same frame only 1% more frequently than Block-Within, which cannot use extra frames in decoding. Tambur uses extra frames to decode only 8% of the time. Block-Multi decodes 24%, 23%, 23%, and 23% of frames with 0, 1, 2, and 3 extra frames, respectively. Each extra frame adds ≈ 33 ms to the end-to-end latency.

¹³The results were similar when we varied the ranges.

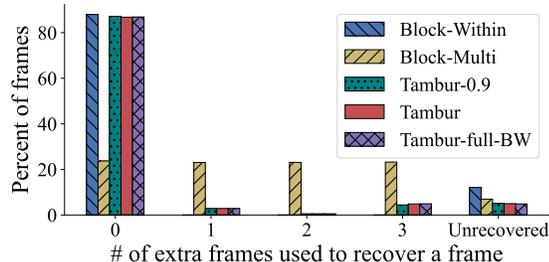

Figure 16: Tambur recovers nearly as many frames as Block-Within using no extra frames and also recovers more overall. Block-Multi recovers an approximately equal number of frames using 0, 1, 2, and 3 extra frames.

E Tail duration of freezes

Recall from Fig. 14b that Tambur, Tambur-0.9, and Tambur-full-BW have higher tail durations of freezes than Block-Multi. The reason for the poor performance is threefold. First, Tambur, Tambur-0.9, and Tambur-full-BW fail to render more frames at the tail, as was discussed in §5.2. Second, the sender generates a keyframe (often ending a freeze) once it learns of recovery failures. Because Block-Within can only recover a frame using the parity packets within the same frame, a keyframe is requested 3 frames sooner (i.e., ≈ 100 ms faster) than when Tambur (or Tambur-0.9) is used. Many of the 78% of freezes under the Block-Within where Tambur does not freeze are therefore short and shift the entire distribution of cumulative duration of freezes for Block-Within, including the tail; if we added 0ms freezes for Tambur (or Tambur-0.9) for these instances, their distributions would likewise shift. Third, encoding across multiple frames can make it harder to recover a keyframe triggered by a freeze of several lost frames. This phenomenon does not impact Block-Within and affects Block-Multi less than any of Tambur, Tambur-0.9, and Tambur-full-BW (e.g., does not affect on Block-Multi whenever the keyframe is in the first position within the block of $(\tau + 1) = 4$ frames). The phenomenon also contributes to a difference in the frequency of recovered frames (Fig. 12a) and rendered frames (Fig. 13a). There is a natural solution that is outside of the scope of this work. When the sender triggers a new keyframe due to a loss, it should stop taking linear combinations of frames from before the new keyframe. Doing so will strictly (a) increase the frequency of displaying frames and (b) decrease the mean and median duration of freezes. It will benefit Tambur, Tambur-0.9, and Tambur-full-BW the most, but it will also improve Block-Multi to a lesser extent.

F Analysis of recovering bursts

Next, we evaluate Tambur’s capabilities for recovering bursts of packets across multiple frames; to do so fairly, we must fix the bandwidth overhead, so “Tambur” refers to Tambur-full-

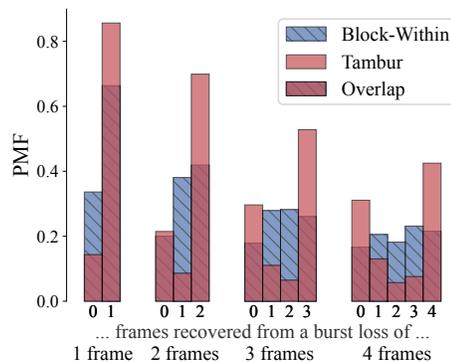

Figure 17: Given the same bandwidth budget as Block-Within, Tambur is more likely to recover all or zero frames from a burst loss over production traces.

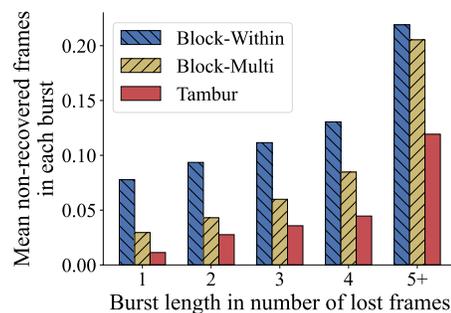

Figure 18: Given the same bandwidth budget as Block-Within/Block-Multi, Tambur provides greater improvement for longer bursts over an emulated network.

BW for the remainder of §F. Fig. 17 shows the distribution of the number of packets recovered for each burst length (in frames) for the offline evaluation. In Fig. 17, the distribution of the number of packets recovered for each burst length (in frames) is shown. Bursts encompassing 2, 3, and 4 frames constitute 23%, 7%, and 3.3% of all lossy events, respectively. For these losses, Tambur recovers all lossy frames 66.8%, 103%, and 97.3% more frequently than Block-Within. For the longer (less frequent) bursts of lengths 3 and 4, when the bandwidth overhead is insufficient, Tambur fails to recover any frames 65.9% and 87% more frequently than the Block-Within. This follows from the Block-Within being more likely to recover some (but not all) of the frames when there is insufficient bandwidth overhead to recover all losses. In contrast, when the bandwidth overhead is insufficient to recover a burst in its entirety, streaming codes are likely to fail to recover all of the frames. However, note that the overall performance of Tambur is still better than the Block-Within: Tambur recovers 21.8%, 12.4%, and 2.3% more frames than the Block-Within for bursts of 2,3, and 4 frames, respectively. Tambur also outperforms Block-Within in recovering losses limited to a single frame, as parity packets sent with later frames can be used in recovery. In short, Tambur performs significantly better for bursts across up to 3 frames than Block-Within and offers

more modest gains for bursts across 4 frames.

We also evaluate Tambur’s effectiveness at recovering bursts in the online evaluation. Because the loss of a single packet of a frame means that the frame is “lost” under our definition of a burst, longer bursts usually only involve being in the bad state for one, two, or sometimes three frames. We consider the mean number of frames recovered among a burst encompassing 1, 2, 3, 4, or greater than 4 frames in Fig. 18. Tambur reduces the frequency of non-recoverable frames by 70.5%, 68.0%, and 65.8% compared to Block-Within over bursts of 2, 3, and 4 frames respectively. Tambur reduces the frequency of non-recoverable frames by 35.8%, 40.3%, and 47.4% compared to Block-Multi over bursts of 2, 3, and 4, respectively.

Gemel: Model Merging for Memory-Efficient, Real-Time Video Analytics at the Edge

Abstract

Video analytics pipelines have steadily shifted to edge deployments to reduce bandwidth overheads and privacy violations, but in doing so, face an ever-growing resource tension. Most notably, edge-box GPUs lack the memory needed to concurrently house the growing number of (increasingly complex) models for real-time inference. Unfortunately, existing solutions that rely on time/space sharing of GPU resources are insufficient as the required swapping delays result in unacceptable frame drops and accuracy loss. We present *model merging*, a new memory management technique that exploits architectural similarities between edge vision models by judiciously sharing their layers (including weights) to reduce workload memory costs and swapping delays. Our system, Gemel, efficiently integrates merging into existing pipelines by (1) leveraging several guiding observations about per-model memory usage and inter-layer dependencies to quickly identify fruitful and accuracy-preserving merging configurations, and (2) altering edge inference schedules to maximize merging benefits. Experiments across diverse workloads reveal that Gemel reduces memory usage by up to 60.7%, and improves overall accuracy by 8-39% relative to time or space sharing alone.

1 Introduction

Fueled by the proliferation of camera deployments and significant advances in deep neural networks (DNNs) for vision processing (e.g., classification, detection) [19, 28, 46, 69, 74], live video analytics have rapidly grown in popularity [25, 35, 60, 71, 113]. Major cities and organizations around the world now employ thousands of cameras to monitor intersections, homes, retail spaces, factories, and more [1, 5, 6, 10]. The generated video feeds are continuously and automatically queried using DNNs to power long-running applications for autonomous driving, football tracking, traffic coordination, business analytics, and surveillance [2, 11–13, 34].

In order to deliver highly-accurate query responses in real time, video analytics deployments have steadily migrated to the edge [25, 78, 107]. More specifically, pipelines routinely incorporate *on-premise* edge servers (e.g., Microsoft Azure Stack Edge [4], Amazon Outposts [3]) that run in hyper-proximity to cameras (in contrast to traditional edge servers [32, 37, 79, 104]), and possess on-board GPUs to aid video processing. These *edge boxes* are used to complement (or even replace [21, 29]) distant cloud servers by locally performing as many inference tasks on live video streams as

* These authors contributed equally to this work.

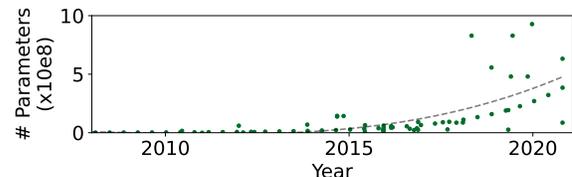

Figure 1: Parameter counts in popular vision DNNs over time. Data drawn from [92].

possible [29, 53, 71, 117]. Generating responses directly on edge boxes reduces transfer delays for shipping data-dense video over wireless links [44, 73, 117] while also bringing resilience to outbound edge-network link failures [7, 80] and compliance with regional data privacy restrictions [77, 85].

To reap the above benefits, video analytics deployments must operate under the limited computation resources offered by edge boxes. On the one hand, due to cost, power, and space constraints, edge boxes typically possess weaker GPUs than their cloud counterparts [4, 21, 95]. On the other hand, analytics deployments face rapidly increasing workloads due to the following trends: (1) more camera feeds to analyze [21, 53, 55], (2) more models to run due to increased popularity and shifts to bring-your-own-model platforms [16, 24, 38, 54], and (3) increased model complexity, primarily through growing numbers of layers and parameters (Figure 1) [15, 56, 57, 108]. Taken together, the result is an ever-worsening resource picture for edge video analytics.

Problems. Although GPU computation resources are holistically constrained on edge boxes, this paper focuses on *GPU memory restrictions*, which have become a primary bottleneck in edge video analytics for three main reasons. First, GPU memory is costly due to its high-bandwidth nature [83, 86, 93], and is thus unlikely to keep pace with the ever-growing memory needs of DNNs (Figure 1). Second, we empirically find that existing memory management techniques that time/space-share GPU resources [26, 39, 50, 56, 94, 110] are insufficient for edge video analytics, resulting in skipped processing on 19-84% of frames, and corresponding accuracy drops up to 43% (§3). The underlying reason is that the costs of loading vision DNNs into GPU memory (i.e., swapping) are prohibitive and often exceed the corresponding inference times, leading to sub-frame-rate (< 30 fps) processing and dropped frames due to SLA violations [94, 114]. Such accuracy drops are unacceptable for important vision tasks, especially given that each generation of vision DNNs brings only 2-10% of accuracy boosts – that after painstaking tuning [22, 52, 64, 98]. Third, compared to computation bottlenecks [29, 39, 40, 60, 71], GPU memory restrictions during inference have been far less explored in video analytics.

Contributions. We tackle this memory challenge by making two main contributions described below. The design and evaluation of our solution are based on a wide range of popular vision DNNs, tasks, videos, and resource settings that reflect workloads observed in both our own multi-city pilot video analytics deployment and in prior studies (§2).

Our first contribution is *model merging*, a fundamentally new approach to tackling GPU memory bottlenecks in edge video analytics that is complementary to time/space-sharing strategies (§4). With merging, we aim to share *architecturally identical* layers across the models in a workload such that only one copy of each shared layer (i.e., one set of weights) must be loaded into GPU memory for all models that include it. In doing so, merging reduces both the number of swaps required to run a workload (by reducing the overall memory footprint) and the cost of each swap (by lowering the amount of new data to load into GPU memory).

Our merging approach is motivated by our (surprising) finding that vision DNNs share substantial numbers of layers that are architecturally (i.e., excluding weights) identical (§4.1). Such commonalities arise not only between identical models (100% sharing), but also across model variants in the same (up to 84.6%) and in different (up to 96.3%) families. The reason is that, despite their (potentially) different goals, vision DNNs ultimately employ traditional computer vision (CV) operations (e.g., convolutions) [22, 64], operate on unified input formats (e.g., raw frames), and perform object-centric tasks (e.g., detection, classification) that rely on common features such as edges, corners, and motion [27, 31, 65, 66, 88, 106, 118, 119].

Our analysis reveals that exploiting these architectural commonalities via merging has the potential to substantially lower memory usage (17.9-86.4%) and boost accuracy (by up to 50%) in practice. However, achieving those benefits is complicated by the fact that edge vision models typically use different weights for common layers due to training nonlinearities [62, 63] and variance in target tasks, objects, and videos; and yet, merging requires using unified weights for each shared layer. Digging deeper, we observe that there exists an *inverse relationship* between the number of shared layers and achieved accuracy during retraining. Intuitively, this is because for shared layers to use unified weights, other layers must adjust their weights accordingly during retraining; the more layers shared, the harder it is for (the fewer) other layers to find weights to accommodate such constraints and successfully learn the target functions [23, 70]. Worse, determining the right layers to merge is further complicated by the fact that (1) it is difficult to predict precisely how many layers will be shareable before accuracy violations occur, and (2) each instance of retraining is costly.

Our second contribution is *Gemel*, an end-to-end system that practically incorporates model merging into edge video analytics by automatically finding and exploiting merging opportunities across user-registered vision DNNs (§5).

Gemel tackles the above challenges by leveraging two key observations: (1) vision DNNs routinely exhibit power-law distributions whereby a small percentage of layers, often towards the end of a model, account for most of the model’s memory usage, and (2) merging decisions are agnostic to inter-layer dependencies, and accordingly, a layer’s mergeability does not improve if other layers are also shared.

Building on these observations, *Gemel* follows an *incremental* merging process whereby it attempts to share one additional layer during each iteration, and selects new layers in a memory-forward manner, i.e., prioritizing the (few) memory-heavy layers. In essence, this approach aims to reap most of the potential memory savings as quickly, and with as few shared layers, as possible. *Gemel* further accelerates the merging process by taking an adaptive approach to retraining that detects and leverages signs of early successes and failures. At the end of each successful iteration, *Gemel* ships the resulting merged models to the appropriate edge servers, and carefully alters the time/space-sharing scheduler – a merging-aware variant of Nexus [94] in our implementation – to maximize merging benefits, i.e., by organizing merged models to reduce the number of swaps, and the delay for each one. Importantly, *Gemel* verifies that merging configurations meet accuracy targets *prior* to deployment at the edge, and also periodically tracks data drift.

Results. We evaluated *Gemel* on a wide range of workloads and edge settings (§2, §6.3). Overall, *Gemel* reduces memory requirements by up to 60.7%, which is 5.9-52.3% more than stem-sharing approaches that are fundamentally restricted to sharing contiguous layers from the start of models (Mainstream [59]), and within 9.3-29.0% of the theoretical maximum savings (that disregard layer weights). These memory savings lead to 13-44% fewer skipped frames and overall accuracy improvements of 8-39% compared to space/time-sharing GPU schedulers alone (Nexus [94]). Source code and datasets for *Gemel* are available at https://github.com/artpad6/gemel_nsd23.

2 Methodology & Pilot Study

We begin by describing the workloads used in this paper. They were largely derived from our experience in deploying a pilot video analytics system in collaboration with two major US cities (one per coast), for road traffic monitoring.

Models and tasks. In line with other video analytics frameworks [16, 24, 38, 54], users in our deployment provided pre-trained models when registering queries to run on different video feeds. Due to the complexity of model development, we observe that users opt to leverage existing (popular) architectures geared for their target task (e.g., YOLOv3 for object detection), and train those models for specific object(s) of interest and datasets (e.g., detecting vehicles at Main St.) to generate a unique set of weights. Despite being allowed, custom architectures were never provided in our deployment.

Accordingly, we selected the 7 most popular families of models across our pilot deployment and recent literature [21, 26, 49, 50, 53, 59–61, 71, 109]: YOLO, Faster RCNN, ResNet, VGG, SSD, Inception, and Mobilenet. From each family, we selected up to 4 model variants (if available) that exhibit different degrees of complexity and compression. For instance, from YOLO, we consider {YOLOv3, Tiny YOLOv3}; similarly, we consider ResNet{18, 50, 101, 152}. The selected models focus on two tasks – object classification and detection – and for each, we train different versions for all combinations of the following objects: people and vehicles (e.g., cars, trucks, motorbikes). Classification and detection accuracy are measured using F1 and mAP [36].

Videos. Our dataset consists of video streams from 12 cameras in our pilot deployment that span two metropolitan areas. From each region, we consider cameras at adjacent intersections, and those spaced farther apart within the same metropolitan area; this enables us to consider different edge box placements, i.e., at a traffic intersection vs. further upstream to service a slightly larger geographic location. From each stream, we scraped 120 minutes of video that cover 24-hour periods from four times of the year.

Edge boxes. Our review of on-premise edge boxes focused on 5 commercial offerings: Microsoft Azure Stack Edge [4], Amazon Outposts [3], Sony REA [97], NVIDIA Jetson [8], and Hailo Edge-AI-box [43]. These servers each possess on-board GPUs and offer 2-16 GB of total GPU memory. Since edge inferences do not typically span multiple GPUs, we focus on model merging and inference scheduling *per GPU*. This does not restrict Gemel to single-GPU settings; rather, it means that our merging and scheduling techniques are applied separately to the DNNs in each GPU, with the assumption that each merged model runs on only one GPU.

Workload construction. Recent works highlight that 10s of videos are usually routed to each edge box [13, 53], which runs upwards of 10 queries (or DNNs) on each feed [16, 21]. Our experience was similar: it was typical to direct the max possible number of feeds to an edge box, with the goal of *minimizing the number of edge boxes required to process the workload*. To cover this space, and since we focus on per-GPU inference optimization, we generated an exhaustive list of all possible workloads sized between 2-50 DNNs using the models above. We then sorted the list in terms of the potential (percentage) memory savings (using the methodology from §4), and selected 15 workloads: 3 random workloads from the lower quartile (i.e., *Low Potential (LP1-3)*), 6 from the middle 50% (i.e., *Medium Potential (MP1-6)*), and 6 from the upper quartile (i.e., *High Potential (HP1-6)*). We chose this ratio to match that from our deployment. MP and HP workloads each constituted 30-50% of the total workloads since (1) users tended to employ the same few model variants from a limited set of popular families, and (2) each user typically used the same architecture (but not weights) for different feeds in a region. LP workloads were less com-

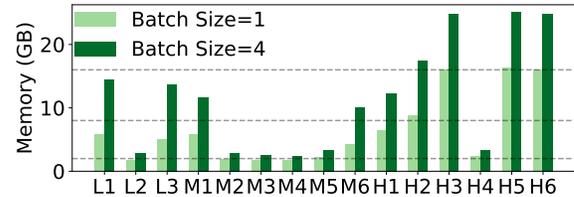

Figure 2: Per-workload memory requirements for two popular batch sizes used in video analytics [94]. Dashed lines represent the available GPU memory on several commercial edge boxes.

mon (<20%), and arose from different users opting for different model families.

Each workload was randomly assigned to one of the cities, with the constituent models being randomly paired with the available videos. The extended version [82] details the workloads, each of which exhibits heterogeneity in terms of the families, tasks, videos, and (combinations of) target objects. In summary, the workloads contain 3-42 queries (avg: 15) across 3-7 video feeds (avg: 5), featuring 2-10 unique models (avg: 6) and 2-5 different objects (avg: 4). We consider additional workloads, models, objects, and videos in §6.3.

Result presentation. End-to-end accuracy depends on the available GPU memory. However, each workload requires a different minimum amount of memory to run, i.e., the GPU should be able to load/run the most memory-intensive model in isolation for a batch size of 1. Further, the memory needed to avoid swapping (i.e., to load all models and run one at a time) also varies per workload; we call this *no_swap*. To ensure comparability across all presented accuracy results and to focus on memory-bottlenecked scenarios, we assign each workload three memory settings to be evaluated on (listed in [82]): (1) the minimum value (*min*), (2) 50% of the *no_swap* value (*50%*), and (3) 75% of the *no_swap* value (*75%*).

3 Motivation

3.1 Memory Pressure in Edge Video Analytics

To run inference with a given model, that model’s layers and parameters must be loaded into the GPU’s memory, with sufficient space reserved to house intermediate data generated while running, e.g., activations. The amount of data generated (and thus, memory consumed) during inference depends on both the model architecture and the batch size used; a higher batch size typically requires more memory.

Figure 2 shows the total amount of memory (i.e., for both loading and running) required for each of our workloads and two batch sizes; the listed numbers exclude the fixed memory that ML frameworks reserve for operation, e.g., 0.8 GB for PyTorch [18]. As shown, many workloads do not directly fit into edge box GPUs, and the number of edge boxes necessary to support a given workload can quickly escalate. For instance, even with a batch size of 1 frame, 73% of our workloads need more than one edge box possessing 2 GB of GPU memory; with a batch size of 4, 60% and 27% require more than one edge box with 8 GB and 16 GB of memory.

Model	Load Memory (Time)	Run Memory (Time)		
		BS=1	BS=2	BS=4
YOLOv3	0.24 (49.5)	0.52 (17.0)	0.73 (24.0)	1.22 (39.9)
ResNet152	0.24 (73.3)	0.65 (24.8)	0.98 (26.3)	1.71 (26.7)
ResNet50	0.12 (27.1)	0.35 (8.4)	0.50 (8.5)	0.84 (8.5)
VGG16	0.54 (72.2)	0.74 (2.1)	0.89 (2.4)	1.18 (2.4)
Tiny YOLOv3	0.04 (6.7)	0.15 (3.0)	0.18 (5.2)	0.24 (5.2)
Faster RCNN	0.73 (117.3)	3.70 (115.4)	6.96 (210.1)	12.47 (379.4)
Inceptionv3	0.12 (11.8)	0.19 (9.1)	0.23 (9.1)	0.34 (9.1)
SSD-VGG	0.11 (16.1)	0.23 (16.5)	0.33 (25.7)	0.51 (44.6)

Table 1: Memory (GB) and time (ms) requirements for loading/running inference with 3 different batch sizes (in frames). Run memory values include load values, but exclude memory needs of serving frameworks. Results use a Tesla P100 GPU.

Table 1 breaks this memory pressure down further by listing the amount of loading and running memory required for representative models in our workloads. When analyzed in the context of the scale of edge video analytics workloads, the picture is bleak, even with a batch size of 1. For example, a 2 GB edge box can support only 1, 2, or 3 VGG16, YOLOv3, or ResNet50 models, respectively, after accounting for the memory needs of the serving framework. Moving up to 8 and 16 GB edge boxes (of course) helps, but not enough, e.g., an 8 GB box can support 13 YOLOv3 or 2 Faster RCNN models, both of which are a drastic drop from the 10s of models that workloads already involve (§2).

3.2 Limitations of Existing GPU Memory Management

Space and time sharing. Existing learning frameworks recommend model allocation at the granularity of an entire GPU [56]. Space-sharing techniques [14, 17] eschew this exclusivity and partition GPU memory per model. Although space-sharing approaches are effective when a workload’s models can fit together in GPU memory, they are insufficient when that does not hold, which is common at the edge (§3.1)

There are two natural solutions when a workload’s models cannot fit together in the target GPU’s memory. The first is to place models on *different* GPUs [39, 94], which resource-constrained edge settings cannot afford. The second is to *time share* the models’ execution in the GPU by *swapping* them in and out of GPU memory (from CPU, via a PCIe interface) [26, 39, 50, 94, 110]. However, as we will show next, time-sharing techniques are bottlenecked by frequent model swapping, which severely limits their utility. More recently, SwapAdvisor [50] and Antman [110] proposed swapping at finer granularities, e.g., individual or a few layers. However, even these approaches are limited in our case because a handful of layers in vision DNNs typically account for most memory usage (§5.2); edge boxes often lack the GPU memory to concurrently house even these expensive singular layers.

We evaluated time-sharing strategies in our setting by considering a hybrid version that *packs* models into GPU memory, and executes as many models as possible while ensuring that swapping costs for the next model to run are hidden. Concretely, we extend Nexus [94] to incorporate such pipelining. Our variant first organizes models in round-robin

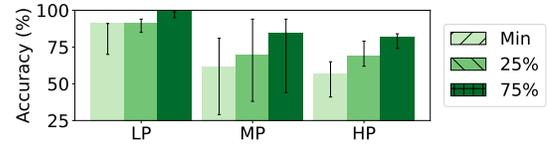

Figure 3: Achieved accuracy with time/space-sharing alone (i.e., using our Nexus variant) for different memory availability (following the definitions in §2). Bars list results for the median workload in each class, with error bars spanning min to max.

order (as Nexus does), and profiles the workload offline to determine the best global list of per-model batch sizes that maximizes the minimum achieved per-model throughput while adhering to an SLA (i.e., a per-frame processing deadline). Using those batch sizes, the scheduler traverses the round robin order with the goal of minimizing GPU idle time: when loading the next model, if there does not exist sufficient memory to load both parameters and intermediates, the most recently run model (i.e., the one whose next use is in the most distant future) is evicted to make space.

Figure 3 shows the accuracy of the Nexus variant on our workloads with an SLA of 100 ms; we saw similar trends for other common SLAs in video analytics [94]. As shown, accuracy drops are substantial, growing up to 43% relative to a setting when there exists sufficient memory to house all models at once. The root cause is the disproportionately high loading times of vision DNNs that must be incurred when swapping. As shown in Table 1, per-model loading delays are 0.98-34.4× larger than the corresponding inference times (for batch size 1). When facing the strict SLAs of video analytics, these loading costs result in the inability to keep pace with incoming frame rates, and thus, dropped (unprocessed) frames; the Nexus variant skipped 19-84% of frames.

Predicting workload characteristics. Another approach is to selectively preload models based on predictions of the target workload [115], e.g., deprioritizing inference on streams at night due to lack of activity. However, in edge video analytics, spatial correlation between streams results in model demands being highly correlated [55, 60, 71, 76].

Compression and quantization. These techniques generate lighter model variants that impose lower memory (and compute) footprints and deliver lower inference times. Some families offer off-the-shelf compressed variants (e.g., Tiny YOLOv3), and techniques such as neural architecture search can be used to develop cheaper variants that are amenable to deployment constraints [40]. Regardless, in reducing model complexity, these cheaper model variants typically sacrifice accuracy and are more susceptible to drift, relative to their more heavy-weight counterparts [21, 100]; consequently, determining the feasibility of using such models in a given setting requires careful tuning and analysis by domain experts.

We consider compression and quantization as orthogonal to merging for two reasons. First, in common workloads that involve a mix of models and tasks (§2), it may not be possible to compress all of the models while delivering sufficient

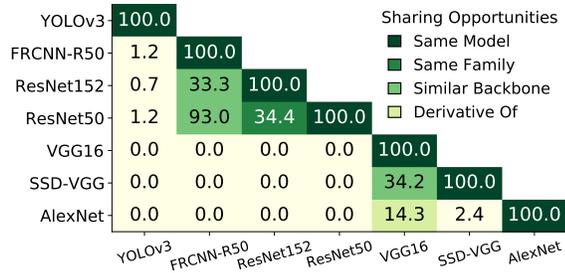

Figure 4: Percentage of architecturally identical layers across different model pairs. See Figure 20 for an extended version.

accuracy. However, even a handful of non-compressed models can exhaust the available GPU memory (§3.1). Second, compressed models exhibit sharing opportunities: our workloads include compressed and non-compressed models (§2), and our results show that Gemel is effective for both (§6).

4 Our Approach: Model Merging

To address the high model loading costs that plague existing memory management strategies when workloads cannot fit together in a GPU’s memory (§3.2), we propose *model merging*. Merging is complementary to time/space sharing of GPU memory, and its goal is straightforward: share layers across models such that only one copy of each shared layer (i.e., layer definition and weights) must be loaded into GPU memory and can be used during inference for all of the models that include it. The benefits are two-fold: (1) reduce the overall memory footprint of a workload, thereby enabling edge boxes to house more models in parallel and perform fewer swaps (or equivalently, lower the number of edge boxes needed to run the workload), and (2) accelerate any remaining swaps by reducing the amount of extra memory that the next model to load requires. Note that merging does not involve sharing intermediates (i.e., layer outputs) for a common layer because models may run on different videos (and thus, inputs). We next highlight the promise for merging in edge video analytics (§4.1), and then lay out the challenges associated with realizing merging in practice (§4.2).

4.1 Opportunities

Commonality of layers. A layer is characterized by both its architecture and its weights. In ML frameworks (e.g., PyTorch, TensorFlow), the architecture is defined by first specifying a layer type (e.g., convolutional, linear, batch normalization), which in turn indicates how the layer transforms inputs, and dictates the set of defining parameters that must be specified (e.g., convolutional: kernel, stride, etc., linear: # of input features, bias, etc.). A layer’s weights are a matrix of numbers whose dimensions match the layer structure. To successfully share a layer across a set of models, that layer must be *architecturally* identical in each model, but its weights need not be the same across appearances.

Architectural equivalence is determined directly from the model definition in the ML framework (i.e., no inference re-

quired): the layers must be of the same type, with identical values for type-specific properties. Using this approach, we studied pairs of 24 different models to identify and analyze layers with identical architectures; Figure 20 presents our comprehensive results. Below, we summarize our findings; Figure 4 lists results for representative model pairs.

Model pairs fall into one of three categories: (1) instances of the same model, (2) different models in the same family (e.g., ResNet variants), and (3) different models in different families. Multiple instances of the same model unsurprisingly match on every layer; this favorable scenario is not uncommon in edge video analytics, as several model architectures tend to dominate the landscape [20] and a given model can be employed on different video feeds or in search of different objects (§2). More interestingly, we also observe sharing opportunities across different models from the same (up to 84.6%) and divergent (up to 96.3%) families.

Models within the same family exhibit significant sharing opportunities as larger variants are typically extended versions of the original base model. For instance, ResNet models share ResNet blocks (groups of 2-3 convolutional layers) that are repeated at different frequencies, as well as the first convolutional layer and final fully-connected layer. As a result, all 41 layers of ResNet18 are shared with ResNet34 (Figure 19). Similarly, in the VGG family, models share the exact same base architecture and add different numbers of convolutional layers, e.g., VGG19 shares all 16 of VGG16’s layers (13 convolutional, 3 fully-connected; Figure 5 (left)).

Sharing for models in different families comes in two main forms: (a) ‘similar backbones’ and (b) ‘derivatives of.’ Scenario (a) includes pairs of detectors that use the same (or similar) backbone networks for feature extraction, e.g., SSDs that use any VGG backbone, or FasterRCNNs that use any ResNet backbone. (a) also includes pairs of classifiers and detectors where the classifier (or a variant) is used as the detector’s backbone. For instance, every layer in the ResNet50 backbone of FasterRCNN (which constitutes 51% of the detector’s layers) appears in the ResNet101 classifier. Similar examples include SSD-VGG with any VGG variant, and SSD-MobileNet with MobileNet. Scenario (b) involves cases where one model family was derived directly from another. For example, VGG was developed by replacing AlexNet’s large kernels with multiple smaller ones [96]; VGG16 and AlexNet share 3 out of 16 layers, including 2 fully-connected layers at the end (Figure 5 (right)). Other examples include InceptionNetV3 [102] with GoogLeNet [101].

In summary, 43% of all pairs of different models present sharing opportunities. Of those with substantial ($\geq 10\%$) common layers, 51% have models in the same family, while 49% involve models from different families; for the latter, 76% are ‘similar backbones’ and 24% are ‘derivatives of.’

These layer similarities generally follow from the fact that the considered models are all vision processing DNNs. That

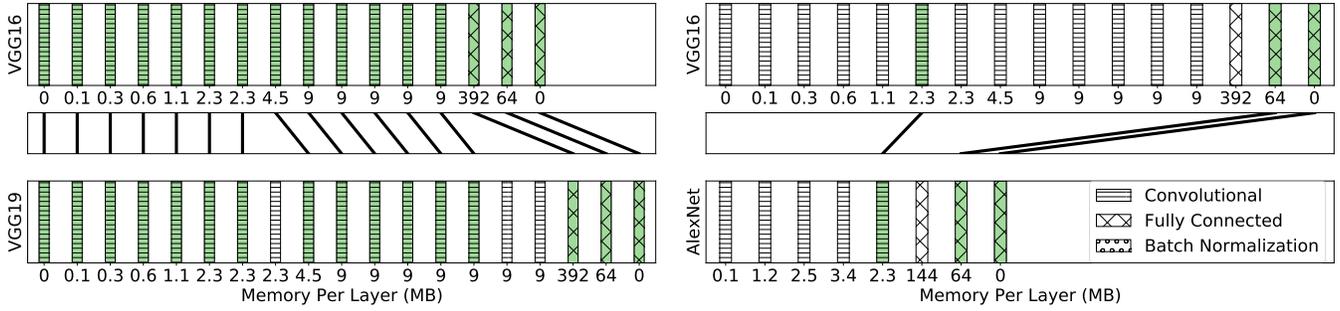

Figure 5: Sharing opportunities between VGG16 and VGG19 (left), and VGG16 and AlexNet (right).

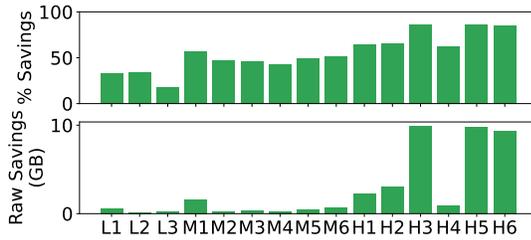

Figure 6: Potential memory savings when all architecturally identical layers are shared across the models in each workload.

is, they all ingest pixel representations of raw images, and employ a series of traditional CV operations [22, 64], e.g., a convolutional layer is applying a learned filter to raw pixel values in preparation for downstream processing. Moreover, the target tasks are rooted in identifying and characterizing objects in the scene using low-level CV features such as detected edges and corners [27, 49, 65, 66, 71, 118, 119].

Prior work has capitalized on such similarities for efficient multi-task learning [30, 59, 112] and architecture search [75, 84]. Those efforts aim to reduce computation overheads by sharing “stems” of models, i.e., contiguous layers (and their generated intermediates) starting from the beginning of the models. In contrast, we aim to exploit architectural similarities to reduce memory overheads via merging. As a result, merging only requires layer definitions and weights to be shared, but not generated intermediate values. This distinction is paramount because, as we will discuss in §5.2, memory-heavy layers typically reside towards the end of vision DNNs. Consequently, stem sharing would require almost all model layers to be shared to reap substantial memory savings, which in turn brings unacceptable accuracy drops (§4.2 and §6). Merging, on the other hand, can share only those memory-heavy layers to simultaneously deliver substantial memory savings and preserve result accuracy.

Potential memory savings and accuracy improvements. Figure 6 shows the memory savings from sharing all of the common layers across the models in each of our workloads; this represents an *upper bound* on merging benefits as it disregards the challenge of identifying an acceptable set of weights per shared layer (§4.2). As shown, the memory savings are substantial: per-workload memory usage dropped

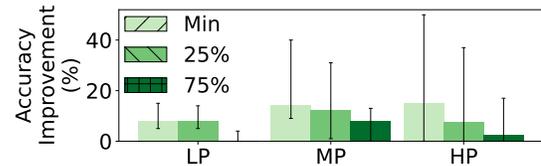

Figure 7: Potential accuracy improvements when sharing all architecturally identical layers. Memory availability is defined in §2, bars list medians, and error bars span min to max.

by 17.9-86.4% relative to no merging, translating to raw savings of 0.2-9.9 GB. Importantly, these savings result in 2 and 4 new workloads fitting entirely (no swapping) on edge boxes with 2 GB and 8 GB of GPU memory (with batch size 1). Similarly, the number of 2 GB edge boxes needed to support each workload drops from 1-9 to 1-4. We further evaluated the resulting impact on end-to-end accuracy by comparing the performance of the Nexus variant from §3.2 when run on workloads with and without (maximal) merging. Models in both cases were ordered in the same way, to maximize the benefits of merging (§5.4). As shown in Figure 7, merging can boost accuracy by up to 50% across our workloads. These benefits are a direct result of lower swapping costs, and the resulting ability to run on 29-61% more frames.

4.2 Challenges

Merging layers for memory reductions requires using shared weights across the models in which those layers appear. However, those shared weights must not result in accuracy violations for any of the models, despite their potentially different architectures/tasks, target objects/videos, etc.; such accuracy drops would forego merging benefits from faster swapping. Concretely, there are two core challenges in practically exploiting the architectural commonalities from §4.1.

Challenge 1: sharing vs. accuracy tension. To maximize memory savings, merging seeks to share as many architecturally identical layers as possible across a workload’s models. However, we observe that accuracy degradations steadily grow as the number of shared layers increases. Figure 8 illustrates this trend by sharing different numbers of identical layers across representative pairs of models that vary on the aforementioned properties, e.g., tar-

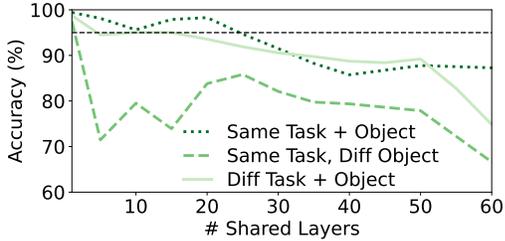

Figure 8: Accuracy after 5 hours of retraining when sharing additional architecturally-identical layers for different model pairs (starting from their origins). Tasks cover detection (Faster RCNN) and classification (ResNet50), and two objects: people, vehicles. Results list the lower per-model accuracies per pair.

get task. These results were obtained when we increase the number of shared layers by moving from start to end in the considered models, but similar trends are observed for other selection strategies (e.g., random) and models.

The reason for this behavior is intuitive: the retraining performed to assess the feasibility of a sharing configuration is *end-to-end* across the considered models. During this process, weights are being tuned for all of the layers in all of the models, with the constraint being that the shared layers each use a unified set of weights. Sharing more layers has three effects: (1) more constraints are being placed on the training, (2) it is harder to find weights for (the shrinking number of) unshared layers that simultaneously accommodate the growing constraints, and (3) learning each model’s desired function becomes more difficult as there exist fewer overall parameters to tune [23, 70]. It is for these reasons that isolated merging strategies such as averaging weights across copies of each shared layer (while keeping other layers unchanged) do not suffice; we find that sharing even single layers in this way almost always results in unacceptable accuracy dips.

Digging deeper, the issue stems from non-convex optimization of DNNs, which leads to several equally good global minima [62, 63]. Thus, training even two identical models on the same dataset, and for the same task/object, often results in divergent weights across each layer, despite the resultant models exhibiting similar overall functionality.

Challenge 2: retraining costs. The retraining involved in determining whether a set of layers to share can meet an accuracy target, and if so, the weights to use, can be prohibitively expensive. For instance, each epoch when jointly retraining two Faster RCNN models that detect cars at nearby intersections (i.e., a simple scenario) took ≈ 35 mins, and different combinations of layer sharing required between 1-10 epochs to converge. These delays grow as more models are considered since training data must reflect the behavior of all of the unmerged models that are involved, e.g., by using the original training datasets for each of those models. Worse, it is difficult to know, a priori, which sharing configurations can meet accuracy targets (and which will not) in a reasonable time frame. For example, the model pairs in Figure 8 have largely different ‘breaking points.’ The result

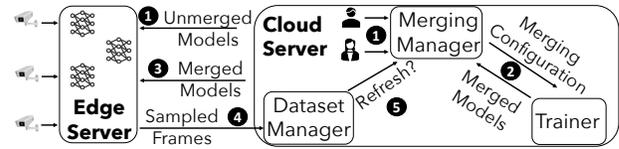

Figure 9: Gemel architecture.

also fails to support the use of intuitive trends to predict the success of sharing configurations: models targeting the same task or object do not exhibit any discernible advantage.

5 Gemel Design

Gemel is an end-to-end system that practically integrates model merging into edge video analytics pipelines by addressing the challenges in §4.2. We first provide an overview of Gemel’s operation, and then describe the core observations (and resulting optimizations) that it leverages to enable timely merging without violating accuracy requirements.

5.1 Overview

Figure 9 shows Gemel’s cloud merging and edge inference workflows. As in existing pipelines [16,60,71], users register inference tasks (or “queries”) at Gemel’s cloud component by providing a DNN, and specifying the input video feed(s) to run on as well as the required accuracy for the results. Upon receiving new queries, Gemel bootstraps edge inference by sending unaltered versions of the registered models to the appropriate edge box(es) ①. When GPU memory is insufficient to house all of those models, edge boxes run the Nexus variant from §3.2 that pipelines inference and model loading to maximize the min per-model throughput.

After initiating edge inference, Gemel’s cloud component begins the merging process, during which it *incrementally* searches through the space of potential merging configurations across the registered models, and evaluates the efficacy of each configuration in terms of both its potential memory savings and its ability to meet accuracy requirements ②. The evaluation of each configuration involves joint retraining and validation of the models participating in merging. Since Gemel’s goal is to ensure that the retrained models deliver sufficient accuracy (relative to the originals) on the target feeds, data for these tasks can be obtained in one of two ways: users can supply the data used to train the original models, or Gemel can automatically generate a dataset by running the supplied model (or a high-fidelity one [60, 116]) on sampled frames from the target feed.

At the end of each merging iteration, if the considered configuration was successfully retrained to meet the accuracy targets for all constituent models, Gemel shares the updated merged models with the appropriate edge boxes ③. New merging results may result in altered edge inference schedules to maximize merging benefits for reducing swapping costs and boosting inference throughput. The iterative merging process for the current workload then continues until (1) the cloud resources dedicated to merging have been ex-

pended, (2) no configurations that can deliver superior memory savings are left to explore, or (3) models with sharing opportunities are either newly registered or deleted by users.

Gemel periodically assesses *data drift* for its merged models. As in prior systems [71, 100], edge servers periodically send sampled frames (and their inference results, if collected) to Gemel’s cloud component 4. These sampled frames are used to augment the datasets considered for re-training merged models, and to track the accuracy of recent results generated at the edge by deployed merged models. For the latter, Gemel runs the original user models on the sampled videos and compares the results to those from the merged models. If accuracy is below the target for any query, Gemel reverts edge inference to use the corresponding original (unmerged) models, and resumes merging and retraining, starting with the previously deployed weights 5.

Implementation. Gemel uses PyTorch [18] to manage cloud merging and edge inference, and is implemented in ≈ 3500 LOC. More details are presented in A.1.

5.2 Guiding Observations

Two key empirical observations guide Gemel’s approach to tackling the challenges in §4.2. We describe them in turn.

Observation 1: power-law memory distributions. We find that vision DNNs commonly exhibit power-law distributions in terms of memory usage, whereby a few “heavy-hitter” layers account for most of the overall model’s memory consumption. Figure 10 illustrates this, showing that for 80% of considered models, 15% of the layers account for 60-91% of memory usage. For example, a single layer in VGG16 is responsible for 392 MB (the entire model is 536 MB) and corresponds to the steep slope around the $x=80\%$ mark. Similarly, Tiny YOLOv3 has three layers (around the 38%, 45%, and 65% marks) that together use 35 MB of its total 42 MB.

Heavy-hitter layers come in one of two forms. The first are the convolutional layers at the end of the feature extractor that condense the numerous low-level features extracted by prior layers (e.g., shapes, colors) into higher-level, more abstract features (e.g., eyes, nose). The second are the subsequent fully-connected layer(s) that learn more robust patterns from all possible combinations of those high-level features, e.g., eyes, nose, and fur might each suggest a dog, but the combination is a stronger indicator. Note that models generally include one such fully-connected layer per sub-task, e.g., detectors have one for finding bounding boxes and one for classifying objects. Memory-heavy fully-connected layers are spatially close to one another (within a few layers), and are usually followed by 1-2 cheap fully-connected layers that extract predictions from the final feature vector.

The main exception is ResNet, whose models use residual layers to address accuracy saturation limitations of prior deep models [47]. ResNet models have memory-heavy ResNet blocks (set of convolutional layers) that repeat at varying frequencies, thereby distributing memory more

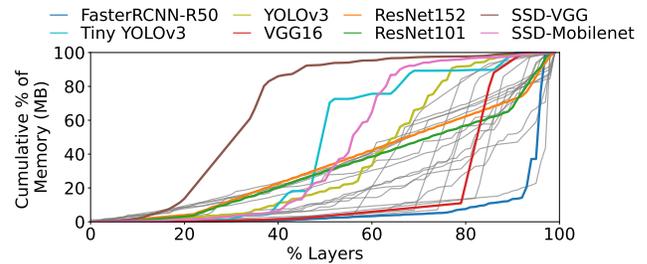

Figure 10: Cumulative memory consumed by each model’s layers moving from start to end of the model. §A.4 has full legend.

evenly across the models, e.g., ResNet101 and ResNet152 repeat the same ResNet block 23 and 36 \times , leading to gradual slopes in Figure 10. DenseNet has the same pattern [51].

Figure 10 also shows that heavy-hitter layers most often appear in the latter half of a model’s architecture (since both forms involve condensing features from earlier layers), complicating the use of stem sharing for memory savings (§4.2). For example, Faster RCNN’s expensive fully-connected layers fall at layers 101 and 104 out of 106, and together account for 76% of total memory. The few cases with heavy-hitters in the middle of a model (between the 20-60% marks) are “single-shot” detectors (SSD-VGG, SSD-Mobilenet, Tiny YOLOv3, YOLOv3) that find bounding boxes and classify objects at once, rather than as disparate subtasks. These models replace the few memory-heavy fully-connected layers (for those subtasks) with many cheaper convolutional layers; doing so extends model lengths and shifts the large jump from memory-heavy *feature extractor* layers to earlier.

These observations have two implications on merging. First, strategies can reap most potential memory benefits by targeting the few heavy-hitter layers in models. Thus, the tension between memory savings and accuracy is far more favorable than that between the number of shared layers and accuracy (Figure 8). Second, strategies should be agnostic to the position of heavy hitters in models, and must support the common case where heavy hitters appear towards the end.

Observation 2: independence of per-layer merging decisions. In DNNs, layers are configured based on input formats, target task, execution time, etc. Hence, a natural assumption is that the ability to share any one layer is dependent on sharing decisions for other layers, e.g., a layer may be shareable if and only if other layers are shared. Prior work has highlighted that inter-layer dependencies primarily arise between neighboring layers, e.g., with transfer learning, performance drops are largest when splitting neighboring layers [112]. Thus, to determine the existence of layer-wise dependencies as it pertains to merging, we focus our analysis on (potential) dependencies between neighboring layers; we also consider other layers via random selection. Using the 25% most memory-heavy layers for each model in our workloads, we test whether accuracy targets are met under different sharing configurations (described in Table 2).

	Only Alone	Only Alternate	Both	Neither
1 Each Side	1.1%	0.0%	97.6%	1.3%
2 Each Side	3.7%	0.0%	95.0%	1.3%
Random	8.5%	0.0%	90.2%	1.3%

Table 2: Sharing a layer alone vs. *alternate* approaches (sharing a layer with one or two neighbors on each side, or with 3 random sets of 1-10 layers). Results are % of runs that meet accuracy targets (aggregated across 80, 90, 95%), and list cases where the layer alone met but an alternate did not, an alternate met but the layer alone did not, both met, and neither met.

As shown, we *never* observe a case where a layer is unable to meet an accuracy target on its own, but it is able to meet the accuracy target when some other layers are also shared (shaded row in Table 2). This is consistent with our finding that sharing more layers leads to larger accuracy degradations (Figure 8) since additional constraints are placed on the weights for those layers, and fewer (unconstrained) non-shared layers exist to help satisfy the constraints. The implication is that layers can be considered independently during merging without harming their potential merging success.

Takeaway. Collectively, these observations motivate an incremental merging process (detailed in §5.3) that attempts to share one new layer at a time, and prioritizes heavy-hitter layers that consume the most memory (and are thus the most fruitful to share). In this manner, memory-heavy layers are considered in the most favorable settings (i.e., with the fewest other shared layers), and each increment only modestly adds to the likelihood of not meeting accuracy targets.

Note. Despite arising across our diverse workloads, these observations are not guarantees. Importantly, violation of these observations only results in merging delays (inefficiencies), but not accuracy breaches; accuracy is explicitly vetted prior to shipping merged models to the edge for inference.

5.3 Merging Heuristic

Gemel begins by enumerating the layers that appear in a workload, and annotating each with a listing of which models the layer appears in (and where) and the total memory it consumes across the workload; we refer to all appearances of a given layer as a ‘group.’ Gemel then sorts this list in descending order of memory consumption, e.g., a 100 MB layer that appears in 4 models would be earlier than a 120 MB layer that appears 3 times. Thus, memory-heavy groups, or those that would yield the largest memory savings if successfully merged, are towards the start of the list.

Gemel then maintains a running merging configuration, and simultaneously merges and trains layers across models in an *incremental* fashion. To begin, Gemel selects the first group from the sorted list (i.e., the one that consumes the most memory in the workload) and attempts to share it across all of the models in which it appears; this group is added to the running configuration. While a subset of models could be considered instead, Gemel aggressively opts to first try sharing across all models in the group, and then to selectively remove appearances of the layer when the resulting accuracy

is insufficient. The reason is that we did not observe any model clustering strategies (e.g., based on task) that identified models consistently unable to share layers.

To retrain and merge the current running configuration, Gemel selects initial weights for the newly added group from a random model that includes that layer. We tried selecting weights from each model (including the one with the highest accuracy) but found no difference in the # of epochs needed to meet accuracy. We also tried default initialization techniques (e.g., Kaiming [48]), which led to lower accuracy. Retraining continues until the merged models each meet their accuracy targets, or a preset time budget elapses (10 epochs by default). If retraining is successful, Gemel adds the next group in the sorted list to the running configuration, and resumes retraining from the weights at the end of the previous iteration. The generated merged models are sent to the edge box and incorporated into edge inference (§5.4).

If retraining is not successful at the end of an iteration, Gemel must decide whether to prune layers from the current group and try again, or to discard the group altogether and move on to the next one in the sorted list. To do this, Gemel follows a strategy that aims to balance fast memory savings and avoidance of unsuccessful training rounds, with priority on the latter since failures can consume 3-10 epochs (each up to 30 min) and provide no new memory savings. Specifically, recall that each time a new group is considered, the number of shared layers in the merging configuration grows by the size of the group. To counter this ‘additive increase,’ upon unsuccessful retraining, Gemel halves the current group, eliminating half of the layer appearances. If the resulting layer appearances consume more memory than the next group, Gemel considers those layers; else, Gemel removes the current group from the running policy, and moves to the next one. In either case, retraining resumes from the weights at the end of the last successful iteration. We compare against alternate merging heuristics in §6.2.

Accelerating retraining. Each iteration requires Gemel to run retraining over many epochs, and validate the results accuracy-wise. To accelerate training and validation, Gemel takes an adaptive approach. During validation, as per-model accuracy values approach their targets, it is often unnecessary to train further on full epochs of data. Instead, Gemel reduces the training data once the accuracy is within a pre-defined threshold of the target. Specifically, Gemel reduces the amount of data so it is inversely proportional to the gap in accuracy normalized by the lift since the previous training. Reducing data on such *early success* directly translates to lower training times. Similarly, Gemel detects *early failures* by looking at the validation results and removing models that are not improving at the same pace as the others after some time (3 epochs by default). We empirically observe that early success and early failure detection drastically (28% on average) reduces retraining times.

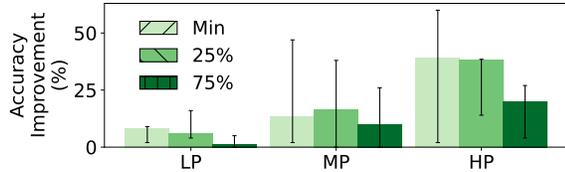

Figure 11: Accuracy improvements with Gemel compared to time/space-sharing alone for different GPU memories (defined in §2). Bars list median workloads, with error bars as min-max.

5.4 Edge Inference

Upon receiving a new set of merged models from Gemel’s cloud component, an edge server quickly incorporates those models into its inference schedule. However, to ensure that merging benefits are maximized, the schedule is altered to reduce the amount of data that must be loaded across the anticipated swaps. During the offline profiling Nexus uses to select per-model batch sizes, Gemel estimates per-workload-iteration swapping delays based on per-model computation costs and swapping delays (both influenced by merging). The idea is that, when merging is used, in addition to ordering models to reduce the number of swaps, models that share the most layers should be placed next to one another in the load order. This lowers the cost of each swap by enabling finer-grained swapping, where only those layers in the next model that are not already in GPU memory must be loaded.

More generally, all schedulers will reap merging benefits in the event that Gemel enables a workload to entirely fit on an edge box (without swapping). Additional benefits depend on the specific scheduler. For schedulers that employ a statically-configured load order [81, 94], Gemel can directly modify the schedule as described above to maximize benefits. Other schedulers [39] dynamically select the load order to optimize for a certain metric. Such schedulers typically incorporate model loading times when estimating the efficacy of different orders, and thus would naturally factor in the effects of merging per swap. Note that merging benefits would be considered in the context of meeting the optimization metric(s) rather than minimizing global loading delays (as in Gemel’s Nexus variant). Lastly, schedulers that ignore load times in favor of policies such as FIFO [105] or priority scheduling [111] will only see merging-induced reductions in loading costs if merged models are (by chance) neighbors in the order. Note that finer-grained [50, 110] and space-sharing [9, 14, 17, 21] schedulers follow the same principles: shared layers should be adjacent in the load orders for the former, while models with the most shared layers should be placed in the same GPU partition for the latter.

6 Evaluation

We primarily evaluated Gemel across the diverse workloads and settings from §2. Our key findings are:

- Gemel improves per-workload accuracies by 8-39% compared to time/space-sharing strategies alone; these im-

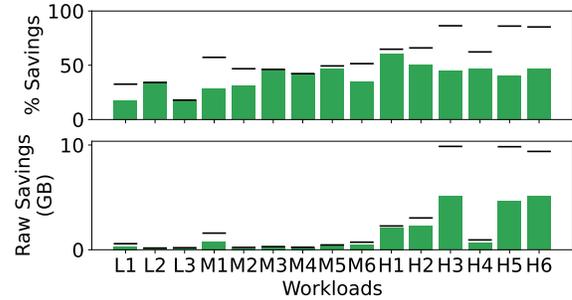

Figure 12: Gemel’s per-workload memory savings. Lines above bars show the theoretical optimal savings from Figure 6.

provements result from Gemel processing 13-44% more frames (while adhering to SLAs).

- Gemel lowers memory needs by 17.5-60.7% (0.2-5.1 GB); savings are 5.9-52.3% more than Mainstream [59] (stem sharing), and within 9.3-29.0% of an optimal that ignores weights (and accuracy drops) when sharing layers.
- More than 70% of Gemel’s memory savings are achieved within the first 24-210 minutes of merging+retraining due to its incremental merging heuristic.

6.1 Overall Performance

End-to-end Accuracy Improvements. We first compare Gemel with time/space-sharing solutions alone, i.e., the Nexus variant running with only unmerged (original) models. Our experiments consider all workloads and resource settings from §2, a per-frame processing SLA of 100 ms, and an accuracy target of 95%; trends hold for other accuracy targets and SLAs, which we consider in §6.2.

Figure 11 presents our results, showing that Gemel improves accuracy by 8.0%, 13.5%, and 39.1% for the median LP, MP, and HP workloads, respectively, when the edge box GPU’s memory is just enough to load and run the largest model in each workload, i.e., the *min* setting. The origin of these benefits is Gemel’s ability to reduce the time blocked on swapping delays by 17.9-84.0%, which enables processing on 13-44% more frames than without merging.

Our results highlight two other points. First, Gemel’s benefits are highest for workloads that are most significantly bottlenecked by memory restrictions (and thus loading costs). For instance, workloads HP1 and LP1 exhibit largely different memory vs. computation profiles: loading costs are 66% of computation costs in the former, but only 15% in the latter. Accordingly, Gemel’s accuracy wins across the available memory settings are 11-60% and 5-16% for workloads HP1 and LP1. Second, Figure 11 shows that, as expected, Gemel’s benefits per workload decrease as the available GPU memory grows, e.g., accuracy improvements drop to 17.5% and 10.2% for the median MP workload when GPU memory grows to 50% and 75% of the total workload memory needs. The reason is straightforward: larger GPU memory yields fewer required swaps without merging.

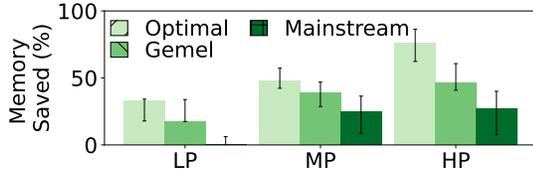

Figure 13: Memory savings with Gemel, an optimal that ignores accuracy, and Mainstream [59]. Bars list the median workload per class, with error bars spanning min to max.

Memory Reductions. Figure 12 lists the memory reductions that Gemel delivers for each considered workload by sharing model layers and the associated weights, i.e., parameter reductions. We note that reported values here are based on Gemel’s final merging results and an accuracy target of 95%; we analyze the incremental nature of Gemel’s merging heuristic in §6.2. As shown, parameter reductions are 17.5-33.9% for LP workloads, 28.6-46.9% for MP workloads, and 40.9-60.7% for HP workloads; the corresponding raw memory savings are 0.2-0.3 GB, 0.2-0.8 GB, and 0.7-5.1 GB, respectively. When analyzed in terms of overall memory usage during inference (i.e., including the parameters, inference framework, and intermediate data generated during model execution), reductions are 4.5-48.1% across the workloads. Wins are generally higher for workloads with larger parameter reductions, with the exception of Workloads LP1 and LP3 (reductions of 6.3% and 4.5%) whose intermediates are particularly large relative to the parameters.

To better contextualize the above memory savings, we compare Gemel with two alternatives. First, we consider a theoretical optimal (*Optimal*) that shares all layers that are architecturally identical across a workload’s models, without considering accuracy (and the need to find shared weights for those layers). Thus, Optimal represents an *upper bound* on Gemel’s potential memory savings. Second, we compare with *Mainstream* [59], a recent stem-sharing approach. To run Mainstream, we trained each model in our workloads several times, each time starting with pre-trained weights (based on ImageNet [90]) and freezing up to different points, e.g., freeze up to layer 10, freeze up to layer 15, etc. We selected the configuration for each model that kept the most layers frozen while meeting the accuracy target (95% relative to no freezing). Then, within each workload, we merged all layers that were shared across the frozen layer set of the constituent models (note that these layers have identical weights) and recorded the resultant memory savings.

Figure 13 shows our results, from which we draw two conclusions. First, Gemel’s memory savings are within 9.3%, 15.0%, and 29.0% of Optimal for the median LP, MP, and HP workloads. Second, Gemel’s memory reductions are 5.9-52.3% larger than Mainstream’s across all workloads. This is a direct consequence of Gemel’s prioritization of memory-heavy layers that routinely appear towards the end of models (§5.2). By requiring shared stems from the start of the models, Mainstream would have to share all layers up to the

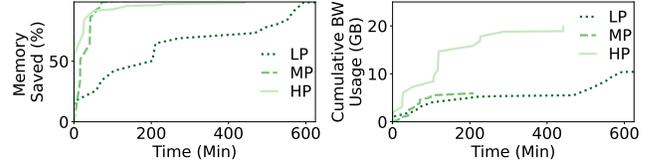

Figure 14: Gemel’s memory savings (left) and cloud-to-edge bandwidth usage (right) over time during incremental merging. Results show the median workload per class.

memory-heavy ones; we find that sharing nearly-entire models is rarely possible while meeting accuracy targets (Figure 8). The high variance in Mainstream’s results are due to the fact that different models drop in accuracy at different rates when more layers are frozen. Classifiers drop relatively slowly (savings up to 70.1%), while detectors are a harder task with faster accuracy drops (Mainstream was unable to share many layers, with savings as low as 1.0%).

6.2 Analyzing Gemel

Incremental memory savings. Key to Gemel’s practicality are its efficient merging heuristic and retraining optimizations that aim to reap memory savings early in the process; indeed, this is important not only to reap accuracy-friendly memory wins quickly, but also to quickly respond to workload changes. As shown in Figure 14 (left), 73% of Gemel’s achieved memory savings for the median HP workload are realized within the first 24 minutes of merging. Similarly, 86% and 64% of the total memory savings are achieved in the first 42 and 210 minutes of merging for median MP and LP workloads, respectively.

Network bandwidth usage. After each successful merging iteration, Gemel ships weights to edge servers for all updated models. As shown in Figure 14 (right), cumulative bandwidth usage during merging is 6.0-19.4 GB for the three workloads. Importantly, bandwidth consumption largely grows after substantial memory savings are already reaped. For example, for the median MP workload, 86% of memory savings are achieved in 42 minutes, while only 2.1 GB (of the total 6.0 GB) of bandwidth is used during that time. The reason is that later merging iterations explore the larger number of lower-memory layers. Thus, Gemel can often deliver large memory savings even in constrained settings with bandwidth caps. Note that shipping weights uses cloud-to-edge (not precious edge-to-cloud) bandwidth.

Micro-benchmarks. We profile the time spent in each of Gemel’s components. Training delays are configurable (Figure 14), but dominate cloud merging, with the remaining <2% of time spent on identifying shareable layers (0.7-1.4s per workload) and serializing/saving weights from successful training (9.1-19.5s per round). The majority of time spent at the edge steadily shifts from model loading to inference as Gemel’s incremental merging results stream in; at the median, time spent blocked reduces from 32.8%, 48.3%, and 52.0% to 22.1%, 34.6%, and 27.9% for the LP, MP, and HP

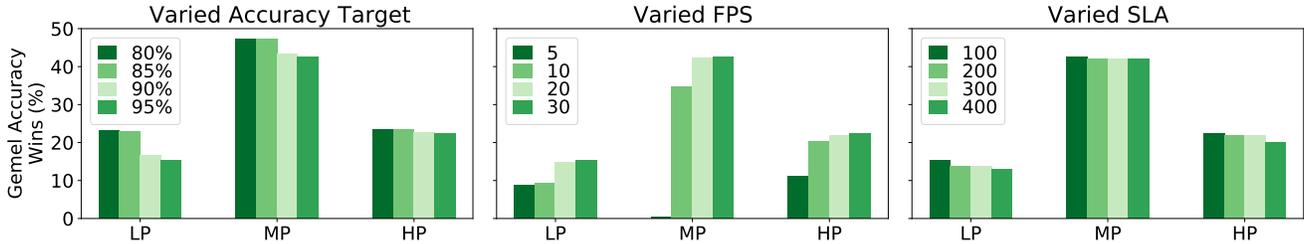

Figure 15: Gemel’s accuracy wins (compared to time/space-sharing alone) with varied accuracy targets, FPS, and SLAs.

workloads respectively. Applying results takes $<.15s$ and is not blocking.

Varying accuracy, FPS, and SLA. To evaluate the impact of each parameter, we conducted experiments using one randomly selected workload from each class. In each experiment, we only vary one parameter, while keeping the other two at the fixed values from above (95%, 30 FPS, 100 ms).

Figure 15 presents our results, which exhibit three trends. First, Gemel’s accuracy wins over time/space-sharing alone grow (by 1.1-7.8% for the three workloads) as accuracy targets drop (from 95% to 80%). This is because certain layers failed to meet 95% during retraining, but did meet a lower accuracy target. Second, Gemel’s accuracy wins drop as input video frame rates (FPS) drop, e.g., from 6.2-42% across the workloads when FPS drops from 30 fps to 5 fps. The reason is that lower FPS values reduce the amount of inference in any time window (assuming a fixed SLA), which in turn adds tolerance to high loading delays. Third, Gemel’s benefits grow as SLAs become stricter: accuracy wins for the three workloads rise by 0.4-2.3% when SLA drops from 400 to 100 ms. This is because tighter SLAs imply more skipped frames for a given swapping delay.

Comparison to other merging heuristics. We consider variants that differ from Gemel in one of two ways: they choose layers to merge in a different order or they merge a different number of layers at a time. We describe the variants of each type below, along with the corresponding results. Our experiments use all workloads from §2, and we report memory saved over time. Figure 16 shows results for two representative workloads (HP3, MP2); the remaining workload results are in §A.4. In summary, no variant consistently outperforms Gemel, and the degradations (in saved memory or merging delays) that each brings to certain workloads (from being overly aggressive or cautious) are substantial.

Rather than merging layers in descending order of memory usage (irrespective of position) as Gemel does, the variants we consider start by merging the models’ earliest layers (*Earliest*), latest layers (*Latest*), and three random layer orderings (*Random*). Across all workloads, these heuristics all resulted in significantly lower memory savings. Among the three, *Latest* performed the best (median of 13.5% of Gemel’s savings), as memory-heavy layers often appear later in a model (but not necessarily the end). For the same rea-

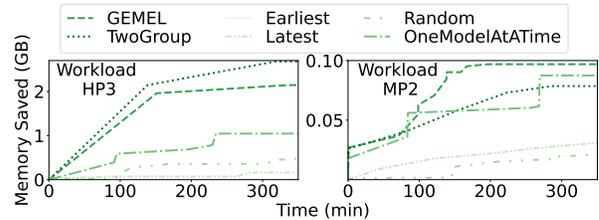

Figure 16: Comparing variants of Gemel’s merging heuristic on two representative workloads.

son, *Earliest* performed the worst (0.2% of Gemel’s savings). *Random*’s performance varied dramatically (0.2% - 72.9%, median of 5.7% of Gemel’s savings) based on whether a memory-heavy layer was selected.

We consider two variants to Gemel’s approach of adding one layer group at a time across all models that layer appears in. First, *TwoGroup* more aggressively adds two groups at a time. This can result in faster memory savings than Gemel (3/15 workloads, including Figure 16 (left)), but most often (8/15 workloads) misses accuracy targets and results in substantial slowdowns (78 min longer to max savings for the median workload). The reason is that, on failure, *TwoGroup* restarts training with 1 group, adding long delay without memory savings, e.g., $x=75-220$ min in Figure 16 (right). Second, *OneModelAtATime* less aggressively shares the selected group’s layer iteratively across the models it appears in. This reaches within 5% of Gemel’s memory savings in 8/15 workloads, but is often unnecessarily slow, e.g., in Figure 16 (left), Gemel successfully considers 5 models at once, while *OneModelAtATime* individually adds models (some of which fail) leading to the flat stretch from 0-91 min.

6.3 Generalization Study

We evaluate Gemel on over 850 more workloads that extend our main ones by adding: (1) new scene types and the objects they bring (e.g., bags, hats, and people at a beach, boats in a canal), and (2) new models, including more variants in the same families (e.g., ResNet, VGG), and entirely new architectures (e.g., GoogLeNet [101], DenseNet [51]). In total, our analysis involves 17 videos (8 scene types), 13 objects, and 16 models; the extended version [82] lists the values.

Constructing workloads. Each query in a workload is parameterized by a set of knobs: *camera feed* (and corresponding *scene type*), *model*, and *object of interest*. To study the

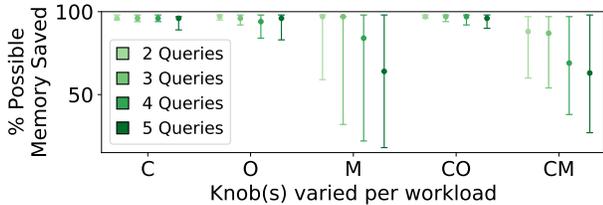

Figure 17: Memory savings across subset of generalization workloads, organized by workload size (color) and knobs varied (Camera, Object, Model). Distributions show median and 25-75% ile; accuracy target was 95%. Figure 22 has full graph.

impact of varying each knob (or combination of knobs) on Gemel’s merging, we construct workloads as follows. For each set of target knobs to vary, we start with a random query and incrementally add new queries that only vary values for the target knobs to generate workloads with 2-5 queries each. We did this up to 30 times each for all target knob sets (as their values permit), excluding only (1) target knob sets that vary the *scene* but not *camera* knob, (2) queries for an *object* that never appears in a given *camera* feed, and (3) workloads with no possible memory sharing opportunities.

Findings. As shown in Figure 17, Gemel’s memory savings are high for 2-query workloads (89-98% of optimal at medians), but steadily degrade as workloads grow. This is expected as increasing workload size is (by design, and unrealistically) increasing heterogeneity in this experiment. The nature of degradation depends on the knob(s) being varied. For all combinations of $\{camera, object, scene\}$, degradations are mild moving from 2- to 5-query workloads (0-8%), showing Gemel’s robustness to variations on those properties. Since *model* is constant in these cases, degradations are because the same set of shareable layers must support more diverse scenarios (making it harder to find shared weights).

The *Model* knob (alone or with other knobs) presents a different picture, with larger drops in median memory savings (2-33%) and broader distributions. We can decompose this into two aspects as workload sizes increase:

- Previously-shared layers appear in the new model: the effect on memory savings heavily depends on where the shared layer appears in the new model; recall that layers can appear in different positions (and thus, serve different roles) across models (Figure 19). Cases where the new model introduces drastically different positions for shared layers (e.g., ResNet variants) account for the low-end of the resultant distributions, while memory savings largely persist when positions of shared layer(s) are similar in the new model (e.g., merging across VGG variants).
- New layers are shareable with the new model: the extra sharing opportunities increase potential savings, but are more challenging to realize as they reduce the number of non-shared layers whose weights help compensate for the constraints from sharing (§4.2).

7 Additional Related Work

Certain systems reuse model components [91], most relatedly via stem sharing for compute savings [59] or sharing operators with identical weights anywhere in models [68]; in contrast, Gemel targets memory savings, and enables sharing architecturally-identical layers anywhere in models even if they have different weights. Layer sharing in multi-task learning is often studied in the context of transfer learning, where models for a task with insufficient data leverage the dataset of a related task [30, 99, 103]; Gemel considers multiple sets of pretrained weights for sharing, each with different goals (e.g., detection vs. classification, different objects).

Other platforms optimize model serving either by tuning video analytics-specific knobs to lower compute footprints [29, 35, 49, 55, 60, 61, 87, 109, 116, 117], or by identifying lightweight variants of individual models that match specific hardware resources [45, 89]; Gemel focuses on memory (not compute) bottlenecks, and optimizes across models. Some frameworks reuse results across frames [31, 33, 42, 67, 71], reducing frame rates for inference and alleviating the impact of model loading delays. Gemel provides benefits at lower FPS (§6.2), and also can alleviate memory pressure across spatially correlated feeds that exhibit limited reuse opportunities at the same time (§3.2).

There exist training optimizations that trade off memory usage for computation overheads [83, 86, 93]; we eschew such techniques given the holistic constraint on compute resources that edge boxes face (§1). Finally, another body of work develops metrics to quantify how similar models will behave [41, 58, 72]. While Gemel does not consider model similarity metrics in its heuristic (we quantitatively observe that ‘model similarity’ is not reflected in layer merging potential), we leave it to future work to explore the relationship between ‘model similarity’ and ‘layer similarity’ in improving Gemel’s prediction of layer merging potential.

8 Conclusion

Model merging is a new memory management technique that exploits architectural similarities across vision DNNs by sharing their common layers (including parameters but not intermediates). Gemel efficiently carries out model merging by quickly finding and retraining accuracy-preserving layer sharing configurations, and scheduling edge inference to maximize merging benefits (8-39% accuracy boosts).

A Appendix

A.1 Implementation Details

Gemel’s main components are training models at the cloud server and running the scheduler at the edge. During training, a single optimizer manages the weights across all considered models; the optimizer holds a single copy of weights for each layer that is shared across the models. Aside from this, Gemel’s training process mirrors classic multi-task training [30]: it forms a collective pool of an equal number of data samples from all models and randomly selects batches from this pool. Samples are run through their respective models, each model calculates its loss individually, and losses are summed over all models. In this way, layers that are shared are updated by the concurrent training of multiple models within a single batch.

The Nexus-variant scheduler chooses when to load and evict models as described in §5.4. To load a model into GPU memory, the scheduler simply calls “.cuda()” on that model’s PyTorch object. PyTorch automatically only loads layer weights not already in GPU memory. However, when evicting a model, PyTorch, by default, removes all of the layers’ weights from GPU memory. This poses a problem if some of those weights are needed by models still in GPU memory (i.e., they are shared). To avoid this, the scheduler: (1) maintains a running list of shared layers that are needed by models currently in GPU memory or next in line to be loaded, and (2) when a model needs to be evicted, only evicts weights corresponding to layers not in the list. Overall, Gemel is implemented in ≈ 3500 LOC: 500 for finding shared layers and sharing them according to the heuristic, 2500 for dataset management and retraining, and 500 for scheduling models at the edge.

A.2 Generalization Workload Query Knobs

Abstract

The breakthroughs in deep learning enable unstructured data to be represented as high-dimensional feature vectors for serving a wide range of applications. Processing vector queries (i.e., finding the nearest neighbor vectors for an input vector) for large unstructured datasets (with billions of items) is challenging, especially for applications with strict service level objectives (SLOs). Existing solutions trade query accuracy for latency, but without any guarantees, causing SLO violations.

This paper presents Auncel, a vector query engine for large unstructured datasets that provides bounded query errors and bounded query latencies. The core idea of Auncel is to exploit local geometric properties of individual query vectors to build a precise error-latency profile (ELP) for each query. This profile enables Auncel to sample the right amount of data to process a given query while satisfying its error or latency requirements. Auncel is a distributed solution that can scale out with multiple workers. We evaluate Auncel with a variety of benchmarking datasets. The experimental results show that Auncel outperforms state-of-the-art approximate solutions by up to 10× on query latency with the same error bound ($\leq 10\%$). In particular, Auncel only takes 25 ms to process a vector query on the DEEP1B dataset that contains one billion items with four c5.metal EC2 instances.

1 Introduction

Vector query engines for unstructured datasets (e.g., images, videos and texts) are a key building block for modern applications including recommendation [1–4], recognition [5–8] and biological information retrieval [9–11]. This is enabled by the breakthroughs in deep learning [12] that allow unstructured data to be represented as high-dimensional feature vectors. A vector query is to find the top- k nearest neighbor vectors in a dataset for an input vector.

With the explosive growth of unstructured data [13, 14], a central challenge for vector query processing is to satisfy strict service level objectives (SLOs) for applications on large unstructured datasets that contain millions and even billions of items. For instance, a face recognition task is to match a human face from an input image against a database of faces. With deep convolutional neural networks [6], each face image is converted into an embedding vector. Consequently, the

recognition task becomes a top- k nearest neighbor (KNN) search problem, i.e., finding the nearest neighbor vector of the query vector among the database vectors. The person corresponding to the nearest neighbor vector is the recognition result. Performing exact KNN search (e.g., through pairwise comparison between query vector and each stored vector) is costly in terms of computation resources, and more importantly, is hard to achieve low query latency. As a result, approximate top- k nearest neighbor (ANN) search [15–18] is widely used by vector query engines to tradeoff query accuracy for latency. The basic idea of ANN search is to sample a subset of the dataset for finding the top- k , and the sampling size affects the query accuracy and latency.

A key requirement for approximate query processing is to provide *performance guarantees* in order to meet SLOs [19–21]. Performance guarantees are defined in terms of error bounds (e.g., $\leq 10\%$ query error) or latency bounds (e.g., ≤ 25 ms query latency). Existing systems [22–29] exploit various ANN algorithms [15–18] and system optimizations to optimize query accuracy and latency. However, these systems do not provide any performance guarantees.

Faiss [22] and AnalyticDB-V [24] are widely-used open-source and commercial vector query engines, respectively. Unfortunately, they do not provide any performance (error or latency) bounds. They build a profile to map query errors to sampling sizes for a given dataset. It is possible to leverage the profile to pick an appropriate sampling size to meet an error bound. But the problem is that the profile is *query-agnostic*: it ignores the characteristics of individual query vectors, and uses a *fixed* sampling size for all query vectors under the same error bound. Consequently, the sampling size is too pessimistic—the maximum sampling size among all query vectors has to be used to meet the error bound. This leads to excessive redundant computation.

Learned Adaptive Early Termination (LAET) [30] is a recent work that leverages machine learning to optimize vector query processing. It trains a gradient boosting decision tree model to predict when to stop searching for a given query in order to reduce query latency. It focuses on average query accuracy, and does not provide any error or latency bounds. LAET includes a heuristic to adapt the decision tree model by multiplying a hyperparameter to the prediction result to meet

a given error bound. But the model treats the entire structured ANN index as a blackbox, which performs poorly on query latency for bounded errors.

More importantly, existing systems focus on a *single-node* setup and use a *single* worker to process each query. Distributed processing is critical for vector queries over large unstructured datasets with billions of items. Conceivably, one can replicate a dataset to multiple workers, and process multiple queries in parallel—one query by each worker. This naive solution has high memory footprint for billion-scale datasets (e.g., 360 GB for DEEP1B [31] dataset). Moreover, it cannot reduce query latency with more workers, making it hard to achieve latency bounds for billion-scale datasets.

We present Auncel, a vector query engine for large unstructured datasets with performance guarantees. Different from existing systems, Auncel allows users to specify an error bound or latency bound for an input vector. The core of Auncel is a query-aware and error-aware *error-latency profile* (ELP) that enables Auncel to minimize the query latency for an error bound and maximize the query accuracy for a latency bound. Auncel is a distributed solution that can reduce the query latency with more workers. To the best of our knowledge, Auncel is the first distributed vector engine that provides bounded errors and bounded latencies.

There are two primary challenges in realizing Auncel. The first challenge is to decide the appropriate sampling size for an individual query vector under a particular error or latency bound. Auncel uses a *whitebox* approach that exploits the geometric properties in the high-dimensional space to explicitly model the relationship between sampling sizes and query errors. This enables Auncel to build more accurate ELPs than existing query-agnostic or blackbox approaches. Auncel immediately terminates the search process when the error bound can be guaranteed based on the ELP to minimize query latency. In terms of the latency bound, Auncel exploits the nature of vector query processing and uses a runtime approach to maximize query accuracy.

The second challenge is to scale Auncel out to multiple workers in order to reduce query latency. A natural approach is to shard a dataset among workers and aggregate workers' results for query processing. The nuance is to correctly set the local error bound for each worker. Naively setting the local error bound to be the target error bound would magnify the global error after aggregation. Auncel applies probability theory to calibrate the local error bound for each worker in order to bound the global error. We theoretically prove that Auncel is able to bound the global error with high probability.

We implement a prototype of Auncel, and extensively evaluate it with a variety of benchmarking datasets. The results show that Auncel outperforms Faiss [22] by 1.3–10× and LAET [30] by 1.4–3.6× on the single-node setup. For the distributed setup, Auncel is able to process a vector query under 25 ms for the DEEP1B dataset which contains one bil-

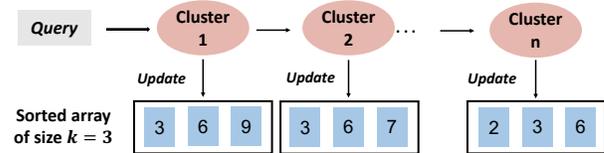

Figure 1: IVF workflow.

lion vectors of 96 dimensions with 128 workers (using four c5.metal EC2 instances).

In summary, we make the following contributions.

- We present Auncel, to the best of our knowledge, the first distributed vector query engine that provides bounded query errors and bounded query latencies.
- We propose a whitebox approach that leverages high-dimensional geometry to build accurate ELPs, and apply probability theory to calibrate each worker to scale out.
- We implement an Auncel prototype. The evaluation shows that Auncel outperforms Faiss by up to 10× and LAET by up to 3.6×, and processes a vector query within 25 ms for billion-scale datasets with 128 workers.

2 Background and Motivation

In this section, we begin by introducing the background of vector queries on unstructured datasets. We then describe current solutions and their limitations to support vector queries on large unstructured datasets, which motivates the design of Auncel. Finally, we describe the challenge to scale out vector query processing.

2.1 Vector Queries on Unstructured Datasets

The common practice for managing and querying unstructured datasets is to use deep neural networks (DNNs) to process each item and represent each item as a high-dimensional feature vector [32–34]. A vector query on an unstructured dataset is to find the top- k vectors in the dataset that are most similar to the query vector. The most widely-used similarity metrics between two vectors are Euclidean distance and Angular distance. KNN search returns the top- k most similar vectors (i.e., nearest neighbors), and ANN search returns the approximate top- k nearest neighbors. KNN becomes impractical for large datasets with millions or billions of items due to long query latency. ANN trades off accuracy for latency, and is the de facto solution for vector query processing on large unstructured datasets. Another reason for the wide adoption of ANN is that it is unnecessary to output the exact top- k items for many vector query processing tasks, as DNN models themselves are not perfect when generating these vectors.

The basic idea of ANN search is to use an indexing structure to sample a subset of the dataset to find the top- k neighbors. Inverted file index (IVF) [15, 25, 35] is a state-of-the-art ANN algorithm. While IVF has many variants, it has the following general workflow. It trains a list of cluster centroids by k -means clustering [36] offline. These cluster centroids form the index of the dataset; each vector is assigned to the closest

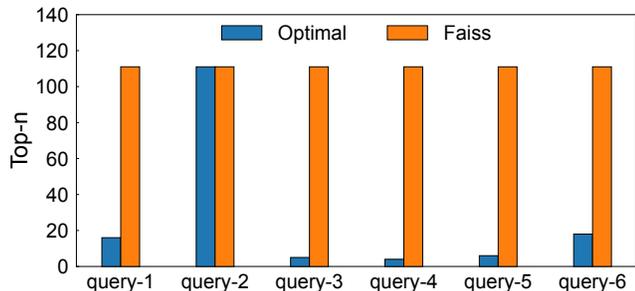

Figure 2: Redundant computation in Faiss.

cluster. Given a query vector, IVF first computes the distance between each centroid and the query vector. Then it chooses the top- n nearest centroids, and processes the corresponding clusters of these centroids one by one. It maintains a sorted array of size k , and updates the array after performing pairwise distance calculation in each cluster as Figure 1. The k vectors remained in the array at the end are returned as the query result. The vectors in the array are called *intermediate result* during the processing. In this figure, each value in the array represents the vector’s index in the ground truth result of exact search. The vectors in the top- n clusters are the sampling vectors. n determines the sampling size, and thus controls the tradeoff between accuracy and latency.

2.2 Bounding Performance for Vector Queries

Providing bounded performance for query processing is a key requirement for meeting SLOs of applications [19–21]. There are two typical types of performance bounds: error bounds and latency bounds. The query processing engine is expected to minimize query latency when given an error bound, and maximize query accuracy when given a latency bound.

Limitations of existing solutions. Existing systems [22–29] do not provide bounded performance, and leave the choice of the sampling size to users. While it is possible to adapt the mechanisms in existing systems to provide bounded performance, simply doing so yields undesirable results. Faiss [22] and AnalyticDB-V [24] build a profile by sampling some queries to map query errors to different n values (exponential power of two in practice to save the map building time) after building an IVF index for a dataset. To guarantee bounded errors, they use the n whose worst-case error is no bigger than the bound. This pessimistic choice of n has poor performance, because it is *query-agnostic*. It ignores the characteristics of individual queries and uses a fixed n for all queries under a given error bound. Some queries may use a smaller n (and thus achieve better latency) without violating the error bound.

To illustrate the problem, we randomly select six query vectors in DEEP10M [31] and assign them the same error bound (10%). In Figure 2, the optimal bars are the minimal values of n to reach the error bound for each query vector, and they are calculated through grid search of parameter n for the six queries respectively. Since Faiss uses the same value

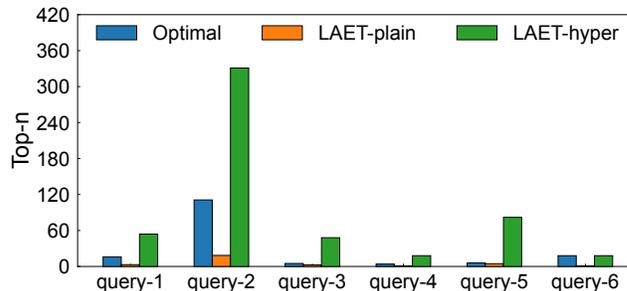

Figure 3: Redundant computation in LAET.

of n for all queries, the value is dominated by query-2; other queries do not need such a large n to meet the error bound. A larger n means searching more clusters, i.e., longer query latency. The naive solution of using a query-agnostic fixed value for n has a $10\times$ gap from the optimal for some queries in this example.

To alleviate this problem, LAET [30] leverages machine learning to adaptively decide n among different query vectors. However, LAET is designed to reduce latency under *average* query error and is incapable to guarantee *bounded* error. It trains a decision tree model with LightBGM [37] and treats IVF index as a blackbox. The model takes the query vector, the intermediate result and some features of the clusters as input and outputs n for a given query. Due to the overhead of running a machine learning model for each query, LAET cannot use complex models and it also simplifies the model input. For instance, it only considers a small portion of intermediate result and cluster centroids. Therefore, the model cannot accurately predict n with blackbox fitting. To guarantee an error bound, LAET includes a heuristic to adapt the model by multiplying a hyperparameter to the prediction result—a tighter bound requires a larger hyperparameter. However, applying such a hyperparameter to all queries given the same error bound induces severely redundant computation with the inaccurate model. This is because this inaccurate blackbox model needs a very large hyperparameter to guarantee the error bound for all queries, but most queries only require a small one. Consequently, the values of n generated by LAET are also far from the optimal. Besides, tuning the hyperparameter for different error bounds is error-agnostic.

We continue with the previous DEEP10M example to show the problem of LAET. As shown in Figure 3, the bars of LAET-plain are lower than those of the optimal, indicating that the plain LAET solution with blackbox fitting is inaccurate to predict top- n and cannot provide bounded errors. LAET-hyper, which is LAET with the aforementioned heuristic, sets the hyperparameter large enough to ensure the bounded error for all the six queries. The hyperparameter is dominated by query-6; other queries can use a smaller hyperparameter, i.e., just enough to match the optimal. Therefore, LAET has the similar problem as Faiss and AnalyticDB-V. The inaccurate blackbox model introduces a $5\times$ gap from the optimal for some queries in this example.

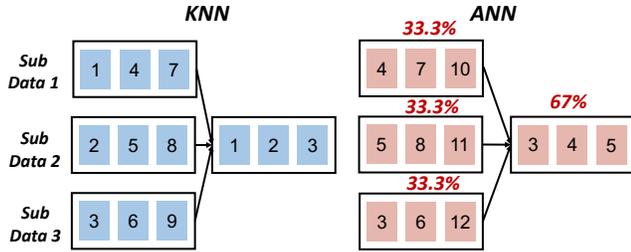

Figure 4: Problem when scaling error bounds.

Opportunity: Geometric structures in ANN indexes. The key to address the problem is building an accurate, lightweight ELP. Our core idea is to exploit the geometric structure and computation pattern of ANN indexes to establish the relationship between sampling sizes and query errors with high-dimensional geometry. The geometric intuition is that a query vector needs a large value of n if the vector is located at the *boundary* of clusters. Similarly, searching a small number of clusters, i.e., a small value of n , is sufficient, if the query vector falls close to a centroid. Thus, we can formulate the entire search procedure with geometric formulas, and use whitebox approach to explicitly model the relationship between sampling sizes and query errors.

2.3 Applying to Distributed Settings

Existing systems focus on a single-node setup and use a single worker to process each query. Replicating the dataset to each worker and processing multiple queries in parallel only increases throughput. It does not help with per-query latency, and has high memory footprint for each worker, both of which are undesirable for billion-scale datasets. A common approach is sharding, i.e., partitioning the dataset among multiple workers. Each worker finds the local top- k in its own shard (i.e., a *map* operation), and then a leader aggregates the local results to the global top- k (i.e., a *reduce* operation). This works well for exact search (KNN), as the aggregated result is identical to the ground truth. However, for approximate search (ANN), the error of the aggregated result is not bounded, even if the error of the local top- k on each worker is bounded.

To see why this is the case, consider the example in Figure 4. The example includes three workers, the value of k is 3, and the error bound is 35%. We show the local top- k at each worker and the aggregated global top- k . Each value represents the corresponding top- k vector's index in the global ground truth result of exact search. The results of KNN is on the left and that of ANN is on the right. In KNN, each worker returns the exact local top- k , and the aggregated top- k vectors are the true top- k (i.e., the ground truth). In ANN, the error of the local top- k at each worker is 33.3%, which satisfies the error bound. However, after aggregating the local top- k , the error of the global top- k is 66.7%; only one vector (with index 3) is in the true global top- k vectors.

To address the problem, we need to calibrate the local error bounds when finding the local top- k at each worker; we cannot

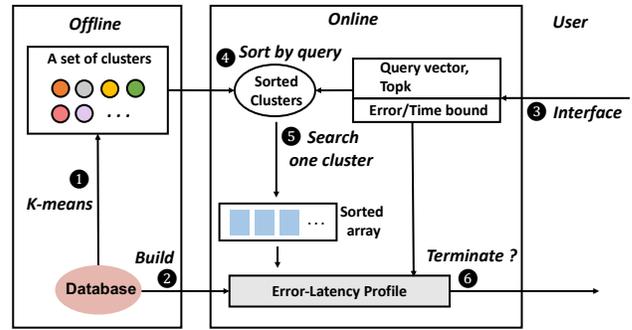

Figure 5: Auncel architecture.

directly use the global error bound. We apply probability theory to calibrate the local error bounds to ensure that the global error is bounded with high probability.

3 Auncel Overview

We present Auncel, a vector query processing engine for large unstructured datasets with performance guarantees. Auncel exploits the geometric properties of ANN index structures to build accurate, lightweight ELPs. Such ELPs enable Auncel to sample just enough data to answer vector queries within their error or latency bounds. To scale out vector query processing for large datasets with billions of items, Auncel adopts map-reduce style dataflow operations, and applies probability theory to calibrate the local error bounds at each worker. Figure 5 shows the overall architecture of Auncel. We provide a brief overview of Auncel in this section.

User interface. Auncel allows users to tradeoff between accuracy and latency with user-defined performance bounds ③. Specially, a user can specify an error bound or a latency bound for a query vector and a value of k (i.e., how many nearest neighbors to return) as follows.

- **Error bound ϵ .** The user specifies an error bound ϵ , and Auncel returns a result within ϵ error as soon as possible.
- **Time bound t .** The user gives a time bound t , and Auncel returns the most accurate result within t time.

Offline. Similar to all query processing engines for unstructured datasets, Auncel first uses IVF to build an ANN index for a given dataset offline ①. IVF divides the vectors in the database into a few clusters with k-means clustering. It maintains the centroids of each cluster; each vector in the dataset is assigned to the closest cluster. In addition to the ANN index, Auncel samples synthetic or example queries to build an ELP for the dataset ②. ELP building techniques include fitting geometric formulas and substituting some complex operators with pre-calculated key-value pairs to reduce overhead.

Online. At runtime, vector queries are issued to Auncel for processing. Each query includes a vector, a value of k , and an error/time bound. To process an incoming query, Auncel first evaluates the distance between the query vector and each

Symbol	Description
q	Query vector
t	Latency bound
ϵ	Error bound
l	Number of clusters
C_i	The i_{th} closest cluster to q (a hyper polyhedron)
ϵ_i	Error after processing $\{C_1 \dots C_i\}$
S	Set of database vectors
S_i	Intermediate result after processing $\{C_1 \dots C_i\}$
S_{gt}	Ground truth result of exact search ($S_{gt} = S_i$)
j^*	$ S_i \cap S_{gt} $ after processing $\{C_1 \dots C_i\}$
$\phi_i(j)$	Scaling factor of the j_{th} element in S_i
$\lambda_i(j)$	Distance between q and the j_{th} element in S_i
$B(r)$	Sphere (Ball) with center q and radius r
$P_j(m)$	$B(\lambda_i(j)) \cap C_m$
$N_j(m)$	Number of the vectors within $\bigcup_{\eta=1}^m P_j(\eta)$
$V(G)$	Volume of geometric body G

Table 1: Key notations in problem formulation.

centroid, and then sorts the clusters by distance in ascending order ④. According to the sorted clusters, Auncel performs pairwise distance calculation between the query vector and each stored vector cluster by cluster, and updates the sorted array (i.e., the intermediate result) ⑤. After processing each cluster, Auncel uses the intermediate result and the centroids to predict the current error based on the ELP ⑥. If the error or time bound can be satisfied, Auncel terminates the search process in ⑥, and returns the vectors in the array as the result.

4 Auncel Design

In this section, we present the design of Auncel. We first describe the problem formulation (§4.1) and the key ideas (§4.2). Then we show how to build error profiles (§4.3) and latency profiles (§4.4). Finally, we describe how to apply our solution to distributed settings (§4.5). Some key notations in the design are listed in Table 1.

4.1 Problem Formulation

We first mathematically formulate the problem of vector query processing on unstructured datasets. Let $S = \{v_1, v_2, \dots, v_N\} \in \mathbb{R}^d$, where S is an unstructured dataset, N is the number of vectors in S , and v_i is a d -dimensional vector in S . Let $q \in \mathbb{R}^d$ be a query vector. Given a value $k \in \mathbb{N}_+$ and $k \leq N$, a vector query with q is to find the top- k nearest neighbors of q in S , according to a pairwise distance function $d(q, v_i)$. The distance function typically computes Euclidean distance or Angular distance between two vectors. The ground truth of the top- k nearest neighbors S_{gt} is obtained when searching in the entire dataset S . S_{gt} are often sorted according to $d(q, v)$.

$$S_{gt} = \underset{v \in S}{\operatorname{argmin}}^k d(q, v) \quad (1)$$

Finding the exact top- k nearest neighbors has high query latency for large datasets, which may violate latency SLOs

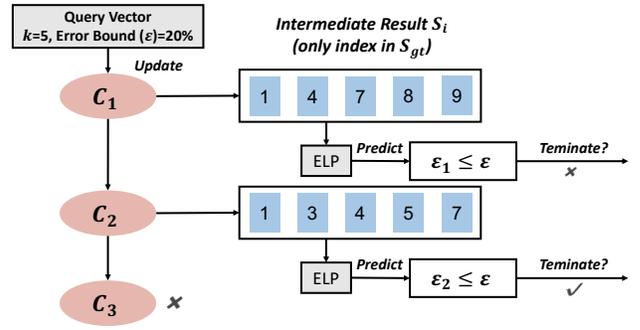

Figure 6: Example to show key idea and workflow of Auncel.

for applications. To trade query accuracy for query latency, a subset $S_a \subset S$ can be sampled to find the approximate top- k nearest neighbors S_r for lower latency.

$$S_r = \underset{v \in S_a}{\operatorname{argmin}}^k d(q, v). \quad (2)$$

The accuracy (recall) and error of S_r are defined as follows.

$$\text{Accuracy} \triangleq \frac{|S_{gt} \cap S_r|}{k} \quad (3)$$

$$\text{Error} \triangleq 1 - \text{Accuracy} \quad (4)$$

4.2 Workflow and Key Idea

Auncel allows users to specify an error bound or a latency bound for a query. When an error bound is given, Auncel minimizes query latency; when a latency bound is given, Auncel maximizes query accuracy. As we have described in §2, the basic approach for processing a vector query with an ANN index is to first compute the distances between the query vector and the centroids of the clusters in the index and then search cluster by cluster based on the ascending order of the distances. The key idea of Auncel is to build an accurate ELP so that after searching each cluster, Auncel can consult the ELP to decide whether to terminate the search.

Workflow of Auncel. We use a concrete example in Figure 6 to illustrate the workflow of Auncel. In this example, the ANN index partitions the dataset into three clusters. Each cluster (C_i) is a polyhedron in d -dimensional space. The value of k in top- k is 5, and the error bound is 20%. The three clusters are sorted in ascending order by their centroids' distances to the query vector. Auncel searches the three clusters based on the order one by one. The three clusters may have different numbers of vectors due to the imbalance property of k-means. It does not impact the error profile since Auncel terminates the search as soon as the current error is guaranteed. However, the imbalance property leads to inaccurate latency profile that we will discuss later in §4.4.

After processing C_1 , Auncel updates the intermediate result (a sorted array) which represents the query vector's top- k

Algorithm 1 Error Profile

```
1:  $\epsilon \leftarrow$  Error Bound,  $i \leftarrow 1$ 
2: while  $i \leq l$  do
3:   Perform search computation in cluster  $C_i$ 
4:   geometric properties  $\leftarrow S_i$ , cluster centroids
5:    $\epsilon_i \leftarrow$  ELP (geometric properties)
6:   if  $\epsilon_i \leq \epsilon$  then
7:     break
8:    $i \leftarrow i + 1$ 
9: Return intermediate result
```

nearest neighbors in C_1 . Each element in the sorted array is a pair of a database vector's index and its distance to the query vector. For simplicity, the figure only shows the element's index in ground truth result. Auncel uses the intermediate result as the input of the ELP to predict the current error, and decides whether to terminate the search. The ground truth vectors have top- k indexes [1, 2, 3, 4, 5] in this example, which is obtained after searching all three clusters. As the intermediate result after searching C_1 is [1, 4, 7, 8, 9], only two vectors in the intermediate result (the two with indexes 1 and 4) belong to the true top- k . Therefore, the current error is 60%, which is still above the error bound 20%. Auncel continues to search C_2 . The intermediate result after searching C_2 contains four vectors in the true top- k (the four with indexes 1, 3, 4 and 5), and the current error decreases to 20%, which satisfies the error bound. Therefore, it is safe for Auncel to terminate the search and return the sorted array as the query result.

The workflow is summarized in Algorithm 1. Predicting the error with ELP in line 5 is the key to guarantee bounded errors and minimize query latency. If the predicted error is smaller than the actual error, the system terminates search too early, and fails to meet the error bound; if the predicted error is larger than the actual error, the system unnecessarily continues to search more clusters, which increases query latency. Thus, the main challenge is to build an accurate ELP to accurately predict the current error after searching each cluster.

Key idea of Auncel. To understand how Auncel addresses this challenge, consider the intermediate result after searching C_1 . The first element in the intermediate result (1) is also the first element in ground truth (sorted array after searching all three clusters). But, the second element (4) is the fourth element in ground truth, and the third element (7) is not in the top- k ($k=5$). We define the scaling factor of the j_{th} element in the intermediate result after processing C_i as follows, where $index_{gt}$ is the element's index in ground truth.

$$\varphi_i(j) \triangleq index_{gt}/j \quad (\geq 1) \quad (5)$$

If $\varphi_i(j)$ is known, then the current error of the intermediate result after searching C_i can be calculated. Specifically, we compute j^* such that

$$j^* = \operatorname{argmax}_j \{j \cdot \varphi_i(j) \leq k\}. \quad (6)$$

The elements from 1 to j^* in the intermediate result belong to the true top- k . j^* is often calculated through binary search. The current error ϵ_i after processing C_i is

$$\epsilon_i = 1 - j^*/k \quad (7)$$

For any j , $\varphi_i(j)$ converges to 1 when i increases to the number of clusters (l). Correspondingly, j^* converges to k and ϵ_i converges to 0. When searching the clusters one by one, Auncel terminates the process immediately when ϵ_i becomes no bigger than the error bound.

Therefore, we convert the problem of building an accurate ELP to accurately estimating $\varphi_i(j)$. We exploit the geometric properties of ANN indexes in high-dimensional space to estimate $\varphi_i(j)$. Since Auncel is designed to provide bounded errors, it is sufficient to estimate the upper bound of scaling factor $\varphi_i(j)$, which we describe next.

4.3 Handling Error Bounds

Auncel minimizes query latency under a given error bound using scaling factors in the i_{th} error prediction (φ_i). We perform a detailed analysis of $\varphi_i(j)$ from a geometric perspective, and design a formula to calculate the upper bound of $\varphi_i(j)$ under the two most prevalent distance metrics.

4.3.1 Scaling Factor under Euclidean Distance

We first focus on Euclidean distance, the most widely-used and intuitive distance metric, which measures the length of the line segment between two anchor vectors in geometry.

We have two key insights. Our first insight is to leverage the geometric structure of the IVF index. IVF shards the entire dataset into l clusters (C) by k -means clustering, and the clusters are sorted as $C = \{C_1, C_2, \dots, C_l\}$. Due to the rule of k -means, C_i is a d -dimensional *polyhedron* and the boundary between C_i and C_j is the $(d-1)$ -dimensional mid-vertical plane of the line segment connecting the two clusters' centroids. Thus, we can divide the entire space into several parts based on these boundaries. Our second insight is to exploit the local geometric properties of q which belongs to C_1 . The top- k ground truth vectors gather around q and form a sphere, $B(\lambda_l(k))$ with radius $\lambda_l(k)$ and center q in d -dimensional space. For any vector within $B(\lambda_l(k))$, it is a member of S_{gt} . For instance, if $B(\lambda_l(k))$ locates within C_1 , it is sufficient to search in the first cluster to get ground truth.

The combination of these two insights allows us to compute $\varphi_i(j)$ with high-dimensional geometry. We know that the k ground truth vectors are distributed in sphere $B(\lambda_l(k))$, and the sphere is divided into many parts by the boundaries between C_1 and other clusters. For example, we have three clusters in total and query vector q in Figure 7. The sorted clusters are $\{C_1, C_2, C_3\}$, and all vectors within the sphere belong to S_{gt} . This sphere is cut into three parts— P_1, P_2, P_3 —by the two boundaries, and N_i is the number of database vectors in the scope of $\bigcup\{P_1 \dots P_i\}$ ($i = 1, 2, 3$). In Figure 7, the numbers of the vectors within the shaded areas are N_1 and N_2 ,

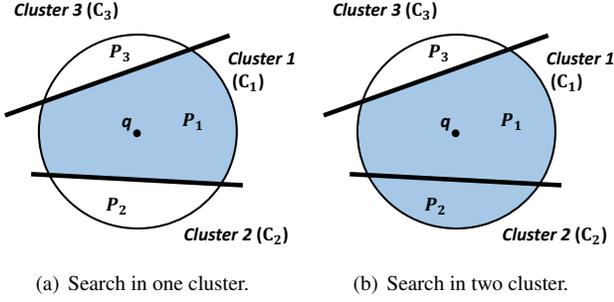

Figure 7: Geometric demo for calculating scaling factor.

respectively. In Figure 7(a), scaling factor $\varphi_1(N_1) = \frac{k}{N_1}$ since the N_{1th} element in S_1 is the k_{th} element in S_{gt} . Figure 7(b) shows the scaling factor $\varphi_2(N_2) = \frac{k}{N_2}$. To extend to general settings, we define $P_j(m)$ as the intersection of $B(\lambda_i(j))$ and C_m after processing C_i . Consequently, $N_j(m)$ is the number of vectors within $\bigcup_{\eta=1}^m P_j(\eta)$ which gives that:

$$\varphi_i(j) = N_j(l)/N_j(i). \quad (8)$$

l is the number of clusters and i represents the current cluster.

We observe that the vectors of real-world datasets conform to *local uniform distribution*, and k in most query workloads is no bigger than 100, which means the vectors within the scope of $B(\lambda_i(k))$ nearly conform to uniform distribution. We provide a measurement in Appendix A.1 to confirm this observation. Let den represents the local density of $B(\lambda_i(k))$. We get that $N_j(m) \approx V(\bigcup_{\eta=1}^m P_j(\eta)) \times den$. Hence,

$$\varphi_i(j) = V(B(\lambda_i(j)))/V\left(\bigcup_{m=1}^i P_j(m)\right). \quad (9)$$

V is the volume function. Since $P_j(1)$ has different geometric meaning with $P_j(m)$ ($m \geq 2$) (spherical cap) and is complex to calculate, we use the following inequation:

$$\begin{aligned} \varphi_i(j) &= \frac{1}{1 - \frac{V(\bigcup_{m=i+1}^l P_j(m))}{V(B(\lambda_i(j)))}} \\ &\leq \frac{1}{1 - \frac{\sum_{m=i+1}^l V(P_j(m))}{V(B(\lambda_i(j)))}} \leq \frac{1}{b - a \times U}. \end{aligned} \quad (10)$$

Different spherical caps (e.g., P_1, P_2 in Figure 7) may intersect with each other. The union of all spherical caps has a smaller volume than the sum of the volumes of all spherical caps, which leads to the first \leq . We apply $b - a \times U$ to substitute such complicated volume calculation in d -dimensional space, where a, b are parameters to fit offline and $a \times U$ is the geometric *upper bound* of the volume ratio. Appendix A.2 contains the detailed analysis of $a \times U$, and we conclude one of the upper bound functions is

$$U = \sum_{m=i+1}^l \arccos(x_m) \quad (0 \leq x_m \leq 1). \quad (11)$$

Algorithm 2 Latency Profile

```

1:  $t \leftarrow$  Time Bound,  $i \leftarrow 1$ 
2:  $t_0 \leftarrow$  CurrentTime()
3: while  $i \leq l$  do
4:   Perform search computation in cluster  $C_i$ 
5:    $t_c \leftarrow$  CurrentTime()
6:   if  $t_c - t_0 \geq t - \delta$  then
7:     break
8:    $i \leftarrow i + 1$ 
9: Return intermediate result

```

where $x_m = \frac{db_m}{\lambda_i(j)}$ and db_m is the distance between query vector and the boundary of C_1, C_m . We do not consider the circumstance when $x_m > 1$.

In Formula 11, the time complexity of calculating the upper bound of $\varphi_i(j)$ is $O(l)$ since $\arccos(x_m)$ only costs constant time. We use binary search to calculate j^* with Formula 6, which concludes that the time complexity to predict ε_i is $O(l \times \log(k))$ while the space complexity is $O(1)$.

4.3.2 Scaling Factor under Angular Distance

Another widely-used vector distance metric is Angular distance, which evaluates the angle between two anchor vectors. Its geometric meaning allows us to transform Angular distance into Euclidean distance. Specifically, we project all database vectors onto the unit sphere in d -dimensional space through *vector normalization*, while maintaining the Angular distance between any vectors. Thus, we substitute angle with the line segment on such unit sphere, and the theoretical analysis in §4.3.1 holds under Angular distance.

4.4 Handling Latency Bounds

Given a latency bound, Auncel maximizes query accuracy for a query vector. Conceivably, one can build a latency profile to capture the relationship between sampling sizes (i.e., the number of clusters to search) and query latencies. Then Auncel can consult the latency profile to get how many clusters to search based on a given latency bound. However, building such a profile is difficult, because the clusters have different sizes and the order of the set of clusters to search vary between different query vectors.

We design a *runtime* solution that exploits the *monotonicity* property of vector query processing to handle latency bounds, obviating the need of building a latency profile offline. Specifically, vector query processing searches the clusters in the ANN index one by one. The search is based on ascending order of the distances between the clusters' centroids and the query vector. The accuracy of the intermediate result increases when searching more clusters. As such, Auncel tracks the used time when searching the clusters, and terminates the search when the used time is close to the time bound. This ensures that Auncel uses as much time as possible in processing to maximize query accuracy. Algorithm 2 shows

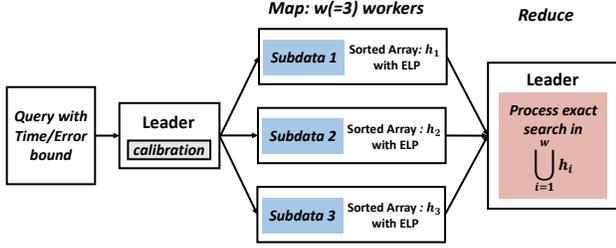

Figure 8: Auncel runtime with map-reduce.

the pseudocode of processing vector queries under latency bounds. To guarantee the search terminates before the time bound, the algorithm stops the search when the used time is a (configurable) δ before the time bound. δ is influenced by the first cluster after Auncel terminates the search, i.e., C_i if the termination condition is triggered after processing C_{i-1} . The larger δ is required if C_i has more vectors and costs more time to process. To guarantee the latency bounds in any circumstances, δ is tuned according to the cluster with the largest number of vectors.

4.5 Applying to Distributed Settings

We emphasize that the distributed solutions mentioned in §2.3 either cannot reduce query latency (i.e., only improve throughput) or leads to error amplification. To scale out, Auncel uses map-reduce style processing to process vector queries with multiple workers while preserving the error and latency bound. Auncel divides distributed vector processing into two phases—a `map` phase and a `reduce` phase. As shown in Figure 8, Auncel randomly and uniformly shards the dataset into multiple partitions. Each worker owns one partition, and builds a local ANN index and a local ELP. One of the workers is elected as the leader, which controls the global query processing.

When a vector query with an error/time bound (which we call global bound) comes, the leader calibrates the bound to get an error/time bound to be used by each worker (which we call local bound). In the `map` phase, each worker uses its local ANN index and ELP to process the query on its own partition. In the `reduce` phase, the leader collects the local results from the workers, and performs exact top- k search on these collected results to produce the final result.

Calibration of error/latency bounds. As we have shown in §2.3, the local errors can be amplified in the `reduce` phase when the local results are aggregated to the final result. Directly using the global error bound as the local error bound in the `map` phase would cause the final error obtained by the `reduce` phase to be larger than the global error bound. To address this problem, we design an error bound calibration mechanism based on probability theory. The leader calibrates the local error bound before distributing the work to the workers in the `map` phase.

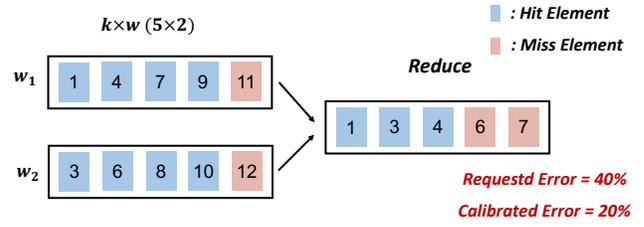

Figure 9: Error calibration of Auncel.

Figure 9 shows an example with two workers to illustrate the calibration mechanism. The global error bound ϵ is 40%, and the local error bound after calibration ϵ_c is 20%. Hit elements are the intersection of S_r and S_{gr} . The `map` phase is done by the workers individually, and the local error at each worker is 20%, which meets the local error bound ϵ_c . The `reduce` phase aggregates the local results and the global error is 40%. While the global error is bigger than 20%, it still meets the global error bound ($\epsilon = 40\%$). The probability of the example in the figure is: $\binom{5}{3} * \binom{5}{5} / \binom{10}{8} = \frac{2}{9}$, where $\binom{n}{m}$ means the *combination number*. From classical models of probability, it means the probability of the random event that selects eight hit elements of all ten ground truth vectors and three elements are situated in the first five ground truth.

Formally, we define the number of hit elements of the first n elements in the ground truth as H_n . The worst case is $H_{k \times w} = k \times w \times (1 - \epsilon_c)$, which means each worker just meets the local error bound. The global error can be represented by $1 - H_k/k$. The probability of a random event $H_k = i$ is

$$P(H_k = i) = \frac{\binom{k}{i} \times \binom{k \times (w-1)}{k \times w \times (1 - \epsilon_c) - i}}{\binom{k \times w}{k \times w \times (1 - \epsilon_c)}}. \quad (12)$$

Thus, the probability of the random event to meet the global error bound is calculated by:

$$P(H_k \geq (k \times (1 - \epsilon))) = \sum_{i=k \times (1 - \epsilon)}^k P(H_k = i). \quad (13)$$

For instance in Figure 9, $P(H_k \geq (k \times (1 - \epsilon))) = P(3) + P(4) + P(5) = \frac{2}{9} + \frac{5}{9} + \frac{2}{9} = 1$, which means the calibrated local error bound (20%) can guarantee the global error (40%) under any circumstances. Auncel starts calibrating ϵ_c from ϵ and decreases ϵ_c by $\frac{1}{k}$ each time. We choose $\frac{1}{k}$ as the loop decrement because the error, which is defined in Formula 3, is a multiple of $\frac{1}{k}$. The probability to guarantee the global error bound ϵ is calculated through Formula 13. If the probability is greater than γ (99.9% used in our prototype), Auncel stops the calibration and distributes the ϵ_c to each worker. Therefore, the probability of failing to guarantee the error bound is less than $1 - \gamma$ ($< 0.1\%$ when $\gamma = 99.9\%$), i.e., Auncel guarantees the error bound with high probability. As for the convergence

time of the calibration algorithm, the calculation time of Formula 12 is constant since the values of combinatorial numbers are pre-calculated offline. The time complexity of Formula 13 is $O(k \times \epsilon)$. Consequently, the convergence time of calibration is $O((k \times \epsilon)^2)$. Since k in real query workloads is not large, the time to calibrate the error bound is relatively small.

Calibrating the latency bound is straightforward since the overhead of the `reduce` phase is negligible compared to the `map` phase. We slightly enlarge δ to include the reduce overhead as the latency calibration.

5 Implementation

We have implemented a system prototype of Auncel with ~ 3000 lines of code in C++ based on Faiss. We use Faiss for building IVF indexes and similarity search, and extend Faiss with building and applying ELPs for performance bounds. Because Faiss does not support distributed processing, we also implement data sharding, and map-reduce operations for distributed query processing. In theory, Auncel can be integrated with any vector query processing engines. We choose Faiss because it is a widely-used open-source vector query processing engine, and is adopted in production like Meta/Facebook. The code of Auncel is open-source and is publicly available at <https://github.com/pkusys/Auncel>.

ELP & Distributed setting. We implement the ELP component of Auncel with C++ Standard Library (STL) and Intel oneMKL [38]. ELP works in the query process and is treated as the process controller (monitor). For the distributed setting, Auncel spawns a worker process for each CPU core, and a server machine contains multiple workers. The entire dataset is sharded among the workers, and each worker processes queries on its own shard. Auncel randomly chooses a machine to spawn a leader process to receive the query and distribute the query with calibrated configurations (§4.5) to each worker. After all workers finishing their own query processing, the leader aggregates local results and returns the final results to the user. Each machine contains a daemon process that manages the local workers on the machine and communicates with the leader using TCP sockets. For leaders, Auncel handles query failures by re-executing the query. When receiving a local result from a worker, the leader creates a consistent backup of the result. Users are able to resume the query with the existing backup files, which is similar with the ideas of traditional primary-backup mechanisms [39, 40].

System optimizations. The ELP component imposes computation overhead to the system because of the complex geometric operations for high-dimensional vectors. We follow Faiss to implement Euclidean distance calculation, Angular distance calculation and vector normalization through SIMD instructions of oneMKL. Since SIMD is designed for vector operations such as inner-product and element-wise addition, it significantly reduces the computation overhead of the ELP component. In addition, we pre-calculate key-value pairs of

Dataset	Dimensions	Database Vectors	Query Vectors	Distance
SIFT10M [41]	128	10M	10K	Euclidean
DEEP10M [31]	96	10M	10K	Euclidean
DEEP1B [31]	96	1B	10K	Euclidean
GIST1M [42]	960	1M	1K	Euclidean
TEXT10M [31]	200	10M	10K	Angular

Table 2: Datasets used in the evaluation.

some operations (e.g., `arccos`) offline and consult the key-value pairs online to improve the performance of these operations.

6 Evaluation

In this section, we empirically evaluate Auncel from the following aspects: (i) end-to-end performance improvement over state-of-the-art solutions; (ii) effectiveness of ELP; (iii) validation of the mathematical formulation; (iv) system overhead of Auncel; and (v) scalability. The summary of the experiments is as follows.

- Auncel outperforms LAET [30] and Faiss [22] by up to $3.6\times$ and $10\times$ on average query latency under the same error bound, respectively (§6.1).
- The ELPs built by Auncel are highly accurate across a range of datasets (§6.2).
- The mathematical formulation of Auncel fits well with real-world datasets (§6.3).
- The runtime overhead of Auncel is within 1%, and building an ELP offline can be done within ten minutes (§6.4).
- Auncel scales out near ideally, and only takes 25 ms to process a query on DEEP1B with 128 workers (§6.5).

Setup. All experiments are conducted on AWS. We use two EC2 instance types, both configured with Ubuntu 18.04 LTS. For the single-node experiments, we use `c5.4xlarge`, which is configured with 16 vCPUs (Intel Xeon Platinum 8275CL) and 32 GB memory. For the scalability experiments, we use `c5.metal`, which is configured with 96 vCPUs (Intel Xeon Platinum 8275CL) and 192 GB memory. The reason of using `c5.metal` for the scalability experiments is the experiments aim to demonstrate the ability of Auncel to support very large datasets and we need large memory to host DEEP1B (nearly 400 GB memory footprint).

Datasets. Table 2 summarizes the preprocessed datasets used in our experiments. These datasets are widely-used benchmarking datasets for vector query processing in both academic and industry [43, 44]. Each dataset consists of database vectors, query vectors and ground truth. For each query vector, the ground truth records the indexes and distances of its top-100 neighbors. SIFT [41] is a dataset of local SIFT image descriptors [45] with ten million database vectors and ten thousand queries. DEEP [31] is a dataset of CNN [46] image embeddings with one billion database vectors and ten thousand queries. The single-node experiments only use ten million database vectors of DEEP, denoted by DEEP10M. The scala-

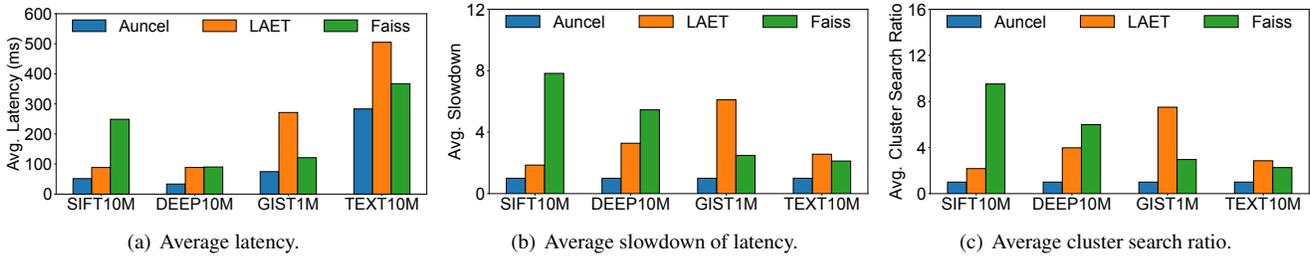

Figure 10: Performance under different datasets.

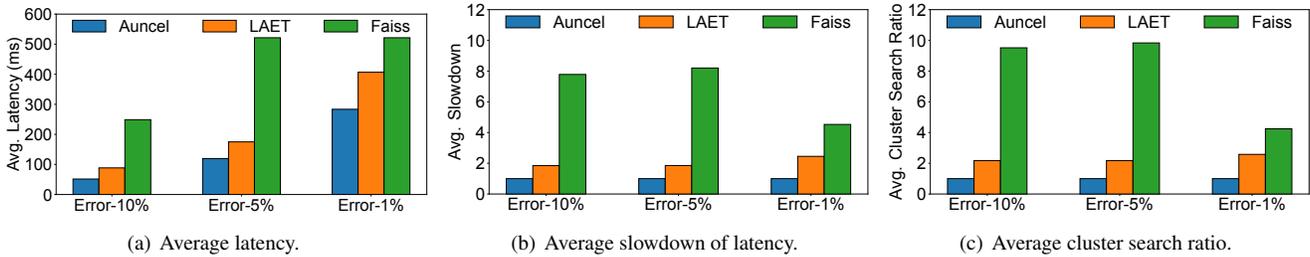

Figure 11: Performance under different error bounds.

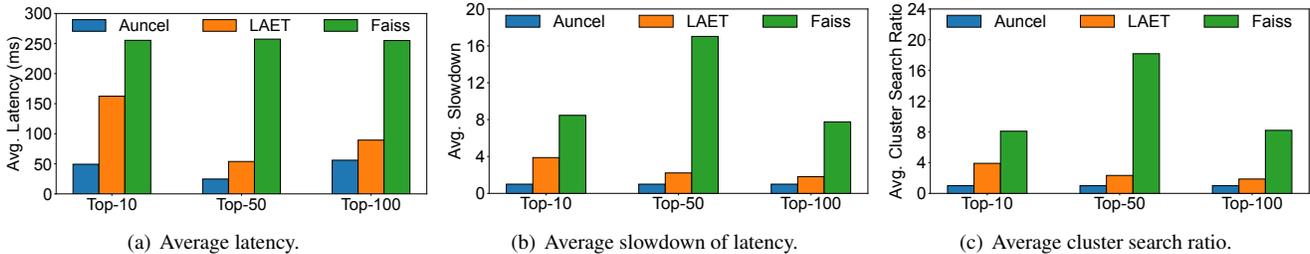

Figure 12: Performance under different values of k .

bility experiments use all database vectors of DEEP, denoted by DEEP1B. GIST [42] is a dataset of global color GIST descriptors [45] with one million database vectors and one thousand query vectors. TEXT [31] is a cross-model [47, 48] dataset of texts and images, where the ten million database vectors and the ten thousand query vectors have different distributions in a shared representation space. The TEXT dataset adopts Angular distance as the distance metric, while the other three datasets use Euclidean distance.

Baselines. We compare Auncel to two baselines.

- Faiss [22] is a widely-used solution for processing vector queries. It uses a fixed approach that picks the same sampling size for all queries under a given error bound.
- LAET [30] is a state-of-the-art solution that uses machine learning to adaptively determines search termination conditions for individual queries.

We emphasize that Faiss and LAET do not provide performance guarantees. To the best of our knowledge, Auncel is the first system that provides performance guarantees for vector query processing. In the experiments, we use the best configurations (e.g., the minimal n in the map for Faiss and the earliest search termination condition for LAET) to guarantee that all queries meet the given error bound. This allows us to

fairly compare the query latency of Auncel, Faiss and LAET, while all three systems satisfy the given error bounds.

Note that it is necessary for all the three systems (Auncel, Faiss and LAET) to train their ELPs offline with some example queries. In the experiments, unless otherwise stated, we randomly split the query vectors into two parts of equal size, one for training and the other for testing. Because Auncel and LAET only perform search on the training queries once, the ELP building times of the two systems are almost the same. However, the grid search method of Faiss requires searching on the training queries for different top- n (exponential power of two in practice to save time), and the building time is tens of times longer than that of Auncel and LAET.

Metrics. We use average end-to-end query latency, $Ave(T_{system})$ as the main evaluation metric, where T_{system} represents the individual query latency of one of the three systems. In addition, we also report average slowdown of latency and average cluster search ratio. Average slowdown of latency is defined as $Ave(\frac{T_{baseline}}{T_{Auncel}})$. Average cluster search ratio is defined as the average ratio between the number of searched clusters by the baseline and that by Auncel, i.e., $Ave(\frac{N_{baseline}}{N_{Auncel}})$, where N represents the number of searched clusters when processing an individual query.

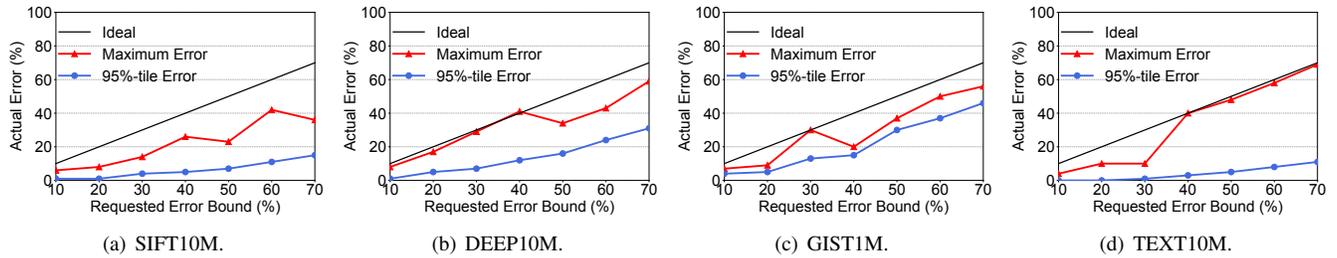

Figure 13: Effectiveness of error profiles.

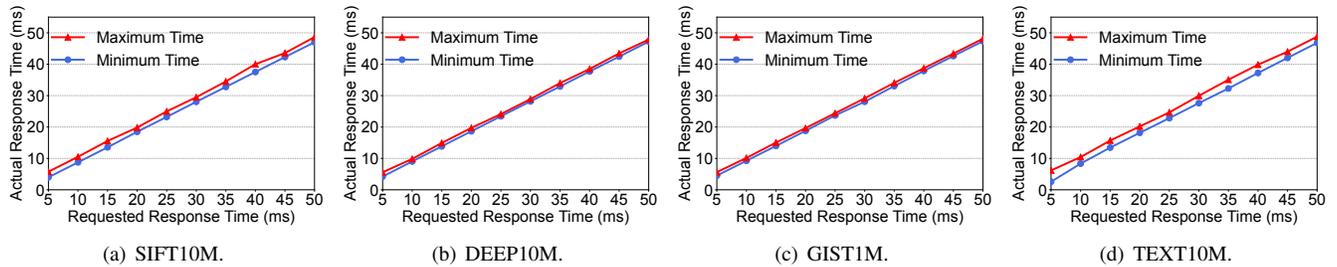

Figure 14: Effectiveness of time profiles.

6.1 Overall Performance

We compare the end-to-end query latency between Auncel, Faiss and LAET under the same error bound. Auncel outperforms Faiss and LAET under different datasets, different error bounds, and different values of k .

Performance under different datasets. We compare Auncel against the baselines on SIFT10M, DEEP10M, GIST1M and TEXT10M. We use one c5.4xlarge EC2 instance. The error bound is 10% and k in top- k is 100 (i.e., returning top-100 nearest neighbors for a query). The results are shown in Figure 10, which we summarize as follows.

- Auncel achieves 1.8–3.6 \times lower average end-to-end latency than LAET and 1.3–4.8 \times lower of that than Faiss under the same error bound. This is because Auncel adaptively and accurately profiles the relationship between errors and sampling sizes, which allows Auncel to sample fewer clusters to generate query results.
- Compared to the gap of average latency between Auncel and the baselines, the gap of average slowdown is larger. This is because Auncel co-adapts individual queries and the error bounds, while the two baselines fail to adapt queries and error bounds at the same time.
- Auncel outperforms the two baselines by up to 9.6 \times in average cluster search ratio. This means Auncel can reduce the search cost by up to 9.6 \times in average while meeting the requested error bound, due to the use of the geometric properties when building ELPs.
- Auncel significantly outperforms Faiss and LAET on all the four datasets, which have different characteristics of data and different metrics of distance (Euclidean and Angular).

Performance under different error bounds. To show that Auncel consistently outperforms the baselines when the error

bound changes, we vary the error bound from 1% to 10% and run the top-100 workload on the SIFT10M dataset. Figure 11 shows the performance under different error bounds. Auncel achieves 1.4–1.7 \times lower average end-to-end latency than LAET and 1.8–4.8 \times lower of that than Faiss.

Performance under different values of k . We also vary the value of k from 10 to 100. We fix the error bound as 10% and run different top- k workloads on the SIFT10M dataset. From Figure 12, we observe that Auncel outperforms LAET and Faiss by 1.6–3.3 \times and 4.6–10 \times on average query latency, respectively. It confirms that Auncel can handle different values of k in top- k .

6.2 Effectiveness of ELP Techniques

In this set of experiments, we evaluate the effectiveness of the ELP building techniques in Auncel.

Error Profiles. To evaluate our error profiling technique, we run Auncel with the top-100 workload on the four datasets. We vary the error bound from 10% to 70%. Figure 13 illustrates the maximum and 95%-tile actual errors. We also plot the ideal straight lines (i.e., actual error equals to error bound) in Figure 13. Note that the measured actual error is always no bigger than the error bound, which demonstrates the ability of Auncel to guarantee bounded errors. As we increase the error bound, the measured actual error increases as well, indicating that Auncel adapts to the error bound. However, the maximum error does not increase monotonically with the error bound on SIFT10M, DEEP10M and GIST1M. This is because the geometric characteristics (e.g., dimension and distribution) of query vectors vary widely across different datasets.

Time Profiles. To evaluate our time profiling technique, we run Auncel with the top-100 workload on the four datasets and

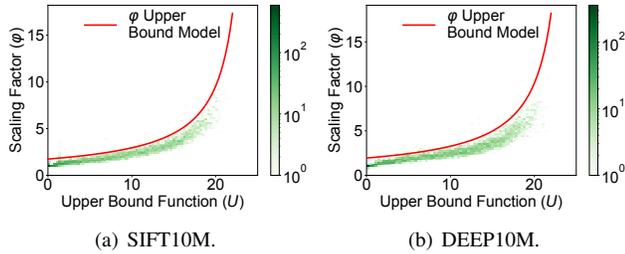

Figure 15: Validation of Formula 10.

report query latency of each query, with a time bound from 5 ms to 50 ms. Figure 14 shows the results of the maximum and minimum end-to-end query latencies. The results show that each query is terminated before the time bound.

6.3 Validation of Mathematical Formulation

This experiment validates that our theoretical model (Formula 10) fits well with real-world unstructured datasets. In ELP initialization, we compute the geometric upper bound function U and collect the corresponding real scaling factor ϕ according to the ground truth. We sample a portion of $U - \phi$ pairs, where ϕ is the maximal in a small interval, to model the tight upper bound of ϕ . The larger interval apparently leads to a tighter upper bound. We then use least squares to fit Formula 10 for these $U - \phi$ pairs. Figure 15 shows the results of the top-100 search workload on SIFT10M and DEEP10M. The results confirm that Formula 10 can well capture the relationship between U and ϕ , which allows Auncel to accurately predict the runtime errors.

6.4 System Overhead

Runtime overhead. To evaluate the runtime overhead of Auncel, we perform an experiment with top- k search workloads on different datasets. We configure Auncel to search fixed number of clusters and make an error prediction after searching each cluster. For comparison, we measure the ELP prediction time and the entire time of query processing. We also vary the value of k from 10 to 100, and run Auncel on SIFT10M. As shown in Table 3 and Table 4, the average latency can hardly be distinguished between Auncel with ELP and Auncel without ELP. The runtime overhead of using ELP in Auncel is within 1%. Note that the average latency almost stays the same from top-10 search to top-100 search. This is because distance computation dominates in the search process such that top- k relevant computation is negligible.

ELP Building Time. We evaluate the offline time taken for ELP building. We configure Auncel to train 50% query vectors with the top-100 workload on different datasets. Table 5 shows that the time to build ELP is within ten minutes, which is relatively small for datasets with ten million vectors.

6.5 Scalability

Auncel shards a dataset into several partitions. For a vector query, it performs local ANN search with ELP in the map

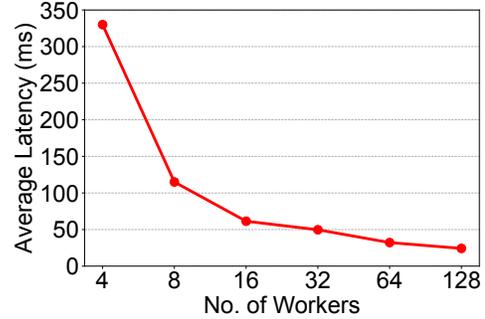

Figure 16: Scalability on multiple workers.

Dataset	Without ELP	With ELP
SIFT10M	68.02 ms	68.41 ms (+0.58%)
DEEP10M	48.16 ms	48.55 ms (+0.81%)
GIST1M	6.86 ms	6.91 ms (+0.70%)
TEXT10M	95.42 ms	96.00 ms (+0.61%)

Table 3: Runtime overhead under different datasets.

Top-K	Without ELP	With ELP
Top-10	68.09 ms	68.47 ms (+0.55%)
Top-50	68.12 ms	68.51 ms (+0.57%)
Top-100	68.02 ms	68.41 ms (+0.58%)

Table 4: Runtime overhead under different values of k .

Dataset	Building Time
SIFT10M	6.20min

TEXT10M	8.65min

Table 5: ELP building time on different datasets.

phase and aggregates the local results in the reduce phase. We evaluate how configurations with different number of workers impact the average latency. We use four c5.metal EC2 instances to verify the scalability of Auncel. In this experiment, we adopt the calibration techniques described in §4.5 to guarantee 10% global bounded error for all queries. We vary the number of workers from 4 to 128, and run the top-100 workload on DEEP1B. Auncel assigns each machine an equal number of workers and spawns a leader worker on one of the machines. The leader worker receives all local top- k results and completes the reduce task. Figure 16 shows that the average latency is almost halved when the number of workers doubles each time, indicating that Auncel scales out *near ideally*. This is because Auncel only transmits the indexes of local top-100 vectors and their corresponding distances to the query vector from the workers to the leader; it does not transmit the raw data of the high-dimensional vectors. The reduce phase to aggregate local results takes only a small portion of the total time. Therefore, Auncel can fully leverage the advantages of data parallelism to scale out.

7 Discussion

Hardware acceleration. Some query engines [23, 49] leverage GPUs to accelerate vector query processing. GPU acceleration works well for small datasets, but is not suitable for large datasets because of limited GPU memory size. Thus, CPUs are widely used in production for large datasets. Also, GPUs are more expensive than CPUs. Therefore, we focus on CPUs for implementation and evaluation in this paper. We remark that the design of Auncel is orthogonal to the underlying hardware. Auncel can be applied to GPUs or other specialized hardware for vector query processing.

Vector compression. Vector compression [50] is proposed to reduce the memory footprint of large datasets. It compresses high-dimensional vectors into low-dimensional space while maintaining the distance property. The number of dimensions in each vector is reduced after vector compression. This technique is orthogonal to Auncel since we only consider the distance property between different vectors. Auncel processes vector queries on a dataset, no matter how many dimensions each vector in the dataset has.

8 Related Work

ANN indexes. Many ANN indexes are proposed to improve query accuracy and reduce query latency, such as IVF [15, 25, 35], graph index [16, 51, 52] and locality sensitive hashing [18, 53–55]. These algorithms perform search on sampling data which trade accuracy for query latency. They leave the sampling size (e.g., top- n in IVF) to users and do not provide bounded performance. These ANN algorithms are orthogonal and complementary to Auncel, and we follow one of the state-of-the-art solutions, IVF, to build Auncel. Besides, ANN algorithms also have different system characteristics [56]. For example, the graph index is more efficient than IVF, but it needs extra memory to hold large graphs. An interesting direction for future work is to build a unified ELP for more ANN indexes and provide bounded performance according to user preferences. Some recent works [30, 57] focus on early stopping conditions of nearest neighbor search to reduce average query latency at a high accuracy, but they do not provide any error or time bound guarantees. With the proliferation of unstructured data and machine learning, ANN on the embedding vectors of unstructured data becomes a key component in many AI applications, such as recommendation [1–4], recognition [5–8] and information retrieval [9–11]. Recent industrial vector data management systems [23, 24, 58] are developed to meet the rapidly increasing demand of these AI applications. They typically build their query processing engines on top of Faiss [22]. As we integrate the Auncel prototype into Faiss, it is convenient for these systems to leverage Auncel to improve vector query processing.

Approximate query processing. Approximate query processing systems [19, 20, 59–61] have gained a lot of popularity

due to the long latency of exact search. These systems all provide time or latency guarantees through probability statistics. However, none of them pays attention to unstructured data represented by vectors. BlinkDB [19] and Quickr [60] focus on structured data and approximate aggregation jobs while ASAP [20] focuses on approximate graph pattern mining. The probability statistics method fails to produce good results on vector queries with performance guarantees. Thus, we introduce a novel high-dimensional geometry theory tailored for vector queries in Auncel. GRASS [21] is a scheduler for approximation jobs in data analytics clusters to alleviate the straggler problem in a map-reduce framework. It is complementary to the distributed design of Auncel since our error and latency calibration mechanism is easy to be integrated into such cluster schedulers. Big data warehouses [62–64] are prevalent in modern cloud services, which provide high-performance query processing. To manage large-scale unstructured data, Auncel can be integrated into these query systems to provide bounded performance. Auncel bridges the gap between approximate query processing and vector queries.

9 Conclusion

We present Auncel, a vector query processing engine that provides bounded errors and latencies on very large unstructured datasets. Auncel exploits the geometric properties of high-dimensional space and the nature of vector query processing to build precise and lightweight ELPs. Auncel is a distributed solution that leverages probability theory to scale out with multiple workers. We demonstrate the performance of Auncel on a variety of datasets. Auncel significantly reduces query latency while meeting error or latency bounds, and scales to billion-scale datasets with latency reduction.

A Appendix

A.1 Validation of Local Uniform Distribution

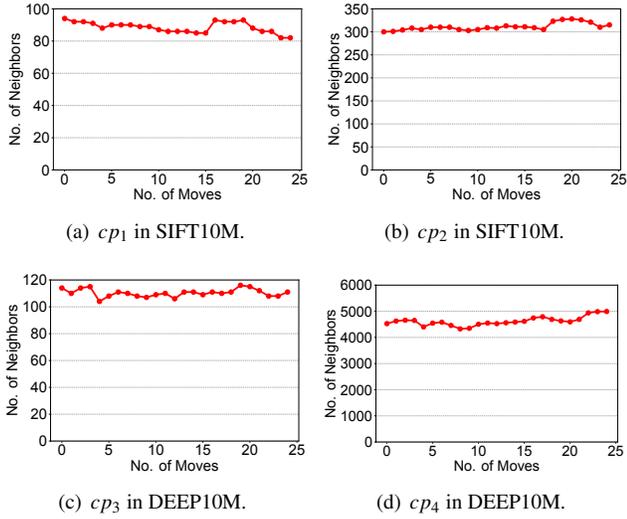

Figure 17: Validation of local uniform distribution.

We emphasize that the assumption about data distribution is *local* uniform distribution rather than uniform distribution. It is because the real-world items are distributed together smoothly. We perform a measurement to validate that vectors conform to local uniform distribution in widely-used unstructured datasets. We randomly pick a central point (cp) in the geometric space and let it do a random walk. Each time cp moves a small distance in either direction, the number of database vectors within a small radius (r) from cp is counted through a sweep. In this measurement, we pick two initial central points for SIFT10M and DEEP10M, respectively. Figure 17 shows the dynamics of the number of cp 's neighbors and how it changes when cp moves. Within 25 moves (i.e., a relatively small local scope), the number of cp 's neighbors fluctuates no more than 14% in the four examples. Consequently, it is reasonable to conclude the local uniform distribution.

A.2 Analysis of Formula 10

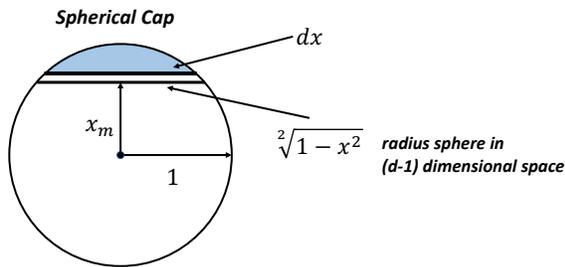

Figure 18: Unit spherical cap.

Let db_m represent the distance between the query vector q and the boundary of C_1, C_m . We leverage cosine theorem to calculate db_m by three anchor vectors, q and the centroid vectors of C_1, C_m , where the boundary is the mid-vertical plane of the line segment connecting the two centroids.

Since only the volume ratio is considered, we simplify the model into unit sphere, which substitutes $\lambda_i(j)$ with unit element (1) and db_m with $x_m = \frac{db_m}{\lambda_i(j)}$ after processing C_i . Thus, $\frac{V(P_i(m))}{V(B(\lambda_i(j)))}$ is identical to the ratio of spherical cap's volume, $V(sc)$ to the volume of the unit sphere as Figure 18 shows. According to properties of high-dimensional space [65], the volume of the unit sphere, $Un(d)$ in d -dimensional space is

$$V(Un(d)) = \frac{\pi^{\frac{d}{2}}}{2\Gamma(\frac{d}{2})}.$$

As for the spherical cap, the exact volume calculation is time-consuming through definite integral. To guarantee the bounded error, it is sufficient to provide an upper bound formula of the ratio. Thus, we derive the following lemma.

Lemma A.1 For any $0 \leq x_m \leq 1$, the fraction of the volume of the hemisphere above the boundary (spherical cap, sc) is $V(sc)$. The unit sphere's volume is $V(Un(d))$ in d -dimensional space ($d \geq 3$). We conclude that $\frac{V(sc)}{V(Un(d))} \leq a \times \arccos(x_m)$, where a is a number corresponding to d .

Proof. The surface area of the intersection of the boundary and the sphere is

$$(1-x^2)^{\frac{d-1}{2}} V(Un(d-1)).$$

Thus, the volume of sc is:

$$V(sc) = V(Un(d-1)) \int_{x_m}^1 (1-x^2)^{\frac{d-1}{2}} dx.$$

Now,

$$\begin{aligned} \frac{V(sc)}{V(Un(d))} &= \frac{V(Un(d-1))}{V(Un(d))} \int_{x_m}^1 (1-x^2)^{\frac{d-1}{2}} dx \\ &\leq a \times \int_{x_m}^1 (1-x^2)^{\frac{d-1}{2}} dx. \end{aligned}$$

As for the upper bound, since $0 \leq (1-x^2) \leq 1$ and $-\frac{1}{2} < 0 < \frac{d-1}{2}$, we have $(1-x^2)^{\frac{d-1}{2}} \leq (1-x^2)^{-\frac{1}{2}}$. Due to the properties of definite integral,

$$\int_{x_m}^1 (1-x^2)^{\frac{d-1}{2}} dx \leq \int_{x_m}^1 (1-x^2)^{-\frac{1}{2}} dx$$

Thus,

$$\frac{V(sc)}{V(Un(d))} \leq a \times \int_{x_m}^1 (1-x^2)^{-\frac{1}{2}} dx = a \times \arccos(x_m).$$

The lemma is concluded by the above proof, and we fit a by sampling queries offline.

Above all, one of U is $\sum_{m=i+1}^l \arccos(x_m)$ in Formula 10 where $a \times U$ represents the upper bound of $\frac{\sum_{m=i+1}^l V(P_j(m))}{V(B(\lambda_i(j)))}$.

Arya: Arbitrary Graph Pattern Mining with Decomposition-based Sampling

Zeying Zhu^{**}, Kan Wu^{†*}, Zaoxing Liu^{*}

^{*}Boston University, [†]University of Wisconsin-Madison

Abstract

Graph pattern mining is compute-intensive in processing massive amounts of graph-structured data. This paper presents Arya, an ultra-fast approximate graph pattern miner that can detect and count arbitrary patterns of a graph. Unlike all prior approximation systems, Arya combines novel graph decomposition theory with edge sampling-based approximation to reduce the complexity of mining complex patterns on graphs with up to tens of billions of edges, a scale that was only possible on supercomputers. Arya can run on a single machine or distributed machines with an Error-Latency Profile (ELP) for users to configure the running time of pattern mining tasks based on different error targets. Our evaluation demonstrates that Arya outperforms existing exact and approximate pattern mining solutions by up to five orders of magnitude. Arya supports graphs with 5 billion edges on a single machine and scales to 10-billion-edge graphs on a 32-server testbed.

1 Introduction

Graph-structured data have been used to represent relationships between entities in various domains, ranging from social networks [23, 39], financial transactions [46, 56], and knowledge bases [4]. There are two main categories of tasks in analyzing graphs: *graph computation* and *graph pattern mining*. Graph computation obtains various properties of a graph, such as PageRank [59] and connected components [41]. Graph pattern mining is more compute-intensive as it discovers structural patterns (i.e., subgraphs), such as motif finding [16, 57], frequent subgraph mining (FSM) [9, 73], and clique counting [21, 40]. These mining tasks are used in various applications, such as counting patterns of financial fraud [1] and detecting suspicious activities on social networks [8].

With graph data reaching multi-billion scales [7, 76], there is an increasing need to mine complex patterns to understand complicated internal relationships [22, 24, 29]. While many graph frameworks have been developed over the years based on various system and algorithmic optimizations, mining complex patterns (e.g., more than 5-vertex) in large graphs remains challenging. The fundamental reason is that pattern mining requires traversing and computing over large intermediate candidate sets, which grow exponentially with

the graph size and pattern complexity. For instance, a recent high-performance mining engine, GraphPi [64], needs several hours to mine a six-vertex pattern in a graph of 1.2 billion edges, using the world’s top-10 supercomputer with 1024 compute nodes (24,576 cores). Other general-purpose graph mining solutions, such as Peregrine [45] and Fractal [33], need more than a day to mine a six-vertex pattern even in small graphs (e.g., 1 million edges) on a 4-server testbed (see details in §7).

To reduce the underlying mining complexity, sampling-based approximation approaches have been proposed, e.g., ASAP [44] leverages a neighborhood sampling approach to approximate the pattern occurrences. Unfortunately, existing sampling-based approaches come with two common issues: (1) When pattern complexity (the numbers of vertices and edges) grows, the number of required sampling algorithm trials (called samplers) increases significantly (e.g., 10^{15} in mining 5-cliques in a billion-edge graph as shown in §2.1), making it infeasible to mine complex patterns in large graphs. (2) Systems like ASAP require developers to define distinct ways to sample a pattern to cover all possible occurrences. It might be easy for simple patterns like triangles: we can randomly pick the first edge, sample the second edge among the first edge’s neighbors, and wait for the third edge to close the triangle. But it is challenging to figure out how to sample complex patterns as there are many distinct sampling ways.

In this paper, we present **Arya**, an approximate mining system that can scale to ultra-large graphs (e.g., 10 billion edges) and mine complex patterns (e.g., 11-vertex). In Arya, we tackle a general approximate mining problem: *Given an input graph, output the approximated occurrences of an arbitrary subgraph*. In many applications, an almost-correct result is sufficient, and the processing time is the key. For instance, a fintech company estimates the frequency of certain complex patterns to quantify the trends of online crime and fraud [24]. The chains of (money laundering) transactions form special patterns and estimating the occurrences of such patterns will help banks and companies to evaluate their operational risks.

Given that designing faster pattern sampling algorithms is theoretically difficult [35], Arya takes a new avenue to **reduce the complexity of the pattern to be sampled**. Inspired by theory advances in graph sampling [14, 34, 36] and graph decomposition [18], our contribution is to bring theory into practice by an end-to-end system design that explores the algorithmic potential of approximate graph mining (e.g., systems

^{*}Equal contribution.

design and optimizations, query accelerations) to meet user requirements (e.g. mining arbitrary patterns and error-latency profiles). Backed by decomposition theory, Arya significantly reduces the inherent approximation complexity of complex patterns in large dense graphs if the pattern can be properly decomposed. Arya has two main components: (1) a pattern decomposer that decomposes a complex pattern into a set of unique simple subpatterns and (2) a parallel estimation engine that generates a number of *samplers* for decomposed subpatterns and constructs an estimated frequency for the original complex pattern.

When designing our pattern decomposer, we need to determine an optimal decomposition of a complex pattern into simpler subgraphs such that it is sufficiently easier to sample the decomposed subpatterns and reconstruct the result for the original pattern. In Arya, we leverage the recent edge-cover-based graph decomposition [18]. The analysis shows that by computing the optimal fractional edge cover of a complex pattern (see §2.2), we can decompose the pattern into a unique collection of unique vertex-disjoint odd cycles and stars, which can be significantly easier to sample than the original pattern. With decomposition, Arya also has unique ways to sample patterns, alleviating the need to explore different sampling methods. Even if a pattern is too simple to be decomposed (e.g., 2-star), Arya performs no worse than existing sampling-based systems.

Once a pattern is decomposed, we build a parallel sampling engine to estimate the pattern occurrence by sampling cycles and stars separately. By extending the edge sampling theory from [15, 18], we build *odd cycle sampler* and *star sampler* with massive parallelism and construct the sampler for the original pattern. Each sampler is essentially a sampling trial aims to find *one instance* of the pattern with a fixed probability p : it merges the sampled odd cycles and stars and tests the remaining edges to find a potential pattern. If the sampled pattern can be formed, the sampler outputs $1/p$; otherwise zero. With a sufficient number of independent samplers, we can obtain an estimated pattern count by averaging the outputs from all samplers (linearity of expectation). To estimate the number of samplers required to achieve the desired accuracy, Arya introduces a heuristic inspired by ASAP [44] to build the Error-Latency Profile (ELP), which takes an error target as the input and infers relevant parameters (e.g., the number of samplers) to configure the graph miner based on bootstrapping (from a small sample of the graph).

With graph decomposition, edge sampling, and a series of system optimizations (e.g., probability-aware scheduling and sampler caching), Arya outperforms *any* existing graph mining systems in scalability. We implement Arya using Memcached to store graph data structures and optimize the most frequent queries to it (e.g., neighbor edges and vertices). We deploy Arya onto three computing scenarios: a single server, a single server with persistent memory, and a cluster with 4 to 32 servers. Our evaluation demonstrates that Arya outper-

forms GraphPi, a state-of-the-art supercomputer-based graph miner, by up to 5 orders of magnitude while incurring a less than 5% error. In addition, Arya outperforms the state-of-the-art approximate mining system [44] by up to $145\times$ and scales to graphs with multi-billion edges. For example, Arya can mine a complex 7-vertex pattern in a 5-billion-edge synthetic graph in several seconds. We open-source Arya and datasets in <https://github.com/Froot-NetSys/Arya>.

In this paper, we make the following contributions.

- We present Arya, an approximate graph miner that scales to large graphs and complex patterns, leveraging advanced graph decomposition theory and edge-based sampling. (§3)
- We introduce techniques to quickly sample decomposed subpatterns and reconstruct the original pattern for approximation, based on the latest cycle/star sampling algorithms. (§4)
- We extend Arya to various distributed settings for heterogeneous graph processing scenarios. (§5)
- We show that Arya mines complex patterns in graphs with 5 billion edges using a single machine and 10 billion edges using multiple machines, a scale that even supercomputer-based systems failed to achieve. (§6,§7)

2 Background and Motivation

In this section, we discuss the background of graph pattern mining and approximate mining algorithms. We then describe the graph decomposition theory that we leverage.

2.1 Graph Pattern Mining

Problem Definition. Graph pattern mining is to find instances of a given pattern in a graph or set of graphs. A pattern is an arbitrary subgraph, which represents user-defined properties attached to the edges and vertices. Pattern mining algorithms aim to find all subgraph instances (called *embeddings*) that match a given pattern of interest. Such matching is usually done via iterating all subgraphs that are *isomorphic* to the input pattern, which is known to be NP-complete. At a high level, the compute complexity of an *exact* pattern mining algorithm is associated with the need to iterate over all possible embeddings in the graph.

Approximate Graph Pattern Mining. Given the search complexity of exact mining algorithms, approximation-based approaches become promising. Approximate analytics is widely used in solving complex big data [58], network telemetry [38, 63], and database problems [11], typically with significantly lower resource overheads. A common idea to perform approximation is to sample a *subset* of the input data uniformly at random and perform analytical tasks over the sampled data. For instance, uniform sampling (e.g., NetFlow and sFlow) has been widely used in monitoring network flows.

• **Advanced pattern sampling:** There is a large body of theoretical work on designing sampling algorithms [44, 47, 60] to mine specific patterns such as triangles and cliques. The

main difference between these algorithms is the way to sample a specific pattern. Intuitively, if a sampling approach can sample a pattern with a higher probability, a smaller number of samplers is required to achieve high accuracy (and thus a shorter completion time). For instance, *neighborhood sampling* is used in ASAP [44]. The main idea of neighborhood sampling is to continuously sample neighbor edges until the pattern can be formed. In mining triangles, each neighborhood sampler starts by sampling an edge uniformly at random and then sampling the second edge from the neighbor edges of the first edge. If there is a third edge in the remaining edges that can form a triangle with the existing two edges, this sampler successfully samples a triangle. Compared to the standard sampling approach that has a $1/m^3$ probability (sampling three edges uniformly at random), neighborhood sampling has a larger probability $1/m \cdot c$ to sample a triangle, where c is the number of neighbor edges of the first edge.

• **Limitations of existing sampling-based systems.** While sampling-based approximation is promising in reducing the computation in graph pattern mining compared to exact algorithms, two significant issues remain:

- (1) Scalability remains an issue in mining complex patterns in (dense) large graphs for systems like ASAP [44]. In particular, the number of required samplers can be prohibitively large, leading to high computation and memory costs. Taking neighborhood sampling as an example, it requires $O(\frac{m^2}{f_p})$ to estimate 4-vertex patterns and $O(\frac{m^3 \Delta}{f_p})$ for 5-vertex patterns, where Δ is the maximum degree in the graph and f_p is the occurrence of the pattern. From 4-vertex to 5-vertex, the computation complexity is increased by up to $O(m\Delta)$, where the number of edges m can be large (e.g., Twitter graph [50] has 1.2 billion edges). This complexity will be increased dramatically for more complex patterns, and this observation is confirmed by ASAP that they cannot scale to more than 5-vertex patterns in their large graphs evaluated in their 16-server testbed.
- (2) Using ASAP, one needs to define how to sample a pattern using their neighborhood API [44]. While it is straightforward to sample simple patterns (e.g., triangle), sampling complex patterns is challenging (e.g., triangle-triangle). For instance, there is only one way to sample a triangle as described above, but there are multiple ways to sample a triangle-triangle (two triangles connected by an edge). It is challenging for developers to figure out all possible samplers when the pattern is even more complex. If samplers do not cover all possible ways to sample patterns, we can see severe underestimations in the final results.

2.2 Approximation with Graph Decomposition

The goal of our system, Arya, is to explore a scalable solution for mining complex patterns in large graphs. One potential way to improve the scalability is to continuously design and develop new sampling techniques that can sample patterns

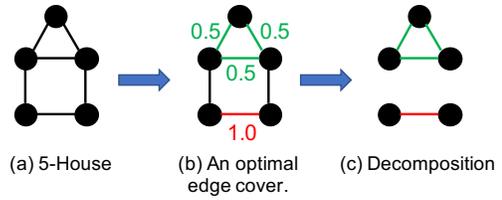

Figure 1: An example of decomposing a pattern.

with higher probabilities. However, the fundamental limitation in this direction is that, we need to sample at least these many of edges and vertices to form a pattern, which implies an upper bound on how large the sampling probability can be on a specific pattern [35].

Instead, Arya aims to take another road to improve the scalability of approximate pattern mining. The question we ask is that *if we cannot improve the sampling technique further, can we instead reduce the complexity of the pattern to be sampled?* We find that, graph decomposition theory [30], which is a powerful tool to reduce the complexity of graph matching and coloring problems, can also be applied jointly with existing sampling techniques to reduce the pattern mining complexity. Recent graph theory advances [18] made a contribution to proving that any subgraph can be decomposed as a collection of vertex-disjoint odd cycles and stars by solving an optimal fractional edge cover problem. This decomposition is a desired property for our purposes, as no matter how complex the patterns are, they can be decomposed into cycles and stars (tackling issue (2)), and these two subpatterns are “easier” cases to be sampled (tackling issue (1)).

Definition 1 ([18]). *Denote the fractional edge cover of a pattern P as $P(V_P, E_P)$, where V_P is the vertex set and E_P is the edge set. $P(V_P, E_P)$ is a mapping $\phi : E_P \rightarrow [0, 1]$ such that for each v in V_P , $\sum_{e \in E_P, v \in e} \phi(e) \geq 1$. The fractional edge cover number is $\sum_{e \in E_P} \phi(e)$.*

The *optimal* fractional cover is to find a subset of edges in the pattern (covering all vertices) that minimum the fractional edge cover number $\rho(P)$ (i.e., $\min \sum_{e \in E_P} \phi(e)$). Intuitively, the key insight (detailed proofs in [18]-A.2) is that for any pattern P , there always exists an optimal fractional cover that maps weights 0.5 to edges that can form odd cycles and maps weights 1.0 to edges that do not belong to any odd cycle (in the cover). This result is powerful because it ensures that we can decompose arbitrary patterns into a collection of odd cycles and stars. Moreover, the analysis further proves that this decomposition reaches optimal bounds for sampling arbitrary patterns, which strengthens our confidence in this decomposition. Thus, we need to calculate the following linear programming (LP), and construct odd cycles with edges of weights 0.5 and stars with edges of weights 1.0:

$$\begin{aligned} & \text{Minimize } \sum_{e \in E_P} \phi(e) \\ & \text{s.t. } \sum_{e \in E_P, v \in e} \phi(e) \geq 1, \forall v \in V_P \end{aligned}$$

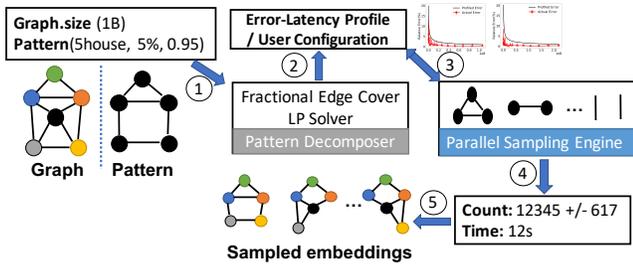

Figure 2: Overall architecture of Arya.

Figure 1 shows a 5-house example to find the optimal fraction cover as (b), and we then decompose 5-house into a three-cycle (if the weight ϕ of each edge is 0.5) and a 1-star (if the weight is 1.0).

Challenges. While the decomposition technique has provable theoretical guarantees, there are several challenges in building a general, distributed system for large-scale approximate graph mining. First, to be of practical use, once a pattern is decomposed into subpatterns, we need a distributed processing engine that optimizes the performance of running a large number of (subpattern) samplers, e.g., how to schedule the execution of the samplers and scale to distributed settings with optimized communication. Second, the graph theory we leverage assumes homogeneous edges and vertices while real-world graphs are often associated with properties. Therefore, the mining queries require *predicate matching* that envisions the technique to be property-aware. Finally, as an approximate processing system, we need to allow users to trade-off accuracy for running time. We need to understand the relationship between errors and actual running time in both single and distributed settings.

3 Arya Overview

We design Arya, an approximate graph pattern mining system leveraging decomposition-based graph sampling. Figure 2 demonstrates the overall architecture of Arya. Arya provides three operating modes to adjust to different compute scenarios: (1) *Single machine* mode that is optimized for local edge and vertex queries; (2) *distributed with replicated graphs* mode where the graph dataset is replicated entirely to multiple machines; (3) *distributed with partitioned graphs* mode that is developed with distributed KV-store (e.g., Memcached) to support arbitrarily partitioned graphs across machines. We provide an overview of different components in Arya and how users can leverage our system to perform approximate mining tasks for arbitrary patterns.

Arya workflow. Arya allows users to mine arbitrary patterns in a graph. As an approximate engine, a user can specify an input pattern and an error budget as follows:

- **Input pattern P :** The user defines an arbitrary subgraph P of the input graph as the pattern to mine in Arya. The user specifies P (in a text file) by adding a list of edges that form the pattern. This pattern will then be decomposed into

a collection of odd cycles and stars via Arya decomposer. Unlike prior approximate mining systems, the user does not need to define the ways to sample the pattern as Arya will always sample stars and odd cycles for arbitrary patterns.

- **Error budget ϵ :** The user specifies an accuracy target by setting an error budget ϵ (e.g., 5%) with a confidence interval (e.g., 95%). Arya is expected to output an approximate result within ϵ error in time T .

After specifying the input pattern and the error budget, Arya first decomposes the pattern via the fractional edge cover LP solver as ①. For building an ELP, the ELP engine will return a required number of samplers (and time) for the error budget ϵ as ② using the parallel sampling engine ③; or the user directly specifies the number of samplers to run. Once the user approves the estimated time, the sampling engine will perform the approximation and return the estimated count with the actual run time as ④. The sampling engine also finds a set of sampled embeddings as ⑤.

Sampling vs. Enumeration. While Arya shows tremendous performance improvements on mining various complex patterns, we observe that Arya works best with the following two assumptions: (1) The graph is *dense* such that there are many pattern occurrences. (2) The decomposed subpatterns need only a few remaining edges to complete the pattern. For (1), it is a fundamental argument between deterministic enumeration-based approaches and sampling-based approaches. When the graph is sparse, it is challenging to find a pattern via random sampling (like “a needle in a haystack”), while it is a better case for enumeration. For (2), if the decomposition of a pattern breaks too many edges, each Arya’s sampler spends extensive efforts on searching the remaining edges to complete the pattern, degrading the execution performance. If these two assumptions do not hold, Arya may experience many failed trials and thus requires more samplers. Therefore, while Arya supports arbitrary pattern mining, the actual runtime depends on the above two key conditions.

4 Basic Design

We now present how Arya enables ultra-fast graph pattern mining by combining pattern decomposition and edge-based sampling as a theoretical foundation. We focus on the single machine design in this section and extend it to distributed settings in the next section.

4.1 Pattern Sampling Algorithms

By leveraging graph decomposition theory (§2.2), a pattern will be represented as a set of vertex-disjoint odd cycles and stars. Our pattern sampler is to sample the relevant odd cycles and stars from the graph and check if there exist remaining edges that complete the pattern. Thus, we introduce two sampling algorithms based on [15, 18] to sample them separately, then use them to construct the pattern. In the algorithms, we denote an odd cycle with $2k + 1$ edges as C_{2k+1} ($k \geq 1$) and a star with l petals as S_l .

Algorithm 1 Odd Cycle Sampler

- 1: **Input:**
 - 2: Graph $G = (V, E)$ where $|E| = m$, an odd cycle C_{2k+1}
 - 3: **Output:**
 - 4: An instance of C_{2k+1} and sampling probability $Pr[C_{2k+1}]$ or 0
 - 5: Sample an edge $e_1 = (u_1, v_1)$ from graph such that $d(u_1) \leq d(v_1)$. \triangleright *sample first edge with an order*
 - 6: Sample $k - 1$ edges $e_2 = (v_2, u_2), \dots, e_k = (v_k, u_k)$ with replacement from G . \triangleright *sample rest edges as the cycle skeleton*
 - 7: Sample a vertex n from the neighbors of u_1 . \triangleright *One more*
 - 8: Check if there are remaining edges $(v_1, u_2), \dots, (v_{k-1}, u_k), (v_k, n)$ in G . If succeeds, output C_{2k+1} and $Pr[C_{2k+1}]$; otherwise, 0.
-

Odd Cycle Sampler. At a high level, our goal here is to sample odd cycles and we can adopt *any* cycle sampling algorithms (e.g., neighborhood sampling [61] used in ASAP [44]). In Arya, we attempt to introduce the algorithm shown in [31] and [18]: first uniformly sample k edges (with the first edge having an order based on the degree), a neighbor edge of the first edge, and then test if there are remaining k edges in the graph to complete a cycle. Compared to ASAP, it is easier for Arya’s sampler to sample an odd cycle using edge sampling since the probability of forming an odd cycle is higher. However, our empirical results show that the two algorithms are comparable for cycles (§7). We adopt this algorithm for two reasons: (1) *Easy to support longer odd cycles*: compared to neighborhood sampling, most of its sampling phase involves only random edge sampling, and thus no need to store nested neighborhood states (e.g. neighbors of neighbors); (2) *Easy to optimize performance* with the hash-based graph structures presented in §4.2 to accelerate queries.

Specially, we present the odd cycle sampler in Algorithm 1. First, we sample a special (directed) edge $e_1 = (u_1, v_1)$ whose first vertex does not have a larger degree than that of the second vertex (Line 5). Second, we sample another $k - 1$ edges uniformly at random with replacement (Line 6). Third, we sample a neighbor edge (n, u_1) of u_1 as the last hoop of the cycle (Line 7). Finally, we need to test if there are remaining k edges in the graph to complete the odd cycle as $(u_1, v_1), (v_1, u_2), \dots, (u_k, v_k), (v_k, n), (n, u_1)$. Since each sampling step is independent, the overall probability to sample this odd cycle is $Pr[C_{2k+1}] = Pr[e_1] \cdot Pr[e_2] \cdot \dots \cdot Pr[e_k] \cdot Pr[n] = \frac{1}{m} \left(\frac{1}{2m}\right)^{k-1} \frac{1}{d(u_1)}$.

Star Sampler. Intuitively, a star consists of a center vertex and a few petals, and sampling a star can be straightforward. There is a broad spectrum of theory work using star samplers as a main or subroutine in various applications (e.g., sparsification, clustering, and matching) [15, 18, 49]. Here, we adopt a common weighted star sampler as in Algorithm 2 (e.g., [15, 18]). We start by selecting a vertex v_1 with proba-

Algorithm 2 Star Sampler

- 1: **Input:**
 - 2: Graph $G = (V, E)$ where $|E| = m$, a star S_l with l pedals
 - 3: **Output:**
 - 4: An instance of S_l and sampling probability $Pr[S_l]$ or 0
 - 5: Sample a vertex $v_1 \in V$ with probability $d_{v_1}/2m$ for any $v_1 \in V$. \triangleright *weighted center vertex sampling*
 - 6: Sample l petal vertices uniformly at random from the neighbors of v_1 without replacement. \triangleright *sample pedals to complete*
 - 7: Output S_l and $Pr[S_l]$ if succeeds; otherwise, 0.
-

bility proportional to its degree $d(v_1)$ (i.e., $\frac{d(v_1)}{2m}$). This step is to sample centers that are more likely to form stars with multiple pedals. In practice, we optimize the query performance by performing an edge sampling as the way to sample v_1 . For instance, if a graph has 50 edges and a vertex v_1 has a degree of 10, randomly sampling an edge is equivalent to sampling a vertex that is v_1 with a probability of 1/10 because there are 10 edges in the graph that are incident to v_1 . This sampled vertex is used as the star center, and we will then sample l vertices from v_1 ’s neighbors uniformly at random without replacement. We will either find such an l -star or return zero from this step. Overall, the probability to sample a star is $Pr[S_l] = Pr[v_1] \cdot Pr[\text{petal_vertices}] = \frac{d_{v_1}}{2m} \binom{d_{v_1}}{l}$.

Approximation for the Original Pattern. We can sample an embedding of the original input pattern if and only if all associated odd cycle samplers and star samplers find their instances. If any sampler does not successfully form their cycle/star embedding, we will terminate this sampler for the original pattern and return zero. Once all the decomposed pattern samplers finish, we need to *reconstruct* the original pattern P by *merging* the cycles/stars and *testing* if the remaining edges between the cycles and the stars do exist in the graph to form the pattern. This is the last step of the whole pattern sampler. During the testing, we list all the possible remaining edges and check if they exist in the graph until there are enough checked edges to complete the pattern. If a complete pattern can be formed with o odd cycles and s stars, the probability of the sampler is $Pr[P] = Pr[C^1] \cdot \dots \cdot Pr[C^o] Pr[S^1] \cdot \dots \cdot Pr[S^s]$. A sampler outputs $R[P] = \frac{1}{Pr[P]}$ if a pattern instance is found; otherwise, it outputs $R[P] = 0$.

In summary, Arya runs a number of such pattern samplers in parallel based on ELP. In the final “reduce” phase, if there are n samplers and sampler i returns result $R_i[P]$, Arya returns $\frac{\sum_{i=1}^n R_i[P]}{n}$ as the final result. This is because Arya’s pattern sampler finds any possible embedding P_i with $Pr[P_i]$. Suppose there are $\#P$ embeddings of the pattern, the expected output of a sampler is $E = \sum_{i=1}^{\#P} \frac{1}{Pr[P_i]} \cdot Pr[P_i] + 0 \cdot (1 - Pr[P_i]) = \#P$. With more samplers, the average of the sampler outputs will be closer to the expected value $\#P$. Therefore, Arya trades more samplers for better accuracy.

4.2 Sampler-Friendly Graph Structures

We observe that both odd cycle and star samplers involve a number of specific queries to the graph data, which are the major computation bottlenecks in the sampler runtime. To improve sampler performance, we summarize the most frequent runtime queries and provide simple, yet effective data structures to accelerate them.

- **Edge sampling:** sample an edge e uniformly at random from the graph.
- **Neighbor sampling** (v, i) : perform a neighborhood sampling on v to obtain the i -th neighbor edge ($i \leq d(v)$) and check what vertex is associated with this edge.
- **Degree checking** v : obtain the degree of vertex v .
- **Edge checking** (u, v) : check if vertices u and v form an edge in the graph.

Given the nature of the queries above in randomized algorithms, we should optimize data stores to accelerate processing. For instance, an edge sampling query can be implemented unoptimized as drawing a random number from the edge list $[1 \dots m]$ and taking a linear traversal to find the exact edge. Instead, we use two auxiliary data stores for performance improvements: (1) An *edge array* that is grouped by vertex with the requirement that all neighbor edges of a vertex are stored consecutively. We observe that many public graph datasets are already stored in this order [6]. (2) A *hash table* that maps vertices to their metadata. Specifically, each vertex has an integer as its ID and its metadata containing the vertex's degree and the starting index of the vertex in the edge array.

4.3 Advanced Pattern Mining Features

Beyond approximating the occurrences of a pattern in a graph, Arya provides users with several advanced features.

Predicate matching. A common way of representing the graph data is in the form of *property graph*, where user-defined properties are attached to the vertices and the edges. Thus, the real-world queries to a property graph may require to match patterns satisfying certain predicates. For instance, a predicate matching query can ask for the count of all 5-House patterns in the graph where all edges are associated with an organization or all vertices meet a certain type.

Arya supports three types of predicates—*at-least-one*, *at-least-percentage*, and *all*. For “at-least-one” or “at-least-percentage” predicates, users are asked to specify a predicate that is applied to at least one (or a percentage or all) of the edges or vertices. Arya can support these predicates since a new property “subgraph” can be maintained and the same sampling techniques can be applied. To perform a predicate matching task, we introduce a *conservative sampling* stage. We first create an auxiliary graph that contains only the edges or the vertices that satisfy the predicate. The odd cycle and star samplers will sample the first (or a percentage of) edges or vertices from the auxiliary graph and then perform the rest of the sampling in the original graph. Different from the non-predicate-case, we need to refine the sampling rates

Algorithm 3 Error-Latency Profile (δ, ϵ)

Input: Original graph G with M edges, sampled subgraph g with m edges (with probability r), pattern P with p edges, error target ϵ , and confidence $1 - \delta$.

Output: Number of estimators N_e for G

```

1:  $avg_{last} \leftarrow \text{inf}$ ,  $range_{last} \leftarrow \text{inf}$ ,  $N_c \leftarrow 10,000$ 
2: while True do
3:   Run Arya 3 times with  $N_c$  samplers on subgraph  $g$ 
4:    $avg_{cur} \leftarrow$  the average count of the 3 trials.
5:    $range_{cur} \leftarrow$  the range (max - min) of the 3 trials.
6:    $\tilde{\epsilon} \leftarrow |avg_{last} - avg_{cur}| / avg_{cur}$ 
7:   if  $\frac{range_{last}}{avg_{last}} < 10\%$  and  $\tilde{\epsilon} < \epsilon$  and  $\frac{range_{cur}}{avg_{cur}} < 10\%$  then
8:      $C \leftarrow \frac{N\tilde{\epsilon}^2 avg_{cur}}{m^{\rho(P)}}$ ,  $h \leftarrow avg_{cur}$ 
9:     Break
10:   $N_c \leftarrow N_c \times 2$ ,  $avg_{last} \leftarrow avg_{cur}$ ,  $range_{last} \leftarrow range_{cur}$ 
11:  $N_e \leftarrow \frac{C \cdot M^{\rho(P)}}{\frac{h\epsilon^2}{r^p} \delta}$   $\triangleright \rho(P)$  is known given  $P$ 

```

based on the number of matched edges or vertices stored in the auxiliary data store. In a simple example, the probability of sampling the first edge uniformly at random is not $1/m$ but $1/m^*$, where m^* is the number of edges that satisfy the predicate. More details can be seen in Appendix A.

Intermediate state caching (e.g., Motifs). We consider two scenarios when some intermediate states can be cached and reused. (a) First, when running multiple mining tasks on the same graph, different patterns may share one or more decomposed subpatterns (i.e., odd cycles and stars). For instance, the decomposed 5-house and triangle patterns share a 3-cycle subpattern. Thus, Arya automatically caches the previous subgraph samplers (3 cycles) to reuse across patterns. (b) Second, some patterns share the same sampling steps in their samplers to form the patterns, e.g., one can sample any 4-motif patterns (except for 3-star) using two 1-star samplers with different remaining edges to complete the patterns. Thus, Arya does not need to sample each 4-motif pattern separately.

4.4 Error Latency Profile (ELP)

Arya allows users to tradeoff accuracy for result latency. As an approximation system, Arya needs to determine the number of samplers for expected errors and running time. Arya uses a heuristic to build the ELP. Our experiments in §7.3 demonstrate the accuracy of the ELP.

According to the mathematical analysis in [18, 30] using Chebyshev's inequality, decomposition-based sampling requires $O(\frac{m^{\rho(P)}}{\#P})$ estimators to provide a $(1 \pm \epsilon)$ -approximation to the ground truth ($\#P$) for any $\epsilon > 0$, where $\rho(P)$ is the minimum fractional edge cover number of pattern P . Furthermore, the actual number of required samplers is lower bounded by $\frac{Cm^{\rho(P)}}{\#P \cdot \epsilon^2 \delta}$ with probability $1 - \delta$ for some constant C . Thus, our goal is to estimate C for a particular graph and a pattern. We

achieve this by using a “sparsified” input graph: we uniformly sample a subgraph from the original graph with probability r (e.g., 30%), and determine an approximate number of needed samplers by running varying numbers of samplers and converging to a stable pattern count. The pseudocode is shown in Algorithm 3. Line 1 gives an initial number of samplers N_c to start with. For a given N_c , the algorithm runs Arya 3 times to obtain the average and range of 3 trails in lines 3 to 5. If the last and current range difference is small enough and when using the current average result as the ground truth, the last average estimated result is within the error target (line 7), we can exit, calculate an estimated C , and treat the current average result as the estimated ground truth h (line 8). Otherwise, ELP exponentially increases N_c (line 10) and proceeds again. Line 11 calculates N_e , the number of samplers for G , based on C and δ , ϵ , M and scaled $\#P$.

5 Scaling Arya to Distributed Settings

In this section, we introduce how Arya is scaled to multiple machines to support larger graphs and more complex patterns. Naturally, a graph store can be distributed in the following three ways: (1) distributed replicated graphs, (2) randomly partitioned graphs, and (3) arbitrarily partitioned graphs. Arya is designed to support all these configurations and arbitrarily partitioned graph is the most challenging one. We introduce several optimizations to improve Arya’s scalability by up to $4.7\times$ over the basic design.

5.1 Distributed Replicated Graphs

Replicated graphs are a common approach for serving input data in distributed graph mining systems, such as Fractal [33] and GraphPi [64]. In Arya, the compute can be distributed directly across the machines if the graphs are replicated. This is because each sampler is independent and each machine will be assigned a subset of required samplers to run on its multiple CPU cores/threads. Each thread takes one sampler at a time. Once the samplers are assigned, there is no communication between machines or samplers until the final aggregation of the results from all the samplers.

5.2 Distributed Partitioned Graphs

The second scenario is when graphs are partitioned to multiple machines. G-thinker [72] and Kudu [52] are example mining systems that assume graphs are partitioned among compute nodes. Similarly, graphs can also be separated from compute nodes in real-world scenarios. Meta, for example, has its own cluster of graph store RIPQ [68]. Arya assumes an API (e.g., `getedge(edgeID)`, `getAdjList(vertexID)`) to access partitioned graphs and can work with either locally partitioned graphs (as in G-thinker) or remote graph stores.

In practice, many partitioning strategies are possible. ASAP [44] requires to partition the graph edges uniformly at random. Graph partition strategies often depend on the workloads (e.g., PageRank [59]). In addition, the graphs may

need to be partitioned based on strategies to be compliant with security and privacy requirements, such as GDPR [3] and GDPR-Neo4j [5]). Unlike ASAP, Arya makes no assumptions about partitioning strategies.

Arya extends its design from replicated graphs to partitioned graphs, with one major challenge to overcome. In contrast to the replicated graph scenario, a graph is partitioned into slices to compute nodes; each node’s samplers will have a potentially large number of random accesses to the graph data stored in other nodes. This poses significant scaling challenges for Arya on partitioned graphs: Arya will be constrained by network communication overheads. A single triangle sampler, for example, entails six graph queries (1 edge sampling, 3 degree checkings, 1 neighbor sampling and 1 edge checking). Each triangle sampler in the Friendster graph [74] generates around 6KB network traffic. To count triangles in Friendster with a 5% error, we will need at least 4 million samplers, which translates to 20 million graph queries and 23GB of network traffic. The computation-communication ratio is approximately $c\frac{p}{(p-1)}$, where c is a constant depending on the pattern and graph, and p is the number of partitions. The detailed analysis is deferred to Appendix C. While the intermediate state caching technique can help reduce communication costs, Arya introduces two more techniques for communication reduction: (1) probability-aware sampler scheduling and (2) batched sampling and communication.

Technique 1: Probability-aware sampler scheduling. A key observation we have is that different decomposed subpattern samplers (e.g., triangle vs. 2-star) have different probabilities to fail (not finding one). According to our Mico graph profiling, a 2-star sampler has a 0.5% failure probability while a triangle sampler has a 92% probability to fail. This is because simpler structures are more likely to be sampled than complex structures in a graph. Based on this observation, we can save communication overheads if we sample these likely-to-fail subpatterns earlier. A lot of such samplers will fail early and we can prune them without running other subpattern samplers. We note that after decomposition, each subpattern sampling occurs independently, and thus the order of subpattern sampling has no effect on the original pattern sampling’s success/failure probability and overall accuracy. Taking the triangle-2star pattern as an example: for each pattern sampler, if sampling the triangle first, it is more likely to fail (92%) and there is no need to sample 2-star in 92% of the cases. Hence, we schedule subpattern samplers in the order of their sampling failure probabilities to achieve better performances.

To do so, we must address an important question: how do we know which subpattern samplers are likely to fail? The answer depends on the pattern and graph. Given the static graph, Arya first offline profiles failure probabilities of popular subpatterns (such as 2-star, triangle) in a small number of trials. Then each pattern counting task can query the failure probability profile for any subpattern samplers. When the failure probability of a subpattern is not in the

profile, we perform an online profile by letting the first set (e.g., 10%) of the samplers collect the failure probabilities information without early pruning. These probabilities will be used to schedule the remaining samplers. This technique is applied to all Arya versions.

Now, we analyze the overheads of Arya’s offline and online profiles. The cost of offline failure profiling is minimal because the overheads are amortized by all queries to the graph, and profiling is limited to simple common subpatterns. For example, profiling simple 2- to 5-stars and triangle subpatterns for the Friendster graph takes only 220ms even for less than 5% error results, whereas a single 5-node pattern query to Friendster can take tens of seconds as we will show in Figure 5(b).

Arya’s online failure probability profiling trades off early pruning opportunities in the query’s first 10% samplers for better subpattern sampling order in its remaining 90% samplers. This approach produces runtime comparable to Arya with perfect subpattern sampling order pre-knowledge and significant improvements over Arya with the worst subpattern sampling order. We use 10% as we found it to be adequate for accurate simple subpattern failure probability profiling.

If the profiled failure probability is inaccurate (which is uncommon as subpatterns are simple patterns that are easy to estimate), Arya may use suboptimal subpattern sampling orders. In this worst case, probability-aware sampling performs similarly to the case of no early pruning.

Technique 2: Batched sampling/communication. Arya reduces overheads from the network stack by using batched sampling and communication. One Arya thread advances a batch of samplers at the same time (vs. progress one sampler until it finishes). When a graph query is required in a sampler, the thread buffers the query and pauses the sampler before moving on to the next sampler in the batch. When all of the samplers in the batch are waiting for graph queries, the thread will begin its batch communication with the graph store (i.e., send out the queries we buffered, for example, with Memcached multi-get).

6 Implementation

We build Arya for both single-machine and distributed graph computing scenarios. The pattern decomposition logic is implemented with Python, and the core components of Arya are written in C++ with 11K LOC. We open-source Arya at [2].

Pattern Decomposition. Arya takes an arbitrary pattern as input and outputs a set of stars and odd-cycles via a pattern decomposition logic. As discussed in §2.2, Arya will find the optimal fractional cover of the input pattern. We use `scipy` linear programming package to find the optimal cover: it takes only 900ms on a single server to decompose complex 20-vertex patterns and less than 400ms for less complex patterns that have fewer than 10 vertices. This running time is negligible compared to the total mining time.

Graph Sampler. There are three versions of sampling logic written in C++: single-machine, distributed replicated graph, and distributed partitioned graph. The former two versions access in-process graph stores, while the distributed partitioned graph version accesses remote graph stores (e.g., Memcached) via TCP. To parallelize the samplers, all Arya versions employ multi-threading. Single-machine version and distributed replicated graph version use the work-stealing algorithm dynamically scheduling computations. A communication thread distributes tasks when the total number of samplers is smaller than required and uses asynchronous communication primitives for work stealing. Worker threads return the results from a batch of samplers to the communication thread when they finish a task. Worker threads then execute the next batch of samplers. We can configure the granularity of a sampling task. For distributed partitioned graph implementation, the master process will initiate samplers on each machine and collect results from each machine when the sampling phase is completed. For evaluating ASAP in a fair setting, we implement ASAP graph samplers using Arya’s system API (which is faster than Spark used in ASAP), including accessing the graph structures and performing edge- and node-related queries.

7 Evaluation

We evaluate Arya on a variety of open-source and synthesized graphs and compare it to the state-of-the-art approximate mining system (ASAP [44]) and exact mining systems (*Single-machine*: Peregrine [45], DwarvesGraph [26], AutoMine [54]. *Distributed*: Fractal [33], GraphPi [64], G-Thinker [72], Kudu [52]). Our experiments demonstrate:

- Compared to single-machine exact mining systems, Arya is up to $105,365\times$ faster than Peregrine within a 5% loss of accuracy when counting complex patterns. To the best of our knowledge, Arya is the first system capable of mining complex patterns (>6 vertices) on giant graphs.
- Compared to distributed mining systems, Arya outperforms Fractal by $62\times$ to $56,842\times$ and GraphPi by up to $988\times$.
- Compared to ASAP, Arya can mine arbitrary patterns in both single-machine and distributed settings. Arya is up to $145\times$ times faster on a single machine and $55\times$ faster in distributed settings, with a 5% error target.
- Arya’s probability-aware scheduling and batched sampling techniques are effective for speeding up Arya by up to $4.7\times$.

Datasets and baselines. We compare Arya to state-of-the-art systems using a set of representative graphs as in Table 1. We obtain the ground truth via running deterministic mining systems such as GraphPi [64] and Peregrine [45]². For datasets used in distributed partitioned graph experiments, the graph

²We are unable to get the mining results of P3 and P4 patterns [64] in the Twitter graph because all tested deterministic miners including GraphPi experienced system crashes or their running time exceeded 24 hours.

Size	Graph	Nodes	Edges	Degrees
Medium	Mico [37]	100,000	1,080,298	22
	Youtube [51]	1,134,890	2,987,624	8
Large	Twitter [50]	41.7 million	1.2 billion	36
	Friendster [75]	65.5 million	1.8 billion	28
Giant	RMAT-5B	500 million	5 billion	
	RMAT-10B	1 billion	10 billion	

Table 1: **Graph datasets used in the evaluation.** We use the RMAT model [48] to generate small and giant synthetic graphs. In the RMAT model, we used default parameters (a, b, c, d) as $(0.44, 0.22, 0.22, 0.22)$.

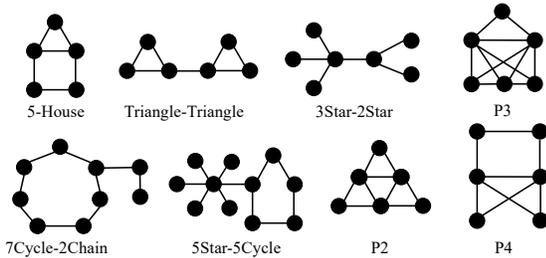

Figure 3: **Evaluated complex patterns.**

is partitioned based on node index hash into relatively similar sizes, and edges belonging to the same node are put into one partition. Since we do not have access to (single-machine) Automine, DwarvesGraph, and (distributed) Kudu, we refer to their performance numbers in a similar setup. Since ASAP is built on Spark, we reimplement its sampling approach using our API for a fair comparison.

Hardware testbed. Our experiments are carried out in three different hardware configurations: (1) Single-machine DRAM, which has 20 CPU cores and 188 GB of DRAM. (2) Single-machine PMEM (persistent memory) with additional $4 \times 128\text{GB}$ Intel Optane DCPM. (3) Distributed settings with 4 to 32 machines in a cluster, each with the same configuration as the single-machine-DRAM. The testbed CPUs are Intel Xeon Silver 4114 clocked at 2.2Ghz per core.

Evaluated patterns. We evaluate both simple patterns (Triangle and 4-Motif) and complex patterns. Most prior systems did not evaluate patterns larger than 5-vertex while Arya can mine arbitrary patterns in large graphs. We describe the complex patterns we evaluate in Figure 3.

7.1 Single-Machine Performance

Overall Performance. We first compare Arya to Peregrine, Automine, Dwarvesgraph, and GraphPi. As shown in Table 2, we evaluate both simple patterns (triangle, 3-Motif) and complex patterns of up to 11 vertices on medium (Mico) and large graphs (Friendster). We also mine the extremely complex patterns such as 3Star-2Star. The results show that Arya significantly outperforms existing systems, particularly in complex patterns. On Mico, complex patterns (3Star-2Star, 7Cycle-2Star, 5Star-5Cycle) always take longer than 24 hours or crash. The long running time of Peregrine illustrates that

Pattern	Graph	System	Runtime	Error/Speedup		
Triangle	Mico	Arya	22ms	0.74%		
		Peregrine	46ms	2×		
		GraphPi	3.5s	159×		
	Friendster	Arya	15ms	1.24%		
		Peregrine	11.3s	782×		
		GraphPi	770.5s	51367×		
3-Motif	Mico	Arya	36ms	0.09%		
		Peregrine	67ms	1.8×		
		DwarvesGraph	48ms	1.3×		
		AutoMine	161ms	4.4×		
		GraphPi	6.86s	190×		
		Friendster	Arya	59ms	0.71%	
	Friendster	Peregrine	20.6s	349×		
		GraphPi	804.4s	13634×		
		4-Motif	Mico	Arya	1.0s	0.42%
				Peregrine	5.2s	5.2×
				DwarvesGraph	1.3s	1.3×
				AutoMine	22s	22×
GraphPi	21s			21×		
Friendster	Arya			13248s	0.76%	
Friendster	Peregrine		2158s	1/6×		
	DwarvesGraph		4369s	1/3×		
	GraphPi		4399s	1/3×		
	3Star-2Star (7 vertices)		Mico	Arya	0.8s	N/A
				Peregrine	>24h	105365×
				GraphPi	2.33s	2.91×
Friendster		Arya	287s	N/A		
		Peregrine	Crashed	N/A		
		GraphPi	924s	3.22×		
7Cycle-2Chain (9 vertices)	Mico	Arya	4s	N/A		
		Peregrine	Crashed	N/A		
		GraphPi	Stuck	N/A		
5Star-5Cycle (11 vertices)	Mico	Arya	211s	N/A		
		Peregrine	>24h	409×		
		GraphPi	Stuck	N/A		
P3 [64]	Mico	Arya	11s	2.5%		
		GraphPi	8.7s	1/1.2×		
P4 [64]	Mico	Arya	6.7s	1.6%		
		GraphPi	13.3s	2×		

Table 2: **Single-machine DRAM: Arya vs. Peregrine, DwarvesGraph, Automine.** This table summarizes runtime of Arya and other graph engines on various patterns (first column) and graphs (second column). Arya has a 5% error target.

existing exact mining systems are fundamentally incapable of mining complex patterns. In contrast, Arya counts 3Star-2Star in Mico in 0.8s, outperforming Peregrine by 105,365×. We observe that while GraphPi completes mining star-related patterns, their results were incorrect, which prevents us to evaluate Arya’s errors in some cases.

In this setting, we also explore an undesirable scenario for Arya (and any sampling-based approaches). In the Friendster graph, the occurrence of 4-Motif is relatively “sparse”, making sampling-based approaches fundamentally more challenging to sample patterns. This is due to the “searching a needle in a haystack” effect and it is an ideal case for traversal-based solutions. Thus, in this scenario, Arya is running 3 to 6 times slower than exact mining solutions.

Table 3 shows results for Arya’s **intermediate state caching** technique under the scenario when running three

Mico	Triangle-Triangle	5-House	Triangle
No Cache	13.3s	4.8s	0.079s
Cache	14.6s	3.0s	0.037s
Speed Up/Down	0.91×	1.6×	21.2×
Youtube	Triangle-Triangle	5-House	Triangle
No Cache	188.7s	297.9s	0.32s
Cache	198.7s	127.6s	0.011s
Speed Up/Down	0.95×	2.3×	27.9×

Table 3: **Arya’s intermediate state caching technique.** This table summarizes runtime and speedup of applying intermediate state caching technique when mining three patterns consecutively. Since these patterns share a common subpattern triangle, Arya caches the triangle samples in mining Triangle-Triangle and reuse them in the 5-House mining. Similarly, Arya also caches additional triangle samples when mining 5-House. These cached triangle samples accelerate the Triangle mining task significantly.

Pattern	Graph	System	Runtime
Triangle	RMAT-5B	Arya (10%)	89s
	RMAT-5B	Arya (5%)	337s
	RMAT-5B	Peregrine	Crashed
3Star-2Star	RMAT-5B	Arya (10%)	395s
	RMAT-5B	Arya (5%)	1583s
	RMAT-5B	Peregrine	Crashed

Table 4: **Scaling single-machine Arya to giant graphs with PMEM.** This table summarizes runtime of Arya (10% and 5% error rates) and Peregrine when mining on RMAT-5B.

mining tasks (Triangle-Triangle, 5-House, and Triangle) on the same graph. Arya can mine multiple patterns one by one. Except for the last pattern Triangle, the sampled subpatterns and their actual sampling probabilities are cached; starting from the second pattern, we can reuse the cached subpatterns instead of sampling new ones and thus the running time is reduced. This experiment shows that when mining multiple patterns with shared subpatterns, Arya can achieve significant speedups (e.g., up to 27.9× for the last task) as the performance bottleneck is sampler computation and performing caching has negligible performance overheads.

We add **persistent memory** into the single machine to mimic large memory machines. On a giant 5-billion-edge graph (RMAT-5B), Arya counts triangles in 337 sec and mines a complex pattern of 7 vertices (3Star-2Star) in less than 30min while Peregrine fails to complete (Table 4).

Arya vs. ASAP. Figure 4 compares the running time of Arya and ASAP for different error rates. Both approximate systems, as expected, require more samplers to achieve lower error rates. However, the performance differences of the two approaches lie in two key factors: (1) the number of samplers needed and (2) the running time of each sampler. Compared to ASAP with the same error rate, Arya usually achieves better runtime because it requires fewer samplers (due to decomposition) and/or individual samplers run faster (due to Arya

uses edge sampling while ASAP uses neighborhood sampling and Arya’s system optimizations). For instance, when the graph is large (e.g., YouTube), the pattern is complex (e.g., 5-House, Triangle-Triangle), Arya requires fewer samplers, each of which is also faster than that of ASAP. Thus, for example, Youtube graph and 5-House pattern (Figure 4 (c)), Arya achieves less than a 5% error rate in 1.2s, whereas ASAP takes 3 min (145× slower). For small dense graphs (e.g., Mico, Figure 4 (b)), Arya and ASAP have comparable performances because they require comparable numbers of samplers, and their samplers have similar running times.

7.2 Scaling Arya on Distributed Settings

Arya can mine graphs that are (a) replicated across servers and (b) partitioned across servers (e.g., simulating geo-distributed graphs). We use a cluster with 4 to 32 servers.

7.2.1 Distributed Replicated Graphs

When graphs are replicated across nodes, Arya mines on each node in parallel and aggregates sampled results in a “reduce” phase. Many existing systems (e.g., Fractal and GraphPi) scale to multiple nodes using replicated graphs.

Overall performance. As depicted in Table 5, we compare Arya to Fractal and GraphPi on a 4-node cluster. In summary, Arya outperforms both Fractal and GraphPi, especially when graph is large and pattern is complex. For example, when mining triangles on the Twitter Graph, Arya achieves a 988× speedup over GraphPi. When the pattern is changed to Triangle-Triangle (a 6-vertex complex pattern), neither Fractal nor GraphPi can complete execution within a day, whereas Arya takes only 393 seconds. Overall, our results show that Arya has a significant advantage when mining complex patterns on large graphs.

Table 6 compares the performance of Arya, GraphPi, and ASAP (Spark version) on larger clusters. Arya outperforms both ASAP (by up to 55×) and GraphPi (by up to 1084×) on simple (e.g., 3-Motif) and complex patterns (e.g. 5-House). Referring to one of GraphPi’s pattern (P2) mining results on a world-class supercomputer (up to 1024 nodes), we can see that approximate graph mining system Arya can achieve even better performance with only 16 nodes, demonstrating significantly better scalability.

Scalability in a Cluster. Figure 6 illustrates how Arya scales as more nodes (or cores) are added to the cluster. The runtime of Arya decreases as more machines are assigned to it. Arya can scale for both small and large graphs, whereas GraphPi cannot scale for larger Twitter graph with more than eight nodes. We find that the scaling of Arya is slightly worse than linear scaling. This is due to increased synchronization overheads of the final results when there are more nodes.

7.2.2 Distributed Partitioned Graphs

Unlike in a replicated graph setup, the graphs are partitioned across machines, and Arya samplers now require communi-

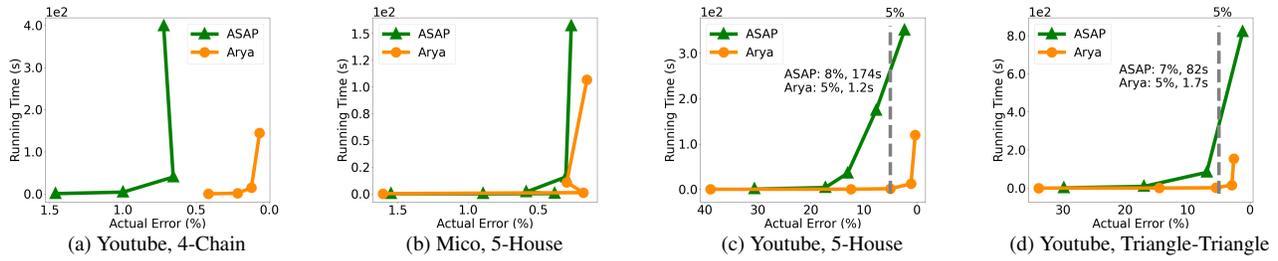

Figure 4: Comparing ASAP and Arya on running time vs. actual errors. This figure compares ASAP (our reimplement for fairness) and Arya’s running time (y axis) v.s. estimation errors (x axis, descending order). We report median absolute error rate % from 10 runs of each experiment. As shown, Arya requires fewer samplings and less runtime for the same error rate as ASAP, especially for large graphs and complex patterns.

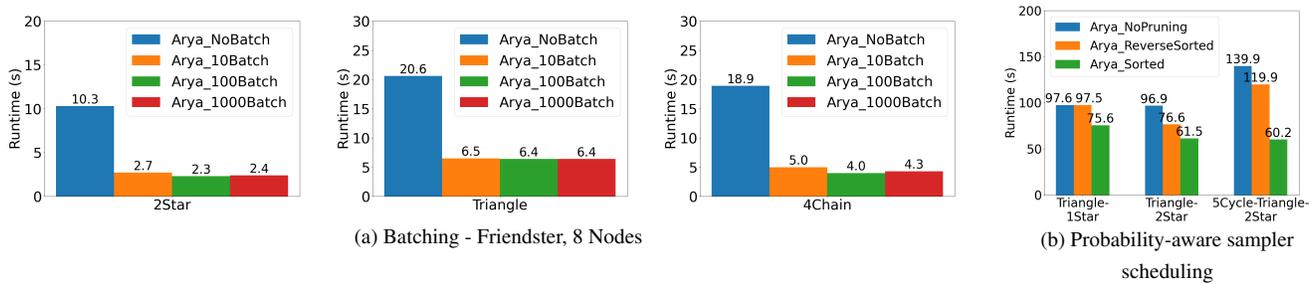

Figure 5: Effectiveness of Arya batching and probability-aware sampler scheduling. This figure compares the performance of Arya with and without 1) batching and 2) probability-aware sampler scheduling techniques. In figure (a), *Arya_NoBatch* represents Arya without batching. *Arya_KBatch* represents Arya with *K* batched sampling and batched communication. We vary *K* between 10 and 1000. In figure (b), *Arya_NoPruning* represents the basic version of Arya, which samples all sampling blocks and then judges them all together. *Arya_Sorted* represents Arya when sampling according to the fail probability of each sampling block and terminating the estimator after any block fails. *Arya_ReverseSorted* is Arya that does sampling based on fail probability in a descending order.

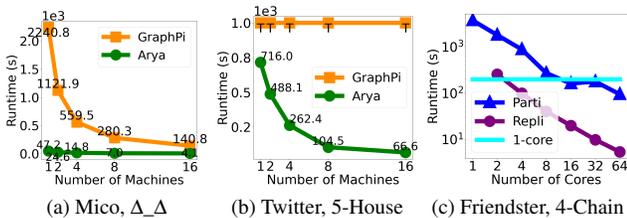

Figure 6: Scalability of Arya. This figure shows the performance of Arya when the number of nodes (cores) with replicated and partitioned graphs varies. We examine both small (Mico) and large (Twitter and Friendster) graphs, as well as various patterns. The letter ‘T’ indicates that the execution time exceeds 24 hours. Δ_Δ denotes Triangle-Triangle pattern. (a) and (b) shows the scalability of replicated-graph version Arya compared with GraphPi. (c) shows the replicated-graph and partitioned-graph versions of Arya compared with single-thread Arya showing the COST metric on Friendster graph and 4-Chain pattern, where ‘Parti’ represents partitioned-graph version and ‘Repli’ represents replicated-graph version.

cations with remote nodes to obtain the necessary sampled edges or neighbors of vertices for testing. In this experiment, graphs are partitioned into machines based on their vertices and associated edges, and is stored in a Memcached instance on each machine. For simplicity, we evenly partition the graph to Memcached nodes.

Effectiveness of Arya Scaling Techniques. We begin by demonstrating the efficacy of batching and probability-aware scheduling techniques in improving Arya performance on

partitioned graph setups. As shown in Figure 5 (a), batching can significantly improve Arya performance on partitioned graph setups. Batching improves Arya 2-Star, Triangle, and 4-Chain mining by 4.5 \times , 3.2 \times , and 4.7 \times , respectively, on eight nodes with Friendster graph. Because we’ve found that batching more than 100 samplers together yields minimal benefits, we set the default batching size to 100.

Figure 5 (b) shows how probability-aware sampler scheduling can help with Arya mining complex patterns. In this experiment, we use two nodes and the Mico graph. As an example, consider the following subpatterns: 2-Stars, triangle, and 5-Cycle. These subpatterns have very different sampling success probabilities: 2-Stars: 99.5%, Triangles: 8%, and 5-Cycles: 0.09%. When mining complex patterns containing these subpatterns, we can see that Arya samples with sorted likely-to-fail subpattern samplers and the early pruning achieves up to 2.3 \times (for 5Cycle-Triangle-2Star) better performance than no pruning. Arya’s samplers with other orderings of subpatterns (e.g., *ReverseSorted*) cannot achieve comparable performance to fail probability sorted sampling.

McSherry’s COST metric [55]. Figure 6 (c) shows the scalability of Arya’s distributed replicated and partitioned versions compared with the runtime of a single thread Arya. The replicated version’s COST is around 2.7 cores because the MPI implementation uses a master thread to poll results from worker threads, using at least 1 core. The partitioned version’s

Pattern	Graph	System	Runtime	Error/Speedup
Triangle	Mico	Arya	0.5s	0.74%
		Fractal	145s	278×
		GraphPi	5.4s	10×
	Youtube	Arya	0.55s	0.78%
		Fractal	317s	576×
		GraphPi	38s	69×
	Twitter	Arya	3.8s	0.96%
		Fractal	>24h	22,736×
		GraphPi	3755s	988×
4-Motif	Mico	Arya	3.3s	0.42%
		Fractal	205s	62×
		GraphPi	33s	10×

		Fractal	>24h	5760×
		GraphPi	11696s	779×
	Twitter	Arya	393s	N/A
		Fractal	failed	N/A
		GraphPi	>24h	220×

Table 5: Distributed replicated graphs (4-nodes).

COST is around 13 cores due to large communication costs in Memcached. In this version, scaling 1-core to 16-core experiments run on a single machine, and 32-core and 64-core experiments run on 2 and 4 machines of 16 cores.

Overall performance. Table 7 summarizes Arya’s overall performance in comparison to G-thinker and Kudu. Kudu is a system that converts single-machine or distributed replicated graph mining systems (such as GraphPi and Automine) to partitioned graph setups. As shown in the table, Arya outperforms all existing exact graph mining systems on small (e.g., Mico) and large (Friendster) graphs, mining simple (e.g., 2-Star) and complex patterns (e.g., Triangle-2Star). The improvement is most noticeable on complex patterns. G-thinker, for example, fails to execute both Triangle-1Star and Triangle-2Star on a small Mico graph within a day; however, Arya can finish in seconds, yielding a speedup of more than 44000×

Mining 10-billion edges graph on a large cluster. Table 8

Pattern	Graph	System	Runtime	Error/Speedup
3-Motif	Twitter	Arya, 16 × 8	2.8s	0.34%
		ASAP, 16 × 8	150s	55×
		GraphPi, 16 × 8	2971s	1084×
5-House	Twitter	Arya, 16 × 16	60s	4.06%

		G-thinker 2 Nodes	>24h	44766×
Triangle-2Star (6 vertices)	Mico	Arya 2 Nodes	1.73s	0.40%
		G-thinker 2 Nodes	Crashed	N/A

Table 7: Distributed Partitioned Graphs: Arya vs. G-thinker vs. Kudu-GraphPi, Kudu-Automine. This table compares Arya and G-thinker and Kudu performance on partitioned graphs. The system column indicates both system name and how many nodes the graph is partitioned to.

shows the Arya runtime with 32 nodes mining patterns on a 10 billion edges graph (RMAT-10B). As shown in the table, Arya can mine huge graphs quickly. It completes triangle counting in 22 minutes for a 5% error rate and 358s for a 10% error rate. When mining 4-Chain, we see similar levels of speed. Arya can mine complex patterns even though it requires more time of sampling on a huge graph; for example, for a pattern with 7 vertices like 3Star-2Star, Arya finishes in 4.2h with a 10% error rate.

7.3 Effectiveness of Arya ELP

Finally, we evaluate the effectiveness of Arya Error-Latency Profiling. In this experiment, we compare the actual error vs. the predicted error from Arya ELP given a variety of amount of samplers. The Arya runtime is proportional to the number of samplers. As depicted in Figure 7, we investigate various patterns (Triangle and 3-Star) on various graphs (Youtube, Friendster, Twitter). We build the error profile by running

Pattern	Graph	System	Runtime
Triangle	RMAT-10B	Arya (10%)	358s
	RMAT-10B	Arya (5%)	1275s
4-Chain	RMAT-10B	Arya (10%)	171s
	RMAT-10B	Arya (5%)	688s
3Star-2Star	RMAT-10B	Arya (10%)	4.2h
	RMAT-10B	Arya (5%)	16.5h

Table 8: **Arya mining 10-billion edges huge graph.** This table summarizes runtime of Arya (10% and 5% error rate) when mining on RMAT-10B on a 32-node cluster.

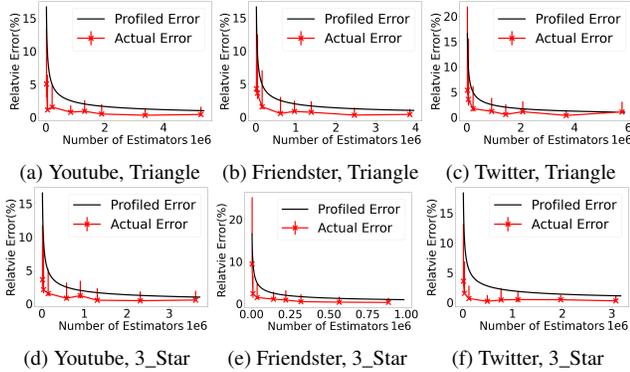

Figure 7: **Relative errors vs. number of estimators for YouTube, Friendster, and Twitter graphs.** Actual error is obtained by compare Arya results with ground truth, and profiled error is the error estimated by ELP given a number of samplers.

different numbers of samplers. We run ten trials for each x-axis value and report the *median* and *variance* error bars. As we can see, Arya ELP yields good upper bounds for the required error targets.

8 Related Work

Single-machine mining systems. A number of single machine exact mining systems have been proposed [26, 28, 43, 45, 54, 70]. These systems leverage a wide spectrum of system optimizations to prune the intermediate state and accelerate the subgraph exploration process. For instance, Peregrine [45] focuses on pattern-aware techniques to reduce the exploration of unnecessary subgraphs. Essentially, it prunes the incomplete subgraphs early if they cannot later form the pattern. Automine [54] and RStream [70] use guided exploration strategies but reduce memory usage. The fundamental performance bottleneck of these exact systems is that *regardless of how optimized the exploration techniques are, one must still explore all the patterns in the graph.* When the pattern occurrences are dense in the graph, this bottleneck will be significant. Arya leverages decomposition-based sampling, which significantly reduces exploration complexity. Another related work is DwarvesGraph [26], which also uses a type of pattern composition to count the decomposed subpatterns separately and thus reduces the overall computation. However, DwarvesGraph’s decomposition technique cannot be

applied with sampling techniques to further reduce search complexity. Some related architecture works leverage different architectures and hardware to accelerate enumerating graph patterns [27, 62, 65–67], while Arya and compared baselines run on general-purpose CPUs.

Distributed mining systems. To scale graph mining tasks on larger graphs, a wide range of distributed mining systems are proposed [10, 17, 25, 33, 53, 64, 69, 72]. Recent systems such as Fractal [33] and GraphPi [64] focused on supporting general-purpose mining tasks. Fractal extends the “embedding-aware” processing model by introducing the concept of *fractoids* and reduces the complexity of its depth-first search exploration. GraphPi is a high-performance graph miner that optimizes computation and communication overheads by introducing a 2-cycle-based automorphism elimination algorithm. GraphPi scales to supercomputers (up to 1024 compute nodes) to support complex pattern mining in large graphs. Arya’s decomposition-based sampling technique further improves the scalability by several orders of magnitude.

Graph approximation theory. There have been rich efforts from theory community to analyze and propose approximate graph algorithms for various graph analytical tasks [12, 13, 18–20, 32, 42, 60, 71]. Among these efforts, only a small subset of them are used in graph systems. None of them are aimed at distributed scenarios, nor do they introduce methods to understand the real-world performance of the algorithms. To bring theory into practice, we entail careful understanding of the algorithmic tradeoffs and the actual computation scenarios. We leverage this rich theoretical foundation to further improve the sampling-based approximate systems and propose a series of sampling-friendly optimizations.

9 Conclusions

We observe that existing graph pattern mining systems cannot scale to complex pattern mining over large graphs as they fail to cope with the explosively growing mining complexity. We propose Arya as an approximate graph miner that combines graph decomposition theory with sampling techniques to achieve optimized mining complexity over arbitrary patterns. Arya can deal with large billion-level graphs even in a single machine and can scale to larger graphs in distributed settings. Our evaluation demonstrates that Arya outperforms state-of-the-art mining systems by up to five orders of magnitude. We posit that Arya can potentially be applied to extreme mining scenarios (e.g., trillion edges) on a small computing base, and we plan to explore this for future work.

A More Details on Predicate Matching

In predicate “all”, queries specify a predicate that is applied to every edge or vertex. For instance, one can query “5-House patterns where all edges have the property NSDI”. To support such a query, Arya introduces a *conservative sampling* stage to generate a new graph (of edges and their vertices) from the original graph, where the predicate condition is applied to every edge; and in the sampling phase, Arya runs only on this new property graph. This step ensures that “all” edges match the predicate.

In predicate “at-least-one”, queries specify a predicate that is applied to at-least one edge or vertex. For example, one such query is “5-House patterns where at-least-one edge has a weight > 66 ”. To support such predicate queries, we change the runtime workflow to take two passes on the graph. In the first pass, edges matching the predicate of weight > 66 are generated as a new graph. In the second pass, every sampler picks the first edge randomly from the new graph. This ensures that the pattern found by the sampler (if it does find one) meets the predicate. For the rest of the edges, the sampler continues sampling on the original graph, which can add zero or more edges that satisfy the predicate. If a duplicated edge is found, we disregard this sampler. This ensures that the probability analysis of Arya to estimate the error still holds.

Similarly, in the predicate “at-least-percentage”, we use the two-pass approach as in the predicate “at-least-one”. The only difference is we need to sample a percentage of edges from the newly generated graph.

B Detailed Explanation of Sampling Algorithms

In this section, we introduce the data structures and probability calculation used in the decomposition sampling. Algorithm 4 and Algorithm 2 describe the building blocks of decomposition sampling in our implementation as [18]. We use sampler trees as sampling data structures for maintaining the (inverse) probability. Figure 8 shows a $(2k + 1)$ -odd cycle sampler tree and an l -star sampler tree representation. Each subpattern (an odd cycle or a star) always has a two-layer sampler tree structure. The first layer is a root node, the second layer contains one or more nodes as leaves and we assign the inverse probability to each leaf.

Odd Cycle Sampler Tree. In Figure 8 (a), e_1, \dots, e_k in the cycle sampler tree root denotes first k edges sampled in Algorithm 4 (line 5 and 6) and n_1, \dots, n_b in b leaves denotes vertices sampled in line 7 and 8 where $b = \lceil d(u_1)/\sqrt{m} \rceil$. This set of nodes and edges can potentially form at most b $(2k + 1)$ -odd cycles in the original graph which are represented in b branches in the cycle sampler tree. The inverse probability of one leaf i is $Pr_i[C_{2k+1}] = Pr[e_1] \cdot Pr[e_2] \cdot \dots \cdot Pr[e_k] \cdot Pr[n_i] = \frac{1}{m} \left(\frac{1}{2m}\right)^{k-1} \frac{1}{d(u_1)}$ if the root edges and the node in the leaf can

Algorithm 4 Odd Cycle Sampler Tree

- 1: **Input:**
- 2: Graph $G = (V, E)$ where $|E| = m$, an odd cycle C_{2k+1}
- 3: **Output:**
- 4: A set consisting of C_{2k+1} or 0

- 5: Sample an edge $e_1 = (u_1, v_1)$ from graph such that $d(u_1) \leq d(v_1)$. \triangleright *sample first edge with an order*
- 6: Sample $k - 1$ edges $e_2 \dots e_k$ with replacement from G . \triangleright *sample rest edges as the cycle skeleton*
- 7: **for** $i = 1$ to $\lceil d(u_1)/\sqrt{m} \rceil$ **do** \triangleright *Sample last hoop edge*
- 8: Sample a vertex n_i from the neighbors of u_1 .
- 9: Test if there are edges in G to complete an odd cycle.

form an odd cycle; otherwise, the inverse probability is defined as $Pr_i[C_{2k+1}] = 0$.

Star Sampler Tree. In Figure 8 (b), v in the root node is the central vertex of the star and v_1, \dots, v_l in the leaf node are l petals. The inverse probability of the leaf is $Pr[S_l] = Pr[v] \cdot Pr[\text{petal_vertices}] = \frac{d_v}{2m} \binom{d_v}{l}$, where m is the total number of edges in graph G .

Approximation for the Original Pattern. Supposing a pattern P consists of o odd cycles $C_{2k_1+1}, \dots, C_{2k_o+1}$ and s stars S_1, \dots, S_s , and $z = 2o + 2s$. A pattern-sampler tree will be a z -level tree which consists of odd cycle sampler subtrees and star sampler subtrees. To obtain the final pattern-sampler tree, we run subpattern samplers in some order. The pattern-sampler tree keeps extending two new layers by connecting each last-layer leaf-node to a new subpattern subtree root. A final sampler tree is shown in Figure 9 (a). We also show a 5-House sampler tree example in Figure 9 (b). As 5-House is decomposed into a triangle and an 1-star (see Figure 1), the first two layers of 5-House sampler tree represent a triangle sampler tree, and for the last two layers each branch represents a 1-star sampler tree.

A path from the root to a leaf in the pattern sampler tree forms a potential pattern. If path j passes connectivity test with remaining edges, the probability of the path is $Pr[P_j] = Pr[C_j^1] \dots Pr[C_j^o] Pr[S_j^1] \dots Pr[S_j^s]$ because subpatterns are sampled independently. The output of a sampler path is $R[P_j] = \frac{1}{Pr[C_j^1] \dots Pr[C_j^o] Pr[S_j^1] \dots Pr[S_j^s]}$ if it forms a pattern after testing; or $R[P_j] = 0$ if it's not. The estimated pattern number outputs by a pattern sampler tree is the average of each path's estimation output, which is $R[P] = \frac{\sum_{j=1}^w R[P_j]}{w}$ supposing we have w final-layer leaves. We aggregate results from all pattern sampler trees as their average number $\frac{\sum_{i=1}^n R_i[P]}{n}$, supposing there are n sampler trees and tree i outputs $R_i[P]$. [18] proves the expectation estimated by $R_i[P]$ is the number of pattern P in graph G (denoted as $\#P$) and variance is bounded.

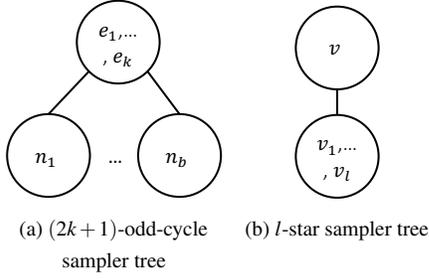

Figure 8: **Subpattern sampler trees used in decomposition.** This figure shows $(2k+1)$ -odd-cycle sampler tree and l -star sampler tree each corresponding to Algorithm 4 and 2.

C Computation-Communication Ratio Analysis in Partitioned-graph Setting

In this section, we calculate computation-communication ratio based on sampler tree implementation. In terms of computation cost, in an l -star sampler, we sample l neighbors randomly and thus the contribution to computation cost is $\Theta(l)$. In a $(2k+1)$ -odd cycle sampler, we sample an edge from the graph first, which is $\Theta(1)$, and then sample $k-1$ edges with cost $\Theta(k-1)$. And then we sample $\lceil d(u_1)/\sqrt{m} \rceil$ vertices from the first node u_1 's neighbors, which costs $\Theta(d(u_1)/\sqrt{m})$, where m is the number of edges in the large graph and $d(u_1)$ is the degree of the start vertex of the first sampled edge. Let $\bar{\Delta}$ denote the average degree of the large graph. Testing completeness of these $\lceil d(u_1)/\sqrt{m} \rceil$ cycles needs to test k edges, whose cost is $\Theta(k \cdot \bar{\Delta})$ after amortizing since our neighbor checking goes through all the neighbors of the start vertex. We also test the remaining edges of the entire pattern connecting each subpattern, and the computation cost is $\Theta(x \cdot \bar{\Delta})$ supposing there are x remaining edges. Supposing the pattern contains s stars and o odd cycles, the total computation cost for one sampler is $\sum_j^s l_j + \sum_i^o (k_i + \frac{\bar{\Delta}}{\sqrt{m}} + k_i \cdot \bar{\Delta}) + x \cdot \bar{\Delta}$ by amortizing the degrees among multiple sampling trials.

Supposing we have p partitions ($p \geq 2$). In our evaluation, we partition the vertices nearly uniformly by hashing the vertices to a machine, the probability of a sampler may not have a vertex's neighbors locally is $\frac{p-1}{p}$. For an l -star sampler, if the central vertex of this star is local to the machine running the sampler algorithm, the communication cost is 0 because we have all the neighbors of a vertex belonging to the partition stay in the same machine; Otherwise, the communication cost is $\Theta(d(u_{central}))$. Therefore, the l -star sampler communication cost is $\Theta(\frac{p-1}{p} d(u_{central}))$. For a $(2k+1)$ -cycle sampler, we first sample an edge, if this edge is not local, we will retrieve all the neighbors for the start vertex. When sampling the next k edges, we may retrieve the neighbor list of a vertex for each edge. Thus the communication cost is $\Theta(\frac{p-1}{p} k \cdot \bar{\Delta})$. To test these k edges and a neighbor of the first vertex form a cycle, we need to test the connectivity of k remaining edges in the $(2k+1)$ -cycle, which cost is $\frac{p-1}{p} k \cdot \bar{\Delta}$.

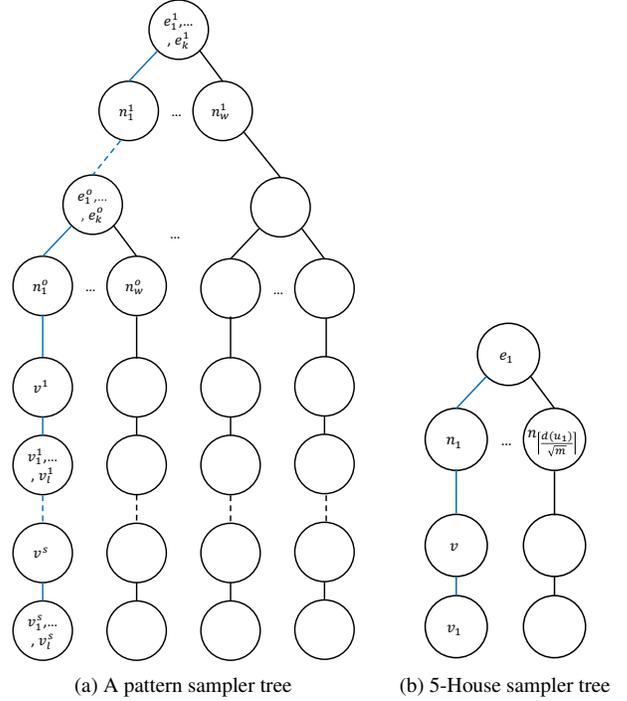

Figure 9: **Pattern sampler trees.** Dotted lines represent there can be multiple other odd cycles or stars in the middle of the layers. Solid lines are connecting root and leaves in a subpattern sampler subtree or from a last cycle leaf node to a first star root node. The blue lines form a path from the root to a last-layer leaf. The labels of some nodes are omitted in the figure.

Plus the x remaining-edge test of the entire pattern, the total communication cost is $\frac{p-1}{p} (\sum_i^o 2k_i \cdot \bar{\Delta} + \sum_j^s \bar{\Delta} + x \cdot \bar{\Delta})$.

Therefore, the computation-communication cost of partitioned Arya is $\frac{p}{p-1} \cdot \frac{\sum_j^s l_j + \sum_i^o k_i + \sum_i^o (\frac{1}{\sqrt{m}} + k_i) \cdot \bar{\Delta} + x \cdot \bar{\Delta}}{(\sum_i^o 2k_i + s + x) \cdot \bar{\Delta}}$, which is approximately $c \frac{p}{p-1}$ where c is a constant related to the pattern and the graph. This communication cost can be reduced by using batching technique mentioned in Section 5.2.

SECRECY: Secure collaborative analytics in untrusted clouds

John Liagouris

Abstract

We present SECRECY, a system for privacy-preserving collaborative analytics as a service. SECRECY allows multiple data holders to contribute their data towards a joint analysis in the cloud, while keeping the data siloed even from the cloud providers. At the same time, it enables cloud providers to offer their services to clients who would have otherwise refused to perform a computation altogether or insisted that it be done on private infrastructure. SECRECY ensures no information leakage and provides provable security guarantees by employing cryptographically secure Multi-Party Computation (MPC).

In SECRECY we take a novel approach to optimizing MPC execution by co-designing multiple layers of the system stack and exposing the MPC costs to the query engine. To achieve practical performance, SECRECY applies physical optimizations that amortize the inherent MPC overheads along with logical optimizations that dramatically reduce the computation, communication, and space requirements during query execution. Our multi-cloud experiments demonstrate that SECRECY improves query performance by over 1000× compared to existing approaches and computes complex analytics on millions of data records with modest use of resources.

1 Introduction

Secure collaborative analytics [20,26,30,47,97] is a family of emerging applications, where multiple data holders are willing to allow certain computations on their collective private data (e.g., for profit, social good, improved services, etc.), provided that the data remain siloed from untrusted entities. For instance, some companies would agree to participate in a gender wage gap study [32] but only if no employee wages are revealed to other companies, as they may lose their competitive advantage. Similarly, researchers from different medical institutions may conduct a large-scale study on the union of their patient records, provided that the data analysis is end-to-end compliant with privacy regulations [2,3]. Another example is private advertising: web users may subscribe to recommenda-

tions based on collaborative filtering as long as their online activity remains hidden from the service provider [85].

To realize the above use cases, we need systems capable of extracting value from sensitive or proprietary data, while protecting the data from untrusted or unauthorized entities. We identify four major requirements for such systems. First, they must ensure no information leakage so that they reveal nothing except the output of the computation the data holders have agreed on. At the same time, they must guarantee security in the absence of trusted resources, as the data holders may lack the expertise or infrastructure needed for secure computation and may need to outsource the analysis to untrusted third parties [45]. Another requirement is to support complex analytics beyond simple statistics, such as relational queries on multiple tables [95]. Lastly, while queries in these use cases are non-interactive, they must complete in reasonable time, e.g., within a few hours.

Enabling secure outsourced analytics with practical performance has been a long-standing research challenge [13]. So far, there exist three general approaches to secure computation with no leakage. The first one is Fully Homomorphic Encryption (FHE) [57] that provides “ideal” security by enabling computation directly on encrypted data. Although there are many implementations that support simple functions [4,6,8,21], FHE is still prohibitively slow for the analytics we consider in this work. A more practical approach is to use secure hardware solutions, like Intel’s SGX, which have been proposed as a faster alternative to cryptography but do not provide provable security [33,74]. A third promising approach is cryptographically secure Multi-Party Computation (MPC) [77]. MPC refers to a family of cryptographic protocols that enable mutually distrusting parties to jointly compute functions on secret (encoded) data without relying on any single trusted entity. MPC is generally faster than FHE-based approaches but still challenging to scale to inputs with more than a few thousand records [22,45,73,95,105].

Recently, systems like Conclave [105], SMCQL [22], Senate [95], and others [23,24,111] have made MPC more accessible to data analysts by providing relational interfaces

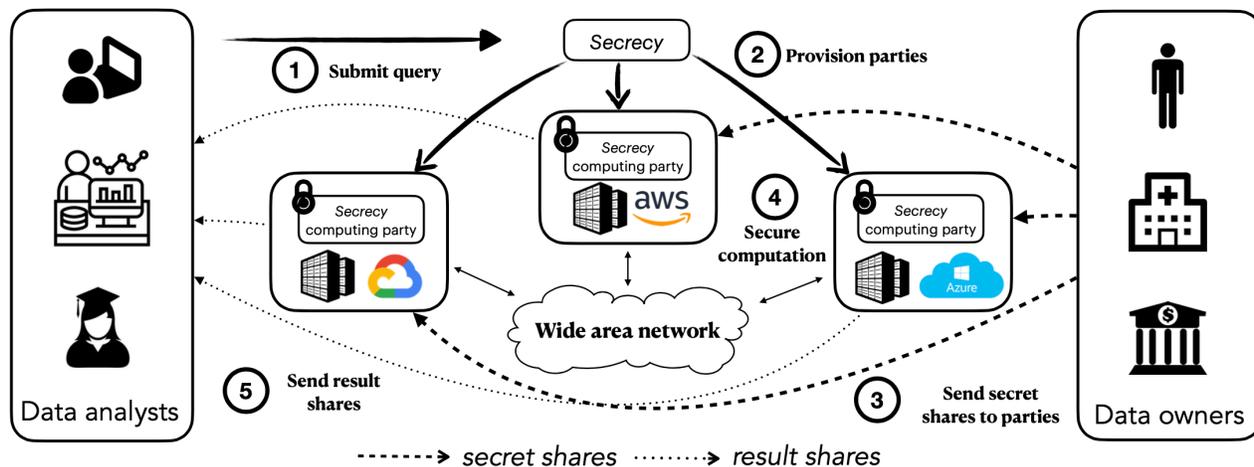

Figure 1: Overview of secure collaborative analytics with SECRECY. Clients (e.g., data analysts) access a catalog with metadata about available private datasets and submit public queries to the SECRECY service. SECRECY performs query planning and provisions computing parties in available non-colluding cloud providers, e.g., GCP, AWS, and Azure. Next, it instructs data owners to distribute *secret shares* (cf. §3) of their data to computing parties. Parties execute the query under MPC and send the results to the analysts. SECRECY considers adversaries who may have complete control over the network. All data remain private as long as an adversary does not compromise the majority of cloud providers.

and automated query planning. However, to achieve practical performance, these works employ optimizations that either leak information to untrusted parties or apply to peer-to-peer settings where data holders also serve as computing parties using trusted resources (we provide more details in §8). Outsourced MPC, on the other hand, removes the computation burden from data holders and has recently gained attention, especially in industry, with systems like Prio [45] Carbyne [11], CrypTen [70] and Cape Privacy’s TF Encrypted [1]. Yet, these frameworks focus on certain statistics or ML workloads and do not support general-purpose analytics.

To fill this gap, we present SECRECY, a new relational MPC system for efficient collaborative analytics in the cloud with no information leakage. In SECRECY we take a fundamentally different approach over prior work and we carefully co-design the MPC protocol, query engine, and distributed runtime into a single platform. SECRECY’s core novelty is a generic cost-based optimization framework for relational MPC that does not rely on trusted infrastructure. As such, it enables data holders and analysts to use untrusted cloud resources on demand and benefit from the “pay-as-you-go” model while retaining the *full* security guarantees of the cryptographic protocols.

Contributions. We make the following contributions:

- We present a relational MPC system, based on secret sharing, that enables efficient collaborative analytics with no information leakage.
- We design vectorized MPC primitives and relational operators that amortize the network I/O of secret sharing. Contrary to prevailing wisdom, we show that this approach can be competitive with widely adopted MPC techniques for relational analytics in both LAN and WAN environments.

- We define an analytical cost model that formulates MPC query costs in terms of secure computation and communication operations. We use this cost model to develop a novel query optimization framework for relational MPC.
- We implement a Volcano-style query processor that leverages the cost model to automatically apply a rich set of logical, physical, and protocol-aware optimizations which can improve performance by orders of magnitude.
- We evaluate SECRECY’s performance and the effectiveness of its optimizations using real and synthetic queries. Our experiments show that SECRECY outperforms state-of-the-art MPC frameworks and scales to much larger datasets.

We believe SECRECY will become a valuable tool to cloud providers, data holders, and analysts by enabling new privacy-preserving applications and marketplaces on existing cloud infrastructure. We will release SECRECY as open-source [9].

2 SECRECY system overview

Figure 1 presents an overview of the SECRECY cloud service. Each party in SECRECY has one or more of the following roles: (i) *data holder or data owner* who provides some input data, (ii) *computing party*, e.g., a cloud provider that provides resources to perform the secure computation, and (iii) *analyst* who issues a query to learn the result. SECRECY supports any number of data owners and uses three computing parties. A “party” is a logical entity and does not necessarily correspond to a single compute node. SECRECY does not make any assumption about the physical deployment: parties can be deployed in private clusters, in a multi-cloud, or across multiple providers in a hybrid or federated cloud.

2.1 Design principles

We have designed SECRECY on the following principles:

1. No information leakage. SECRECY reveals nothing about the input, output, or intermediate data and the execution metadata to untrusted parties, including the cloud providers. It completely hides access patterns, intermediate, and output result sizes. SECRECY does not require data owners to annotate attributes as sensitive or non-sensitive and does not try to sidestep the secure computation. It executes all operations under MPC and protects all attributes to prevent inference attacks that exploit correlations or functional dependencies in the data which may be unknown to data owners.

2. No reliance on trusted execution environments. SECRECY does not rely on any (semi-)trusted party, honest broker or specialized secure hardware. To remove barriers for adoption, we target general-purpose compute and cloud.

3. Decoupling of roles. In SECRECY, a party may have any combination of roles, that is, data owners can (but do not have to) also act as computing parties and/or analysts without affecting the security guarantees. Query optimization in SECRECY does not rely on data ownership and does not require data owners to participate in MPC using trusted resources. Due to decoupling, SECRECY can effectively use a small number of computing parties to support any number of data owners without affecting the scalability of secure computation.

4. High expressivity. SECRECY's protocol does not pose any restriction on the types of queries that can be supported. While there exist many efficient protocols for specific instances of MPC operators, these are often not composable. In SECRECY, we have decided to provide general operator implementations that are independent of the data characteristics and can be composed with each other to create arbitrary query plans.

2.2 Threat model and security guarantees

SECRECY protects data throughout the entire lifecycle and treats the query itself as *public*, i.e., it assumes that data owners and analysts have previously agreed on a relational query to compute and this query is known to the computing parties, as in prior works [22–24, 95, 105]. To evaluate the query, SECRECY servers execute an identical computation and exchange messages with each other according to a protocol. All communication in a SECRECY deployment must be done via authenticated and encrypted channels (e.g., using TLS).

Threat model. SECRECY assumes “honest-but-curious” parties and can withstand adversaries who have two types of capabilities. First, adversaries have complete control over the network and can monitor all network links. Second, adversaries may compromise one computing party and can see all of its internal state (e.g., memory contents, access patterns, and data sent/received) but without altering its execution. That said, most of the techniques we present in this work are also

compatible with malicious-secure MPC protocols where parties can deviate from the protocol arbitrarily (cf. §5.4).

Security guarantees. We have purposely designed SECRECY in a modular fashion to ensure it can directly inherit all security guarantees of the underlying MPC protocol. SECRECY relies on the semi-honest 3-party replicated secret sharing protocol by Araki et al. [17, 81]. The protocol provides two types of guarantees: (i) *privacy*, meaning that computing parties do not learn anything about the data, and (ii) *correctness*, meaning that all participants are convinced that the computation output is accurate. As long as the computing parties do not collude, the SECRECY servers cannot learn anything beyond the size of the input data (which can also be padded by the data owners). Only the designated analysts learn the result of the query. SECRECY does not use differential privacy to protect the result from possible inference attacks by the analysts but it could be easily augmented to do so (cf. §8). We also stress that formal verification of the SECRECY software is out of scope for this work (but an exciting future direction). For a detailed security analysis please refer to Appendix B.

2.3 Cost-based secure query optimization

Cost-based query optimization on plaintext data relies on selectivity estimations to reduce the size of intermediate results. MPC operators, however, are *oblivious*, i.e., their control flow is independent of the input data and incurs exactly the same accesses for all inputs of the same size. Oblivious operators do not reveal the size of intermediate data to prevent reconstruction attacks based on selectivity statistics [60, 69, 84]. As a consequence, traditional selectivity-based techniques for plaintext queries [41], such as join reordering or filter push-down, are not effective when optimizing plans under MPC. For instance, given that oblivious selections do not reduce the size of intermediate data, pushing a filter down does not improve the cost of subsequent operators in the plan.

To devise effective optimizations under MPC, we express the plan costs in terms of secure computation and communication operations. In SECRECY, we define three types of costs:

- The **operation cost**, C_o , which is determined by the number of primitive MPC operations per party. Primitive operations can be *local* ($+$, \oplus), which do not require communication, or *remote* (\times , \wedge), which require some message exchange between parties (cf. §3).
- The **synchronization cost**, C_s , given by the number of communication rounds across parties that are inherent in MPC. Each round corresponds to a barrier, i.e. a synchronization point in the distributed execution, where parties must exchange data in order to proceed.
- The **cost of composition**, C_c , which is also measured in operations and communication rounds required to compose oblivious relational operators under MPC.

SECRECY applies automatic optimizations that aim to mini-

mize at least one of these three costs. We present a comprehensive cost analysis of oblivious operators and their composition in §4. Contrary to plaintext query optimization where estimations are often erroneous [76], in MPC we can use the typical dynamic programming approach from database optimizers [98] to compute *exact* plan costs at compile time, since C_o , C_s , and C_c do not depend on the data distribution.

3 Background on MPC

MPC protocols follow one of two general techniques: obscuring the truth table of each operation using Yao’s *garbled circuits* [114], or performing operations over encoded data using *secret sharing* [100]. So far, garbled circuits has been the preferred method to securely compute Boolean circuits in high-latency environments, as they only need a small (constant) number of rounds between computing parties at the cost of incurring a large memory overhead [73]. On the other hand, secret sharing-based approaches require more rounds (that depend on the input size) but have a small memory footprint and consume less overall bandwidth. In this work we employ secret sharing in the honest-majority setting that is reasonable for many real use cases [20,25,26,28,101]. Looking ahead, in §7 we will demonstrate that SECRECY’s optimizations make secret sharing competitive in both LAN and WAN settings.

3.1 Replicated secret sharing

SECRECY encodes an ℓ -bit string of sensitive data s by splitting it into three *secret shares* s_1 , s_2 , and s_3 that individually have the uniform distribution over all possible ℓ -bit strings (for privacy) and collectively suffice to specify s (for correctness). Computing parties are placed on a *logical ring* and each party P_i receives two of the shares s_i and s_{i+1} (i.e., P_1 receives s_1 , s_2 , P_2 receives s_2 , s_3 , and P_3 receives s_3 , s_1). Hence, any two parties can reconstruct a secret if they collude, but any single party cannot, no matter how powerful it is. SECRECY supports two secret sharing formats (and can also transition from one to the other): *boolean* secret sharing in which $s = s_1 \oplus s_2 \oplus s_3$, where \oplus denotes the bitwise XOR operation, and *additive* or *arithmetic* secret sharing in which $s = s_1 + s_2 + s_3 \bmod 2^\ell$.

3.2 Oblivious primitives

In this section, we provide an overview of the oblivious primitives we use throughout our work. Let s , t be two secrets, and $op(s, t)$ an operation on these secrets. The primitives allow SECRECY servers to start with shares of s and t and jointly compute shares of the result $op(s, t)$ without learning anything about s and t . Each server can use these shares in subsequent operations or send them to the analysts, who can reconstruct the true output of $op(s, t)$. We stress that our oblivious relational operators in §4 are agnostic of the underlying

primitives and it would be perfectly possible to implement primitives based on other MPC protocols without affecting the applicability of the optimizations in §5.

Basic operations. When given boolean secret-shared data corresponding to ℓ -bit strings s and t , parties can compute shares of the bitwise XOR $s \oplus t$ locally (i.e., without communication) and shares of the bitwise AND st with synchronization cost equal to $C_s(\text{AND}) = 1$ round of communication. The operation cost is the same in both cases, i.e., $C_o(\text{XOR}) = C_o(\text{AND}) = \ell$ (we consider 1-bit boolean operations to have unit cost). Similarly, given two secrets u and v that have been arithmetically shared, parties can compute shares of the sum $u + v$ locally (similarly to XOR) and shares of the product $u \cdot v$ with 1 communication round (similarly to the bitwise AND operation).

Mixed-mode operations. The above boolean and arithmetic operations are universal and can be used to compute *any* function. Moreover, there exist well-known constructions of several specific operations with fast instantiations based on boolean and/or arithmetic sharing. In SECRECY we implement several such oblivious operations: (in)equality, a compare-and-swap multiplexer, boolean addition with a ripple-carry adder, boolean-to-arithmetic conversion, and more.

For details on the SECRECY primitives, please refer to §A.1.

4 SECRECY operators and cost model

In this section, we first provide an overview of oblivious operators in SECRECY along with their asymptotic costs (§4.1) and the costs of their composition under MPC (§4.2). We then explain how SECRECY computes exact plan costs in §4.3. Although, in practice, the SECRECY planner uses the detailed cost formulas from Appendix A, knowledge of the asymptotic costs is sufficient to follow the optimizations in §5.

4.1 Oblivious relational operators

SECRECY supports a rich class of oblivious relational operators: SELECT, PROJECT, (SEMI-) JOIN, GROUP-BY, DISTINCT, and ORDER-BY with LIMIT. It also supports the following aggregations under MPC: COUNT, SUM, MIN/MAX, and global AVG.

All operators have the same semantics as their plaintext counterparts but their control flow is data independent; in practice, this means that the SECRECY code does not have any `if` statements that depend (either directly or indirectly) on the input data. At a high level, oblivious selection requires a linear scan over the input relation, join and semi-join operators require a nested-loop over the two inputs, whereas order-by, distinct, and group-by are based on a sorting network.

In all cases, operator predicates can be arbitrary logical expressions with atoms that may also include arithmetic expressions ($+$, \times , $=$, $>$, $<$, \neq , \geq , \leq) and are evaluated under MPC

Operator	#operations (#messages)	#communication rounds
SELECT	$O(n)$	$O(1)$
JOIN	$O(n \cdot m)$	$O(1)$
SEMI-JOIN	$O(n \cdot m)$	$O(\log m)$
ORDER-BY	$O(n \cdot \log^2 n)$	$O(\log^2 n)$
DISTINCT	$O(n \cdot \log^2 n)$	$O(\log^2 n)$
GROUP-BY	$O(n \cdot \log^2 n)$	$O(\log^2 n)$
MASK	$O(n)$	$O(1)$

Table 1: Summary of operation (C_o) and synchronization costs (C_s) for general oblivious relational operators *w.r.t.* the cardinalities (n , m) of the input relation(s). The asymptotic number of operations equals the asymptotic number of messages per computing party, as each individual operation on secret shares involves a constant number of message exchanges under MPC. Independent messages can be batched in rounds as shown in the rightmost column.

using the oblivious primitives of §3.2. All operators except PROJECT and ORDER-BY append a new attribute to each record of their input relation that stores a (secret-shared) *valid bit*: this bit denotes whether the record belongs to the output of the operator and is computed under MPC.

Table 1 shows the asymptotic operation and synchronization costs per operator with respect to the input size. MASK is a special operator used by SECRECY to hide records (with “garbage” values) upon a condition. The formal operator semantics and their exact costs are given in §A.2.

4.2 Composing oblivious operators

We define the composition of two operators as applying the second operator to the output of the first. One merit of our approach is that all operators of §4.1 reveal nothing about their output or access patterns and can be arbitrarily composed into an *end-to-end oblivious* plan without special treatment.

Let op_1 and op_2 be two SECRECY operators. In general, the composition $op_2(op_1(R))$ has an *extra cost* (additional to the cost of applying the operators op_1 and op_2) as it requires evaluating under MPC a logical expression e_c for each generated tuple. We define the *composition cost* of $op_2(op_1(R))$ as the cost of evaluating e_c on all records generated by op_2 . The expression e_c depends on the types of operators. For example, composing two selections, each one appending a valid bit to the input relation, requires ANDing the two bits for each record. Table 2 shows the asymptotic composition costs for different operator pairs. The detailed costs are given in §A.3.

Note that applying the distinct operator to the output of a selection, a group-by or a (semi-)join requires a linear number of rounds. This is a significant increase over the $O(\log^2 n)$ rounds required by distinct when applied to a base relation (cf. Table 1). In §5.2, we propose an optimization that reduces the cost of these compositions to a logarithmic factor.

4.3 Computing optimal plan costs

SECRECY’s query planner is based on a typical bottom-up dynamic programming algorithm [98] that computes optimal

Operator pair(s)	#rounds
{SELECT, (SEMI-) JOIN, GROUP-BY, DISTINCT} → DISTINCT	$O(n)$
DISTINCT → {SELECT, (SEMI-) JOIN}	$O(1)$
SELECT ↔ (SEMI-) JOIN	$O(1)$
GROUP-BY → {SELECT, (SEMI-) JOIN}	$O(1)$
{SELECT, (SEMI-) JOIN, DISTINCT, GROUP-BY} → GROUP-BY	$O(\log^2 n)$

Table 2: Summary of composition costs (C_c) in number of rounds for pairs of operators in SECRECY *w.r.t.* the number of generated records (n). Arrows denote the order of applying the two operators. Composition incurs a small constant number of boolean operations per record, so its cost in number of operations is $O(n)$ in all cases.

plans based on our analytical cost model and a set of transformation rules that we present in §5. The algorithm identifies all operators in the input query and proceeds in stages: at each stage it creates bigger plans by adding a new operator to sub-plans from the previous stage. Initially, the set of possible sub-plans includes scans of the input relations. When creating a new (sub-)plan, the algorithm checks for all applicable transformation rules and applies them exhaustively to generate equivalent (sub-)plans with lower cost. The cost of a plan is computed as follows. Each time an operator op is added to a sub-plan, SECRECY computes the operation and synchronization costs $C_o(op)$ and $C_s(op)$. If the operator is applied to the output of another operator, SECRECY also computes the composition cost C_c . To do so, it augments the current plan with a special operator $op_{e_c}(op_i(op_j(...)))$ that applies the composition predicate e_c (§4.2). $C_o(op_{e_c})$ and $C_s(op_{e_c})$ amount to the cost of composing the operators op_i and op_j in number of operations and rounds respectively. For a plan with k operators, the total cost is $\sum_{i=1}^k \alpha C_o(i) + \beta C_s(i)$, where α, β are parameters of the deployment. The algorithm returns the plan with the minimum cost from the final stage.

5 SECRECY optimizations for relational MPC

Here we present the optimizations we introduce in SECRECY to speed up MPC query execution: (i) logical transformation rules, such as operator reordering and decomposition (§5.1), (ii) physical optimizations, such as operator fusion, vectorized primitives and message batching (§5.2), and (iii) secret-sharing optimizations that further reduce the number of communication rounds for certain operators (§5.3). Table 3 summarizes the notation used in the remainder of the paper.

Target queries. Our work focuses on collaborative analytics under MPC where two or more data owners want to outsource queries on their collective data without compromising privacy. We consider all inputs as sensitive and assume that data owners wish to protect their raw data and avoid revealing attributes of base relations in query results. For example, employing MPC to compute a query that includes patient names along with their diagnoses in the SELECT clause is pointless. Thus, we target queries that return global or per-group aggregates and/or distinct results, as in prior works.

Symbol	Description
ℓ	length of the share representation in bits
R, S	relations with cardinality $ R $ and $ S $
$\sigma_\phi(R)$	selection with predicate ϕ
$R \bowtie_\theta S$	join with predicate θ
$R \ltimes_\theta S$	left semi-join with predicate θ
$\delta_a(R)$	distinct operator on attribute a
$\gamma_a^g(R)$	group-by operator on attribute a with aggregation function g
$s_{\uparrow a}(R)$	sort on attribute a (ascending)

Table 3: Notation used in the paper

5.1 Logical transformation rules

SECURITY uses three types of logical transformations that reorder and decompose operators to reduce the MPC costs:

5.1.1 Blocking operator push-down

Blocking oblivious operators (GROUP-BY, DISTINCT, ORDER-BY) materialize and sort their entire input before producing any output tuple. Contrary to a plaintext optimizer that would most likely place sorting after selective operators, in MPC we have an incentive to push blocking operators down, as close to the input as possible. Since oblivious operators do not reduce the size of intermediate data, sorting the input is clearly the best option. Blocking operator push-down can provide considerable performance improvements in practice, even if the asymptotic costs do not change. As an example, consider the rule that pushes ORDER-BY before a selection, i.e., $s_{\uparrow a}(\sigma_\phi(R)) \rightarrow \sigma_\phi(s_{\uparrow a}(R))$. Although this rule would not generate a more efficient plan in plaintext evaluation, it does so in the MPC setting. This is because the operations required by the oblivious ORDER-BY depend on the cardinality and the number of attributes of the input relation. Applying the selection after the order-by reduces the actual (but not the asymptotic) operation cost, as σ_ϕ appends one attribute to R .

Applicability. Rules in this class are valid relational transformations with no special applicability conditions under MPC.

5.1.2 Join push-up

The second class of rules leverage the fact that JOIN is the only operator whose output is larger than its input. Based on this, we have an incentive to perform joins as late as possible in the query plan so that we avoid applying other operators to join results, especially those that require materializing the join output. For example, placing a blocking operator after a join requires sorting the cartesian product of the input relations, which increases the operation cost of the blocking operator to $O(n^2 \log^2 n)$ and the synchronization cost by $4\times$.

Example. Consider the following query:

```
Q1: SELECT DISTINCT R.id
     FROM R, S
     WHERE R.id = S.id
```

and the rule $\delta_{id}(R \bowtie_{id=id} S) \rightarrow \delta_{id}(R) \bowtie_{id=id} \delta_{id}(S)$. Let R and S have the same cardinality n . A plan that applies

```
1  $s_{\uparrow a_\theta \uparrow a_k}(R)$ ; //sort input relation  $R$  on  $a_\theta, a_k$ 
2 let  $d \leftarrow \lfloor R \rfloor / 2$ ; //Distance of tuples to aggregate
3 while  $d \geq 1$  do
4   for each pair of tuples  $(t_i, t_{i+d}), 0 \leq i < |R| - d$ , do
5     //Are tuples in the same group?
6     let  $b \leftarrow t_i[a_k] \stackrel{?}{=} t_{i+d}[a_k]$ ;
7     //Are tuples in semi-join output too?
8     let  $b_c \leftarrow b \wedge t_i[a_\theta] \wedge t_{i+d}[a_\theta]$ ; //  $b_c$  is a bit
9     //Oblivious aggregation via multiplexing
10     $t_i[a_g] \leftarrow b_c \cdot (t_i[a_g] + t_{i+d}[a_g]) + (1 - b_c) \cdot t_i[a_g]$ ;
11     $t_{i+d}[a_v] \leftarrow \neg b_c$ ; //  $a_v$  is the valid bit
12    mask  $t_{i+d}$  when  $t_{i+d}[a_v] = 0$ ;
13   $d = d/2$ ;
14 mask remaining tuples with  $t[a_v] = 0$  and shuffle  $R$ ;
```

Algorithm 1: 2^{nd} phase of Join-Aggregation decomposition

DISTINCT after the join operator requires $O(n^2 \log^2 n)$ operations. On the other hand, pushing DISTINCT before JOIN reduces the operation cost to $O(n^2)$ and the composition cost from $O(n^2)$ to $O(1)$ in number of rounds. The asymptotic synchronization cost is the same for both plans, i.e. $O(\log^2 n)$, but the actual number of rounds when DISTINCT is pushed before JOIN is $4\times$ lower.

Applicability. Rules in this class have the same applicability conditions as similar rules for plaintext queries [42, 113], even though their goal is different. In our setting, the re-orderings do not aim to reduce the size of intermediate data. In fact, a plan that applies DISTINCT on a JOIN input produces exactly the same amount of intermediate data as a plan where DISTINCT is placed after JOIN, yet our analysis reveals that the second plan has higher MPC costs.

5.1.3 Join-Aggregation decomposition

Consider a query plan where a JOIN on attribute a_j is followed by a GROUP-BY on another attribute $a_k \neq a_j$. In this case, pushing the GROUP-BY down does not yield a semantically equivalent plan. Still, we can optimize the plan by decomposing the aggregation in two phases and push the first and most expensive phase of GROUP-BY before the JOIN.

Let R, S be the join inputs, where R includes the group-by key a_k . The first phase of the decomposition sorts R on a_k and computes a semi-join on a_j that appends two attributes to R : the valid bit a_θ introduced by the semi-join, and a second attribute a_g that stores the result of a partial aggregation¹ (we come back to this later).

In the second phase, we compute the final aggregates per a_k using Algorithm 1, which takes into account the attribute a_θ and updates the partial aggregates a_g in-place using odd-even aggregation. The decomposition essentially replaces the join

¹In case the aggregation function is AVG, we need to keep the value sum (numerator) and count (denominator) as separate secret-shared attributes in R .

with a semi-join and a partial aggregation in order to avoid performing the aggregation on the cartesian product $R \times S$. This way, we significantly reduce the number of operations and communication rounds, but also ensure that the space requirements remain bounded by $|R|$, since the join output is not materialized. Note that this optimization is fundamentally different than performing a partial aggregation in the clear (by the data owners) and then computing the global aggregates under MPC [22, 95]; in our case, all data are secret-shared amongst parties and *both* phases are under MPC.

Example. Consider the following query:

```
Q2: SELECT R.ak, COUNT(*)
      FROM R, S
      WHERE R.id = S.id
      GROUP BY R.ak
```

Let R and S have the same cardinality n . The plan that applies `GROUP-BY` to the join output requires $O(n^2 \log^2 n)$ operations and $O(\log^2 n)$ communication rounds. When decomposing the aggregation $\gamma_{a_k}^{\text{COUNT}(\ast)}$ in two phases, the operation cost is reduced to $O(n^2)$ and the synchronization cost is $4\times$ lower. The space requirements are also reduced from $O(n^2)$ to $O(n)$. In our example, the partial aggregation corresponds to the function $t[a_\theta] = \sum_{\forall t' \in S} \theta(t, t')$, $t \in R$, where $\theta(t, t') := t[\text{id}] \stackrel{?}{=} t'[\text{id}]$. Similar partial aggregations can be defined for `SUM`, `MIN/MAX`, and `AVG`.

Decomposition with DISTINCT. A similar idea can also be employed when the join is followed by a `DISTINCT`. The transformation rule in this case is $\delta_{R.a}(R \bowtie_\theta S) \rightarrow \delta'_a(s \uparrow_{R.a_\theta}, \uparrow_{R.a}(R \bowtie_\theta S))$, where a_θ denotes the semi-join bit and $\delta'(\cdot)$ is the final phase of distinct that compares adjacent tuples with $a_\theta = 1$. For example, the plan $\delta_{R.a}(R \bowtie_{b=b} S)$ can be replaced with the equivalent plan $\delta'_{R.a}(s \uparrow_{R.a_\theta}, \uparrow_{R.a}(R \bowtie_{b=b} S))$ to reduce the operation cost from $O(n^2 \log^2 n)$ to $O(n^2)$ and the synchronization cost from $O(n^2)$ to $O(\log^2 n)$.

Applicability. The decomposition technique we described is applicable to any θ -join followed by (i) a `GROUP-BY` with aggregation or (ii) a `DISTINCT` operator, under the condition that the group-by or distinct keys belong to one join input.

5.2 Physical optimizations

We now describe a set of physical optimizations in `SECURITY`.

5.2.1 Predicate fusion

Fusion is a common optimization in plaintext query planning, e.g., when predicates of multiple filters are merged and executed by a single operator. Fusion has been recently used to speed up secure ML pipelines in Cerebro [117] and is also applicable to oblivious relational operators. In our setting, fusion is achieved by identifying independent operations that can be executed efficiently within the same communication

round. For example, if the equality check of an equi-join and a selection are independent of each other, a fused operator requires $\lceil \log \ell \rceil + 1$ rounds instead of $2\lceil \log \ell \rceil + 1$ (cf. §A). Next, we describe a somewhat more interesting case of fusion.

5.2.2 Operator fusion

Recall that applying `DISTINCT` after `SELECT` requires n communication rounds (§4.2). We can avoid this overhead by fusing the two operators in a different way, that is, sorting the input relation on the selection bit first and then on the distinct attribute. Sorting on two (instead of one) attributes adds a small constant factor to each oblivious compare-and-swap operation, hence, the asymptotic complexity of the sorting step remains the same. When distinct is applied to the output of other operators, including selections and (semi-)joins, this physical optimization keeps the number of rounds required for the composition low.

Example. Consider the following query:

```
Q3: SELECT DISTINCT id
      FROM R
      WHERE ak = 'c'
```

Fusing the distinct and selection operators reduces the number of communication rounds from $O(n)$ to $O(\log^2 n)$, as if the distinct operator was applied only to R (without a selection). `DISTINCT` can be fused with a join or a semi-join operator in a similar way. In this case, the distinct operator takes into account the (semi-)join bit.

5.2.3 Vectorization and message batching

In secret sharing protocols, non-local operations require exchanging very small messages. Applying multiple such independent operations in a vectorized fashion and exchanging the respective messages in bulk improves performance tremendously. Consider applying a selection with an equality predicate on a relation with n tuples. Performing oblivious equality on one tuple requires $\lceil \log \ell \rceil$ rounds. Applying the selection tuple-by-tuple and sending messages eagerly (as soon as they are generated) results in $n \cdot \lceil \log \ell \rceil$ rounds. Instead, if we apply independent selections across the entire relation and exchange messages in bulk, we can reduce the total synchronization cost to $\lceil \log \ell \rceil$. We have designed all `SECURITY` primitives to apply vectorization and message batching by default, otherwise the cost of secret sharing is prohibitive. Costs in Tables 1 & 2 already take message batching into account.

5.3 Secret-sharing optimizations

Here we propose optimizations that take advantage of mixed-mode MPC protocols which permit both arithmetic and boolean computations. While `SECURITY` uses boolean secret sharing for most operations, computing arithmetic expressions or aggregations like `COUNT` and `SUM` on boolean shares

requires using a ripple-carry adder (RCA), which in turn requires many communication rounds. Performing these operations on additive shares would require no communication, but converting shares from one format to another can be expensive. Below, we describe two optimizations that avoid the RCA in aggregations and predicates with constants.

5.3.1 Dual sharing

The straight-forward approach of switching from boolean to additive shares (and vice versa) based on the type of operation does not pay off; the conversion itself relies on RCA, which has to be applied twice to switch to the other representation and back. The cost-effective way would be to evaluate logical expressions using boolean shares and arithmetic expressions using additive shares. However, this is not always possible because arithmetic and boolean expressions in oblivious queries often need to be composed into the same formula. We mitigate this problem using a dual secret-sharing scheme.

Recall the example query **Q2** from §5.1.3 that applies an aggregation function to the output of a join according to Algorithm 1. The attribute a_θ in Algorithm 1 is a single-bit attribute denoting that the respective tuple is included in the join result. During oblivious evaluation, each party has a boolean share of this bit that is used to compute the arithmetic expression in line 6. The naïve approach is to evaluate the following equivalent logical expression directly on the boolean shares of b_c , $t_i[a_g]$, and $t_{i+d}[a_g]$:

$$t_i[a_g] \leftarrow b_c \wedge \text{RCA}(t_i[a_g], t_{i+d}[a_g]) \oplus \bar{b}_c \wedge t_i[a_g]$$

where RCA is the oblivious ripple-carry adder primitive, b_c is a string of ℓ bits (the length of a_g) all of which are set equal to b_c , and \bar{b}_c is the binary complement of b_c . Evaluating the above expression requires ℓ communication rounds for RCA plus two more rounds for the logical ANDs (\wedge). On the contrary, SECRECY evaluates the equivalent formula in line 6 of Algorithm 1 in four rounds (independent from ℓ) as follows. First, parties use arithmetic shares for the attribute a_g to compute the addition locally. Second, each time they compute the bit b_c in line 5, they exchange boolean as well as arithmetic shares of its value. To do this efficiently, we rely on the single-bit conversion protocol also used in CryptTen [70], which requires two rounds of communication. Having boolean and arithmetic shares of b_c allows SECRECY to use it in boolean and arithmetic expressions without paying the cost of RCA.

5.3.2 Proactive sharing

The previous optimization relies on b_c being a single bit. In many cases, however, we need to compose boolean and additive shares of arbitrary values. Representative examples are join predicates with arithmetic expressions on boolean shares, e.g. $(R.a - S.a \geq c)$, where a is an attribute and c is a constant. We can speedup the oblivious evaluation of

such predicates by proactively asking the data owners to send shares of the expression results. In the previous example, if parties receive boolean shares of $S.a + c$ they can avoid computing the boolean addition with RCA. A similar technique is also applicable for selection predicates with constants. In this case, to compute $a > c$, if parties receive shares of $a - c$ and $c - a$, they can transform the binary equality to a local comparison with zero. Note that proactive sharing is fundamentally different than having data owners perform local filters or pre-aggregations prior to sharing. In the latter case, the computing parties might learn the selectivity of a filter or the number of groups in an aggregation (if results are not padded). In our case, parties simply receive additional shares and will not learn anything about the intermediate query results.

5.4 Generality of optimizations

The logical and physical query optimizations constructed in this work (§5.1-5.2) apply generally to any mixed-mode MPC protocol that supports the primitives we describe in §3.2. This includes protocols that remain secure in the face of a malicious adversary who can deviate from the protocol arbitrarily (e.g., [46, 71, 89]), and (authenticated) garbled circuit protocols [109, 114] combined with conversions to arithmetic secret sharing [50, 89] as needed. SECRECY can also support alternative instantiations of oblivious primitives with different cost profiles, such as constant-round equality and comparisons with higher operation costs [48, 86].

While the secret-sharing optimizations of §5.3 are specific to SECRECY’s underlying MPC protocol (§3.1), we expect that similar techniques can be developed also for other protocols. Extending the SECRECY planner to consider the cost profiles of various building blocks is an exciting avenue for future work. We provide a formal discussion of generality in Appendix B.

6 SECRECY implementation

Despite a rich open-source ecosystem of general-purpose MPC frameworks [62], we found that existing tools either lack support for general relational operations (with θ -predicates) or cannot effectively amortize network I/O. For these reasons, we implemented SECRECY in C/C++, entirely from scratch. We designed our secure primitives to operate directly on relations and we also built a library of general oblivious relational operators that can be combined into arbitrary query plans.

System overview. Figure 2 shows the SECRECY architecture and software stack. Data analysts submit queries through a client application that exposes a SQL interface and provides a query planner that performs query rewriting and cost-based optimization. Data owners use the secret-sharing generation module to distribute random shares of their data to the computing parties. Computing parties can be deployed on premises,

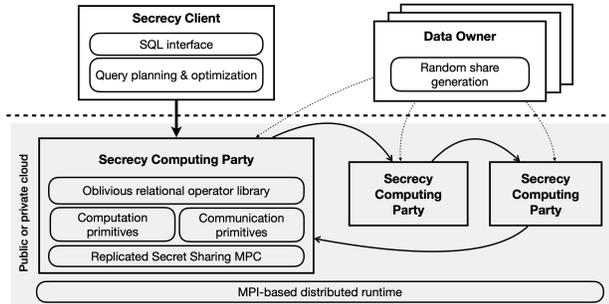

Figure 2: The SECRECY system consists of (i) a client application that can be used by data analysts to submit queries, (ii) a data owner application to generate and distribute secret shares, and (iii) three computing parties that execute queries under MPC.

in a hybrid cloud, or across multiple clouds. To automate cloud deployment we use Ansible [7]. The parties’ software stack consists of (i) a custom implementation of the replicated secret sharing protocol, (ii) a library of secure computation and communication primitives, and (iii) a library of oblivious relational operators. The distributed runtime and communication layer are based on MPI [5]. Each party is a separate MPI process that handles both computation and communication.

Operator pipelining. SECRECY relational operators and secure primitives are designed to process table rows in batches. The batch size is configurable and allows SECRECY to compute expensive operators, such as joins, with full control over memory requirements. While batching does not reduce the total number of operations, we leverage it to compute on large inputs in a pipelined fashion, without running out of memory or switching to a disk-based evaluation.

Query planning and execution. Upon startup, the parties establish connections to each other and learn the process IDs of other parties. Next, they receive shares for each input relation from the data owners. Queries are specified either in SQL (and go through query planning) or in a declarative DSL that allows seamless operator composition by abstracting MPC details. For SQL parsing we use the Hyrise parser [12]. SECRECY’s planner generates the optimal query plan as explained in §4.3. To evaluate a query, parties execute the same oblivious physical plan on their random shares and return the results to the designated client. We use a 64-bit share representation by default, so $\ell = 64$ (cf. Table 3).

7 Experimental evaluation

Our experimental evaluation is structured into four parts:

Benefits of query optimization. In §7.2, we evaluate the benefits of SECRECY’s optimizations on eight real and synthetic queries. We show that SECRECY’s cost-based optimizer reduces the runtime of complex queries by up to three orders of magnitude both in a LAN and a multi-cloud setting.

Performance on real and synthetic queries. In §7.3 we evaluate SECRECY’s performance as input sizes grow. We use queries that include selections, group-by, distinct, semi-join, and theta-joins with both equality and inequality predicates. Our results demonstrate that SECRECY can scale to millions of input rows and evaluate complex queries in reasonable time with modest use of resources.

Micro-benchmarks. In §7.4, we evaluate individual logical, physical, and secret-sharing optimizations on the three queries from §5.1-5.3. Our results demonstrate that pushing down blocking operators reduces execution time by up to 1000× and enables queries to scale to 100× larger inputs. Further, we show that operator fusion and dual sharing improve execution time by an order of magnitude in the WAN setting.

Comparison with state-of-the-art frameworks. In §7.5, we compare SECRECY with SMCQL [22] and the 2-party semi-honest version of EMP [108]. We choose SMCQL (the ORAM-based version) as the only open-source relational framework with semi-honest security and no leakage. We also choose the EMP library since it is used by all recent systems, namely Shrinkwrap [23], SAQE [24], a new version of SMCQL, and Senate [95]. Although none of these systems is publicly available, they all build their relational MPC engines on top of EMP. We show that SECRECY outperforms them both and can comfortably process much larger datasets.

We provide additional micro-benchmarks and experiments with EMP in Appendix D.

7.1 Evaluation setup

We use three cloud deployments: (i) AWS-LAN uses an *EC2 r5.xlarge* instance per party in the *us-east-2* region, (ii) AWS-WAN distributes parties across *us-east-2* (Ohio), *us-east-1* (Virginia), and *us-west-1* (California), and (iii) MULTI-CLOUD distributes parties across three different cloud providers, namely AWS (Ohio), Google Cloud (South Carolina), and Azure (Virginia). VMs have 32GB of memory and run Ubuntu 20.04, C99, gcc 5.4.0, and MPICH 3.3.2. Measurements are averaged over at least three runs and plotted in log-scale, unless otherwise specified.

Queries. We use 11 queries for evaluation, including five real-world queries from previous MPC works [22–24, 95, 105]. Three are medical queries [22]: *Comorbidity* returns the ten most common diagnoses of individuals in a cohort, *Recurrent C.Diff.* returns the distinct ids of patients who have been diagnosed with *cdiff* and have two consecutive infections between 15 and 56 days apart, and *Aspirin Count* returns the number of patients who have been diagnosed with heart disease and have been prescribed aspirin after the diagnosis was made. We also use queries from other MPC application areas [95]: *Password Reuse* asks for users with the same password across different websites, while *Credit Score* asks for persons whose credit scores across different agencies have

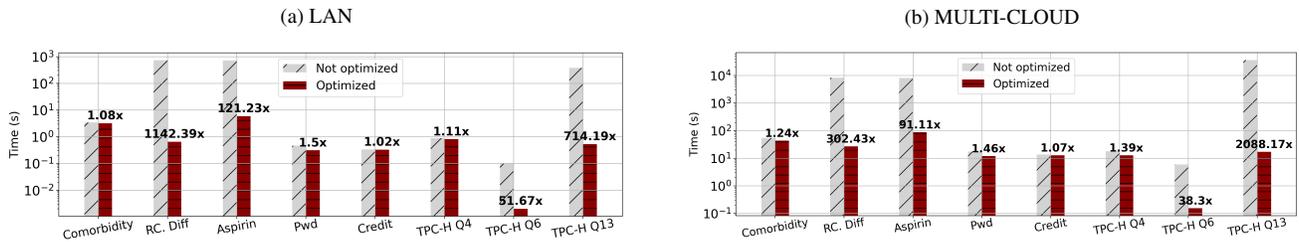

Figure 3: SECRECY end-to-end performance when optimizations are enabled (Optimized) and disabled (Not optimized) for real and synthetic queries. Logical and physical optimizations result in over 1000× lower execution times, while secret-sharing optimizations improve performance by up to ~ 52×. Not optimized plans still use vectorization and message batching (§5.2.3), otherwise the cost of secret sharing is prohibitive.

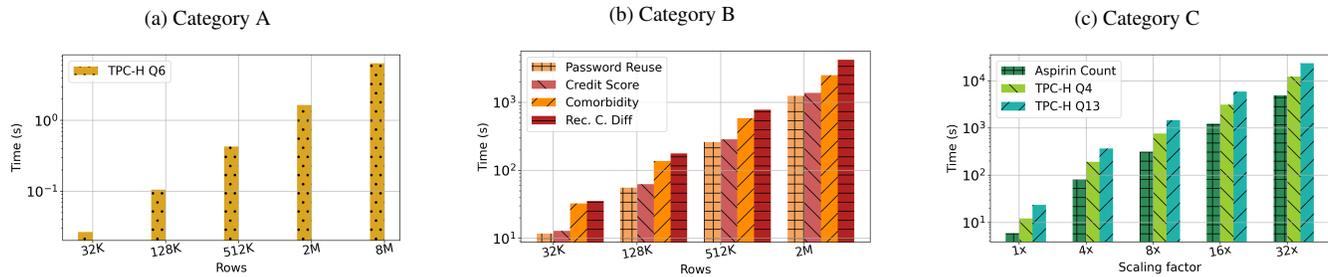

Figure 4: Scaling behavior of optimized real and synthetic queries on SECRECY

significant discrepancies in a particular year. In addition to the real-world queries, we use the TPC-H queries (Q4, Q6, Q13) [103] that have been used in SAQE [24]. Finally, to evaluate the performance gains from each optimization in isolation, we use Q1, Q2, Q3 from §5.1-5.3.

Datasets. All experiments use randomly generated tables with 64-bit values. Note that SECRECY’s MPC protocol assumes a fixed-size representation of shares that is implementation-specific and could be increased to any 2^k value. We also highlight that using random inputs is no different than using real data, as all operators are oblivious and the data distribution does not affect the amount of computation or communication. Regardless if the input is real or random, parties compute on secret shares, which are by definition random. In all experiments we designate one party as the data owner who distributes shares and learns the results. SECRECY uses exactly three computing parties; therefore, the number of data owners and analysts does not affect query performance, only the cumulative input size does.

7.2 Benefits of query optimization

We compare the performance of 8 queries optimized by SECRECY with that of plans without the optimizations of §5. For a fair comparison, we implement baseline plans using SECRECY’s batched operators. Although this favors the baseline, the communication cost of MPC is otherwise prohibitive and queries cannot scale beyond a few hundred input rows. We execute each plan with 1K rows per input relation. For Q4 (resp. Q13), we use 1K rows for LINEITEM (resp. ORDERS) and maintain the size ratio with the other input relation as specified in the TPC-H benchmark. For Comorbidity, we use

a cohort of 256 patients. We run this experiment on AWS-LAN and MULTI-CLOUD and present the results in Figure 3.

In the LAN setting, SECRECY achieves the highest speedups for *Recurrent C.Diff.*, *Aspirin Count*, and Q13, that is, 1142×, 121×, and 714× lower execution times, respectively. Optimized plans for these queries leverage join push-up (*Aspirin Count*), fusion (*Recurrent C.Diff.*), and join-aggregation decomposition (Q13). The optimized plans for *Comorbidity*, *Password Reuse*, Q4, and Q6 leverage dual and proactive sharing, achieving up to 52× speedup compared to the baseline. Finally, the *Credit Score* query leverages dual sharing which, in this case, provides a modest improvement. SECRECY achieves significant speedups in the wide area, too. The performance improvement is higher for *Comorbidity*, Q4, and Q13 in the multi-cloud setting, as these queries leverage optimizations that primarily reduce the synchronization cost. We evaluate the benefit of individual optimizations in §7.4.

7.3 Performance on real and synthetic queries

We now run the optimized plans with increasing input sizes in AWS-LAN and report total execution time. For these experiments, we group queries into three categories of increasing complexity. *Category A* includes queries with selections and global aggregations, *Category B* includes queries with select and group-by or distinct operators, and *Category C* includes queries with select, group-by and (semi-)join operators. Figure 4 presents the results.

Q6 in *Category A* consists of five selections and a global aggregation. It requires minimal communication that is independent of the input relation cardinality. As a result, it scales comfortably to large inputs and takes ~ 6s for 8M rows.

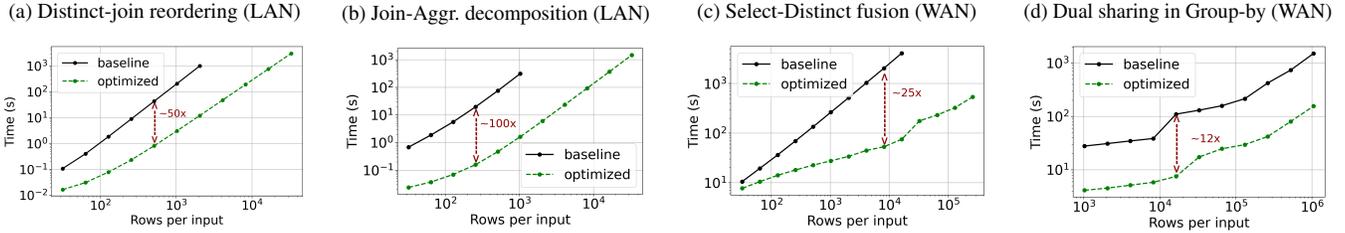

Figure 5: Performance improvement of individual optimizations applied by the SECRECY planner

Queries in *Category B* scale to millions of input rows as well. The cost of these queries is dominated by the oblivious group-by and distinct operators. At 2M rows, *Recurrent C.Diff.* completes in $\sim 1.2h$ and *Password Reuse* in $\sim 20min$.

The cost of queries in *Category C* is dominated by joins and semi-joins. The size ratio between the two inputs of each query is different: for Q4 and Q13, we use the ratio specified in the TPC-H benchmark whereas, for *Aspirin Count*, we use inputs of equal size. In Figure 4c, Scaling factor $1\times$ corresponds to 1K rows for the small input. As we increase the input sizes, we always keep their ratio fixed. At scaling factor $32\times$, the most expensive query is Q13, which is optimized with join-aggregation decomposition and takes $\sim 6.5h$ on 295K rows. At the same scaling factor, Q4 completes in $\sim 3.4h$ on 164K rows, and *Aspirin Count* in $\sim 1.3h$.

While MPC protocols remain expensive for real-time queries, our results demonstrate that offline collaborative analytics on millions of records entirely under MPC are viable.

7.4 Micro-benchmarks

We now use the queries of §5 (Q1, Q2, Q3) to evaluate the impact of SECRECY’s optimizations in isolation. We run each query with and without the particular optimization and measure total execution time. Distinct-join reordering and join-aggregation decomposition primarily reduce the operation cost and we evaluate them in AWS-LAN. Fusion and dual sharing reduce the synchronization cost and we evaluate them in AWS-WAN. Figure 5 shows the results.

Distinct-Join reordering. The optimized plan of Q1 pushes the JOIN after DISTINCT and, thus, only sorts a relation of n rows instead of n^2 . Figure 5a shows that the optimized plan is up to $50\times$ faster than the baseline, which runs out of memory for even modest input sizes.

Join-Aggregation decomposition. The baseline plan of Q2 materializes the result of the join and then applies the grouping and aggregation. Instead, the optimized plan decomposes the aggregation in two phases (cf. §5.1.3). As shown in Figure 5b, this optimization provides $100\times$ lower execution time than that of the baseline plan. Further, the baseline plan runs out of memory for inputs larger than 1K rows.

Operator fusion. The baseline plan of Q3 applies the oblivious selection before DISTINCT, while the optimized plan

	Comorbidity	Recurrent C. Diff.	Aspirin Count
SMCQL	91s	358s	365s
SECRECY	0.083s	0.092s	0.171s

Table 4: SMCQL and SECRECY execution times in LAN for the three medical queries from [22] on 25 tuples per input relation.

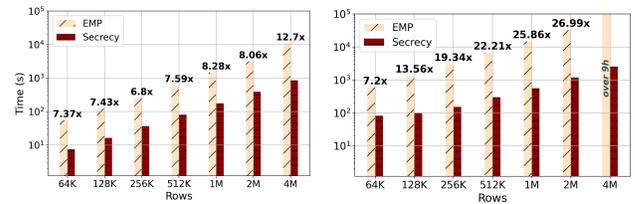

Figure 6: Performance comparison of the oblivious sort operator on EMP and SECRECY in LAN (left) and WAN (right).

fuses the two operators and performs the DISTINCT computation in bulk (cf. §5.2.2). Figure 5c shows that this optimization provides more than $25\times$ speedup for large inputs and allows the query to scale to much larger inputs.

Dual sharing. We also evaluate SECRECY’s ability to switch between arithmetic and boolean sharing to reduce communication costs for certain operations. For this experiment, we compare the run-time of the optimized GROUP-BY-COUNT operator (cf. §5.3) to that of a baseline operator that uses boolean sharing only and, hence, relies on the ripple-carry adder to compute the COUNT. Figure 5d plots the results. The baseline operator is $10\times$ slower than the optimized one, as it requires 64 additional rounds of communication per input row.

7.5 Comparison with other MPC frameworks

Existing 3-party frameworks [62] are either proprietary, e.g. [27], or they only support specific operators, such as unique-joins [82, 99], that cannot be used for any of the queries we consider. We stress that EMP and SMCQL use 2-party garbled circuit protocols that are not directly comparable with SECRECY’s. The purpose of these experiments is to showcase the end-to-end performance of the available solutions for relational MPC and not to compare the underlying protocols.

Comparison with SMCQL. In the first set of experiments, we aim to reproduce the results presented in SMCQL [22, Fig. 7] on our experimental setup. We run the three medical queries on SMCQL and SECRECY, using a sample of 25

rows per data owner (50 in total), and present the results in Table 4. We use the plans and default configuration of protected and public attributes, as in the SMCQL project repository. `SECREC`Y is over 1000× faster than SMCQL in all queries.

Comparison with EMP. EMP is a general-purpose MPC framework and does not provide relational operators or query planning. Nevertheless, we include a comparison with EMP because it is the MPC library underpinning several non-open-source relational frameworks (e.g., Shrinkwrap, SAQE, and Senate). For these experiments, we use the oblivious sort operation from the EMP repository [108] that has the same asymptotic complexity with the respective `SECREC`Y sort. Figure 6 shows the results in `AWS-LAN` and `AWS-WAN` for input sizes ranging from 64K to 4M rows. The performance gap between `SECREC`Y and EMP is significant. `SECREC`Y is up to 12.7× faster in LAN (~3h vs 14min for 4M input rows). In the WAN setting, `SECREC`Y sorts 4M rows in 42min, while EMP could not complete the computation within 9h.

8 Related Work

Relational MPC systems. We distinguish two lines of work in this space that are often combined. The first line targets peer-to-peer deployments and reduces multi-party computation by pushing parts of the query to data owners (for plaintext evaluation) or executing the protocol within subsets of the computing parties [13, 22, 44, 95, 105]. The second line includes systems that trade off MPC performance with controlled information leakage [23, 24, 64, 105, 111]. We summarize each system’s preconditions and guarantees in Table 5 and provide more details in Appendix C. Function secret sharing in Splinter [106] allows for private queries on public data, which is the opposite to our goal.

Our approach has several advantages over, and is also complementary with, many of the prior techniques. `SECREC`Y’s optimizations are agnostic to data ownership and retain the full security guarantees of MPC, merely optimizing its execution. More importantly, this work provides a strong foundation for a unified query optimization framework that can accommodate multi-cloud, peer-to-peer, and hybrid deployments. Prior techniques can be ported into `SECREC`Y by plugging in appropriate cost functions and query transformation rules. For example, pushing parts of the query to data owners, as in Conclave [105], can be done via transformation rules that introduce plaintext operators with certain placement constraints.

Enclave-based approaches. In this line of work, parties process the plaintext data within a physically protected environment. Enclave-based approaches aim to minimize RAM requirements, pad intermediate results, and hide access patterns in untrusted storage. The works by Agrawal et al. [14] and Arasu et al. [19] focus on database queries in this setting.

More recent systems such as OblIDB [52], Opaque [116], StealthDB [104], and OCQ [49] rely on Intel’s SGX.

Enclave-based systems typically achieve better performance than MPC systems but require different trust assumptions and are susceptible to attacks [33, 35, 36, 59, 74, 75, 107, 112]. Some of these threats can be ameliorated using oblivious operators within the enclave. Our logical optimizations from §5.1 could also be applied in this setting to reduce the number of operations and memory requirements.

System optimizations for MPC. Improving the performance of secure computation via system optimizations is an active research topic. MAGE [73] proposed an interesting technique to reduce the inherent memory overhead of homomorphic encryption and garbled circuits (cf. §3). As `SECREC`Y relies on secret sharing, its memory footprint is small. Instead, secret sharing incurs a higher communication cost, which we amortize using vectorization and message batching (§5.2.3). MPC performance can be further improved by offloading secure primitives to hardware accelerators [54, 55, 79, 102]. Most works in this space focus on ML workloads but similar techniques could also be applied to relational operators.

MPC operators, algorithms, and cost models. Various related works focus on standalone oblivious relational operators, e.g. building group-by from oblivious sort [66], equi-joins [15, 72, 82, 93], or common aggregations [45, 51]. `SECREC`Y is driven by real-world applications that typically require oblivious evaluation of queries with multiple operators. Motivated by similar needs, Wang et al. [110] presented a secure version of the Yannakakis’ algorithm, while Ion et al. [65] and Buddhavarapu et al. [34] studied unique-key joins followed by simple aggregations. These works do not provide general cost-based MPC query optimization and they operate in the peer-to-peer setting, where data owners participate in the protocol execution using trusted resources. Recently, CostCO [53] did some nice work on modeling the cost of general MPC programs. Our cost model focuses on relational operators and is tightly integrated with the query planner.

Encrypted DBs. Existing practical solutions in secure database outsourcing [56] operate in a client-server setting and reveal or “leak” information to the database server. Systems based on property-based encryption like CryptDB [96] offer full SQL support and legacy compliance, but each query reveals information that can be used in reconstruction attacks [37, 58, 60, 61, 69, 78, 80, 84]. Systems based on structural encryption [38, 67, 88, 94, 115] provide semantic security that does not eliminate access pattern leaks. SDB [64, 111] uses secret sharing but leaks information to the server whereas Cipherbase [18] relies on a trusted machine. These systems support only one data owner and it would require public-key encryption to evaluate queries that span multiple datasets [31].

Differential Privacy (DP). Systems like DJoin [83], DStress [87], and others [29, 43, 63] use DP to ensure that the out-

Framework	MPC Protocol	Information Leakage	Trusted Party	Query Execution	Main Optimization Objective	Optimization Conditions
Conclave [105]	Secret Sharing / Garbled Circuits	Controlled (Hybrid operators)	Yes	Hybrid	Minimize the use of secure computation	1. Data owners serve as computing parties 2. Data owners provide privacy annotations 3. There exists an additional trusted party
SMCQL [22]	Garbled Circuits / ORAM	No	No ¹	Hybrid	Minimize the use of secure computation	1. Data owners serve as computing parties 2. Data owners provide privacy annotations 3. There exists an honest broker
Shrinkwrap [23]	Garbled Circuits / ORAM	Controlled (Diff. Privacy)	No	Hybrid	Calibrate padding of intermediate results	1. Data owners serve as computing parties 2. Data owners provide privacy annotations and intermediate result sensitivities
SAQE [24]	Garbled Circuits	Controlled (Diff. Privacy)	No	Hybrid	Choose sampling rate for approximate answers	1. Data owners serve as computing parties 2. Data owners provide privacy annotations and differential privacy budgets
Senate [95] ²	Garbled Circuits	No	No	Hybrid	Reduce joint computation to subsets of parties	1. Data owners serve as computing parties 2. Input or intermediate relations are owned by subsets of the computing parties
SDB [64, 111] ³	Secret Sharing	Yes (operator dependent)	No	Hybrid	Reduce data encryption and decryption costs	1. Data owner serves as computing party 2. Data owner provides privacy annotations
SECRECY	Rep. Secret Sharing	No	No	End-to-end under MPC	Reduce MPC costs (§ 2.3 and § 4-5)	None

¹ SMCQL relies on an honest broker that may see protected data in the clear during query evaluation [22, § 5.1].

² Senate provides security against malicious parties whereas all other systems adopt a semi-honest model.

³ SDB adopts a typical DBaaS model with one data owner and does not support collaborative analytics.

Table 5: Summary of MPC-based systems for relational analytics. Hybrid execution splits the query plan into a plaintext part (executed by the data owners) and an oblivious part (executed under MPC) and requires data owners to participate in the computation using trusted resources. The rest of the optimizations supported by each system are applicable under one or more of the listed conditions in the rightmost column.

put of a query reveals little about any one input record. This property is independent of (yet symbiotic with) MPC’s guarantee that the act of computing the query reveals no more than what may be inferred from its output. The SECRECY primitives from §3.2 can express arbitrary computations and could also be used to add DP noise under MPC. We leave this as future work.

9 Conclusions

This work presents SECRECY, a new system for efficient secure analytics in the cloud with no information leakage. SECRECY can enable new data markets and socially-beneficial data analyses while protecting private data. Our results show that logical optimizations coupled with careful system design can make MPC practical for complex analytics on millions of data records. In the future, we plan to extend SECRECY with multi-objective query optimization that considers cloud fees, data-parallelism via oblivious hashing (e.g. [91, 92]), and support for malicious-secure MPC (e.g., [16, 71]).

Acknowledgments

We would like to thank the anonymous reviewers for their valuable feedback and James Mickens for shepherding the paper. We also thank Jonathan Appavoo, Orran Krieger, Ran Canetti, Leo Reyzin, Azer Bestavros, Kinan Dak Albab, and Ben Getchell for their comments on an early version of this work, Eric Chen for automating the SECRECY deployment, and the MOC Alliance for providing access to their cloud. This work has been partially supported by a Red Hat Col-

laboratory grant (No. 2022-01-RH02) and a Hariri Institute Focused Research Project Award. M. Varia’s work is supported by the DARPA SIEVE program under Agreement No. HR00112020021 and the National Science Foundation under Grants No. 1414119, 1718135, 1801564, and 1931714.

A ANALYTICAL COST MODEL

A.1 Oblivious SECRECY primitives

Boolean operations. As explained in §3.2, we consider that each single-bit operation on shares has unit cost, so the operation cost of both XOR and AND operations is $C_o(\text{XOR}) = C_o(\text{AND}) = \ell$, where ℓ is the length of the share representation in bits. Recall that the synchronization cost of XOR is $C_s(\text{XOR}) = 0$ whereas the synchronization cost of AND is $C_s(\text{AND}) = 1$ round of communication. We further explain these costs below.

In SECRECY, each party starts with two shares of the input secrets s, t and ends up with two shares of the output. Initially, P_1 has s_1, s_2, t_1, t_2 whereas P_2 has s_2, s_3, t_2, t_3 , and P_3 has s_3, s_1, t_3, t_1 . Observe that $s \oplus t = (s_1 \oplus s_2 \oplus s_3) \oplus (t_1 \oplus t_2 \oplus t_3) = (s_1 \oplus t_1) \oplus (s_2 \oplus t_2) \oplus (s_3 \oplus t_3)$. Each parenthesis corresponds to a share of $s \oplus t$ and each party can compute two out of the three shares by simply XORing its input shares.

Logical AND is a bit more complex. Observe that $st = (s_1 \oplus s_2 \oplus s_3) \wedge (t_1 \oplus t_2 \oplus t_3)$. After distributing the AND over the XOR and doing some rearrangement we have $st = (s_1 t_1 \oplus s_1 t_2 \oplus s_2 t_1) \oplus (s_2 t_2 \oplus s_2 t_3 \oplus s_3 t_2) \oplus (s_3 t_3 \oplus s_3 t_1 \oplus s_1 t_3)$. Again, each parenthesis corresponds to a share of st . Using its input shares, each party can locally compute one of these shares. The parties then XOR this share with a fresh sharing of the number 0 (which is created locally) so that the final share is uniformly distributed [17]. In the end, each party sends the computed share to its successor on the ring (clockwise) so that all parties end up with two shares of st . Logical OR and NOT are based on the XOR and AND primitives.

Equality/Inequality. Using these boolean operations, parties can jointly compute $s \stackrel{?}{=} t$ (resp. $s \stackrel{?}{<} t$) by computing a sharing of $s \oplus t$ and then taking the oblivious boolean-AND of each of the bits of this string (resp., taking the value of s_i at the first bit i in which the two strings differ). As a result, taking the equality of ℓ -bit strings requires $C_o(\text{eq}) = 2\ell - 1$ operations (namely, ℓ XORs plus $\ell - 1$ ANDs) and $C_s(\text{eq}) = \lceil \log \ell \rceil$ rounds. Similarly, inequality comparison has $C_o(\text{ineq}) = 4\ell - 3$ and $C_s(\text{ineq}) = \lceil \log(\ell + 1) \rceil$. As special cases, $s < 0$ requires no communication, and equality with a public constant $s=c$ can also be done locally provided that the data owners have secret-shared the results of $s - c$ and $c - s$ [70].

Compare-and-swap. The parties can calculate the min and max of two strings. Setting $b = (s < t)$, we can use a multiplexer to compute $s' = \min\{s, t\} = bs \oplus (1 \oplus b)t$ and $t' = \max\{s, t\} = (1 \oplus b)s \oplus bt$. Evaluating these formulas requires 6 more operations and 1 more synchronization round beyond the cost of the oblivious inequality.

Sort and shuffle. Given an array of n secret-shared strings, each of length ℓ , oblivious sort in SECRECY is based on a bitonic sorter that comprises $\log n \cdot (\log n + 1)/2$ stages and

performs $n/2$ independent compare-and-swap operators in each stage. Hence, sorting has operational cost $C_o(\text{sort}_n) = \frac{1}{4}n \log n \cdot (\log n + 1) \cdot (C_o(\text{ineq}) + 6)$ and synchronization cost $C_s(\text{sort}_n) = \frac{1}{2} \log n \cdot (\log n + 1) \cdot (C_s(\text{ineq}) + 1)$. We can obliviously shuffle values in a similar fashion: each party appends an attribute that is populated with locally generated random values, sorts the values on this attribute, and then discards it.

Boolean addition. Given boolean-shared integers s and t , computing the boolean share of $s + t$ using a ripple-carry adder [68] can be done with $C_o(\text{RCA}) = 5\ell - 3$ operations in $C_s(\text{RCA}) = \ell$ rounds.

Arithmetic operations. Arithmetic addition and multiplication work similarly to XOR and AND respectively (see above). Scalar multiplication $c \cdot u$, where c is a public constant, does not require communication.

Conversion. We can convert between additive and boolean sharings [50, 81, 89] by securely computing all of the XOR and AND gates in a ripple-carry adder. Single-bit conversion can be done in two rounds with the simple protocol that is also used in CrypTen [70].

A.2 Oblivious SECRECY operators

Let R, S , and T be relations with cardinalities $|R|, |S|$, and $|T|$ respectively. Let also $t[a_i]$ be the value of attribute a_i in tuple t . To simplify the presentation, we describe each operator based on the logical (i.e., secret) relations and not the random shares distributed across parties. That is, when we say that “an operator is applied to a relation R and defines another relation T ”, in practice this means that each party begins with shares of R , performs some MPC operations on the shares, and ends up with shares of T .

PROJECT. Oblivious projection has the same semantics as its plaintext counterpart. The operation and synchronization costs of oblivious PROJECT are both zero since each party can locally disregard the shares corresponding to the filtered attributes.

SELECT. An oblivious selection with predicate φ on a relation R defines a new relation:

$$T = \{t \cup \{\varphi(t)\} \mid t \in R\}$$

with the same cardinality as R , i.e. $|T| = |R|$, and one more single-bit attribute for each tuple $t \in R$ that contains φ 's result when applied to t . This bit denotes whether t is included in the output relation T and is securely computed under MPC so that its true value remains hidden (i.e., secret-shared) from the computing parties. Note that, in contrast to a typical selection in the clear, oblivious selection defines a relation with the same cardinality as the input, i.e., it does not remove tuples from R so that the true size of T is kept secret.

Costs: The operation cost of SELECT is $C_o(\sigma_\varphi(R)) = \frac{C_o(\varphi(t)) \cdot |R|}{|R|}$, $t \in R$, where $C_o(\varphi(t))$ is the operation cost

of evaluating ϕ on a single tuple $t \in R$. Since predicate evaluation can be performed independently for each tuple in R , the total number of rounds to perform the `SELECT` equals the number of rounds to evaluate the selection predicate on a single tuple, i.e., $C_s(\sigma_\phi(R)) = C_s(\phi(t))$, $t \in R$.

Both $C_o(\phi(t))$ and $C_s(\phi(t))$ are independent of the actual t contents: they only depend on ϕ 's syntax and the lengths of the attributes used in ϕ . In `SECURITY`, a predicate ϕ can be an arbitrary logical expression with atoms that may also include arithmetic expressions ($+$, \times , $=$, $>$, $<$, \neq , \geq , \leq) and is constructed using the primitives of §A.1. Consider the example predicate $\phi := \text{age} > 30 \text{ AND } \text{age} < 40$ that requires `ANDING` the results of two oblivious inequalities under MPC. Based on the costs of primitive operations, we have: $C_o(\phi(t)) = 2C_o(\text{ineq}) + C_o(\text{AND})$ and $C_s(\phi(t)) = C_s(\text{ineq}) + 1$. In §5.3, we described a technique we use in `SECURITY` that can reduce selections to local operations (with $C_s = 0$).

JOIN. An oblivious θ -join between two relations R and S , denoted with $R \bowtie_\theta S$, defines a new relation:

$$T = \{(t \cup t' \cup \{\theta(t, t')\}) \mid t \in R \wedge t' \in S\}$$

where $t \cup t'$ is a new tuple that contains all attributes of $t \in R$ along with all attributes of $t' \in S$, and $\theta(t, t')$ is θ 's result when applied to the pair of tuples (t, t') . T is the cartesian product of the input relations ($R \times S$), where each tuple is augmented with a (secret-shared) bit denoting whether the tuple t “matches” with tuple t' according to θ . We emphasize that our focus in this work is on general-purpose oblivious joins that can support arbitrary predicates; there also exist special cases of oblivious join algorithms, e.g., primary- and foreign-key equi-joins with lower asymptotic complexity [15, 72, 82, 93] or compositions of equi-joins with specific operators [34] that could be added to `SECURITY` if desired.

Costs: The general oblivious `JOIN` requires a nested-loop over the input relations to check all possible pairs, so its operation cost is $C_o(R \bowtie_\theta S) = C_o(\theta(t, t')) \cdot |R| \cdot |S|$, $t \in R, t' \in S$. However, the total number of communication rounds to evaluate the `JOIN` is independent of the input cardinality; it only depends on the join predicate θ , i.e., $C_s(R \bowtie_\theta S) = C_s(\theta(t, t'))$, $t \in R, t' \in S$. For example, a range join $R \bowtie_{a < b} S$ has $C_o(R \bowtie_{a < b} S) = 2|R| \cdot |S| \cdot C_o(\text{ineq})$ and $C_s(R \bowtie_{a < b} S) = C_s(\text{ineq})$. The constant asymptotic complexity in number of rounds with respect to the input cardinality holds for *any* θ -join. Join predicates in `SECURITY` can be arbitrary expressions whose cost is computed as explained above for selection predicates.

SEMI-JOIN. An oblivious (left) semi-join between two relations R and S on a predicate θ , denoted with $R \ltimes_\theta S$, defines a new relation:

$$T = \{(t \cup \bigvee_{t' \in S} \theta(t, t')) \mid t \in R\}$$

with the same cardinality as R , i.e. $|T| = |R|$, and one more attribute that stores the result of the formula $f(\theta, t, S) =$

$\bigvee_{t' \in S} \theta(t, t')$, $t \in R$ indicating whether the tuple in R “matches” any tuple in S .

Costs: The operation cost of the general oblivious `SEMI-JOIN` is $C_o(R \ltimes_\theta S) = C_o(f(\theta, t, S)) \cdot |R| = C_o(\theta(t, t')) \cdot |R| \cdot |S| + |R| \cdot (|S| - 1)$, $t \in R, t' \in S$. The formula $f(\theta, t, S)$ can be evaluated independently for each tuple $t \in R$ using a binary tree of `OR` operations, therefore, the synchronization cost of the semi-join is $C_s(R \ltimes_\theta S) = C_s(\theta(t, t')) + \lceil \log |S| \rceil$, $t \in R, t' \in S$ (i.e., independent of $|R|$).

ORDER-BY. Oblivious order-by on attribute a_k has the same semantics as the non-oblivious operator. Hereafter, sorting a relation R with m attributes on ascending (resp. descending) order of an attribute a_k , $1 \leq k \leq m$, is denoted as $s_{\uparrow a_k}(R) = T$ (resp. $s_{\downarrow a_k}(R) = T$). We define order-by on multiple attributes using the standard semantics. For example, sorting a relation R first on attribute a_k (ascending) and then on a_n (descending) is denoted as $s_{\uparrow a_k \downarrow a_n}(R)$. An order-by operator is often followed by a `LIMIT` that defines the number of tuples the operator must output.

Costs: Oblivious `ORDER-BY` in `SECURITY` relies on a bitonic sorter of §A.1 that internally uses an oblivious multiplexer. Hence, the operation and synchronization costs are $C_o(s_{\uparrow a}(R)) = C_o(\text{sort}_{|R|})$ and $C_s(s_{\uparrow a}(R)) = C_s(\text{sort}_{|R|})$, as given in §A.1. In this case, the number of operations required by each oblivious multiplexing is linear to the number of attributes in the input relation, however, the total number of rounds depends only on the cardinality of the input. The analysis assumes one sorting attribute; adding more sorting attributes increases the number of operations and communication rounds in each comparison by a small constant factor.

GROUP-BY with aggregation. An oblivious group-by aggregation on a relation R with m attributes defines a new relation $T = \{f(t') \mid t' = t \cup \{a_g, a_v\}, t \in R\}$ with the same cardinality as R , i.e. $|T| = |R|$, and two more attributes: a_g that stores the result of the aggregation, and a_v that denotes whether the tuple t is ‘valid’, i.e., included in the output. Let a_k be the group-by key and a_w the attribute whose values are aggregated. Let also $S = [t_1[a_w], t_2[a_w], \dots, t_u[a_w]]$ be the list of values for attribute a_w for all tuples $t_1, t_2, \dots, t_u \in R$ that belong to the same group, i.e., $t_1[a_k] = t_2[a_k] = \dots = t_u[a_k]$, $1 \leq u \leq |R|$. The function f in T 's definition above is defined as follows:

$$f(t_i) = \begin{cases} t_i[a_g] = \text{agg}(S), t_i[a_v] = 1, & i = u', 1 \leq u' \leq u \\ t_{inv}, & i \neq u', 1 \leq i \leq u \end{cases}$$

where t_{inv} is a tuple with $t_{inv}[a_v] = 0$ and the rest of the attributes set to a special reserved value, while $\text{agg}(S)$ is the aggregation function, e.g. `MIN`, `MAX`, `COUNT`, `SUM`, `AVG`, and is implemented using the primitives of §A.1. Put simply, oblivious aggregation sets the value of a_g for one tuple per group equal to the result of the aggregation for that group and updates (in-place) all other tuples with “garbage.” This operation

is followed by an oblivious shuffling to hide the group boundaries when opening the relations to the learner (and only if there is no subsequent shuffling in the query plan). Groups can be defined on multiple attributes using the standard semantics.

Costs: The `GROUP-BY` operator $\gamma_{a_k}^{agg}(R)$ breaks into two phases: an oblivious sort on the group-by key(s) and an odd-even aggregation [66] applied to the sorted input. The odd-even aggregation performs $(|R|(\log |R| - 1) + 1) \cdot C_o(agg(t, t'))$ operations in $\log |R| \cdot C_s(agg(t, t'))$ rounds, where $C_o(agg(t, t'))$ and $C_s(agg(t, t'))$ are the operation and synchronization costs, respectively, of applying the aggregation function to a single pair of tuples $t, t' \in R$ (independent of $|R|$). Accounting for the initial sorting on the group-by keys, the total operation cost of the oblivious group-by is $C_o(\gamma_{a_k}^{agg}(R)) = C_o(s_{\uparrow a_k}(R)) + (|R|(\log |R| - 1) + 1) \cdot C_o(agg(t, t'))$. The total synchronization cost is $C_s(\gamma_{a_k}^{agg}(R)) = C_s(s_{\uparrow a_k}(R)) + \log |R| \cdot C_s(agg(t, t'))$. The analysis can be easily extended to multiple group-by keys.

DISTINCT. The oblivious distinct operator is a special case of group-by with aggregation, assuming that a_k is not the group-by key as before but the attribute where distinct is applied. For distinct, there is no a_g attribute and the function f is defined as follows:

$$f(t_i) = \begin{cases} t_i[a_v] = 1, & i = u', \quad 1 \leq u' \leq u \\ t_i[a_v] = 0, & i \neq u', \quad 1 \leq i \leq u \end{cases}$$

Distinct marks one tuple per group as ‘valid’ and the rest as ‘invalid’.

Costs: The `DISTINCT` operator includes an oblivious sort on the distinct attribute(s) followed by a second phase where the operator compares adjacent tuples in the sorted input to set the distinct bit a_v . Setting the distinct bit for each tuple is independent from the rest of the tuples, so all distinct bit operations can be performed in bulk. The total operation cost $C_o(\delta a_k(R)) = C_o(s_{\uparrow a_k}(R)) + (|R| - 1) \cdot C_o(eq)$ and synchronization cost $C_s(\delta a_k(R)) = C_s(s_{\uparrow a_k}(R)) + C_o(eq)$ of oblivious distinct are dominated by the oblivious sort.

MASK. Let t_{inv} be a tuple with all attributes set to a special reserved value. A mask operator with predicate p on a relation R defines a new relation $T = \{f(t) \mid t \in R\}$, where:

$$f(t) = \begin{cases} t, & p(t) = 0 \\ t_{inv}, & p(t) = 1 \end{cases}$$

Mask is used at the end of the query, just before opening the result to the learner, and only if there is no previous masking. The cost analysis of `MASK` is similar to that of `SELECT`.

Global aggregations. `SECURITY` also supports global aggregations without a group-by clause. The total operation cost of a global aggregation is $C_o(agg(R)) = C_o(agg(t, t')) \cdot$

$(|R| - 1)$, where $C_o(agg(t, t'))$ is the operation cost of applying the aggregation function to a single pair of tuples $t, t' \in R$. The total synchronization cost is $C_s(agg(R)) = C_s(agg(t, t')) \cdot \lceil \log |R| \rceil$, since the aggregation can be applied using a binary tree of function evaluations.

A.3 Composition of oblivious operators

Composing selections and joins. Recall that selections, joins, and semi-joins append a single-bit attribute to their input relation that indicates whether the tuple is included in the output. To compose a pair of such operators, we compute both single-bit attributes and take their conjunction under MPC. For example, for two selection operators σ_1 and σ_2 with predicates φ_1, φ_2 , the composition $\sigma_2(\sigma_1(R))$ defines a new relation $T = \{t \cup \{e_c = \varphi_1(t) \wedge \varphi_2(t)\} \mid t \in R\}$. The cost of composition in this case is the cost of evaluating the expression $\varphi_1(t) \wedge \varphi_2(t)$ for each tuple in T . This includes $|T|$ independent boolean ANDs which can be evaluated in one round.

Composing distinct with other operators. Applying a selection or a (semi-)join to the result of `DISTINCT` requires one communication round to compute the conjunction of the selection or (semi-) join bit with the bit a_v generated by distinct. However, applying `DISTINCT` to the output of a selection, a (semi-)join or a group-by operator, requires some care. Consider the case where `DISTINCT` is applied to the output of a selection. Let a_ϕ be the attribute added by the selection and a_k be the distinct attribute. To set the distinct bit a_v at each tuple, we must make sure there are no other tuples with the same attribute a_k , with $a_\phi = 1$, and whose distinct bit a_v is already set. To do so, the distinct operator must process tuples *sequentially* and the composition itself requires n rounds, where n is the cardinality of the input. This results in a significant increase over the $O(\log^2 n)$ rounds required by distinct when applied to a base relation. Applying distinct to the output of a group-by or (semi-)join incurs a linear number of rounds for the same reason. In §5.2, we proposed an optimization that reduces the cost of these compositions to a logarithmic factor.

Composing group-by with other operators. To perform a group-by on the result of a selection or (semi-)join, the group-by operator must apply the aggregation function to all tuples in the same group that are also included in the output of the previous operator. Consider the case of applying group-by to a selection result. To identify the aforementioned tuples, we need to evaluate the formula:

$$b \leftarrow b \wedge t_i[a_\phi] \wedge t_j[a_\phi]$$

at each step of the group-by operator, where b is the bit that denotes whether the tuples t_i and t_j belong to the same group and a_ϕ is the selection bit. This formula includes two boolean ANDs that require two communication rounds. Applying

group-by to the output of a (semi-)join has the same composition cost; in this case, we replace a_ϕ in the above formula with the (semi-)join attribute a_θ .

To apply a selection to the result of GROUP-BY, we must compute a boolean AND between the selection bit a_ϕ and the ‘valid’ bit a_v of each tuple generated by the group-by. The cost of composition in number of rounds is independent of the group-by result cardinality, as all boolean ANDs can be applied in bulk. The same holds when applying a (semi-)join to the output of group-by. Finally, composing two group-by operators has the same cost with applying GROUP-BY to the result of selection, as described above.

Composing order-by with other operators. Composing ORDER-BY with other operators is straight-forward. Applying an operator to the output of order-by has zero composition cost. The converse operation, applying ORDER-BY to the output of an operator, requires a few more boolean operations per oblivious compare-and-swap (due to the attribute/s appended by the previous operator), but does not incur additional communication rounds.

B SECURITY ANALYSIS

We have purposely designed SECRECY in a modular *black-box* fashion, with a hierarchy of *MPC protocol functionalities* \rightarrow *oblivious primitives* \rightarrow *relational operators* \rightarrow *optimizations*. This design choice provides two benefits: (i) immediate *inheritance* of all security guarantees provided by the underlying MPC protocol, and (ii) *flexibility* to support different protocols in the future that might have a different number of parties, threshold, and threat model.

Inheritance of security guarantees. SECRECY relies on a set of functionalities that must be provided by the MPC protocol. These functionalities enable parties to receive secret-shared inputs and return secret-shared outputs: (i) \mathcal{F}_{add} and $\mathcal{F}_{\text{mult}}$ that add and multiply their inputs, (ii) \mathcal{F}_{xor} and \mathcal{F}_{and} that take boolean operations of their inputs, (iii) \mathcal{F}_{a2b} and \mathcal{F}_{b2a} that perform conversions between arithmetic and boolean representations, (iv) \mathcal{F}_{eq} and \mathcal{F}_{cmp} to compute the equality and comparison predicates (where the hardest step of the latter usually involves extracting the most significant bit of an arithmetic-shared value), and (v) \mathcal{F}_{sh} and \mathcal{F}_{rec} that allow external participants to secret-share data to and reconstruct data from the computing parties.

In this section, we argue that SECRECY retains the security guarantees provided by the underlying MPC protocol, or equivalently that it retains the security guarantees of these ideal functionalities. Our reasoning shows that SECRECY compiles each query into a sequence of calls to these functionalities that is *oblivious*, meaning that its control flow is independent of its input and all data remains hidden:

1. SECRECY calls the functionalities of the MPC protocol

in a black-box manner. As a result, computing parties always operate on secret-shared data; only \mathcal{F}_{rec} provides any data in the clear (namely to the learner), and SECRECY only calls this functionality once at the end of the query execution.

2. The control flow of each relational operator (§A.2) is oblivious, i.e., data-independent. Concretely, SELECT and PROJECT always require a single pass over the input, (semi-)JOINS require a nested for-loop over the two inputs, ORDER-BY is based on an oblivious sorting network, and GROUP-BY and DISTINCT consist of an ORDER-BY followed by an additional oblivious step (to apply the aggregation and identify the unique records, respectively).
3. SECRECY composes relational operators (§A.3) using the protocol functionalities (e.g., taking ANDs under MPC) within an oblivious linear scan over the output of the composition.
4. The logical and physical transformations of §5 rewrite the oblivious sequence of calls to the protocol functionalities into a new semantically equivalent sequence of calls that is also oblivious and has lower execution cost.

As a result, semi-honest security of the full SECRECY protocol follows by inspection of the ideal functionalities. Privacy is satisfied against all parties because none of the functionalities ever provides a (non-secret-shared) output to the data owners or computing parties, and only the final \mathcal{F}_{rec} provides an output to the analyst as desired. Correctness of the full protocol follows immediately from correctness of each individual functionality.

Generality of optimizations. The logical and physical query optimizations constructed in this work (§5.1-5.2) apply generally to any mixed-mode MPC protocol that supports the set of functionalities we describe above. This level of abstraction is commonly used by modern mixed-mode MPC protocols (e.g., [17, 39, 40, 46, 50, 71, 81, 89, 90]).

If providing malicious security, we require these functionalities to validate the shares of their inputs and outputs (e.g., using an information-theoretic MAC or replicated sharing), either immediately or with delayed validation before invoking \mathcal{F}_{rec} . As a consequence, SECRECY satisfies correctness against the computing parties because input validation binds them to provide the output of the prior step as the input shares into the next functionality. Additionally, correctness against the data owners and analyst follow from the fact that, aside from the data owners’ initial sharing through \mathcal{F}_{sh} , none of the functionalities allow them to provide an input so they cannot influence the protocol execution.

As a result, the techniques from SECRECY can be applied to any N -party MPC protocol that provides semi-honest or malicious security against T adversarial parties. In particular, SECRECY can be instantiated with 2, 3, and 4-party secret

sharing-based protocols that remain secure in the face of a malicious adversary who can deviate from the protocol arbitrarily (e.g., [46, 71, 89]), or with (authenticated) garbled circuit protocols [109, 114] combined with occasional conversions to arithmetic secret sharing [50, 89] as needed. Protocols that provide the stronger cryptographic guarantee of robustness often do so by running several MPC executions both before and after evicting the malicious party, and by the same logic as above SECRECY even maintains the robust security of these protocols.

C SUMMARY OF MPC-BASED SYSTEMS FOR RELATIONAL ANALYTICS

Here we provide more details on existing systems for relational MPC summarized in Table 5. Hybrid execution splits the query plan into parts that can be evaluated in plaintext by a single party (the appropriate data owner) versus parts that inherently require multiple parties' data (executed under MPC). Therefore, hybrid execution is only feasible when data owners can compute part of the query on premise. SMCQL, SDB, and Conclave can further sidestep MPC when some attributes have been annotated as non-sensitive. Shrinkwrap and SAQE build on SMCQL to calibrate leakage based on user-provided privacy budgets, and Senate reduces joint computation when some relations are owned by subsets of the computing parties. This is common in peer-to-peer MPC but does not occur in a typical outsourced setting like the one of Figure 1, where all computing parties receive shares of the input data.

As shown in Table 5, Senate is the only relational system with support for malicious security. Due to its hybrid execution model, Senate requires additional steps to verify the integrity of local computations by the data owners (not to be confused with formal software verification). While SECRECY currently focuses on semi-honest security, the Araki et al. protocol [17] and subsequent mixed-mode ABY³ protocols [81] can be extended to provide malicious security with low computational cost [16, 71]. By optimizing MPC rather than sidestepping it, a malicious-secure version of SECRECY would not impose any new restriction on the supported set of queries or the mixed-mode MPC protocol utilized.

D ADDITIONAL EXPERIMENTS

D.1 Performance of SECRECY primitives

Here we present a set of micro-benchmarks that evaluate the performance of SECRECY's MPC primitives in AWS-LAN.

Effect of message batching on communication latency. In the first experiment, we measure the latency of inter-party communication using two messaging strategies. Recall that, during a message exchange, each party sends one message to its successor and receives one message from its predecessor

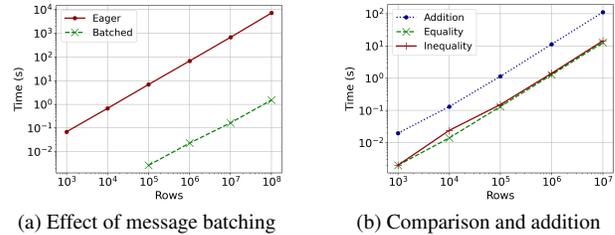

Figure 7: Performance of oblivious SECRECY primitives

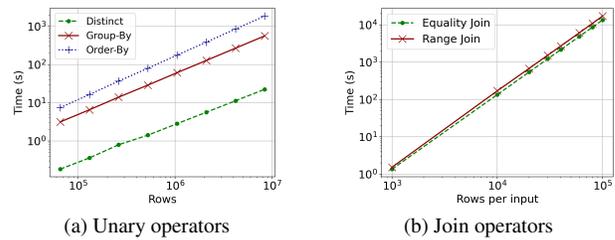

Figure 8: Performance of oblivious SECRECY operators

on the logical 'ring'. *Eager* exchanges data among parties as soon as they are generated, thus, producing a large number of small messages. The *Batched* strategy, on the other hand, collects data into batches and exchanges them only when computation cannot otherwise make progress, thus, producing as few as possible, albeit large messages.

We run this experiment with increasing data sizes and measure the total time from initiating the exchange until all parties complete the exchange. Figure 7a shows the results. We see that batching provides two to four orders of magnitude lower latency than eager messaging. Using batching in our experimental setup, parties can exchange 100M 64-bit data shares in 2s. These results reflect the network performance in our cloud testbed. We expect better performance in dedicated clusters with high-speed networks and higher latencies if the computing parties communicate over the internet.

Performance of secure computation primitives. We now evaluate the performance of oblivious primitives that require communication among parties. These include equality, inequality, and addition with the ripple-carry adder. In Figure 7b we show the execution time of oblivious primitives as we increase the input size from 1K rows to 10M rows. All primitives scale well with the input size as they all depend on a constant number of communication rounds. Equality requires six rounds. Inequality requires seven rounds and more memory than equality. Boolean addition is not as computation-intensive as inequality, but requires a higher number of rounds (64).

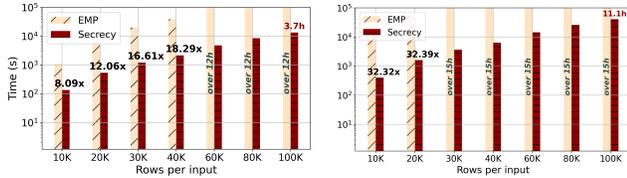

Figure 9: Performance comparison of an oblivious join operator on EMP and SECRECY in LAN (left) and WAN (right).

D.2 Performance of SECRECY operators

The next set of experiments evaluates the performance of SECRECY’s relational operators. We apply DISTINCT, GROUP-BY, ORDER-BY, and JOIN (equality and range) to relations of increasing size and measure the total execution time per operator in AWS-LAN. We empirically verify the cost analysis of §A and show that our vectorized implementations are efficient and scale to millions of input rows with a single CPU thread. Figure 8 shows the results.

Unary operators. In Figure 8a, we plot the execution time of unary operators vs the input size. Recall from §A.2 that DISTINCT and GROUP-BY are both based on sorting and, thus, their cost includes the cost of ORDER-BY for unsorted inputs of the same cardinality. To shed more light on the performance of DISTINCT and GROUP-BY, Figure 8a only shows the execution time of their second phase, that is, after the input is sorted and, for GROUP-BY, before the final shuffling (which has identical performance to sorting).

For an input relation with n rows, DISTINCT performs $n - 1$ equality comparisons, one for each pair of adjacent rows. Since all these comparisons are independent, our vectorized implementation uses batching, thus, applying DISTINCT to the entire input in six rounds of communication (the number of rounds required for oblivious equality on pairs of 64-bit shares). As a result, DISTINCT scales well with the input size and can process 10M rows in 20s. GROUP BY is slower than DISTINCT, as it requires significantly more rounds of communication, logarithmic to the input size. Finally, ORDER BY relies on our implementation of bitonic sort, where all $\frac{n}{2}$ comparisons at each level are batched within the same round.

Joins. The oblivious join operators in SECRECY hide the size of their output, thus, they compute the cartesian product between the two input relations and produce a bit share for all pairs of records, resulting in an output with $n \cdot m$ entries. We run both operators with $n = m$, for increasing input sizes, and plot the results in Figure 8b. The figure includes equi-join and range-join results for up to 100K rows per input, as we capped the duration of this experiment to 5h. SECRECY executes joins in batches without materializing their entire output at once. As a result, it can perform 10B equality and inequality comparisons under MPC within the experiment duration limit.

D.3 EMP vs SECRECY on oblivious join

Here we compare EMP with SECRECY using an oblivious join operator that is based on the sample program from the SoK project [10]. For these experiments, we use inputs of the same cardinality and increase the size from 10K to 100K rows per input. We cap the time of these experiments to 12h. Fig. 9 plots the results in AWS-LAN and AWS-WAN. Within the experiment duration, EMP can evaluate joins on up to 40K rows per input (in 11h). SECRECY is 18× faster for the same input size and can process up to 100K rows per input in less than 4h.

E QUERIES USED IN THE PAPER

Here we list the queries used in §7 (in SQL syntax):

Comorbidity:

```
SELECT diag, COUNT(*) cnt
FROM diagnosis
WHERE pid IN cdiff_cohort
GROUP BY diag
ORDER BY cnt DESC
LIMIT 10
```

Recurrent C. Diff.:

```
WITH rcd AS (
    SELECT pid, time, row_no
    FROM diagnosis
    WHERE diag=cdiff)
SELECT DISTINCT pid
FROM rcd r1 JOIN rcd r2 ON r1.pid = r2.pid
WHERE r2.time - r1.time >= 15 DAYS
AND r2.time - r1.time <= 56 DAYS
AND r2.row_no = r1.row_no + 1
```

Aspirin Count:

```
SELECT count(DISTINCT pid)
FROM diagnosis as d, medication as m on
d.pid = m.pid
WHERE d.diag = hd AND m.med = aspirin
AND d.time <= m.time
```

Password Reuse:

```
SELECT ID
FROM R
GROUP BY ID, PWD
HAVING COUNT(*)>1
```

Credit Score:

```
SELECT S.ID
FROM (
    SELECT ID, MIN(CS) as cs1, MAX(CS) as cs2
    FROM R
    WHERE R.year=2019
    GROUP-BY ID ) as S
WHERE S.cs2 - S.cs1 > c
```

TPC-H Q4:

```
SELECT o_orderpriority, count(*) as order_count
FROM orders
WHERE o_orderdate >= date '[DATE]' AND
      o_orderdate < date '[DATE]' + interval '3' month
AND EXISTS (
  SELECT *
  FROM lineitem
  WHERE l_orderkey = o_orderkey
  AND l_commitdate < l_receiptdate
)
GROUP BY o_orderpriority
ORDER BY o_orderpriority
```

TPC-H Q6:

```
SELECT sum(l_extendedprice*l_discount) as revenue
FROM lineitem
WHERE l_shipdate >= date '[DATE]' AND
      l_shipdate < date '[DATE]' + interval '1' year
AND l_discount between [DISCOUNT] - 0.01
AND [DISCOUNT] + 0.01 and l_quantity < [QUANTITY]
```

TPC-H Q13:

```
SELECT c_count, count(*) as custdist
FROM (
  SELECT c_custkey, count(o_orderkey)
  FROM customer left outer join orders ON
    c_custkey = o_custkey
    AND o_comment = '[WORD]'
  GROUP BY c_custkey
) as c_orders (c_custkey, c_count)
GROUP BY c_count
ORDER BY custdist desc, c_count desc
```

FLASH: Towards a High-performance Hardware Acceleration Architecture for Cross-silo Federated Learning

Junxue Zhang^{1,2}, Xiaodian Cheng^{1,2}, Wei Wang², Liu Yang^{1,2}, Jinbin Hu¹, Kai Chen¹

Abstract

Cross-silo federated learning (FL) adopts various cryptographic operations to preserve data privacy, which introduces significant performance overhead. In this paper, we identify nine widely-used cryptographic operations and design an efficient hardware architecture to accelerate them. However, directly offloading them on hardware statically leads to (1) inadequate hardware acceleration due to the limited resources allocated to each operation; (2) insufficient resource utilization, since different operations are used at different times. To address these challenges, we propose FLASH, a high-performance hardware acceleration architecture for cross-silo FL systems. At its heart, FLASH extracts two basic operators—modular exponentiation and multiplication—behind the nine cryptographic operations and implements them as highly-performant engines to achieve adequate acceleration. Furthermore, it leverages a dataflow scheduling scheme to dynamically compose different cryptographic operations based on these basic engines to obtain sufficient resource utilization. We have implemented a fully-functional FLASH prototype with Xilinx VU13P FPGA and integrated it with FATE, the most widely-adopted cross-silo FL framework. Experimental results show that, for the nine cryptographic operations, FLASH achieves up to $14.0\times$ and $3.4\times$ acceleration over CPU and GPU, translating to up to $6.8\times$ and $2.0\times$ speedup for realistic FL applications, respectively. We finally evaluate the FLASH design as an ASIC, and it achieves $23.6\times$ performance improvement upon the FPGA prototype.

1 Introduction

Training a high-quality machine learning model requires massive data, which is likely to be distributed across different institutions or companies in the real world. However, the increasing concern about data privacy and emerging regulations and lawsuits restrict these data from being collected together in one place for centralized training. To solve this problem, federated learning (FL) has been proposed to enable distributed learning among these *data silos* by performing local computation within a data silo and securely aggregating the intermediate results (*e.g.*, gradients/parameters) to generate a global model without revealing any original data to the outside world [44, 48, 89].

To ensure the security of cross-silo FL, various cryptographic techniques have been used. For example, partially homomorphic encryptions (PHE), *e.g.*, Paillier, have been used to enable parameter computation/aggregation directly on ciphertexts [73]. RSA is used to build the blind signature-based Private Set Intersections (PSI) for sample alignment [45]. In

this paper, we perform a comprehensive analysis of existing cross-silo FL applications and identify nine widely-used cryptographic operations, such as encryption/decryption, computation over ciphertexts, *etc.* (more details in §3.1). While preserving privacy, these cryptographic operations significantly degrade the performance (§3.2). For example, our experiments show that these operations cause up to $60.74\times$ performance degradation. The reasons are two-fold: (1) they are of high computational complexity, *e.g.*, Paillier encryption has a $O(2^N)$ ¹ time complexity; (2) they introduce large number calculations, *e.g.*, additively HE and RSA encryption generate 2048-bit ciphertexts which need to be broken down to multiple 64-bit numbers and executed with limited parallelism on current CPU architecture.

In this paper, we ask: *can we offload these cryptographic operations to dedicated hardware to accelerate cross-silo FL?* Towards answering this question, our first attempt went with GPU. However, as we will reveal in §3.3, the cryptographic operations used in cross-silo FL involve complicated computation stages and dramatically inflate the data, making them inappropriate for GPUs. While GPU is ideal for performing data parallelism over tensors with short numbers, *e.g.*, single-precision floats, it fails to provide efficient pipeline execution for cryptographic operations with large numbers, *e.g.*, 2048-bit integers. The reason is that the limited size of the shared memory within one Streaming Multiprocessor (SM) causes frequent data exchange between external and on-chip shared memory during the pipeline execution, significantly compromising the performance. While it might be feasible to work around the limitation of GPUs, it requires complex mechanisms such as a complex memory orchestration system. Our paper does not take this direction (§6).

To further accelerate cross-silo FL, we seek a more efficient hardware acceleration architecture beyond the existing GPU architecture. To this end, we choose to use FPGA as a prototype and further explore an Application-specific Integrated Circuit (ASIC). We believe such customized hardware architecture will exhibit several desired properties for our purpose. First, it is possible to tailor a hardware architecture for efficient cross-silo FL by customizing the hardware circuits from scratch, so that we can design an optimized fine-grained pipelining with flexible bit-width support for accelerating cryptographic operations. Second, the customized hardware architecture allows us to provide sufficient on-chip memory for storing large numbers used in the processing pipeline for superior performance. However, while promising, we identify

¹ N is the bit-width of the exponent n , and n is the public key in Paillier encryption.

that directly offloading the nine cryptographic operations to the hardware statically will pose two key challenges (§3.3):

- **Inadequate hardware acceleration due to limited resources.** To achieve high performance, one operation may need multiple hardware instances for high parallelism. However, as the hardware resource of a chip is limited, directly offloading all these nice operations to the hardware causes inadequate resources to speed up each operation, leading to suboptimal performance. Our implementation with this approach on a Xilinx VU13P FPGA [23] chip shows that each operation only achieves $\sim 50\%$ acceleration on average.
- **Insufficient resource utilization due to static offloading.** Different FL applications use different cryptographic operations, and within each application, different operations are used at different times. Consequently, statically offloading *all* the operations as a whole results in resource under-utilization because not all the operations are used at all times simultaneously.

To address the challenges, we take a closer look at these nine cryptographic operations and observe that almost all of them build upon two basic operators: *modular exponentiation and modular multiplication*. Based on this observation, we propose FLASH, a high-performance hardware acceleration architecture for cross-silo federated learning (§4). At its core, FLASH uses the majority of hardware resources to implement the two basic operators as high-performance engines to achieve adequate hardware acceleration. We also design fine-grained pipelines with sufficient on-chip memory to improve both the intra- and inter-engine execution efficiency for superior performance. Furthermore, based on these basic engines, FLASH adopts a dataflow scheduling module to dynamically compose these engines into different cryptographic operations on-demand to achieve high resource utilization.

We have provided a down-scale but full functional implementation of FLASH with Xilinx VU13P FPGA [23]² for prototyping purpose, integrated it with FATE [2]—the most widely-adopted cross-silo FL framework—and evaluated it extensively with real-world FL applications. We compare the performance of FLASH with (1) the vanilla FATE, which uses GMP [19] to implement these cryptographic operations with CPU. GMP provides a highly-optimized implementation for modular multiplication and exponentiation operations, which uses many optimization algorithms, including but not limited to the two mentioned in our paper. We choose Intel Xeon Silver 4114 CPU similar to prior works [76]; (2) the FATE where the cryptographic operations are accelerated by NVIDIA P4³

²We use FPGA for prototyping purposes, so we do not consider the price advantages/disadvantages of the VU13P FPGA chip.

³We note that latest NVIDIA A100 [9]/H100 [10] may have a better performance than P4/VU13P, however, they are much more expensive while still sharing the architectural deficiency of GPU in general as discussed in §3.3. The focus of FLASH is to pursue a more efficient hardware acceleration architecture for cross-silo FL.

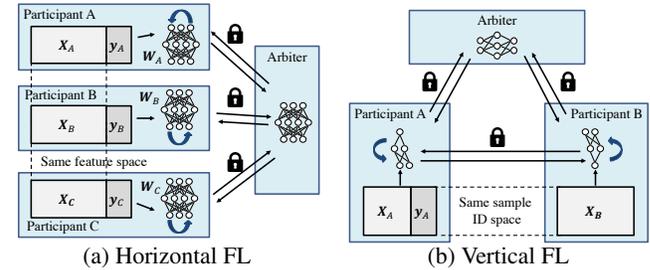

Figure 1: Two paradigms of cross-silo FL.

GPU [11, 43]. Here we use P4 GPU because it has the closest INT8 TOPS (although $\sim 2\times$ better) as FLASH (we typically use INT8 TOPS to denote the general computation power of a chip). P4 has ~ 20 INT8 TOPS [11]. VU13P has ~ 38.3 INT8 DSP TOPS while reaching peak 891MHz operation frequency [23, 24]. As FLASH uses 300MHz, it achieves ~ 12.9 DSP INT8 TOPS. Moreover, both of them are built with 16nm technology. Finally, with the standard Synopsys software tools (*e.g.*, Design Compiler [14], VCS [16] and Prime Time [15]), we further evaluate the performance of FLASH if implemented as an ASIC.

Overall, some of our key results are as follows:

- Across the nine concrete cryptographic operations (§6.2), FLASH (with FPGA implementation) outperforms CPU and GPU by $10.4\times - 14.0\times$ and $1.4\times - 3.4\times$, respectively.
- Over the nine realistic FL applications (§6.3), FLASH (with FPGA implementation) can consistently outperform CPU and GPU by up to $6.8\times$ and $2.0\times$, respectively.
- Our software evaluation of FLASH as an ASIC with 12nm and 28nm fabrication techniques (§6.5) shows that it can achieve $23.6\times$ and $7.1\times$ *additional* performance improvement upon the FPGA implementation, respectively.

As a final note, we are fully aware that there exist various other privacy-preserving techniques [27, 71, 81, 85]. However, in current industry-level deployments, Paillier and RSA schemes built with the nine cryptographic operations we investigated in this work are, to date, the most widely adopted approach in cross-silo FL systems [2, 41, 49], primarily due to the reason that they can achieve relatively better performance and are easier to use compared to other privacy-preserving schemes. Our goal is to provide plug-and-play acceleration capability for these industry-level cross-silo FL systems.

2 Cross-silo Federated Learning

FL was first proposed by Google to train a language model for keyboard input prediction from massive Android devices without leaking privacy-sensitive data [36, 90]. Recently, FL has evolved from the above cross-device scenarios to collaboratively train machine learning models across different data silos, *i.e.*, cross-silo FL [44, 48, 89]. A data silo is a repository or collection of data under the control of a single entity (*e.g.*, institution, company, *etc.*), and is isolated from other entities due to the ever-improving management regulations

or laws [50]. Cross-silo FL enables machine learning among these data silos and supports both vertical and horizontal FL.

Horizontal FL: As shown in Figure 1a, participants in Horizontal FL have different sample spaces but the same feature space, and each participant owns the labels of its samples. In most cases, there is an arbiter for parameter aggregation (the arbiter is a third-party server to assist the FL computations). To train a model, each participant trains local model w with its own samples and encrypts its model weights via PHE (e.g., Paillier [74]). Then all participants send their encrypted weights to the arbiter, and the arbiter directly performs an aggregation over the received ciphertexts to obtain the global model. Eventually, the arbiter sends the aggregated global model to all participants for next-round computation.

Vertical FL: As shown in Figure 1b, participants in Vertical FL have the same sample space but different feature spaces. Only one participant holds the label of the FL task. Before training a model, all participants have to align the samples among different data silos based on the common IDs (similar to joining two tables in a database based on the common IDs). One of the most commonly used algorithms is RSA blind signature-based PSI (RSA-PSI) [45]. After sample alignment, all participants can follow a pre-defined protocol for model training, such as Vertical Linear Regression (Please see Table 1 in [89]) and SecureBoost [42]. During the process, participants use PHE to encrypt their intermediate results and exchange them with other participants or the arbiter.

For interested readers, we have provided a detailed explanation of how cross-silo FL works and its security analysis in Appendix A.

Summary: Various cryptographic technics are used in cross-silo FL. These cryptographic technics are composed of various operations, e.g., data encryption/decryption via additively HE, computation over ciphertext, etc., and we call these operations as *cryptographic operations* in this paper.

3 Analysis of Cryptographic Operations

3.1 Cryptographic Operations

In this section, we present nine cryptographic operations that are widely used in cross-silo FL. Our study is based on the implementation of FATE [2], the most widely adopted open-source framework for cross-silo FL. However, our analysis can also be applied to other cross-silo FL frameworks, e.g., FedLearner [4], TF Encrypted [18], etc. Specifically, these nine cryptographic operations are as follows:

01. Paillier Encryption. This operation uses Paillier [28, 73], an additively homomorphic cryptographic algorithm, to encrypt cleartexts into ciphertexts. The operation is mainly used for protecting the intermediate data during model training.

02. Paillier Decryption. This operation decrypts Paillier ciphertexts into cleartexts. It is used when participants need to decrypt the intermediate results for local model updates in the training phase.

03. Ciphertext Matrix Addition. This operation is used to add two matrices (or vectors/values) of ciphertexts. As Paillier is used, ciphertexts can be summed up.

04. Ciphertext & Cleartext Matrix Element-wise Multiplication. This operation performs Hadamard product [58] between ciphertext matrix and cleartext matrix.

05. Ciphertext & Cleartext Matrix Multiplication⁴. This operation performs matrix multiplication between two matrices of ciphertexts and cleartexts, respectively.

06. Ciphertext Histogram Building. This operation performs addition operations over encrypted gradient statistics to build decision trees [42].

07. RSA Encryption/Decryption. This operation conducts encryption or decryption with the public or private key of the RSA algorithm correspondingly. This operation is used when multiple participants try to perform PSI for sample alignment [45].

08. RSA Blind. This operation blinds the cleartexts with encrypted random numbers.

09. RSA Unblind. This operation unblinds RSA ciphertexts to remove the random numbers from the ciphertexts.

As shown subsequently (§3.2), these cryptographic operations have a large impact on the performance of cross-silo FL applications due to the following two reasons:

- **High time complexity:** These operations are of high computation complexity, e.g., Paillier encryption has a time complexity of $O(2^N)$. Thus these algorithms are expensive to compute.
- **Large number computation:** Cryptographic operations significantly inflate data, yielding large numbers, e.g., 2048-bit integer. The large number will need to be divided into multiple small numbers and executed on the current CPU architecture with limited parallelism.

3.2 Quantifying the Performance Impact

We now quantify the performance impact of these cryptographic operations with realistic cross-silo FL applications through testbed experiments.

Our testbed is equipped with an Intel Xeon Silver 4114 CPU [5] and 192GB memory. We choose three most widely-adopted vertical FL applications and one horizontal FL application for evaluation: RSA blind signature-based PSI (RSA-PSI), Vertical Logistic Regression (VLR) [53], SecureBoost Decision Tree (SBT) [42] and Horizontal Logistic Regression (HLR). The dataset we use is a commercial dataset from a bank with $\sim 100,000$ samples and 80 features. For vertical FL applications, the dataset is vertically partitioned into two parts: one part contains 80 features while the other contains one feature. We first perform RSA-PSI to obtain the

⁴To efficiently process a large matrix, we will use optimization algorithms such as blocking the matrix and performing multiplications of the blocked matrices. Thus this operation is not a simple combination of matrix element-wise multiplication (04) and addition (03).

Applications & Their Sub-tasks	Involved Operations	w/o CO (s)	w CO (s)	Degradation	
RSA-PSI	Computing intersection	O7, O8, O9	7.91	20.62	2.60× ↓
VLR (One Epoch) Total: 12.05× ↓	Encrypting logits	O1	0	32.05	-
	Aggregating logits	O3	0.63	2.04	3.23× ↓
	Computing fore gradients ^a	O3, O4	0.74	2.92	3.93× ↓
	Computing gradients	O3, O4, O5	3.77	135.96	36.08× ↓
	Decrypting gradients	O2	0	0.04	-
	Computing loss	O1, O3, O4	4.08	8.22	2.02× ↓
SBT (One Epoch) Total: 3.49× ↓ ^b	Encrypting gradients	O1	0	54.71	-
	Aggregating gradients	O3, O6	12.02	223.91	18.62× ↓
	Split information synchronization	O2	3.62	13.03	3.60× ↓
HLR (One Epoch) Total: 60.74× ↓ ^b	Computing gradients	O3, O4, O5	1.73	177.94	102.80× ↓
	Model update	O3, O4	0.0002	0.10	526.10× ↓
	Model re-encryption	O1, O2	0	0.69	-

^a According to Federated Logistic Regression [53], the gradient computation takes two steps: fore gradients computation and gradients computation.

^b The overall performance degradation of SBT/HLR is smaller than the sum of those sub-tasks because we do not include pure cleartext computation or networking communication sub-tasks in the table.

Table 1: Performance penalty caused by cryptographic operations (CO) with different cross-silo FL applications.

data intersection. Then, we run VLR and SBT over the data intersection, respectively. For horizontal FL, the dataset is horizontally partitioned into two parts, each with $\sim 50,000$ samples. The four applications are executed both with cryptographic operations implemented using GMP (w/ CO) and without cryptographic operations (w/o CO). To implement model training w/o CO, we modify the code of FATE to skip these cryptographic operations. To perform a fine-grained analysis, we also break down these four applications into sub-tasks, and for each sub-task, we show the adopted cryptographic operations. All the applications are executed with ten CPU cores in parallel. Table 1 shows the results, and we make the following observations:

- **Cryptographic operations considerably degrade the performance.** In general, cryptographic operations significantly degrade the performance of cross-silo FL applications. In our experiment, the cryptographic operations cause RSA-PSI, VLR, SBT and HLR to suffer 2.60×, 12.05×, 3.49× and 60.74× performance degradation, respectively. Moreover, the combinations of these cryptographic operations can degrade the performance from $\sim 2.02\times$ to $\sim 526.10\times$.
- **Not all the cryptographic operations are used at all times simultaneously.** Different FL applications use different cryptographic operations, and even within a single application, different sub-tasks use different operations.

3.3 Challenges of Offloading Cryptographic Operations

To accelerate these cryptographic operations, we chose GPU as our first attempt, as it has been widely adopted in various offloading scenarios. However, as our exploration proceeds, we find that the cryptographic operations in cross-silo FL require complicated pipeline computation and significantly inflate the data, posing the following challenges for GPU.

The hardware architecture of GPU is tailored for performing data parallelism over tensors, which are mostly short numbers. However, as we will show in §4.2.1, to efficiently

execute cryptographic operations, we have to use several steps to optimize the computation, *e.g.*, Montgomery Modular Multiplication [65], in which pipeline parallelism is needed. Furthermore, massive large numbers should be stored in the shared memory during the pipeline execution. However, these large numbers, *e.g.*, 2048-bit integer numbers, can easily overflow the on-chip memory of the GPU. For example, the amount of shared memory per SM is 96 KB for NVIDIA V100 [13]. No more than 384 2048-bit integer numbers can be stored inside one SM. Therefore, after processing a small amount of data, the GPU has to swap data between the shared memory and external memory, interrupting the pipeline execution. While it is possible to solve the aforementioned limitations, it requires complicated memory orchestration, such as a suitable double-buffering [33], which may pose further challenges.

To this end, our paper does not take this direction but moves one step further beyond the existing GPU architecture, by seeking a more efficient, customized hardware acceleration architecture for cross-silo FL. We envision that with a customized hardware architecture, we can implement fine-grained pipelining for those cryptographic operations with large numbers. The hardware can also support variable bit-widths to match the cross-silo FL scenarios where different public key sizes are used (which yield large numbers with different bit-widths). Furthermore, with a customized design, we are able to invest sufficient on-chip memory for caching large numbers used in the pipeline execution. The data swapping between on-chip and external memory can be part of the pipeline to avoid the performance penalty mentioned above.

In this paper, we follow the rule-of-thumb approach to use FPGA as a prototype and evaluate the potential of ASIC via software tools [30, 51, 87]. However, we confront the following two challenges in our design:

1. **Inadequate hardware acceleration due to limited resources.** As identified in §3.2, all the cryptographic operations cause a performance penalty, so we should offload all of them to hardware. Furthermore, to realize sufficient accelera-

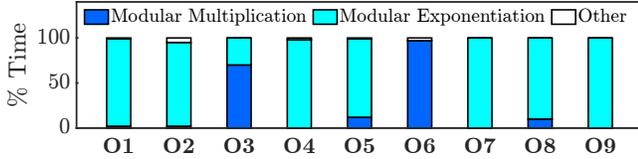

Figure 2: Cryptographic operation computation time analysis.

tion, each operation requires multiple hardware instances of accelerating modules/circuits for high parallelism. However, in practice, the hardware chip has limited resources, and if we naïvely offload all cryptographic operations to the chip, each operation has inadequate resources to be fully accelerated. Taking the DSP resources as an example, our preliminary implementation on VU13P FPGA [23] chip shows that to accelerate Paillier encryption (O1) by $2\times$, we need to use 2630 DSPs. Yet, a high-end FPGA chip, such as VU13P [23], only has 12288 DSPs, leaving < 1365 DSPs for one operation on average⁵ (some DSPs are reserved for PCIe, memory controller, *etc.*). Thus, directly offloading *all* operations on VU13P FPGA chip leads to only $\sim 50\%$ acceleration on average. A similar problem also applies to the ASIC design.

2. Insufficient resource utilization due to static offloading. Different from software, hardware function is static after being configured/programmed/taped out, thus it cannot change its function dynamically. Nevertheless, as shown in §3.2, not all the cryptographic operations are used at all times simultaneously. Consequently, if we statically offload all cryptographic operations on the hardware chip, only part of these cryptographic operations is used at a time. Therefore, such static offloading causes low resource utilization and further leads to suboptimal performance.

3.4 Opportunities with Accelerating Basic Operators

To overcome the above challenges, we further take a look at the internal of these nine cryptographic operations. We discover that *all* these operations are composed of two basic operators: modular multiplication and exponentiation. Then we further find that the performance of these operations is mainly decided by the two basic operators.

Paillier Encryption: Given the public key (n, g) and data m ($0 \leq m < n$), the Paillier encryption algorithm takes two steps: (1) selecting a random number r where $0 < r < n$ and $r \in \mathbb{Z}_n^*$; (2) computing ciphertext $c = g^m \cdot r^n \bmod n^2$. The formula can also be simplified to $c = (1 + mn) \cdot r^n \bmod n^2$ by setting $g = (1 + n)$. We use $[[\cdot]]$ to denote the Paillier encryption, e.g., $c = [[m]]$.

Homomorphic Addition: Given two plaintext a and b , homomorphic addition guarantees that $[[a]] \oplus [[b]] = [[a + b]]$. In Paillier cryptosystem, $[[a]] \oplus [[b]]$ is defined as $[[a]] * [[b]] \bmod n^2$. The homomorphic addition is used by operations O3, O5 and O6.

⁵We will show later that all these nine operations share similar building blocks, thus they require similar resources to implement.

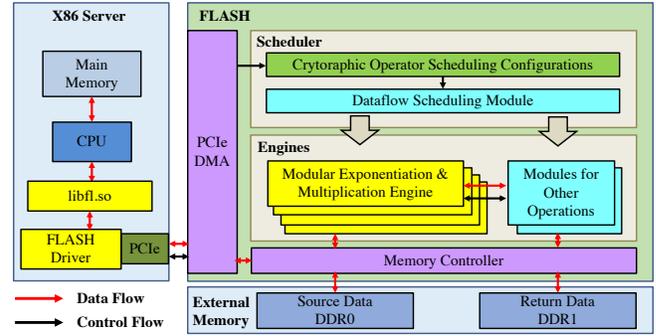

Figure 3: FLASH architecture.

Homomorphic Multiplication: Given a plaintext a and k , the homomorphic multiplication is denoted by $k \cdot [[a]]$. It can be actually regarded as a homomorphic addition: $\Sigma^k [[a]]$. Thus, $k \cdot [[a]] = [[a]]^k \bmod n^2$. The homomorphic multiplication is used by operations O4 and O5.

Paillier Decryption: Given the public key (n, g) , private key (p, q) and ciphertext c , the Paillier Decryption algorithm can be optimized via Chinese Remainder Theorem (CRT) to reduce the original workload to only about one-quarter of the original decryption algorithm. To use CRT, we define L_p and L_q to be $L_p(x) = \frac{x-1}{p}$ and $L_q(x) = \frac{x-1}{q}$. The decryption algorithm takes the following three steps: (1) computing $m_p = L_p(c^{p-1} \bmod p^2) L_p(g^{p-1} \bmod p^2)^{-1} \bmod p$; (2) computing $m_q = L_q(c^{q-1} \bmod q^2) L_q(g^{q-1} \bmod q^2)^{-1} \bmod q$; and (3) computing plaintext $m = \text{CRT}(m_p, m_q) \bmod n$.

RSA-related Operations: The RSA-related operations are used in RSA blind signature-based PSI [45]. It is commonly known that the core of these RSA-related algorithms is either modular multiplication or modular exponentiation.

Through the above mathematical analysis, we find that *all* cryptographic operations used in cross-silo FL are built upon the two basic operators: modular multiplication and exponentiation⁶. Then, we further perform testbed experiments to investigate how these two basic operators impact the performance of the nine original cryptographic operations. The results are shown in Figure 2. Clearly, we find that across *all* nine original operations, the two basic operators occupy $> 95\%$ of the total execution time.

Observation: We can compose all the nine cryptographic operations with these two basic operators, and by accelerating these two basic operators, all the nine original operations used in cross-silo FL applications can be effectively accelerated.

4 The FLASH Design

Inspired by the above observation, we present FLASH, a high-performance hardware acceleration architecture for cross-silo FL. This section describes how we design FLASH in detail. Please note that our design has been fully implemented in our FLASH prototype with FPGAs as well as rigorously evaluated

⁶Appendix B and C provide more details of these operations.

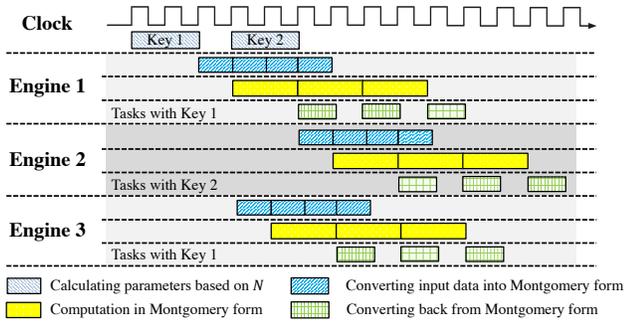

Figure 4: Pipeline executions of both inter- and intra-engines.

with the Synopsys tools for the ASIC.

4.1 Architecture Overview

Figure 3 shows the overall architecture of FLASH. It contains a hardware acceleration card and an integrated software package. The accelerator card can be plugged into a server via PCIe Gen3×16 interface. The server is installed with cross-silo FL software, *e.g.*, FATE. The software can invoke FLASH’s software package to *offload* the cryptographic operations on the card for efficient acceleration.

The idea of our FLASH design is that it does not directly offload all cryptographic operations on the hardware, but leverages the insights of our observation to (1) utilize the limited programmable resource for most performance-critical basic operators: modular exponentiation and multiplication to achieve *adequate acceleration* (§4.2), and (2) design an on-chip dataflow scheduling module to dynamically compose different cryptographic operations on-demand based on these engines, achieving *high resource utilization* (§4.3). In addition, to make FLASH a general solution to support a wide range of cross-silo FL frameworks, our software package provides standard APIs. In this way, different cross-silo FL software can utilize FLASH by harnessing its APIs (§4.4).

4.2 Modular Exponentiation and Multiplication Engines

To implement modular exponentiation and multiplication operators as high-performance engines on hardware, FLASH makes the following design decisions. First, instead of directly offloading the modular exponentiation and multiplication operators, we optimize the algorithms of the two operators to make them suitable for the hardware implementation (§4.2.1). Second, based on the optimized algorithms, FLASH further leverages pipelining technologies to efficiently execute them with high parallelism (§4.2.2). Third, we provide sufficient on-chip memory for pipeline execution and make the data transfer as part of the pipeline to efficiently exchange data between off-chip memory and engines (§4.2.3).

4.2.1 Algorithm Optimization

The mathematical formulas of the two basic operators: modular exponentiation (Equation 1) and multiplication (Equation 2) are as follows:

Algorithm 1 Montgomery Modular Multiplication

▷ Given 3 input numbers X, Y and N , the Montgomery Modular Multiplication outputs $Z = X \cdot Y \cdot R^{-1} \pmod N$, where R is a power of 2 and $\lceil \log_2 R \rceil = \lceil \log_2 N \rceil$.

Input: $X = (X_{d-1}, \dots, X_0), Y = (Y_{d-1}, \dots, Y_0), N = (N_{d-1}, \dots, N_0), N'$, where $N' = (-N)^{-1} \pmod r$, $\triangleright N'$ is pre-computed in S1
 $r = 2^w, d = \lceil \log_r N \rceil + 1$, $\triangleright r$ and d is used to split data
 $\text{gcd}(N, r) = 1$, with $N \times N' \equiv -1 \pmod r$

Output: $Z = \text{ModMult}(X, Y, N) = X \times Y \times R^{-1} \pmod N$

```

1:  $Z = (Z_{d-1}, \dots, Z_0) = 0$  ▷ Initialization
2: for all  $i = 0, 1, \dots, d - 1$  do ▷ Loop on Y
3:    $\alpha = [X_0 \times Y_i]_{\text{low}}$ 
4:    $\beta = \alpha + Z_0$ 
5:    $q = [\beta \times N']_{\text{low}}$ 
6:    $\delta_1 = \alpha + [q \times N_0]_{\text{low}}$ 
7:    $\delta_2 = \delta_1 + Z_0$ 
8:    $Z_0 = [\delta_2]_{\text{low}}$ 
9:    $C = [\delta_2]_{\text{high}}$ 
10:  for all  $j = 1, 2, \dots, d - 1$  do ▷ Loop on X
11:     $\delta_0 = [X_{j-1} \times Y_i]_{\text{high}} + [q \times N_{j-1}]_{\text{high}}$ 
12:     $\delta_1 = \delta_0 + [X_j \times Y_i]_{\text{low}} + [q \times N_j]_{\text{low}}$ 
13:     $\delta_2 = \delta_1 + Z_j + C$ 
14:     $Z_{j-1} = [\delta_2]_{\text{low}}$ 
15:     $C = [\delta_2]_{\text{high}}$  ▷ Carry higher bits
16:  end for
17:   $Z_{d-1} = C$ 
18: end for
19: if  $Z \geq N$  then
20:    $Z = Z - N$ 
21: end if
22: return  $Z$ 

```

$$P = m^e \pmod n \quad m, e, n \in \mathbb{Z}^+ \quad (1)$$

$$P = ab \pmod n \quad a, b, n \in \mathbb{Z}^+ \quad (2)$$

When used in cryptographic operations, all the numbers a, b, m, n are large numbers, leading to high computation complexity. Therefore, before designing FLASH’s engines, we first apply some commonly-used optimization strategies in the cryptographic research community to optimize the two basic operators, including Binary Exponentiation [52] and Montgomery Modular Multiplication [65], *etc.* The advantages of using these optimization strategies are: (1) lowering the number of multiplications used in modular exponentiation from $O(2^N)$ to $O(N)$ (N is the bit-width of e), and (2) replacing the modulo operation with the hardware-friendly bit-shifting operation. Appendix D provides details of how they work.

After applying these optimization methods, FLASH’s modular exponentiation and multiplication operators require the following four stages to complete the computation:

S1. Preparing common data needed in Montgomery space based on the input data n . Since, in both Paillier and RSA cryptosystems, n is decided by the public key, we can reuse these prepared data for all computations with the same public key. This is common in cross-silo FL applications as they use one key for all cryptographic operations within one application.

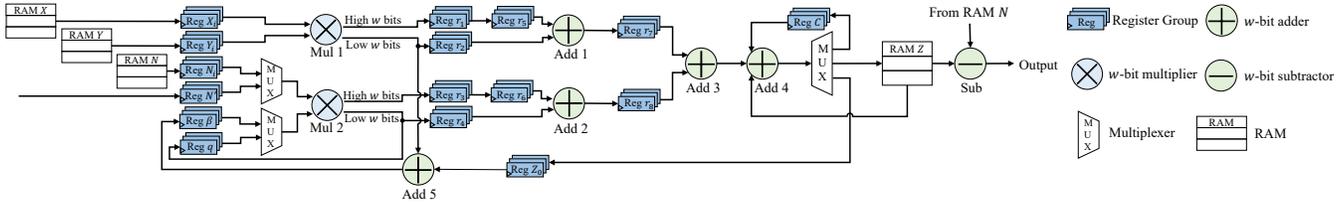

Figure 5: The Montgomery Modular Multiplication engine circuit design. Our circuit uses two multipliers and four on-chip RAMs for efficient pipelining. For more details of how this circuit works, please refer to [Appendix E](#).

- S2. Performing input data pre-processing and converting them into Montgomery space.
- S3. Performing computation in Montgomery form. Major operations in this stage include large-number multiplication, addition, and bit-shifting. No modulo operation is needed.
- S4. Converting all output data of the operators out of Montgomery space.

4.2.2 Pipelining

We next introduce how FLASH efficiently performs the above four computation stages via inter- and intra-engine pipelining.

Inter-engine pipelining: To enable inter-engine pipelining, FLASH employs an engine pipeline stage manager to control the execution strategies for different stages. [Figure 4](#) gives an overview of how these stages are pipelined. First, FLASH reserves S1 as a standalone stage, which can be executed in advance once it obtains the public key. Second, for all computation tasks with the same public key (Engine 1 and 3 in [Figure 4](#)), they can be executed in parallel once their data preparation is completed (S1). The start time of these engines may have a small gap of several clock cycles because FLASH adopts a round-robin strategy to dispatch stage executions. Third, for tasks with different keys (Engine 2 in [Figure 4](#)), they can be executed independently.

Intra-engine pipelining: FLASH further performs intra-engine pipelining within the most computation-intensive stage S3 to accelerate the stage’s internal execution. The key design goals are: (1) FLASH should support variable bit-widths thus the application can choose the key length based on their security requirements; (2) the hardware resources should be fully utilized to achieve superb performance.

To achieve the first goal, FLASH builds an efficient pipeline that processes data based on radix- 2^w arithmetic [60] (we use $w = 64$ in FLASH’s implementation). Given any input data, we split it into d w -bit integers. For example, $d = 16$ when bit-width of X is 1024, and $d = 32$ when bit-width of X is 2048. Theoretically, the pipeline can be adapted for input data with any bit-width as long as the bit-width is or can be extended by complementary zeros to the integer multiple of d . After data splitting, the complete algorithm of S3 (Montgomery Modular Multiplication) is shown in [Algorithm 1](#). Note, compared to the original Montgomery Modular Multiplication (shown in [Algorithm D.2](#) in [Appendix D.2](#)), we make the following optimizations to make the algorithm more

hardware-friendly: (1) the computation of S (*i.e.*, line 6 in [Algorithm D.2](#)) is separated into computations of lower w bits and higher w bits so that the bit-width required in operations (*e.g.*, addition) is halved; (2) the first iteration of the inner loop where $j = 0$ is unrolled to remove the conditionals in the original algorithm (*i.e.*, line 7 to 9 in [Algorithm D.2](#)) and keep the consistency of computation logic.

In [Algorithm 1](#), the most computation-intensive operations are the multiplications of $X_j \times Y_i$ and $q \times N_j$ respectively (both operations require d^2 w -bit multiplications). Moreover, the data required in these two multiplications are totally independent. Therefore, we use two multipliers (one 64-bit multiplier consists of 32 DSP48E2 slices [22] on our FPGA prototype), Mul 1 and Mul 2, for these two multiplication operations as well (operations assigned to Mul 1 and Mul 2 are marked with red and green respectively in [Algorithm 1](#)). Since the multiplier can continuously process data, to fully utilize the multiplier, we have the following design decisions. First, we design a circuit to fully pipeline the inner loop (line 10 to 16 of [Algorithm 1](#)). The circuit is shown in [Figure 5](#) and due to the limited space, we defer a detailed description of how it works in [Appendix E](#). Second, when the multiplications of i -th iteration finish and some other operations are still under execution, *e.g.*, addition operations in the right part of the [Figure 5](#), FLASH allows direct starting the multiplications in $i + 1$ -th iteration to minimize the delay between different iterations. We also use [Figure 6](#) to visualize how the operations in S3 are efficiently pipelined.

4.2.3 On-chip & Off-chip Memory

To provide sufficient on-chip memory for efficient pipeline execution, FLASH allocates four memory units for each modular multiplication and exponentiation engine (shown in [Figure 5](#)). For our FPGA prototype implementation, we use 4×36 Kbit BRAM units. While the on-chip memory is mainly used for pipeline execution, FLASH further exploits external memory (shown in [Figure 3](#)) for input, output and intermediate data storage. To achieve high performance, data exchange between on-chip and off-chip memory is part of the pipeline itself, *i.e.*, when the data at the on-chip memory is consumed, FLASH simultaneously fetches new data from the off-chip memory, so that the data fetching time can overlap with the computation time. As the data fetch time is typically shorter than the computation time, it effectively hides the off-chip

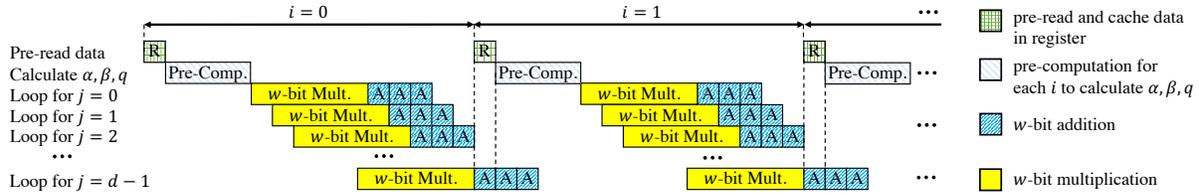

Figure 6: Efficient pipelining of Montgomery Modular Multiplication.

memory access latency, leading to perfect pipelining.

Moreover, we also design a hierarchical data distribution mechanism to solve the design difficulties encountered when manipulating large external memory. Specifically, instead of directly using long paths to send data from the memory controller to all engines, FLASH distributes data at multiple layers. Such a hierarchical mechanism leads to two advantages: (1) low design difficulties: since a small fan-out with short logical paths is required in each layer, the placement of the circuits is much easier; (2) improved performance: because the time constraints of the short path are much easier to meet, such method can allow a high operating frequency. Due to the limited space, we defer a detailed introduction in [Appendix F](#).

4.3 Dataflow Scheduling

We now introduce how FLASH composes various cryptographic operations over basic engines through dataflow scheduling. First, we show how our engines can work at different modes ([§4.3.1](#)). Then, we present how different cryptographic operations are constructed by combining particular engines ([§4.3.2](#)).

4.3.1 Dynamic Engine Switching

To build various cryptographic operations over basic engines, FLASH needs to enable dynamic engine switching between modular exponentiation and multiplication. Mathematically, modular exponentiation can be realized by performing modular multiplication multiple times. Thus, FLASH leverages a hardware control module to achieve it without reconfiguring hardware (it is almost impossible to reconfigure the ASIC). Specifically, to accelerate modular exponentiation, FLASH constructs a dataflow loop over the multiplication engine multiple times. In contrast, when the engine needs to execute modular multiplication, FLASH directs the dataflow through the modular multiplication engine once. While the design works well for most cryptographic operations that use either modular exponentiation or multiplication, it cannot directly support operations that simultaneously require both modular exponentiation and multiplication, *e.g.*, Paillier encryption (**O1**), matrix multiplication (**O5**), in which FLASH has to decide the ratio of engines in different modes.

How to decide the ratio? We use domain knowledge in cross-silo FL applications to decide the ratio. Taking matrix multiplication operation (**O5**) as an example, it first performs ciphertexts and cleartexts multiplication (requires modular exponentiation) and then ciphertexts addition (requires modu-

lar multiplication). Considering the modular exponentiation, the exponent e is a cleartext, which has a common bit-width of 64. As mentioned in [§4.2.1](#), since we use Binary Exponentiation to optimize the modular exponentiation, the number of modular multiplication required may vary from 64 to 127 depending on the specific value of cleartext. On average, 96 modular multiplications are required. Thus, the throughput of the modular exponentiation should be $\sim 1/96$ of modular multiplication. Based on this, we can adjust the ratio of the engines working in different modes to make the throughput of both modular exponentiation and modular multiplication balanced. In this way, the hardware resources can be efficiently utilized and no engines will sit idle.

4.3.2 Building Cryptographic Operations

As shown in [Figure 7a](#), the core idea of dataflow scheduling is to use an on-chip controller to dynamically determine: (1) which data paths (they are logical paths that do not reflect the physical wiring) should be active, and (2) what to put in the engine slots, based on which operation is offloaded. Each engine slot contains one data splitting module and one data merging module to distribute data to different engines and aggregate results from these engines, respectively. These data splitting and merging modules have physical wires to all engines, and by configuring which wires are active, we can logically assign engines to these engine slots. We also design a hierarchical data distribution mechanism, as mentioned in [§4.2.3](#), for better performance.

Specifically, we can construct a Paillier encryption operator by following the dataflow scheduling strategy shown in [Figure 7b](#). As mentioned in [§3.4](#), the Paillier encryption follows equation: $c = (1 + mn) \cdot r^n \pmod{n^2}$. So we can distribute the data m, n, n^2 to modular multiplication engines (these engines are denoted E_1) to calculate $r_1 = mn \pmod{n^2}$ and distribute the data r, n, n^2 to modular exponentiation engines (these engines are denoted E_2) to calculate $r_2 = r^n \pmod{n^2}$. Then the results can be further sent to modular multiplication engine (these engines are denoted E_3) to calculate $(1 + r_1) \times r_2 \pmod{n^2}$. Please note that the $1 + r_1$ is completed in the input data pre-processing stage (S2 in [§4.2.1](#)) with a lightweight dedicated hardware module. The ratios of E_1 , E_2 and E_3 are determined through the strategies discussed above, thus we can assign particular numbers of engines to these engine slots. Similarly, [Figure 7c](#) shows the dataflow used in Paillier decryption. In this case, FLASH uses other modules besides modular exponentiation and multiplication engines to real-

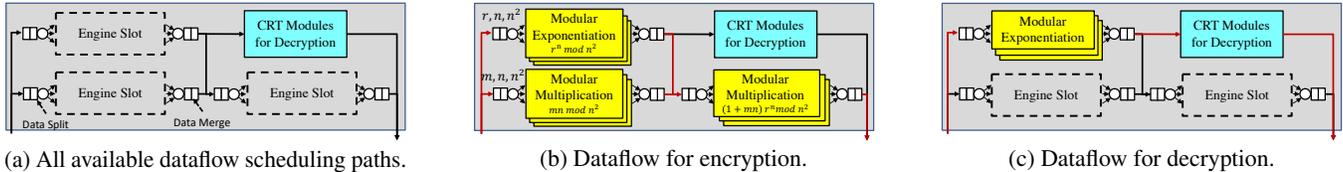

Figure 7: Dataflow scheduling. Black arrow indicates all available paths for dataflow scheduling while red arrow indicates the active paths for a particular cryptographic operation. Each engine slot can have multiple engines.

ize the decryption operation. In particular, we use CRT to optimize the decryption algorithm as discussed in §3.4, thus FLASH implements several CRT modules to accelerate this operation. We put all engines, working in modular exponentiation mode, in the top left corner engine slot to achieve high resource utilization.

4.4 Software Integration

While our current implementation integrates FLASH with FATE, the design of FLASH is generic and works with other cross-silo FL systems/frameworks. They can harness FLASH by using the standard APIs.

For easy integration, FLASH provides Python NumPy-similar APIs as shown in Listing 1. The Python APIs are also wrappers of the C/C++ library: `libfl.so`. Besides providing standard APIs, the `libfl.so` library manipulates the status of all installed FLASH accelerators, such as temperature, workload, etc.

By using these APIs, users can easily create encrypted scalar, vector, or matrix via Paillier or RSA encryption method. Users can further perform homomorphic addition and multiplication operations over these data. To reduce the data exchange between the FLASH accelerator and the host, we put the computation results on the off-chip memory unless the `get` API is used. As shown in §4.2.3, the data exchange between on-chip and off-chip memory is efficiently pipelined, leading to better end-to-end performance. Moreover, since `libfl.so` works in a stateless way, it can be easily scaled out to support different tasks from various FL applications.

Listing 1: FLASH’s NumPy-like APIs

```
import flash_np as np
# Generating two Paillier-encrypted arrays accelerated by FLASH
x1 = np.array([1, 2, 3], encryption="paillier")
x2 = np.array([4, 5, 6], encryption="paillier")

x3 = x1 + x2 # Homomorphic addition
x4 = np.array([1, 2, 3], encryption=None)
x5 = x4 * x1 # Ciphertext & cleartext multiplication

x3.decrypt() # Decrypting the ciphertext
x5.decrypt()

x3.get() # Transferring the data from accelerator to host
x5.get()
```

Multi-accelerator Support: The server-side software also enables multi-accelerator support. If there are multiple FLASH accelerators on the server, when applications invoke the APIs, `libfl.so` will break the task into multiple sub-tasks and dispatch them to multiple accelerators. The dispatching

strategy is the least workload first and can be configured to use different strategies, such as round-robin.

5 Implementation

Prototype Implementation with FPGA: We implement FLASH with FPGA using $\sim 30,000$ lines of Verilog [84] code. We use Xilinx Virtex UltraScale+ VU13P chip [23] in our implementation. FLASH implements 300 modular exponentiation and multiplication engines with the chip. As the VU13P chip consists of four dies, we need to distribute components on different dies in a balanced way to achieve high resource utilization. In our implementation, we first place large modules such as PCIe and DDR controllers on separate dies with the consideration that they should be close to the location of their corresponding I/O pins. Then, with the settle-down of large modules, we place different numbers of engines on different dies to make the resource utilization of each die approximately the same to avoid the possibility of local congestion. As a final note, the operation frequency of our FPGA implementation is 300MHz while we achieved $\sim 88\%$ DSP resource utilization, which, to the best of our knowledge, is relatively high in FPGA’s industry [92].

Server-side Software Stack Implementation: Our implementation of FLASH’s server-side software contains $\sim 10,000$ lines of C/C++ and Python code. This includes modifications of FATE to harness FLASH’s acceleration capacity. We mainly modify the `federatedml` module [3] in FATE by replacing normal collection operations with FLASH’s NumPy-like APIs. We further use Xilinx DMA (XDMA) IP Reference driver [21] for high-performance direct memory access through the PCIe interface.

Evaluating FLASH as ASIC: We leverage multiple standard software to assess the FLASH design as an ASIC. Specifically, we first use Synopsys Design Compiler [14] to convert FLASH’s design logics into physical implementations, *i.e.*, netlist, over both 12nm and 28nm technology libraries. Then, we use Synopsys VCS [16] to verify that the generated netlist functions correctly and use Synopsys Prime Time [15] for static timing analysis to validate that the netlist satisfies all timing constraints. More evaluation results of the ASIC performance will be discussed in §6.5.

6 Evaluation

In this section, we first present our evaluation methodology (§6.1). Then we show that for the nine cryptographic

operations, FLASH achieves up to $14.0\times$ and $3.4\times$ acceleration over CPU and GPU (§6.2), translating up to $6.8\times$ and $2.0\times$ speedup for realistic FL applications (§6.3), respectively. Finally, we evaluate the performance of FLASH as an ASIC (§6.5).

6.1 Methodology

Environment Setup: We use two X86 servers in our setup. Each server is equipped with a Mellanox CX-4 NIC [6] and connected to a Mellanox SN2100 [7] switch via 40Gbps DAC cables. To reflect realistic networking situations in real-world cross-silo FL deployments, we use `netem` [8] to limit the networking bandwidth to be 50Mbps⁷. As to other hardware configurations, each server is equipped with one Intel Xeon Silver 4114 CPU [5], 192GB memory, and one FLASH acceleration card (In the multi-accelerator experiment, each server will be installed with multiple acceleration cards). We deploy FATE v1.5 as the cross-silo FL framework.

Schemes Compared: We mainly compare the performance achieved by FLASH with that achieved by: (1) Original FATE that uses a highly-optimized GMP library to execute cryptographic operations with CPU (denoted as CPU in the following charts). We choose Intel Xeon Silver 4114 CPU similar to prior works [76]. All CPU experiments are executed with all ten physical cores in parallel. (2) GPU-based accelerator

⁷More details on how network bandwidth affects FLASH are shown in §6.4

(denoted as GPU). We extend the GPU implementation of HAFLO [43] which only implements logistic regression. Note that only the cryptographic operations are accelerated by GPU in our experiments. We use NVIDIA P4 GPU because it has the same technology of 16nm and achieves the closest INT8 TOPS as FLASH (although $\sim 2\times$ better. P4 reaches ~ 20 INT8 TOPS while FLASH achieves ~ 12.9 INT8 TOPS).

Performance Metrics: We use *the number of operations performed per second (OP/s)* as the metric when evaluating the performance of cryptographic operations, and *acceleration ratio over CPU/GPU* as the metric when evaluating FL applications.

6.2 Cryptographic Operations

To demonstrate that FLASH can efficiently accelerate the nine cryptographic operations, we compare the performance achieved by CPU, GPU, and FLASH, respectively. For operations **O4** and **O5**, we also evaluate different exponent bit-widths (32bit – 1024bit). The experiment results are shown in Figure 8a. In general, FLASH can consistently outperform CPU and GPU for all cryptographic operations. Specifically, FLASH outperforms CPU by $7.7\times$ – $14.0\times$ and GPU by $1.4\times$ – $3.4\times$, showing that FLASH’s hardware architecture fits the computational requirements of these cryptographic operations. Furthermore, we observe that when handling a larger exponent, FLASH tends to achieve a better acceleration ratio. For example, FLASH achieves $13.6\times$ acceleration than CPU when evaluating O4 with $e = 1024\text{bit}$, but drops to $7.7\times$ with $e = 32\text{bit}$. The results show that when the computation is more intensive, *i.e.*, with a large exponent, FLASH can achieve even better performance.

Multi-accelerator Support: We inspect how FLASH performs when we use multiple FLASH acceleration cards to speed up cryptographic operations. We evaluate one, two and three accelerators, denoted as FLASH-1, FLASH-2 and FLASH-3 respectively. For space limitation, we only pick some operations for demonstration: **O1**, **O2**, **O3**, **O4** with

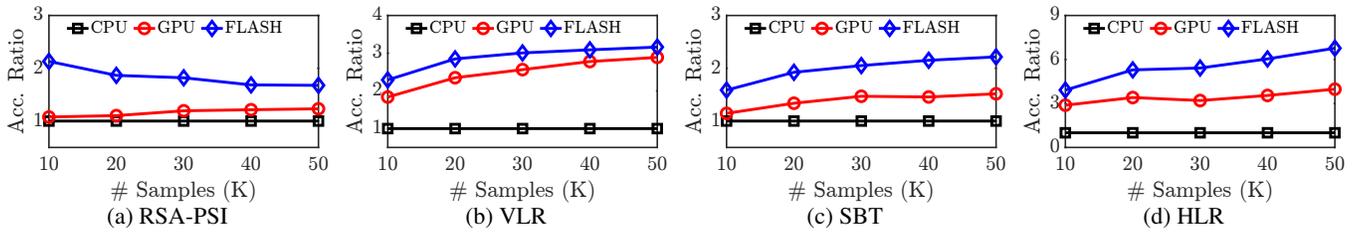

Figure 9: Performance of RSA-PSI, VLR, SBT, and HLR with changing data volumes.

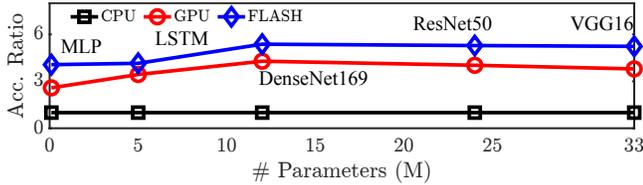

Figure 10: Performance of five deep learning applications.

$e = 1024\text{bit}$, **O5** with $e = 1024\text{bit}$, and **O7**. The results are shown in Figure 8b. We observe that for most cryptographic operations, *e.g.*, **O1**, **O2**, **O4**, **O5** and **O7**, the overall performance of FLASH is almost linear to the number of accelerators: FLASH-2 achieves $1.90\times - 1.98\times$ while FLASH-3 achieves $2.89\times - 2.95\times$ speedup for these operations. However, for **O3**, FLASH-2 and FLASH-3 only achieve $1.47\times$ and $1.80\times$ acceleration, respectively. The reason is as follows: the computation workload of **O3** is relatively low, thus the control overhead, *e.g.*, multi-accelerator synchronization, takes a considerable portion, leading to non-linear speedup. However, in the real-world use case, we envision that FLASH with multiple accelerators would still be an efficient solution to accelerate large-scale cross-silo FL applications.

Comparison with Other Paillier Accelerators: To give readers a better understanding of how efficient the FLASH’s hardware design is, we further compare FLASH with some state-of-the-art hardware-based solutions, *e.g.*, Paillier Cryptoprocessor (PCP) [80], HLS [91], and SoC [31] based solutions. Moreover, due to the limited hardware resources, some of these works only implement a subset of cryptographic operations supported by FLASH. The comparison results are shown in Table 2. PCP and HLS report their data with public key $N = 1024\text{bit}$, while SoC uses $N = 2048\text{bit}$, thus we report the performance of FLASH with both $N = 1024$ and 2048bit . The results show that, compared to PCP, HLS and SoC, FLASH consumes $10.97\times$, $1.80\times$, $4.88\times$ DSP resources, but delivers $28.95\times$, $7.77\times$, and $10.75\times$ encryption acceleration and $93.15\times$, $20.56\times$, and $34.38\times$ decryption acceleration, respectively. The results demonstrate that by using inter- & intra-engine pipelining and dataflow scheduling, FLASH can (1) deliver much better performance if utilizing comparable resources, and (2) support more complete functions.

6.3 Cross-silo FL Applications

We then present how FLASH can accelerate real-world cross-silo FL applications, including both vertical and horizontal. The models and datasets used are shown in Table 3. For ver-

tical FL, before performing the model training algorithms, we first run a commonly used sample alignment algorithm: RSA blind signature-based PSI (RSA-PSI). Then, we perform Vertical Logistic Regression (VLR) [53] and Secure Boosting Tree (SBT) [42] algorithms over the data intersection (generated from PSI), respectively. For horizontal FL, we mainly evaluate Horizontal Logistic Regression (HLR) and five deep learning applications with different parameters. Each application runs a fixed number of epochs.

RSA-PSI, VLR, SBT, and HLR: The performance of RSA-PSI, VLR, SBT, and HLR is related to the data volumes. Thus we evaluate FLASH with different data volumes. The results are shown in Figure 9. In general, FLASH consistently outperforms CPU and GPU by achieving $1.6\times - 6.8\times$ and $1.1\times - 2.0\times$ acceleration ratio respectively. The results have demonstrated that by designing a tailored hardware acceleration architecture for cross-silo FL, we can effectively speed up FL applications and outperform the existing CPU/GPU architectures. Furthermore, we also notice that for RSA-PSI and VLR, GPU tends to reach a similar acceleration ratio as FLASH while processing more data. The reason is that for RSA-PSI and VLR, the cleartext computation, which is purely executed on the CPU, takes a significant portion of the total computation time. For example, in VLR, when handling 50K data samples in one epoch, after sufficient acceleration, the ciphertext computation takes $< 10\%$ of the total computation time. Therefore, the performance is mainly decided by the time of cleartext computation when the cryptographic operations are sufficiently accelerated, which leads to the results that FLASH and GPU achieve similar acceleration ratios over CPU. In contrast, for HLR and SBT, FLASH can achieve a higher acceleration ratio than GPU because the cryptographic operations of these two applications consume a significant portion of the total computation time.

Deep Learning Applications: We have further evaluated five deep learning models of different numbers of parameters with horizontal FL. The results are shown in Figure 10. We find that FLASH can outperform CPU and GPU by achieving $4.1\times - 5.4\times$ and $1.2\times - 1.6\times$ acceleration ratio respectively due to a similar reason discussed above. Furthermore, we note that for models with more parameters, *e.g.*, DenseNet169, ResNet50, VGG16, FLASH can achieve a higher speedup than models with fewer parameters, *e.g.*, MLP, LSTM. This experiment implies that for more computation-intensive tasks, FLASH can deliver more notable results.

	28nm Technology Library (Actual Op. Frequency: 800MHz)			12nm Technology Library (Actual Op. Frequency: 1120MHz)

Table 4: ASIC resource evaluation for both 28nm and 12nm technology libraries.

Correctness: In addition to evaluating the performance of the above nine cross-silo FL applications, we also validate the final results of all compared schemes (we avoid the randomness by setting an identical random seed). Results have shown that all schemes yield identical results, showing that FLASH does not affect the correctness of model training.

Summary: Implemented as an FPGA prototype, FLASH has already largely outperformed CPU and achieved moderately better performance than GPU with comparable price. We also understand that high-end GPUs, *e.g.*, A100 [9], H100 [10], may outperform FLASH’s FPGA prototype due to more advanced foundry technology, which are also of much higher price. However, they still share the drawbacks as mentioned in §3.3. The goal of our paper is to design a more efficient hardware acceleration architecture for cross-silo FL beyond existing CPU/GPU architectures. As we will demonstrate in §6.5, if implemented as an ASIC, the performance of FLASH can be significantly improved, which should boost the acceleration ratio for these applications to a much higher level.

6.4 FLASH Deep-dive

In this part, we mainly investigate (1) how the number of participants and (2) how the varying network bandwidth affects the performance of FLASH respectively.

Number of Participants: We evaluate VLR with two to five participants and measure the acceleration ratio of FLASH over CPU. The experiment result is shown in Figure 11a and we observe that in general, the number of participants does not largely impact the acceleration of FLASH.

Varying Bandwidth Setting: In this part, we use netem [8] to limit the available bandwidth between the two participants from 10Mbps to 100Mbps. We run VLR and measure the execution time of one iteration with both CPU and FLASH. Figure 11b shows the results and we can observe that when the bandwidth is over 50Mbps, the running times of both CPU and FLASH are stable, where FLASH outperforms CPU by $\sim 3\times$. The results show that the varying network bandwidth does not have a noticeable impact on FLASH.

6.5 ASIC Performance Assessment

Given that our FPGA-based prototype implementation of FLASH has performance limitations due to the intrinsic drawback of FPGA (*e.g.*, low operation frequency), in this section we intend to demonstrate some preliminary results of how FLASH performs as an ASIC. As introduced in §5, we use

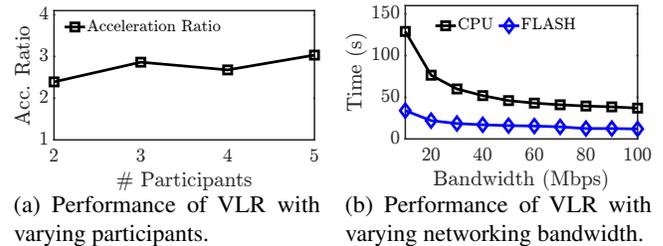

Figure 11: FLASH deep-dive.

standard software tools to assess the performance of FLASH if implemented as an ASIC. We evaluate FLASH’s ASIC implementation with two technology libraries: 28nm and 12nm. Based on the industry experience, we set the operating frequency to be 1000MHz and 1400MHz, respectively, for these two technology libraries. Furthermore, we set the die area to be $\sim 130\text{mm}^2$. We believe this setting could balance the performance and power consumption for FLASH.

The detailed evaluation includes the following steps: First, we perform logic synthesis using Synopsys Design Compiler [14] to convert FLASH’s design into netlist under the frequency and die area constraints. Table 4 illustrates the results. With 28nm technology library, we can allocate 800 modular multiplication and exponentiation engines successfully, while with 12nm technology library, we can allocate 1900 such engines. Second, we use Synopsys VCS [16] and Synopsys Prime Time [15] to confirm that both netlists are valid and function correctly. The third step is to estimate the performance gain of FLASH as an ASIC. Since the actual operating frequency after physical design should be lower than logic synthesis, we reduce the actual operation frequency by multiplying 80% by the design target for a conservative purpose.

Then, our final performance estimation is as follows. With 28nm technology library, we can allocate $2.67\times$ engines compared to our FPGA implementation (800 v.s. 300), and the operation frequency of these engines is $2.67\times$ that of the FPGA implementation (800MHz v.s. 300MHz), leading to an overall $7.11\times$ performance gain on modular exponentiation operator (we use modular exponentiation operator as the metrics since it can fulfill the computation capacity of an engine). With 12nm technology library, we can allocate $6.33\times$ engines (1900 v.s. 300) with $3.73\times$ operation frequency (1120MHz v.s. 300MHz), and achieve $23.64\times$ overall performance improvement. To give our readers a better understanding of FLASH’s performance as an ASIC, we also

evaluate the modular exponentiation operator with a state-of-the-art GPU – NVIDIA A100 [9], our results show that A100 can only achieve $5.78\times$ performance gain than our downscale FPGA prototype. Finally, we estimate the power consumption for a single engine, which is $\sim 16.6\text{mWatt}$ with 28nm technology library. Thus, the total power consumption for all engines is $\sim 13.28\text{Watt}$. Although we do not have the power consumption data of other parts, *e.g.*, PCIe controller, we believe the total power consumption of FLASH as an ASIC should be significantly lower than the 120Watt of our FPGA implementation.

7 Discussion

Benefit to Future GPU/TPU Design: Nowadays, GPU [9–13] and TPU [63] have been widely adopted to accelerate deep learning applications. These accelerators mainly target accelerating convolution operations with tensors, where most numbers are short floats. In contrast, FLASH targets accelerating the identified nine cryptographic operations that are widely adopted in cross-silo FL. Moreover, most numbers used in FLASH are large numbers with a bit-width of 2048 bit or even longer. However, in some cross-silo applications, *e.g.*, horizontal deep learning in §6.3, both convolution and cryptographic operations exist. Therefore, we can foresee a co-design of GPU/TPU with FLASH in the future. For example, GPU/TPU can efficiently accelerate the local model training while FLASH is used to accelerate the model encryption and aggregation. We will make FLASH as an IP core in the future, and thus GPU/TPU vendors can use FLASH in their design to accomplish the aforementioned co-design.

FLASH v.s. Other GPU/FPGA Implementations: Some existing works also target accelerating modular exponentiation operations with GPU [43, 54, 61] or FPGA [29, 31, 34, 35, 80, 83, 91], which leverage similar algorithm optimization methods, *e.g.*, Binary Exponentiation [52] and Montgomery Modular Multiplication [65]. Yet, none of them performs a thorough analysis towards *all* cryptographic operations used in cross-silo FL and offloads them efficiently on the hardware-based accelerator as FLASH. Moreover, our idea of composing various cryptographic operations based on the two basic operators via dataflow scheduling is designed for the cross-silo FL scenarios, making FLASH a unique solution compared to prior FPGA-based implementations. As a final note, our design of FLASH is not limited to FPGA but is also applied to ASICs.

Extending to Other Application Domains: While FLASH is introduced for accelerating cross-silo FL, it can speed up applications in other domains as well. First, the Paillier and RSA cryptosystems used in cross-silo FL are also widely adopted in other domains. Thus FLASH can accelerate applications built on them, *e.g.*, electronic voting [47], electronic cash [38], and threshold cryptosystem [46]. Second, since FLASH’s core idea is to accelerate modular multiplication

and exponentiation operators, cryptographic systems/operations built on them, such as Diffie-Hellman key exchange [56], can also benefit from FLASH.

8 Related Works

Besides the related works discussed in §7, we further cover the following two related directions in this section.

Accelerating FL: Recently, due to the increasing deployment of FL, various research works have emerged to accelerate FL. MAGE proposes to optimize the secure computation from a memory perspective [67]. BatchCrypt tries to optimize the Paillier encryption by encoding a batch of quantized gradients into a long integer and encrypting it in one batch [95]. VF²Boost proposes a novel training protocol to reduce the idle time of each participant [49]. Relative to them, we design FLASH from a different angle: accelerating the cryptographic operations used in FL, and our FLASH could be easily combined with these prior works.

Domain Specific Accelerator (DSA): DSA has recently been an emerging research topic that adopts hardware, *e.g.*, FPGA, ASIC, *etc.*, to accelerate particular applications [37, 62, 64, 75, 75, 76, 79, 93, 94]. For example, Tiara [94] uses FPGA and a programmable switch to accelerate layer-4 load balancing. FlowBlaze [75] offloads complex networking functions to a NetFPGA SmartNIC. hXDP [37] proposes to use FPGA to accelerate eBPF programs for fast XDP execution. MicroRec [62] offloads neural networks to FPGA to implement efficient recommendation systems. Various DSAs have been proposed to accelerate fully homomorphic encryption (FHE) [96], such as HEAX [76], F1 [78], BTS [64] and CraterLake [79]. Similar to them, FLASH follows the principle of DSA to design a hardware-based solution to efficiently accelerate cross-silo FL.

9 Conclusion

This paper presented FLASH, a hardware acceleration architecture for cross-silo FL. We have provided a fully functional FPGA prototype and evaluated our design as an ASIC. Extensive experiments with realistic applications and cryptographic operations have shown that FLASH is a viable solution.

Appendix

A Cross-silo Federated Learning

Cross-silo federated learning (FL) denotes the scenario where companies or institutions collaboratively train machine learning models without data privacy leakage [39, 40, 44, 48, 88, 89]. Compared with cross-device FL, where participants are mobile devices, cross-silo FL focuses more on data security and incentive mechanism. From the data partition angle, Yang *et al.* proposed to categorize FL into horizontal FL, vertical FL, and federated transfer learning [70]. Federated transfer learning has rarely been applied in the industry and remains in the research stage. In most cases, cross-device FL contains only horizontal FL, while cross-silo FL usually contains both horizontal and vertical FL. Because of the different data partition situations, horizontal and vertical FL are different in model construction, protocol design as well as the utilized cryptographic systems.

A.1 Cross-silo Horizontal FL

Participants in horizontal FL have different sample ID spaces but the same feature space, as shown in Figure 1a. Each participant owns the labels of their samples. Therefore, horizontal FL enlarges the number of training samples to train a model with better generalization ability. In most cases, there is a third-party central server for parameter aggregation.

The t^{th} iteration of the training process among three participants is shown as follows:

1. All participants negotiate about keys for encryption.
2. Each participant i trains local model \mathbf{w}_i^t with its own samples and encrypts its model weights to $[[\mathbf{w}_i^t]]$ with either additively homomorphic encryption (e.g., Paillier [74]).
3. Each participant i sends the encrypted weights to the central server.
4. The server receives the encrypted local model weights from all participants and aggregates them to global model weights $\frac{\sum_i [[\mathbf{w}_i^t]]}{n}$, where n stands for the number of participants. Because the weights are encrypted via additively homomorphic encryption, we can directly perform an aggregation over the ciphertext.
5. The central server sends the aggregated global weights to all participants.
6. Each participant receives the global weights and decrypts them locally. Then the participant can update its local model \mathbf{w}_i^{t+1} with the decrypted global model.

After the federated training process, each participant obtains the same well-trained model. Thus, each participant can perform model inference locally.

A.2 Cross-silo Vertical FL

Participants in vertical FL scenarios have the same sample ID space but different feature spaces, as shown in Figure 1b. Under normal circumstances, only one participant holds the label of the FL task, which is called the active party. The other participants without labeling information are called passive parties. Compared with horizontal FL, vertical FL could enrich the feature information of samples. Unlike horizontal FL, the training process of vertical FL is conducted after the entity alignment stage, which aligns common samples while protecting privacy. Besides, the training schema of vertical FL is also different from horizontal FL. More specifically, each participant only owns part of the model parameters corresponding to the local feature dimensions. Hence, vertical FL cannot simply conduct the secure aggregation as horizontal FL does. In addition, various machine learning algorithms do not have a unified design of the vertical FL implementation.

Taking the federated linear regression [89] between two participants as an example, we illustrate the training process as follows:

1. Participants and the third-party central server negotiate about keys for encryption.

2. Passive party B computes local point estimate $u_{B,j}^t$ and partial loss $L_{B,j}^t$ for the j^{th} aligned sample, then encrypts them to $[[u_{B,j}^t]]$ and $[[L_{B,j}^t]]$ with Paillier [74]. Active party A calculates local point estimate $u_{A,j}^t$.
3. Passive party B sends the encrypted numbers to the active party A .
4. Active party A receives the encrypted numbers and computes the total loss $[[L_j^t]]$ and the intermediate results $[[d_j^t]]$ used to calculate gradients.
5. Active party A sends $[[L_j^t]]$ to server and $[[d_j^t]]$ to passive party B .
6. Party B and party A separately compute encrypted gradients $[[\frac{\partial L_j^t}{\partial \mathbf{w}_B^t}]]$ and $[[\frac{\partial L_j^t}{\partial \mathbf{w}_A^t}]]$ and add random masks.
7. Both parties send the encrypted and masked gradients to the central server.
8. The third-party central server decrypts the received ciphertext to get the plain-text masked gradients and sends them back.
9. Party B and party A respectively remove the random masks from gradients and update the local partial model.

All participants of vertical FL should be involved in the inference stage since each of them only owns part of the whole model.

A.3 Security Analysis of Cross-silo FL

The adopted FL algorithms in this paper are proved secure under the semi-honest assumption [42, 89]. The semi-honest assumption means that each party does not violate the federated protocols and only tries to infer the sensitive data of other parties from the received messages. For the horizontal FL models, the transmitted model updates are protected by additively HE for aggregation. Therefore, nothing can be learned by the arbiter. Moreover, each party obtains the aggregated model updates and can only calculate the average model updates of the other parties. Hence, given more than two parties, the model updates computed over the local data of one party cannot be leaked to the other parties [89]. For the vertical federated linear models, the transmitted intermediate results are protected by random masks and HE, which reveals no information. Furthermore, from the obtained model updates, one party cannot infer the sensitive data of other parties without prior knowledge of their data structures [89]. For the vertical SecureBoost model, the active party with labels could learn some information agreed in advance, such as the instance spaces and the responsible parties of splits. However, under the protection of HE, the original data records of one party cannot be revealed to other parties, either [42].

B Paillier Cryptosystem

Paillier Cryptosystem [73] is a widely-used additively (i.e., partially) homomorphic encryption scheme. Paillier cryp-

tosystem supports two kinds of operations, including the addition of two values of ciphertext and multiplication between ciphertext and cleartext. We will introduce Paillier key generation, encryption and decryption respectively in the following section.

Key Generation: Key generation of Paillier Cryptosystem follows the following steps.

1. Choose two random prime numbers p and q which satisfy that $\gcd(pq, (p-1)(q-1)) = 1$, where \gcd stands for the greatest common divisor.
2. Compute $n = p \cdot q$.
3. Compute $\lambda = \text{lcm}(p-1, q-1)$, where lcm means the least common multiple.
4. Randomly select an integer g which satisfies that $\gcd(L_n(g^\lambda \bmod n^2), n) = 1$. Function $L_n(x)$ is defined as $L_n(x) = (x-1)/n$.
5. Compute $\mu = [L_n(g^\lambda \bmod n^2)]^{-1} \bmod n$.

After the above computation, we will obtain the public key: (n, g) and private key: (λ, μ) respectively.

Encryption: The encryption algorithm of Paillier is straightforward and follows the following equation.

$$c = g^m \cdot r^n \bmod n^2. \quad (\text{B.1})$$

Optimization of Encryption: The encryption can be accelerated by assigning public key g as $n+1$. Therefore, the encryption algorithm is simplified as follows.

$$\begin{aligned} c &= g^m \cdot r^n \bmod n^2 \\ &= (n+1)^m \cdot r^n \bmod n^2 \\ &= \left[\left(\sum_{i=0}^m \binom{m}{i} \cdot n^i \right) \cdot r^n \right] \bmod n^2 \\ &= [(1+m \cdot n) \cdot r^n] \bmod n^2 \end{aligned} \quad (\text{B.2})$$

One modular exponentiation operation is saved by this optimization. FLASH uses the optimized encryption for better performance.

Decryption: Paillier ciphertext c is decrypted to plaintext m with both public key (n, g) and private key (λ, μ) :

$$m = L_n(c^\lambda \bmod n^2) \cdot \mu \bmod n \quad (\text{B.3})$$

Optimization of Decryption: The workload of the decryption algorithm of Paillier can be reduced with the Chinese Remainder Theorem (CRT). In this scheme, prime numbers p and q generated with the key pair are considered as the private key. The process of optimized decryption is shown below:

1. Compute $h_p = L_p(g^{p-1} \bmod p^2)^{-1} \bmod p$ and $h_q = L_q(g^{q-1} \bmod q^2)^{-1} \bmod q$.
2. Compute $m_p = L_p(c^{p-1} \bmod p^2) \cdot h_p \bmod p$ and $m_q = L_q(c^{q-1} \bmod q^2) \cdot h_q \bmod q$. Function $L_p(x)$ and $L_q(x)$ are defined by $L_p(x) = (x-1)/p$ and $L_q(x) = (x-1)/q$.

It can be proved that $m_p = m \bmod p$ and $m_q = m \bmod q$, where m is the plaintext corresponding to ciphertext c .

3. Apply CRT to recombine the modular residues. $m = \text{CRT}(m_p, m_q) \bmod pq$.

With the optimization above, the workload can be reduced to only about one-quarter of the original decryption algorithm, leading to better performance. FLASH also uses optimized decryption in its implementation.

C RSA Intersection

RSA (Rivest–Shamir–Adleman) is an asymmetric public-private key method used to securely transfer data [77]. The whole RSA algorithm mainly contains three operations: key generation, encryption, and decryption.

Key Generation: The generation process is shown below:

1. Randomly choose two distinct prime numbers p and q .
2. Compute $n = p \cdot q$.
3. Compute $\lambda(n) = \text{lcm}(p-1, q-1)$.
4. Randomly choose a number e such that $1 < e < \lambda(n)$ and $\gcd(e, \lambda(n)) = 1$.
5. Compute d by solving $d \cdot e = 1 \bmod \lambda(n)$.

Generally speaking, (n, e) is regarded as a public key, while d is regarded as a private key.

Encryption: Using public key (n, e) , plain-text message m is encrypted to cipher-text message c :

$$c = m^e \bmod n. \quad (\text{C.4})$$

Decryption: Using private key d , cipher-text message c is decrypted to plain-text message m :

$$m = c^d \bmod n. \quad (\text{C.5})$$

RSA-based PSI: The RSA-based private set intersection can protect the privacy of sample ID out of the intersection set with the mechanism of blind RSA signature [45, 69]. We take the two-party setting as an example. Party A contains three user IDs, *i.e.*, $\mathcal{X}_A = \{x_1, x_2, x_3\}$, while party B contains four user IDs, *i.e.*, $\mathcal{X}_B = \{x_1, x_2, x_4, x_5\}$. They want to find their common users via RSA-based intersection:

1. Party A generates RSA keys n, e, d and sends public key (n, e) to party B .
2. Party B blinds and encrypts its user IDs \mathcal{X}_B to $\mathcal{Y}_B = \{H(x) \bmod n \cdot r^e \bmod n \mid x \in \mathcal{X}_B\}$, where r is a unique random number for each x , and sends \mathcal{Y}_B to party A .
3. Party A signs the received \mathcal{Y}_B , obtains $\mathcal{Z}_B = \{y^d \bmod n = r \cdot H(x)^d \bmod n \mid y \in \mathcal{Y}_B\}$ and sends \mathcal{Z}_B to party B .
4. Party A also signs its own user IDs, gets $\mathcal{D}_A = \{H(H(x))^d \mid x \in \mathcal{X}_A\}$ and sends \mathcal{D}_A to party B .
5. Party B unblinds the received \mathcal{Z}_B and obtains $\mathcal{D}_B = \{H(z/r \bmod n) = H(H(x))^d \mid z \in \mathcal{Z}_B\}$.

6. Party B computes $\mathcal{D}_A \cap \mathcal{D}_B = \{H(H(x_1))^d, H(H(x_2))^d\}$ and gets common user IDs $\{x_1, x_2\}$.

$H(\cdot)$ denotes the hash function. After party B knows the overlapping users, it could choose whether to inform party A according to different scenarios.

D Modular Exponentiation & Multiplication Algorithm Optimization

D.1 Binary Exponentiation

Modular exponentiation is defined as $P = m^e \bmod N$, as shown in Equation 1. In the naïve algorithm, m is multiplied by itself for e times, and the algorithm uses $e - 1$ multiplications to obtain the result. Therefore, if e is a large integer, the computation time is dramatic. As a result, to optimize the computation, people usually apply binary exponentiation optimization to reduce the dramatic computation time. Algorithm D.1 shows the process of the binary exponentiation optimization algorithm.

Algorithm D.1 Binary Exponentiation

Input: m, e, N , where $N > 0$

Output: $P = m^e \bmod N$

```

1:  $P = 1$  ▷ Initialization
2: while  $e > 1$  do
3:   if  $e$  is odd then
4:      $P = P \cdot m \bmod N$ 
5:   end if
6:    $e = e \gg 1$ 
7:    $m = m^2 \bmod N$ 
8: end while
9: return  $P$ 

```

The idea of binary exponentiation is to reduce the number of multiplications by using the binary representation of the exponent e . As a result, we only need to compute at most $2\lceil \log_2 e \rceil$ multiplications, which is much smaller than $e - 1$. Since the time complexity of modular exponentiation is determined by the number of multiplications, binary exponentiation can reduce its time complexity from $O(e)$ to $O(\log e)$. Worth mentioning, the modulo computation can be performed after each multiplication because of the distribution law in modular arithmetic: $(a \bmod N)(b \bmod N) \equiv ab \bmod N$.

Summary: By using the binary exponentiation optimization algorithm, we can largely optimize the time complexity of modular exponentiation computation.

D.2 Montgomery Modular Multiplication

After applying the binary exponentiation optimization algorithm as shown in §D.1, we lower the time complexity of modular exponentiation computation by reducing the number of multiplications. However, after each multiplication, we have to perform one modulo operation. Although we can implement modulo operation on hardware with Cyclic Reduction and Barrett Reduction algorithms [32], the performance

Algorithm D.2 Montgomery Modular Multiplication

▷ Given three input numbers X, Y and N , the Montgomery Modular Multiplication outputs $Z = X \cdot Y \cdot R^{-1} \bmod N$, where R is a power of 2 and $\lceil \log_2 R \rceil = \lceil \log_2 N \rceil$.

Input: $X = (X_{d-1}, \dots, X_0), Y = (Y_{d-1}, \dots, Y_0), N = (N_{d-1}, \dots, N_0), N'$, where

$N' = (-N)^{-1} \bmod r$, ▷ N' is pre-computed in S1
 $r = 2^w, d = \lceil \log_r N \rceil + 1$, ▷ r and d is used to split data
 $\gcd(N, r) = 1$, with $N \times N' \equiv -1 \bmod r$

Output: $Z = \text{ModMult}(X, Y, N) = X \times Y \times R^{-1} \bmod N$

```

1:  $Z = (Z_{d-1}, \dots, Z_0) = 0$  ▷ Initialization
2: for all  $i = 0, 1, \dots, d - 1$  do ▷ Loop on  $Y$ 
3:    $q = (Z_0 + X_0 \times Y_i) \times N' \bmod r$ 
4:    $C = 0$ 
5:   for all  $j = 0, 2, \dots, d - 1$  do ▷ Loop on  $X$ 
6:      $S = Z_j + X_j \times Y_i + q \times N_j + C$ 
7:     if  $j > 0$  then
8:        $Z_{j-1} = S \bmod r$ 
9:     end if
10:     $C = S \gg w$  ▷ Carry higher bits
11:   end for
12:    $Z_{d-1} = C$ 
13: end for
14: if  $Z \geq N$  then
15:    $Z = Z - N$ 
16: end if
17: return  $Z$ 

```

of these algorithms is still not satisfying because of the division operations used in these algorithms. Therefore, FLASH utilizes Montgomery Modular Multiplication [65] to replace the modulo operation with a bit-shifting operation, which is more hardware-friendly.

The process of applying Montgomery Modular Multiplication includes three major steps: (1) converting the data into Montgomery space, (2) computing the modular multiplication in the Montgomery space, and (3) converting the data back from Montgomery space. Before going into details, we will first describe Algorithm D.2. This algorithm implements efficient $A * B * R^{-1} \bmod N$ in a hardware-friendly way. The key optimization of the algorithm is the introduction of the divider $R = r^d$. Thus the division can be easily implemented by bit-shifting since r is a power-of-2 integer, and after the division, the result is an integer within $[0, 2N)$ and no more modulo operation is needed. Afterward, we will show details of each step in the following sections.

Converting the data into Montgomery space: Before applying Montgomery Modular Multiplication, the input numbers should be converted to Montgomery space. The conversion formula is $A = a \cdot R \bmod N$. It can also be written as $A = a \cdot R^2 \cdot R^{-1} \bmod N$, so we can leverage Algorithm D.2 to efficiently calculate it. In the formula, a is one of the multiplicands of modular multiplication. A is the Montgomery space of a . N is the modulus. R is a power of 2 and it satisfies the condition that $\lceil \log_2 R \rceil = \lceil \log_2 N \rceil$.

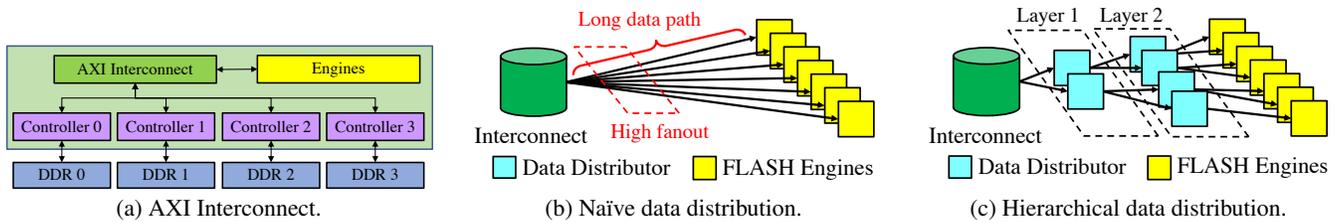

Figure D.1: FLASH adopts hierarchical data distribution to enable efficient data exchange between on-chip and off-chip memory.

Computing the modular multiplication in the Montgomery space: We can directly use [Algorithm D.2](#) to efficiently calculate the modular multiplication.

Converting the data back from Montgomery space: To convert a number out of Montgomery space, the conversion formula is $p = P \cdot R^{-1} \bmod N$. p is the result of modular multiplication. P is the Montgomery format of p . Similarly, we can leverage [Algorithm D.2](#) to complete the computation.

Parameter Computation: In the above steps, we notice that if N , which is usually the public key in cryptosystems, remains unchanged, $R^2 \bmod N$ (e.g., used in converting the data into Montgomery space) and $(-N)^{-1} \bmod r$ (e.g., line 3 and 8 in [Algorithm D.2](#)) remain constant values. We call these constant values parameters in this paper, and we show that we can compute these parameters in advance and avoid duplicate calculations to improve the performance further.

Summary: By applying the Montgomery Modular Multiplication, we mainly replace the modulo operation with a hardware-friendly bit-shifting operation, which improves the performance of modular multiplication/exponentiation on hardware.

E The Montgomery Modular Multiplication Circuit Design

In this section, we will describe how our Montgomery Modular Multiplication Circuit works (shown in [Figure 5](#)).

According to [Algorithm 1](#), the outer loop iterates over operand Y . Therefore, the circuit sequentially reads different Y_i from RAM Y and performs execution over them. The workflow of our Montgomery Modular Multiplication circuit contains four steps. Steps 1 and 2 in the following introduction focus on the workflow for a fixed Y_i while steps 3 and 4 show how we bridge the operations between iterations with different i and obtain the final result. We use Reg to represent the register group.

1. X_0 and Y_i are sent to Mul 1 to get a $2w$ -bit multiplication result. The higher w bits of the result are cached in Reg r_1 . The lower w bits, denoted as α in [Algorithm 1](#), are cached in both Reg α and r_7 . The numbers stored in Reg α are used for the calculation of β via Add 5. With β and N' available, their multiplication result q can be obtained from the output of Mul 2. After that, q is sent back to the input of Mul 2 and multiplied with N_0 . Similarly, the higher w bits of the multiplication result are cached in Reg r_3 and the

lower w bits are sent to Reg r_8 . Combining data cached in r_7 and r_8 , it is straightforward to get δ_1 and δ_2 with several addition units. The results of addition, Z_0 and C , are cached in Reg Z_0 and Reg C for subsequent operations.

2. Following step 1, the inner loop for j begins. Different iterations of the inner loop are fully pipelined, which implies the j th iteration is executed by the circuit just one cycle after the $(j-1)$ th iteration. At the beginning of the pipeline, Mul 1 and Mul 2 simultaneously calculate $X_j \times Y_i$ and $q \times N_j$. The higher w bits and lower w bits of the results are separately cached in different registers. Please note that we use Reg r_5 and r_6 to register the higher w bits in the circuit for one more cycle compared to the lower w bits so that δ_1 can be calculated through the addition between higher w bits from the $(j-1)$ th iteration and lower w bits from the j th iteration (i.e., line 12 in [Algorithm 1](#)). After the calculation of δ_1 , the subsequent calculation of δ_2 can also be simply executed by the adders in the pipeline. The intermediate results, Z_{j-1} and C , are cached in RAM Z and Reg C .
3. We begin the execution of the $(i+1)$ th iteration of the outer loop when all the multiplications in the i th iteration accomplish. Although some operations like addition are still in progress, the multipliers are free to start the multiplications in Step 1 for the $(i+1)$ th iteration.
4. After accomplishing the outer loop, the result Z should be stored in RAM Z . If $Z < N$, we directly output Z . Otherwise, we calculate $Z - N$ as the final output.

F Hierarchical Data Distribution

While the design in [§4.2.3](#) is efficient, it also introduces a practical problem. As shown in [Figure D.1a](#), FLASH adopts AXI interconnect to manipulate the external memory [68, 72]. However, as the on-chip memory units are placed near each engine for low latency, naively distributing data from the AXI interconnect to these memory units, as shown in [Figure D.1b](#), leads to high fan-out near interconnect and long data paths. These two issues will cause (1) large design difficulties for circuits placement because there are too many long paths to be placed near interconnect; (2) degraded performance because long paths cause large delay for the circuits.

To solve the problem, we design a hierarchical data distribution mechanism as shown in [Figure D.1c](#). Instead of directly sending data to all engines, FLASH distributes data

Figure G.2: FLASH integrates with cross-silo FL frameworks by providing an integrated software package.

at multiple layers. At each layer, the data distributors receive data from the previous layer and further distribute data to the data distributors/engines in the next layer. Suppose we have m engines and n layers, the fan-out of each data distributor is $\sim \log_n m$, which is much smaller than m . As a result, FLASH achieves a much smaller fan-out and shortened logical data path. These two advantages first reduce the design complexity because a small fan-out with short logical paths will make the circuits' placement much easier. Furthermore, they also improve performance because they allow a high operating frequency by restricting the delay of all logic paths. In our FPGA implementation, the delay of all logic data paths is within 3.3ns, thus we can achieve a high FPGA operation frequency of 300MHz [20].

G Software Stack Architecture

Figure G.2 illustrates how FLASH integrates with the cross-silo FL software. As introduced in §4.4, FLASH's software stack contains Xilinx DMA Driver [21], `libfl.so` library and its corresponding Python wrapper.

On Modular Learning of Distributed Systems for Predicting End-to-End Latency

Abstract

An emerging trend in cloud deployments is to adopt machine learning (ML) models to characterize end-to-end system performance. Despite early success, such methods can incur significant costs when adapting to the *deployment dynamics* of distributed systems like service scaling-out and replacement. They require hours or even days for data collection and model training, otherwise models may drift to result in unacceptable inaccuracy. This problem arises from the practice of modeling the entire system with *monolithic* models. We propose Fluxion, a framework to model end-to-end system latency with *modularized learning*. Fluxion introduces learning assignment, a new abstraction that allows modeling individual sub-components. With a consistent interface, multiple learning assignments can then be dynamically composed into an *inference graph*, to model a complex distributed system on the fly. Changes in a system sub-component only involve updating the corresponding learning assignment, thus significantly reducing costs. Using three systems with up to 142 microservices on a 100-VM cluster, Fluxion shows a performance modeling MAE (mean absolute error) up to 68.41% lower than monolithic models. In turn, this lower MAE allows better system performance tuning, e.g., a speed up for 90-percentile end-to-end latency by up to $1.57\times$. All these are achieved under various system deployment dynamics.

1 Introduction

Predicting cloud system performance is critical for improving the end-user experience. While this problem has been traditionally addressed with analysis and handcrafted performance models, an emerging trend is to incorporate machine learning (ML) techniques for performance modeling [7, 9, 23]. Such approaches [2, 3, 6, 13, 14, 20, 21, 34, 41] typically use *monolithic* ML models, to predict the performance (e.g., user request

latency), given configurable knobs of the system component (e.g., cache size) and observable states (e.g., request rate).

In recent years, the microservice architecture has gained popularity in building distributed cloud systems [1, 12, 18, 25, 40]. Its per-service flexibility enables continuous integration and continuous delivery (CI/CD), and per-service horizontal scaling (e.g., replication) and vertical scaling (e.g., capacity adjustments) can handle load dynamics. Interestingly, the monolithic approach of modeling the entire system could still be applicable to such distributed systems, and doing so frees operators from explicitly modeling service dependencies.

Unfortunately, our first-hand experience at Microsoft suggests inherent limitations in effectively learning distributed system's *end-to-end* performance. There is a need to continually adapt performance models to the *deployment dynamics*. As services are independently scaled and replaced over time, deployment updates become frequent operations.

Continually updating monolithic models can incur significant time costs, especially if deployment dynamics are handled in an ad-hoc way. First, collecting a sufficient amount of training data can be time-consuming, as new system dynamics can take minutes and even hours to be fully warmed-up and stable [39]. Second, designing and training a new model can also be time-consuming, even with the help of automation tools [4, 19, 27]. For example, a system evaluated in §5 has 142 microservices, and requires a performance model that considers 1,034 service knobs and states. Collecting sufficient data points to train such a complex monolithic model takes us ~ 46 hours, and model training takes additional ~ 24 hours. Such a practice hinders the practicality of monolithic approach, for performance tuning in the real world.

Given the above challenges, we advocate *modularized learning* for microservice-based distributed systems. Our key observation is the locality of deployment dynamics, where changes happen at the granularity of system components (e.g., microservices). So, modularized learning models the performance of each service individually, and carefully composes these models on-demand to follow deployment dynamics.

Fluxion is a framework that realizes modularized learning

This work was done when Zilin Fang, Yuqing Xie, and Zhao Lucis Li were interns at Microsoft Research.

to model end-to-end latency while handling system deployment dynamics efficiently and effectively. Fluxion introduces *learning assignment*, an abstraction to model each service in a distributed system. Learning assignment is instantiated on each service instance to model its performance metrics (e.g., latency). It can accommodate any service and different ML modeling techniques (e.g., DNN or Gaussian process). Learning assignments can be composed into an *inference graph* to model a large complex system, similar to how services are composed into an end-to-end system. Changes in a service of the system only induce modeling errors in the corresponding learning assignments. Since the configurations and internal logic of other services remain the same, their corresponding learning assignments along with their modeling accuracy also remain unchanged. Therefore, Fluxion only needs to update the learning assignments corresponding to the changed service, thus significantly reducing the costs.

Three unique characteristics enable learning assignment to handle system deployment dynamics effectively. First, to capture the impact from other services, learning assignment defines external performance dependencies as part of modeling inputs. This enables the composability — multiple assignments can be composed into an inference graph, to follow service dependencies of a complex distributed system on the fly. Second, instead of considering only the performance metric of interest (e.g., p90 latency), learning assignments can take in a spectrum of performance metrics from upstream assignments (e.g., p50–p99 latencies) in inference graph. This allows a learning assignment to better observe (and capture) the impacts of system deployment dynamics from upstream assignments. Finally, to capture the temporal system dynamics, a learning assignment can host one or more ML models trained in different time periods and scales.

In summary, this paper makes the following contributions. (1) We propose a modular approach to modeling end-to-end latency for complex and dynamic distributed systems, exemplified by microservice systems. (2) The abstraction of learning assignment and the resulting inference graph effectively capture intrinsic system dynamics, as well as dependencies among services. (3) We conduct comprehensive experiments to demonstrate the significantly superior performance of Fluxion over existing approaches, under various system deployment dynamics. In some microservice systems spanning 100 VMs, Fluxion’s performance model exhibits up to 68% lower MAE (mean absolute error). In turn, this enables better system performance optimization, or p90 latency speed up by up to $1.57\times$ over the use of baselines. At the same time, Fluxion reduces the model training time by up to 99.98%.

2 Background and Motivations

2.1 Performance Prediction and Modeling

Performance models predict the *end-to-end system performance* (e.g., user request latencies), given *observable states*

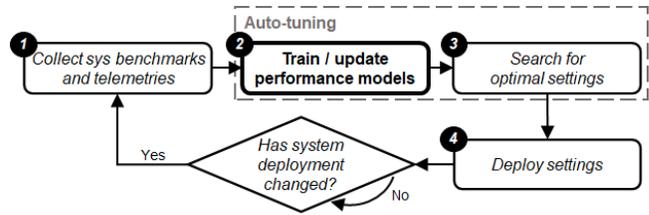

Figure 1: General workflow of auto-tuning. Fluxion focuses on *step #2*, or the efficiency in adapting performance models to system deployment dynamics.

(e.g., per-service request rates) and *configurable knobs* (e.g., per-service cache size and thresholds). Performance models can be analytically constructed with mathematical formulations, but doing so does not scale well with the size or complexity of large-scale distributed systems. A typical microservice system can have hundreds (and even thousands [40]) of services, and requests can traverse 40+ services [25].

Learned performance model. Advances in machine learning (ML) enable performance modeling to be learned, with regression techniques such as Gaussian process and DNN. Like previous efforts that model monolithic systems [2, 3, 9, 13, 21, 23], it is possible to treat an entire microservice system as a black-box. To match system deployment scale, ML models can monolithically grow in size (e.g., adding DNN neurons). Furthermore, black-box modeling eliminates the need to explicitly consider service interactions and dependencies.

For training performance models, each training data point consists of inputs (i.e., per-service knob settings and observable states) and an output (i.e., a system performance measurement). Data are collected through benchmarks in controlled environment (e.g., testbeds or isolated sections in production), or telemetries in production. Trained models may be evaluated with testing data, which are collected in the same fashion. One common evaluation metric for performance modeling is MAE (mean absolute error) [37], or the average magnitude of errors in a set of test predictions made by the model.

Performance auto-tuning scenario. As Fig 1 illustrates, performance models can drive auto-tuning [2, 3, 21–23]. The goal is to guide non-system-experts to set system knobs, to optimize for a performance metric. Auto-tuning relies on optimizers (*step #3*), which iteratively search for global optimum in the modeled space. Each iteration algorithmically selects new knob setting (for performance model to predict), based on performance predictions from previous iterations.

2.2 High Costs to Maintain ML Models

We observe significant time costs in continually keeping ML-based performance models updated to system deployment dynamics. Deployment dynamics make performance models drift over time and impact modeling accuracy, hence auto-tuning outcomes (c.f. §5). Main sources of deployment

dynamics include (1) system scaling, i.e., replicating or reclaiming service instances, and (2) continuous integration and delivery (CI/CD), i.e., replacing existing services.

We discuss the breakdown of time costs below.

Problem #1: Collecting training data points for performance modeling can be time-consuming. As the model complexity grows, the number of training data points necessary also grows. However, each benchmark requires the system to be fully warmed-up and stable [39]. In our cases, one benchmark can take up to 15 minutes, and collecting sufficient data points can require ~46 hours.

The problem exacerbates as distributed cloud systems require a significantly higher model complexity than previously considered. Unlike monolithic systems with ~20 knobs and states to consider, this number can quickly add up to hundreds and thousands for microservice-based systems. For example, Train-Ticket [31] has 41 services. At initialization, it has 242 model inputs: 148 configuration knobs (e.g., MongoDB’s `eviction_dirty_target`), 94 states (e.g., Docker’s `cpu-limit` and `per-service requests per second`). As Train-Ticket scales-out by a factor of 6, there is a total of 210 service instances, and 1,020 model inputs.

Problem #2: Designing and training new models for performance modeling can be time-consuming. Keeping performance models updated goes beyond simply fine-tuning models with recent benchmarks. In many cases, the required changes lie in the model structure. One motivating example is how replicating services essentially alters the deployment, with respect to the available knobs, service states, and service dependencies. As a result, we need a new model of different input dimension and even different modeling technique.

Although AutoML toolkits can automate this process to some extent, our experience suggests that it can take at least 20 hours to produce a reasonably accurate ML model for performance modeling. Furthermore, it is not feasible to pre-train all monolithic models for all possible deployment setups. Since services can be independently replaced and arbitrarily scaled, the number of possible deployment setups is unbounded.

2.3 Modularized Learning

The principle of modularity has been proven in engineering scalable and elastic systems. It provides opportunities to realize ML-based performance modeling in an agile and accurate way. Instead of monolithically modeling the end-to-end latency of distributed systems with one performance model, we propose *modularized learning* that breaks down this model to align with a deployment’s modular units.

Challenges. To practice modularity, it is natural to independently model each system component, e.g., a microservice. Given system components can have vastly different configuration knobs and states, different types of ML models can be chosen for individual system components. The key challenges are: (1) to represent different system components, possibly

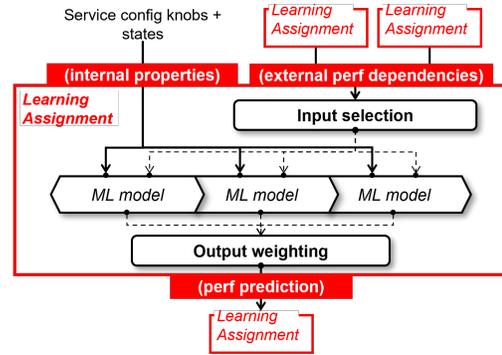

Figure 2: Learning assignment is a wrapper for ML models. It has a consistent interface for composability.

using different ML techniques, with a *consistent interface*; and (2) to have a *composability criteria* that combines these component representations into an end-to-end ML model for performance modeling.

3 Fluxion Framework

Fluxion is a framework that realizes modularized learning for distributed systems. To address the two challenges discussed in §2.3, Fluxion introduces *learning assignment* to abstract away model and component heterogeneity and provide a unified interface to model service-level latency (§3.1). Moreover, Fluxion presents *inference graph* to dynamically compose assignments into an end-to-end performance model (§3.2).

3.1 Learning Assignments

A learning assignment is a basic modeling unit. It hosts one or more ML models that collectively model a modular unit in distributed systems. Since system deployment dynamics typically happen at the unit of services (e.g., scaling and replacing services), assignments are instantiated on a *per-service-instance* and *per-performance-metric*¹ basis. When deployment dynamics happen, this mapping of modular units allows Fluxion to localize changes to some learning assignments. Fig 2 illustrates the internal structure of an assignment, and we elaborate the details next.

Interface. The learning assignment interface is designed to abstract service-level performance for ML models. Modeling individual services is different from modeling the entire system monolithically. The former needs to take service dependencies into account. E.g., a service’s observed latency inherently includes the latency of its downstream services [10].

Therefore, in addition to internal configuration knobs and internal observable states, the assignment inputs further include external performance dependencies (e.g., downstream service latency). The assignment output is a service-level

¹E.g., p50 and p90 latencies require two learning assignments.

performance metric. This interface addresses *challenge #1* — the consistent service-level performance metrics as input and output, together with the heterogeneous internal states and knobs, are sufficiently general to model different services and to host ML models of different modeling techniques, and a learning assignment’s output can be connected to another assignment as an external performance dependency.

Exposing a spectrum of performance metrics. To predict the end-to-end latency more accurately, a learning assignment may expect the external performance dependencies to be a spectrum of performance metrics from dependent services. For example, to predict end-to-end p90 latency, a learning assignment may require p50–p90 latencies of the downstream services (and even their CPU utilization and disk throughput), so as to decide which metrics are appropriate for consideration. This allows a learning assignment to better observe the extent of impacts that system deployment dynamics impose on its downstream services.

However, not all performance metrics are *highly* relevant to the one being predicted. An example is the bottom-percentile latencies *vs.* the top-percentile latencies. Including irrelevant performance metrics incurs additional costs. The first is the training costs. As unnecessary inputs add noise to the training dataset, some ML models would need more data points to distinguish and learn from the relevant inputs. And collecting training data points can be time-consuming (c.f. §2.2). The second is the unnecessary learning assignments introduced to predict these irrelevant metrics.

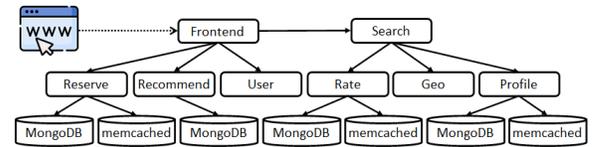

To this end, learning assignment introduces "input selection" (shown in Fig 2) to prune unnecessary metrics and the corresponding learning assignments. The problem of input selection can be formulated as follows. Given a set of k learning assignments (m_k) as inputs to a specific learning assignment, we want to find the k -dimensional binary weight vector (w_k^*). w_k^* should minimize the prediction error of an weighted sum of m_k , over a batch of n data points (inputs X , and outputs Y). This is formulated as the following equation:

$$w_k^* = \operatorname{argmin}_{w_k \in W} \left(\sum_{i=1}^n Y_i - f(w_k, m_k(X_i)) \right)^2. \quad (1)$$

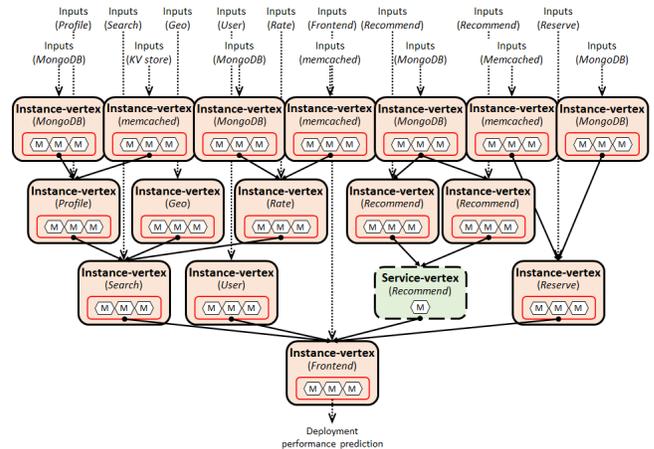

The goal is to search for w_k^* , or the optimal k -dimensional binary vector. f is a predefined function that aggregate outputs of k learning assignments, and it can be hand-written code or non-linear functions such as neural networks. We can expand f as follows:

$$f(w, m(X)) = \frac{\sum_{i=1}^k w^{(i)} m^{(i)}(X)}{\sum_{i=1}^k w^{(i)}}. \quad (2)$$

In practice, k can be large. For example, RocksDB has $k = 99$ performance metrics. To select three relevant metrics need to search 941,094 possible combinations. To find a solution effectively, §4.1 presents one generic approach in the current implementation of Fluxion.

(a) Execution graph

(b) Inference graph

Figure 3: A simplified inference graph of a microservice application, Hotel Reservation. Vertices represent services, and directed edges capture performance dependencies among services. Graph inputs include configuration knobs and observable service states. (M) represents models. In this example, the Recommend service is scaled out to two instances.

Capturing system’s temporal dynamics. A learning assignment can host multiple ML models trained in different time periods and scales. Doing so promotes the reuse of previously learned models, in order to better capture temporal dynamics and predict recurring patterns. An example is the daily variations in incoming request rates. In this case, we can train a new model with data points collected each day.

Learning assignment introduces "output weighting" (shown in Fig 2) to weight over outputs from different time periods/scales and reduce all models’ outputs to one succinct value. The formulation of output weighting is similar to that of input selection, except that k assignments are changed to k internal models and w_k^* here is a k -dimensional vector of continuous numbers between 0 and 1 inclusively. And the output is computed as the weighted sum of all k models’ outputs.

Similarly, to find a good combination of weights is computationally expensive. §4.1 presents one generic approach in the current implementation of Fluxion.

3.2 Inference Graph of Learning Assignments

Inference graph is a set of interconnected learning assignments. It represents the performance modeling of an end-to-

end system. From external user's perspective, inference graph has the same input/output semantics as monolithic models. In other words, inference graph exposes the following performance modeling inputs: all services' configuration knobs and observable states. Its output predicts for an end-to-end performance metric: the end-to-end tail latency in our case. Inference graph addresses *challenge #2*, i.e., the composability criteria to compose learning assignments.

3.2.1 Inference Graph Construction

Fig 3 illustrates a simplified inference graph for a microservice system, Hotel Reservation [11].

Graph vertices. An inference graph has two types of vertices: instance-vertices and service-vertices (c.f. Fig 3b). Instance-vertices correspond to the learning assignments modeling the performance of service instances. They expose learning assignment inputs (e.g., service configuration knobs, observable states, and external performance dependencies) and output (e.g., a service-level performance metric). Service-vertices aggregate instance-vertices that model the same service and performance metric. In Fig 3b, the Recommend service (marked in dash-line) is scaled out to two instances.

Graph edges. Graph edges are directed dataflows, and they satisfy services' external performance dependencies. To draw the edges correctly, we leverage the observation that the performance dependency of two services is the *reverse* of their execution dependency. Since an upstream service invokes RPC calls to its downstream service, the upstream service's latency would depend on the latency of downstream service. Hence an edge should be connected from the learning assignment (i.e., vertex) representing the downstream service to the one representing the upstream service (i.e., the reverse direction of the service execution order).

Handling deployment dynamics through inference graph updating. Since graph vertices and edges have a strong correspondence to services in the system deployment, orchestration-induced dynamics can be localized to certain regions of the inference graph. This implies that other regions can remain unchanged. Fluxion provides APIs to update graph for common orchestration operations (c.f. §4.1.2). First, scaling-out a service is conceptually equivalent to replicating the corresponding instance-vertices, to match the number of deployed instances. Similarly, scaling-in a service removes some of the corresponding instance-vertices. Second, upgrading a service (or even a migration from MySQL to PostgreSQL) is conceptually equivalent to replacing old service's instance-vertices with new service's.

3.2.2 Graph Inferencing to Predict End-to-End Latency

Graph inferencing is performed through graph traversal. The traversal starts from graph vertices that do not have external

performance dependencies, or services that do not invoke any downstream services (e.g., the top vertices in Fig 3b). At each vertex, the learning assignment output metric is computed with its ML models. Following graph edges, the output is then passed to subsequent vertices as an external performance dependency. The traversal stops at the last vertex in the graph, or typically the gateway service in a deployment. The output of this last vertex is the output of the graph, and it predicts the end-to-end system performance.

3.2.3 Inference Graph Re-training

Inference can be performed immediately after graph is composed, but in cases where the prediction error rate is high, re-training can mitigate the problem. Fluxion identifies two major error sources. And, it can effectively reduce the re-training costs by taking advantage of the inherent modularity in the graph, rather than re-designing and re-training the entire monolithic model. Particularly, graph prediction errors can be traced back to some subsets of vertices.

Graph error source #1: New learning assignments. New learning assignments are required when new services are deployed to microservice systems or existing services are being updated. From our experience, their high MAE is typically due to insufficient training, especially by non-ML-experts. This case can be mitigated with the use of AutoML toolkits. Another possibility is service-vertices. Since they aggregate instance-vertices, scaling out/in a service requires them to have a new model with a new input dimension. Localizing new assignments is trivial, and the information is available through recording graph manipulations over time.

Graph error source #2: Unforeseen prediction inputs. Unforeseen prediction inputs can happen when the system receives unforeseen request types, or unexpected request ratios. This is a situation monolithic models also have to handle. As different requests stress different service-to-service execution paths, a service can observe unfamiliar states (e.g., requests per second and CPU utilization) or even downstream service performance. In the monolithic approach, the solution is to re-train the monolithic models. Modularized learning gives new optimization opportunities. Fluxion only needs to retrain the learning assignments being impacted to better handle these prediction inputs.

Identifying the impacted assignments, i.e., vertices in the inference graph, to address *error source #2* can be non-trivial. This step is not simply about identifying vertices whose learning assignments have the largest prediction MAE. A well-trained learning assignment can still output unexpected predictions if it receives erroneous inputs from another. The reason is that local errors of individual assignments can propagate. This is an artifact of how the inference graph output is a function of all its models. As graph traversal passes the prediction of a learning assignment to another assignment,

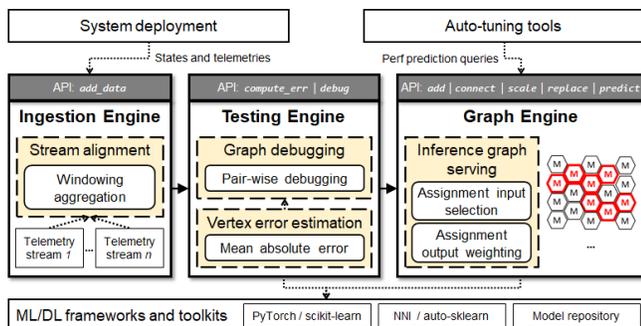

Figure 4: Fluxion architecture overview. It is implemented as three engines. Graph Engine hosts inference graphs. Testing Engine implements features for graph uncertainty estimation and graph debugging. Ingestion Engine ingests and buffers streams of telemetries, for ML model training and testing.

prediction errors propagate and accumulate.

Unfortunately, it is not trivial to analytically derive formulas describing the error accumulation. As ML models apply non-linear transformations to inputs, this non-linearity also transforms input errors to prediction errors. Furthermore, a learning assignment can have multiple model inputs. Not only can different model inputs be weighted differently, but they can also be of predictions from different assignments.

Pair-wise debugging approach. Fluxion implements a pair-wise debugging approach for *error source #2*. This is an iterative process, and each iteration selects one vertex. The core idea is to evaluate the likelihood that the vertex’s prediction error is due to its own learning assignment or parent vertices.

System operators provide a test dataset, which contains recent deployment benchmarks. Fluxion then computes the test MAE for each graph vertex. And, it computes the Pearson correlation, or $r(mae_{parent}, mae_{child})$, for each directly connected pair of graph vertices. With all r s computed, the debugging procedure follows a depth-first traversal. It starts from the last graph vertex (i.e., the vertex that produces the graph output), and performs the following steps — (**step #1**) with respect to the current vertex, we rank all parent vertices by their r in descending order. (**step #2**) If the top-ranked parent vertex has an r larger than 0, we traverse the edge to it and repeat step #1. (**step #3**) Otherwise, if the top-ranked parent vertex does not have an r larger than 0, we stop and return the current vertex as the debugging result.

4 Implementation

Current implementation has 13,012 SLOC, supports PyTorch and scikit-learn models, and integrates NNI [27]. Fig 4 shows an overview. A model repository stores models in serialized form and retrieves them with the unique model ID.

4.1 Graph Engine (GE)

GE serves inference graphs. During auto-tuning, the optimizer queries GE for performance predictions, just like how it would query monolithic models. GE implements the input selection strategy and the output weighting strategy (c.f. §3.1), and it offers APIs to manipulate inference graphs.

Input selection strategy. Our implementation is based on Thompson sampling with Beta distribution [30]. For a learning assignment, each external performance dependency has a Beta distribution, to estimate the probability of being selected for w_k^* . The probability density is governed by two variables, α and β . A larger α increases the mean probability, and a larger $(\alpha + \beta)$ decreases the probability variance.

α s and β s are initialized to 0, or system operators can manually specify a larger α to favor certain performance metrics. Then, the input selection strategy repeatedly updates α s and β s as follows. Each round starts by randomly generating a combination of models — specifically, we generate random numbers from each β -distribution and select k performance metrics with the largest number. This combination is then evaluated for the prediction accuracy. If the current round results in a higher accuracy than the first round, we increment each performance metric’s α value, otherwise the β value.

This process of updating α and β repeats for a user-defined number of rounds, or if the random selection converges for several rounds. Upon termination, we again generate random numbers from each β -distribution and select k performance metrics with the largest number.

Output weighting strategy. Our implementation is based on differential evolution for stochastic minimization [33]. It makes no assumptions on the search space distribution, and it is easy-to-use due to few hyperparameters. Differential evolution is initialized with a population of starting points in the search space. In rounds of mutation-recombination-selection, it moves towards the optimum.

A subset of the initial population can be based on cached w_k^* s. So, the N initial population ($w_1^0, w_2^0, \dots, w_N^0$) consists of uniformly random candidates and previously computed w_k^* . At each round G , differential evolution creates mutant vectors storing combinations of individuals (w_i^G, w_j^G, w_k^G) that are randomly chosen from the current population. Mutant vectors are then mixed with a pre-determined population candidate, to produce a new trial candidate. With data points selected by the Ingestion Engine, we then evaluate this trial candidate. If the new trial candidate yields a better prediction accuracy, it is added to the population.

This process of updating population repeats for a user-defined number of rounds, or if the population converges for several rounds. Upon termination, the population candidate that best maximizes Equation 2 is returned.

4.1.1 Learning Assignment APIs

LA.init(X_names, y_name) sets the labels for assignment inputs and output.

LA.add(X, y, del) adds a new model, and trains the new model with input X and output data y . `del` specifies whether existing models should be deleted.

LA.input_selection(X, y) runs the input selection strategy with the inputs X and output y .

LA.output_weighting(X, y) runs the output weighting strategy with the inputs X and output y .

LA.predict(X) predicts for X .

4.1.2 Graph Update APIs

GE.add(s_name, p_name, a_ptr) adds a new instance-vertex in the graph, to represent one instance of the service `s_name` for the performance metric `p_name`. `a_ptr` points to the learning assignment instance.

GE.connect(s1_name, s2_name) specifies the performance dependency from the service `s1_name` to `s2_name`. Since a service can have multiple performance metrics, `GE.connect` adds directed edges for all combinations of `s1_name`'s and `s2_name`'s metrics. It matches learning assignments' input and output labels to make the connection.

GE.scale(s_name, num_inst) replicates/removes instance-vertices to match `num_inst`, for all `s_name`'s performance metrics. And, for each performance metric, it adds a service-vertex to aggregate instance-vertices. These service-vertices are initialized to an input dimension of `num_inst`, and they can be trained by invoking `GE.fit`.

GE.replace(s_name, p_name, a_ptr) updates instance vertices to reference the new learning assignment `a_ptr`. Service-vertex needs to be initialized by `GE.fit`.

GE.fit(s_name, p_name, time_window) creates a learning assignment, for the service-vertex of `s_name` service and `p_name` metric. Then, it retrieves data points within the last `time_window` seconds from IE, and invokes `LA.add`.

4.2 Testing Engine (TE)

TE implements functionalities to support graph testing. First, `TE.compute_err` computes the per-vertex test error, with the test dataset given in the argument. The current implementation uses the mean absolute error. The test dataset is in a tabular format; each row represents one system benchmark, and columns record service config knob settings and performance measurements. Second, `TE.debug` starts the graph debugging strategy and returns a learning assignment's name.

4.3 Ingestion Engine (IE)

IE ingests and buffers per-service telemetry streams for ML model training and testing. A stream contains one time-series

data type, which can be a performance metric, a configuration knob, or an observable state. Data are published to IE by `IE.add_data`. They are in JSON format with the following fields: `stream_uri`, `type`, `seq_num`, and `val`. The `type` field can be "continuous", "discrete", or "choices". The `seq_num` field is an incrementing integer such as the Unix timestamp.

5 Evaluation

We evaluate and demonstrate the superior performance of Fluxion, with three complex microservice systems on up to 100 VMs, under deployment dynamics like service scale-out and replacement. Our major results include:

(1) Fluxion consistently maintains a lower performance modeling MAE (mean absolute error). Considering the case of gradually scaling Hotel Reservation from 15 to 142 services, Fluxion's MAE is 29.14% lower on average and up to 68.41% lower than comparison baselines.

(2) Fluxion's lower MAE enables better end-to-end system latency. Considering the case of switching from baselines to Fluxion, auto-tuning optimizers achieve a speedup of $1.24\times$ on average (and up to $1.44\times$), for TrainTicket's 90th-percentile latency.

(3) Using a 30-day Azure trace, results show that Fluxion can capture system dynamics in the temporal dimension. By recognizing and adapting to the recurring patterns, the daily training time is reduced by up to 99.98%.

5.1 Microservice Systems

We evaluate the effectiveness of Fluxion, by measuring both the performance modeling accuracy improvement (or MAE *reduction*), and the resulting latency improvement for microservice-based systems. Our evaluations are based on case studies — as microservice systems are orchestrated to exhibit deployment dynamics, we run auto-tuning to continually optimize their tail latency, i.e., the 90th-percentile latency.

Microservice system setup. We deploy three systems: (1) TrainTicket [31], with 41 unique services, (2) Hotel Reservation, with 15 unique services from DeathStarBench [11], (3) Boutique, with 11 unique services from Google [15]. Services are managed by Kubernetes, and they can be replicated and replaced. KubeDNS is used for round-robin load-balancing. Services log per-request latencies for all remote procedure calls, and measurements are centrally stored in an InfluxDB. Appendix lists each system's knobs. For databases, we select top knobs that have been identified to impact read/write latency in production, by Microsoft engineers.

Experiment setup. Our comparison baselines are performance models of monolithic Gaussian process (GP) and multi-layer perceptron (DNN) models. These baselines are common in recent performance optimization efforts [2, 3, 6, 7, 9, 13, 14, 20, 21, 23, 34, 41]. GP uses Matern(5/2) kernel [3]. We

use NNI [27] to tune DNN hyper-parameters: number of hidden layers, hidden layer size, and initial learning rate. We construct Fluxion graphs with APIs in §4.1.1, and learning assignments use GP. Externally, baselines and Fluxion graph have the same inputs and output (c.f. Appendix).

Our testbeds are 3 clusters on Azure — 100-VM cluster (with Intel E5-2673 CPU and 54GB RAM) for Train Ticket and Hotel Reservation; 6-VM cluster (with Intel 8272CL CPU and 8GB RAM) for Hotel Reservation; a 9-VM cluster (with Intel 8171M CPU and 16GB RAM) for Boutique.

Methodology. We send workloads of requests, with wrk2 [38] and Locust [24] (c.f. Appendix). We periodically induce the following stresses to trigger orchestrations, hence deployment dynamics. First, we change the requests per second (RPS) or ratio of request types, to stress different services and paths. This stress then triggers Kubernetes’ HPA (Horizontal Pod Autoscaler) to replicate or reclaim multiple services, to maintain an average service CPU utilization of 60%. Second, we replace a service. Third, we scale-out the entire system.

After each orchestration operation (i.e., deployment dynamics), we first ensure all modeling approaches’ inputs match system knobs. This step involves training new baselines, and also re-composing Fluxion’s graph. In addition, to evaluate how different approaches would improve with further training, we collect new training dataset. Each iteration performs one random benchmark and measures per-request latencies for ~10 minutes. To compare prediction MAE (mean absolute error), we collect an additional 100 random benchmarks as the testing dataset. MAE is computed as the average error between a benchmark’s actual latency and predicted latency.

5.1.1 Performance Modeling Error Reduction

We evaluate how well Fluxion reduces the MAE of predicting the end-to-end latency, as compared to baselines. In the presence of deployment dynamics, a consistently lower MAE suggests a more robust performance modeling.

For TrainTicket, Fig 5b shows that Fluxion consistently maintains a lower MAE (i.e., MAE reduction is always greater than 0) for predicting 90th-percentile latency. It achieves 7.30–38.92% and 4.88%–29.22% lower MAE than monolithic GP and DNN baselines, respectively; this translates to an average MAE reduction of 2,181.89 μ s and 1,547.27 μ s. Similarly, for Hotel Reservation on the 100-VM cluster, Fig 7b shows that Fluxion achieves 34.82–60.05% and 27.24–57.39% lower MAE than monolithic GP and DNN baselines, respectively; this translates to an average MAE reduction of 7,298.78 μ s and 6,858.30 μ s. For Hotel Reservation on the 6-VM cluster, Fig 6b shows that Fluxion achieves 10.04–68.41% and 10.87–66.14% lower MAE than baselines; this translates to an average MAE reduction of 2,814.09 μ s and 2,205.70 μ s. Finally, Fig 8b shows Fluxion’s lower MAE, for Boutique.

Right after deployment dynamics happen (i.e., orchestration operations), the MAEs of all approaches increase. How-

Step	Triggered orchestration	Service	Knob+state
(1) Init RPS (=50)	Deploy "TrainTicket"	49	242
(2) Stress RPS (=100)	Scale-out <i>Station</i> (2 \times)	50	247
(3) Change req ratio	Scale-out <i>Station</i> (2 \times), <i>Route</i> (2 \times)	51	252
(4) Change req ratio	Scale-out <i>Station</i> (2 \times), <i>Route</i> (2 \times), <i>Order</i> (2 \times)	53	262
(5) Stress RPS (=250)	Scale-out <i>Station</i> (5 \times), <i>Route</i> (6 \times), <i>Order</i> (4 \times)	62	307
(6) Stress scale	Scale-out <i>all</i> services (3 \times)	105	510
(7) Replace services	<i>TiDB</i> replaces <i>MySQL</i>	49	242

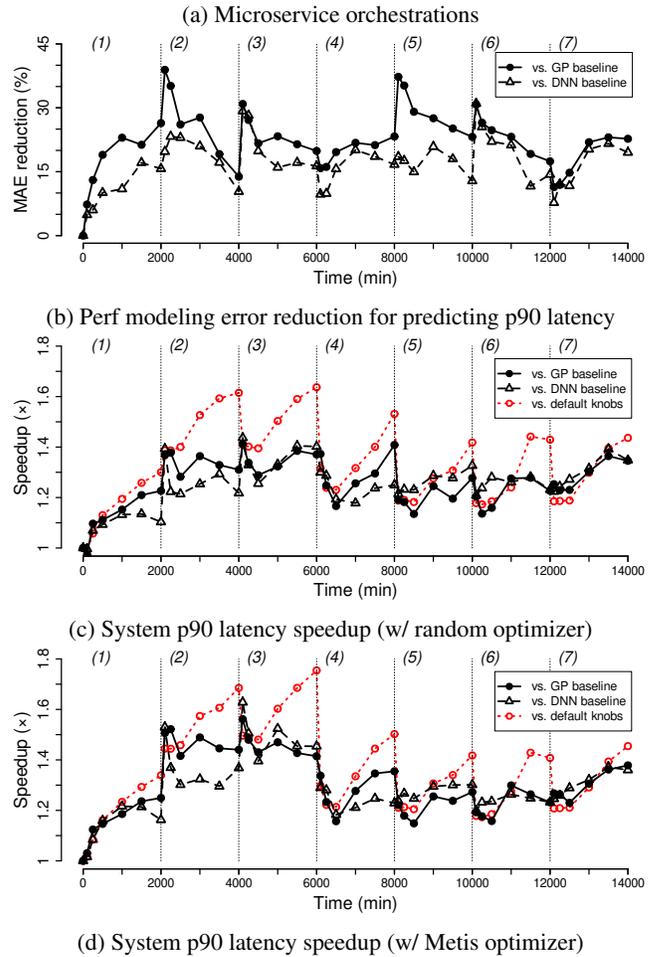

Figure 5: TrainTicket on 100-VM cluster (Intel 2673).

ever, compared to baselines, the *relative* MAE reduction of Fluxion becomes significantly higher after an orchestration operation. Since monolithic baselines require entirely new models, their modeling accuracy can improve only after collecting sufficient data points and training. For example, as we gradually scale-out Hotel Reservation from 15 to 142 services, we need new GP and DNN baselines to accommodate the input dimension that grows from 63 to 1,034. Furthermore, Table 6a shows an operation (Step #6) that replaces all Memcached services by Redis. Although the input dimension here does not change, we need new baselines because Redis

Step	Triggered orchestration	Service	Knob+state
(1) Init RPS (=50)	Deploy "Hotel Reservation"	15	63
(2) Stress RPS (=500)	Scale-out <i>Reservation</i> (2×)	17	72
(3) Change req ratio	Scale-out <i>Reservation</i> (2×), <i>Rate</i> (2×)	19	80
(4) Stress RPS (=800), change req ratio	Scale-out <i>all services</i> (3×)	37	139
(5) Stress scale	Scale-out <i>all services</i> (4×)	48	177
(6) Replace services	<i>Redis</i> replaces <i>Memcached</i>	15	63

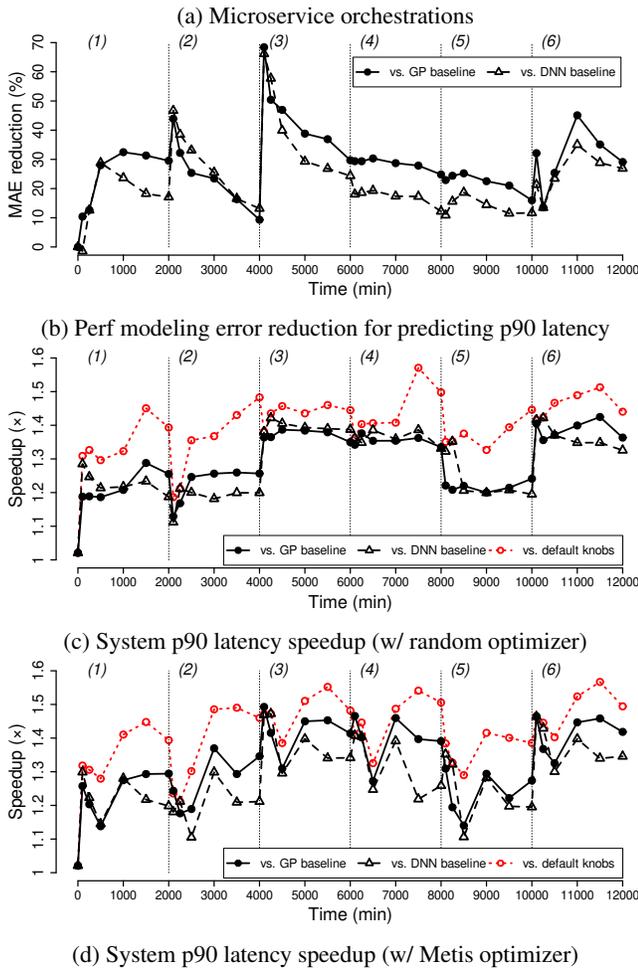

Figure 6: Hotel Reservation on 6-VM cluster (Intel 8272CL).

brings a different set of configuration knobs to performance modeling.

On the other hand, Fluxion is able to localize the inference graph regions (or some learning assignments) that require updating, without changing the rest of the graph. For example, when Hotel Reservation scales-out from 15 to 142 services, graph updates replicate all services' instance-vertices and train their service-vertices. The former incurs no costs, and the latter represents only 15 of the 157 learning assignments in the inference graph. Similar observations can be made for TrainTicket (c.f. Fig 5) and Boutique (c.f. Fig 8).

Step	Triggered orchestration	Service	Knob+state
(1) Init RPS (=50)	Deploy "Hotel Reservation"	15	63
(2) Stress RPS (=1,200), change req ratio	Scale-out <i>all services</i> (6×)	70	253
(3) Stress scale	Scale-out <i>all services</i> (6×), <i>all Memcached</i> (10×)	142	1,034

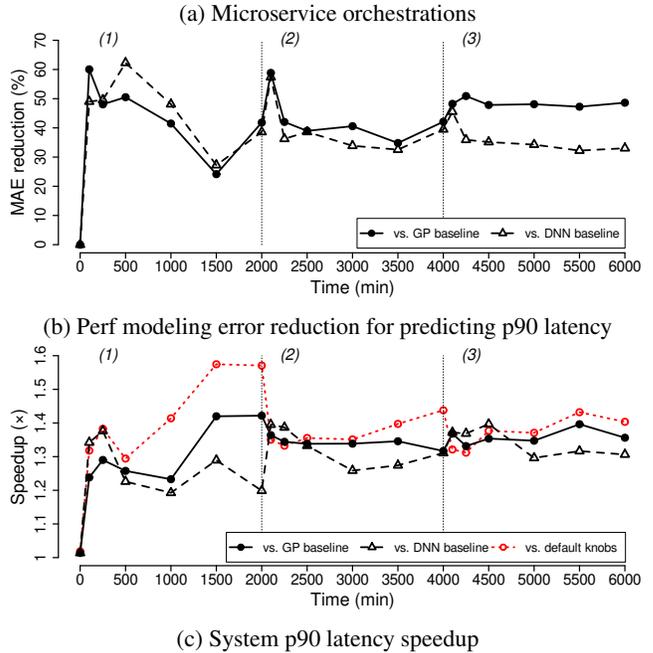

Figure 7: Hotel Reservation on 100-VM cluster (Intel 2673).

5.1.2 Model Adaptation Time Reduction

After each orchestration operation, all modeling approaches are updated to match inputs to system knobs. While baselines need to be re-trained, Fluxion minimizes the overhead by localizing updates to some inference graph regions. If none or only a small number of regions need updating, graph can immediately achieve low prediction MAE, without collecting training data points. Since collecting data points can be time-consuming (c.f. §2.2), if more training data points are necessary, the modeling accuracy will take longer to improve.

We take a deep dive into TrainTicket. After an orchestration operation, both monolithic GP and DNN baselines generally need at least 300–400 data points, in order to train new monolithic models that have an MAE close to what Fluxion can achieve with only 10–25 data points. If each system benchmark takes ~10 minutes, this is a reduction of 2,900–3,750 minutes (or up to 30× reduction).

Furthermore, we highlight the case where Hotel Reservation is scaled-out to 142 services. With 500 data points, monolithic GP and DNN models achieve an MAE of 29,576.57μs and 22,575.57μs, respectively. On the other hand, with only 10 data points, Fluxion can already achieve an MAE of 17,716.25μs. Since Fluxion needs to update only a small subset of the learning assignments in the graph, it requires

Step	Triggered orchestration	Service	Knob+state
(1) Init RPS (=100)	Deploy "Boutique"	11	63
(2) Stress RPS (=200), stress scale	Scale-out <i>all</i> services (2 \times)	22	126
(3) Stress RPS (=300), stress scale	Scale-out <i>all</i> services (3 \times)	33	189

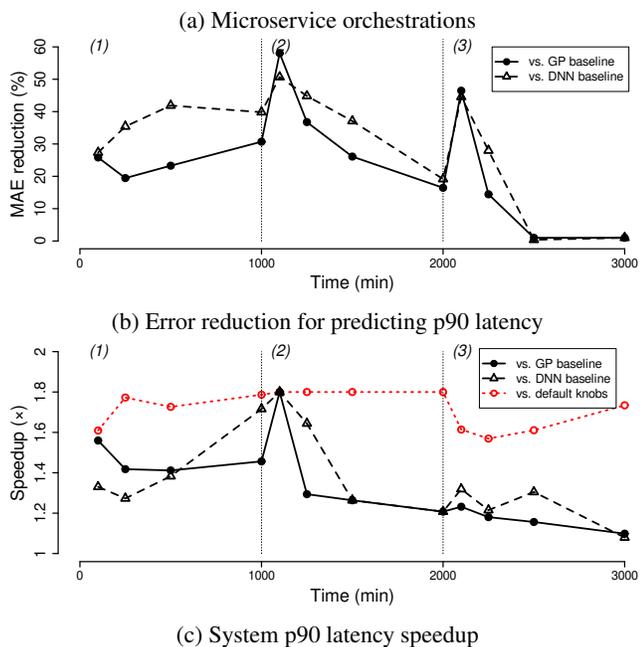

Figure 8: Boutique on 9-VM cluster (Intel 8171M).

much fewer training data points.

5.1.3 End-to-end System Latency Speedup

Intuitively, a better performance model should enable better performance optimization. Based on Fluxion’s MAE reduction shown in §5.1.1, this subsection now quantifies how it can better reduce end-to-end system latencies. To do so, we couple performance models with auto-tuning optimizers (c.f. §2.1): (1) a random optimizer that selects the best knob setting from randomly generated 100,000 settings, and (2) Metis [21].

Fig 5c and 5d show TrainTicket’s 90th-percentile latency speedup from using Fluxion, over baselines. With Fluxion, the random optimizer achieves a speedup up to 1.41 \times and 1.43 \times , over GP and DNN baselines, respectively; the Metis optimizer achieves a speedup up to 1.52 \times and 1.62 \times . While the choice of optimizer can impact the auto-tuning outcome, using Fluxion can result in better performance optimization. Even as we introduce deployment dynamics, the speedup is always greater than 1. We note that figures also plot the speedup over default knobs, to demonstrate the benefits of performance optimization.

Fig 7c shows similar observations for Hotel Reservation on the 100-VM cluster — with Fluxion, the random optimizer achieves a 90th-percentile latency speedup up to 1.43 \times and

1.40 \times , as compared to relying on GP and DNN baselines, respectively. Even for the last orchestration step where Hotel Reservation is scaled-out to 142 services, the speedup can be up to 1.40 \times and 1.39 \times . Furthermore, compared to the default knob setting, Fluxion achieves a maximum speedup of 1.57 \times .

Fig 6c and Fig 6d illustrate the results for Hotel Reservation on the 6-VM cluster. Fluxion helps the Metis optimizer to achieve a speedup up to 1.49 \times and 1.47 \times , over GP and DNN baselines, respectively. Fig 8c shows Boutique, where the random optimizer achieves a speedup up to 1.81 \times and 1.79 \times , over GP and DNN baselines, respectively.

5.2 Microbenchmarks

5.2.1 Exposing a Spectrum of Performance Metrics

We evaluate the benefits of exposing a spectrum of metrics for external performance dependencies. To do so, we compare the following inference graphs that predicting Hotel Reservation’s 90th-percentile latency. In the first inference graph, all services’ learning assignments consider (50, 80–99)th-percentile latencies as external performance dependencies from downstream services. In the second inference graph, they consider only the target performance metric, or the 90th-percentile latency. The last inference graph considers only (50, 85, 90, 95)th-percentile latencies, which are suggested by Fluxion’s input selection strategy.

We delve into the case when Hotel Reservation is scaled-out by a factor of 6. If we consider all (50, 80–99)th-percentile latencies, the graph MAE is 9,722.53 μ s. This is a 10.87% lower MAE, as compared to the second inference graph’s MAE of 10,779.22 μ s. Even across a sequence of orchestrations on the 6-VM cluster, the first inference graph MAE is at least 1.39% lower than the second inference graph. We note that the trade off is the inference graph size — the first graph has 2,170 vertices and 17,647 edges, but the second graph has only 110 vertices and 167 edges. Since each vertex references a learning assignment, this trade off can have a significant implication in terms of the training costs, i.e., 660 more learning assignments to train.

The third latency graph tries to include only highly relevant metrics. In the case of scaling-out Hotel Reservation above, this graph achieves a MAE of 10,091.87 μ s, or 6.81% lower than considering only the 90th-percentile latency. Furthermore, compared to considering all (50, 80–99)th-percentile latencies, the third latency graph reduces the graph size to 419 vertices and 1,055 edges. Although there is a modest 3.80% increase in MAE, the number of necessary learning assignments reduces by 561.

5.2.2 Capturing System’s Temporal Dynamics

We evaluate how well learning assignments can re-use previously trained models to adapt to recurring patterns in temporal dynamics. Our evaluations are based on a case study, which

auto-tunes per-service VM resource allocations by predicting incoming VM request’s max CPU utilization and lifetime. Particularly, as the VM utilization pattern changes over time, models are trained and added to learning assignments, which then use output weighting to compute outputs.

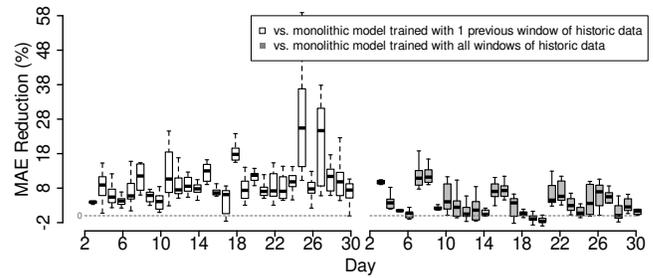

Experiment methodology. We use the 30-day Azure VM utilization trace as the workload, and this production trace was recorded in 2019 [26]. It records resource utilization measurements (e.g., 5-min CPU utilization and VM lifetime) and VM metadata (e.g., VM size and encrypted subscription/deployment ID) for 2,695,548 VM requests.

Following Cortez et al. [7], our baselines are monolithic random forest and extreme gradient boosting tree (XGBoost), for modeling VM’s max CPU utilization and lifetime, respectively. And, these metrics are bucketized. Model inputs include encrypted subscription/deployment ID, requested VM size/category, hour of the day, day of the week. We re-train monolithic baselines at the beginning of each day in the trace, with data points from the previous day or all past days. Furthermore, to ensure comparison baselines are properly trained, we tune their hyper-parameters with NNI [27].

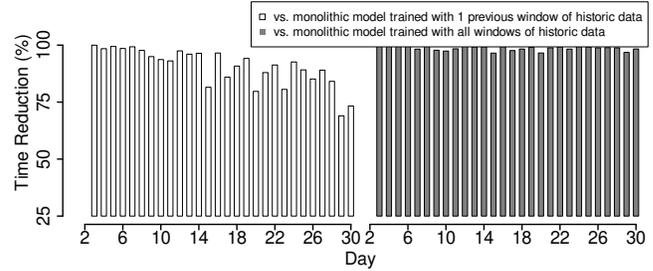

For Fluxion, we set up two learning assignments to represent VM’s max CPU utilization and lifetime. We then discretize the continuous trace into non-overlapping batches by days. At the end of each day in the trace, Fluxion evaluates the mean absolute error (MAE). A new model is trained and added only if this MAE is below 85%. The learning assignment gradually accumulates models for future re-uses, and its output is the weighted sum of all its models’ predictions. We re-compute the weights by invoking `GE.fit()` every two hours, with recent data points.

Performance modeling error reduction. Fig 9a and Fig 10a suggest that Fluxion can significantly reduce the daily modeling MAE. One reason is that `GE.fit()` can quickly re-adjust weights with the output weighting strategy, rather than going through expensive model training. In summary, compared to baselines trained with the previous day of data, the daily MAE reduction is 2.04%–11.25% and 3.97%–25.43%, for predicting max CPU utilization and lifetime, respectively. Compared to baselines trained with all historic data, the daily MAE reduction is 0.64%–6.49% and -1.16%–11.20%, for predicting max CPU utilization and lifetime, respectively. We note that there are days (e.g., day #20) where Fluxion has a slightly higher MAE than baselines. The reason is that these days exhibit a pattern that significantly drifts from previous days.

Model adaptation cost reduction. Fig 9b and Fig 10b suggest that Fluxion significantly reduces the daily training time, i.e., the time spent on model training and `GE.fit()`. We note that this reduction varies by days, as Fluxion does not need to train new models every day. By re-using models, it trains only a total of 20 and 23 models for predicting VM’s max CPU utilization and lifetime, respectively. Furthermore, `GE.fit()` is relatively lightweight — invoking `GE.fit()` 12 times a day

(a) Perf modeling error reduction

(b) Adaptation time reduction

Figure 9: Benefits of learning assignments in predicting VM lifetime in the Azure 30-day trace, compared to baselines. The output weighting strategy promotes the re-use of models trained at different time periods. We evaluate the prediction error every two hours to produce daily boxplots.

takes $\sim 1,620$ and $\sim 1,480$ seconds, for modeling VM’s max CPU utilization and lifetime, respectively. So, compared to monolithic random forest and XGBoost baselines trained with the previous day of data, Fluxion reduces the daily training time by 34.93–99.97% and 68.99–99.98%, respectively. Compared to monolithic random forest and XGBoost baselines trained with all historic data, Fluxion reduces the daily training time by 64.55–99.96% and 96.51–99.98%, respectively.

5.2.3 Graph Re-training

As mentioned in §3.2.3, there are two error sources. As previous evaluation has shown Fluxion’s benefit on *error source #1* (new learning assignments), this section focuses on *error source #2* (unforeseen prediction inputs). As the incoming request pattern changes, different service-to-service execution paths are stressed. We evaluate how well Fluxion can identify the learning assignments at fault in the inference graph.

We conduct experiments by altering the ratio of four request types in the wrk2 workload generator: `search`, `recommend`, `reserve`, and `user`. After we scale-out Hotel Reservation by a factor of 6, we increase the ratio of `search`, `recommend`, and `user` requests from 10% to 30%. At this point, the graph MAE for predicting the 90th-percentile latency is 12,444.63 μ s. Then, the first iteration of graph debugging identifies MongoDB’s learning assignment. After adding a new model trained with recent data points, the graph MAE reduces to

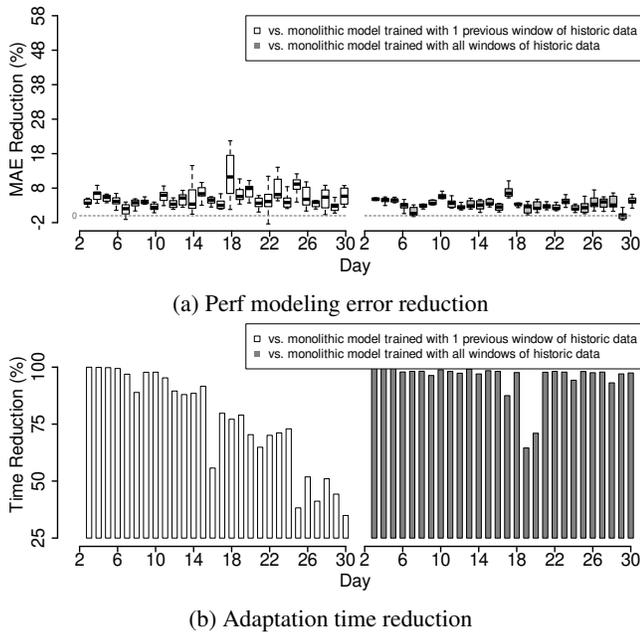

Figure 10: Benefits of learning assignments in predicting VM’s max CPU utilization in the Azure 30-day trace, compared to baselines. Output weighting promotes the re-use of models trained at different time periods. We evaluate the prediction error every two hours to produce daily boxplots.

11,024.66 μ s (or a 11.41% reduction). Subsequent iterations identify the following services: User, Recommendation, and Geo; updating these services reduces MAE to 10,190.89 μ s (or a 18.11% reduction), 9,483.48 μ s (or a 23.79% reduction), and 9,352.04 μ s (or a 24.85% reduction). Beyond this point, the graph MAE reduction starts to exhibit a diminishing return.

6 Related Work

Auto-tuning. Performance tuning for distributed systems is a problem that has continuously received attentions. Instead of relying on heuristics, previous efforts have demonstrated the feasibility of ML-based auto-tuning, for systems ranging from databases [2, 20, 21, 36], storage [6], VM instances [3, 7, 13, 14, 41], cloud services [23], and big data analytics [34].

The focus of this paper is not to apply auto-tuning to new system scenarios, nor to propose new ML techniques. Rather, we are motivated by the limitations of driving auto-tuning with monolithic performance models, especially in the presence of deployment dynamics. We take the first step at abstractions and pieces to systematically bring the concept of modularity to performance modeling. Furthermore, one key question addressed is how this process should be standardized and generalized, without being coupled to specific modeling techniques and systems.

Ensemble of models. The system community has proposed

model ensemble as a research opportunity to improve the development speed and adoption in the real world. Stoica et al. [32] describe this opportunity as composable AI systems. Their goal is to query multiple models in different patterns to balance the tradeoff between accuracy, latency, and throughput of a model serving system. In contrast, Fluxion focuses on providing performance modeling for modern systems.

Ensemble learning is a popular machine learning approach that combines multiple models to achieve a higher prediction accuracy on a given dataset [16, 17, 28]. Representative efforts include bagging [5], boosting [8] and so on. Unlike Fluxion, these techniques do not consider system deployment dynamics and the inherent modularity of ML-based performance model for large complex distributed systems.

Previous research efforts have also applied ensemble learning, to realize incremental learning [29, 35]. They inspire our design for learning assignments to keep a list of models.

7 Discussion

We discuss overarching issues regarding modularity level. Fluxion’s current design closely follows the system modularity of services, but a finer or coarser modularity level might also seem viable. For Fluxion, the main difference would be in the number of learning assignments. Having said that, we choose the modularity level of services, in order to align with what deployment orchestrations typically operate on. While developers could carefully craft a monolithic system that outperforms service-based counterpart, doing so would complicate everyday CI/CD orchestrations in production. Therefore, we advocate developers to follow the well-known principle of engineering cohesive and loosely coupled services. And, for training, these services should expose appropriate knobs and performance feedback.

8 Conclusion

We report the design and implementation of Fluxion. Fluxion applies the principle of modularity to make performance modeling practical for distributed systems such as microservices. Even under deployment dynamics, empirical results show that Fluxion consistently maintains a higher performance modeling accuracy than monolithic models. This in turn enables auto-tuning tools to better reduce end-to-end system latencies.

A Appendix

This appendix provides further information regarding our experiment setup in §5.

- Table 1, 2, and 3 list features (i.e., configuration knobs and states) that we use as performance model inputs, for our three microservice systems. These tables break down these features by microservices.
- Our Fluxion inference graphs use Gaussian Process (GP) models in learning assignments. These GP models use the Matern(5/2) kernel.
- We use NNI to automatically tune hyperparameters for the DNN baseline: the number of hidden layers (3–7), each hidden layer size (100–2,048), and the initial learning rate (0.001–0.1). We budget 24 hours of NNI for each baseline.
- We rely on scripts provided by microservice systems, to generate different request payloads. These requests are then sent by wrk2 or Locust, as recommended by each system. They are available here: Hotel Reservation (<https://github.com/delimitrou/DeathStarBench/tree/master/hotelReservation/wrk2>), Boutique (<https://github.com/GoogleCloudPlatform/microservices-demo/tree/main/src/loadgenerator>), and TrainTicket (<https://github.com/FudanSELab/train-ticket/issues/131>).

SelfTune: Tuning Cluster Managers

Abstract

Large-scale cloud providers rely on cluster managers for container allocation and load balancing (e.g., Kubernetes), VM provisioning (e.g., Protean), and other management tasks. These cluster managers use algorithms or heuristics whose behavior depends upon multiple configuration parameters. Currently, operators manually set these parameters using a combination of domain knowledge and limited testing. In very large-scale and dynamic environments, these manually-set parameters may lead to sub-optimal cluster states, adversely affecting important metrics such as latency and throughput.

In this paper we describe SelfTune, a framework that automatically tunes such parameters in deployment. SelfTune piggybacks on the iterative nature of cluster managers which, through multiple iterations, drives a cluster to a desired state. Using a simple interface, developers integrate SelfTune into the cluster manager code, which then uses a principled reinforcement learning algorithm to tune important parameters over time. We have deployed SelfTune on tens of thousands of machines that run a large-scale background task scheduler at Microsoft. SelfTune has improved throughput by as much as 20% in this deployment by continuously tuning a key configuration parameter that determines the number of jobs concurrently accessing CPU and disk on every machine. We also evaluate SelfTune with two Azure FaaS workloads, the Kubernetes Vertical Pod Autoscaler, and the DeathStar microservice benchmark. In all cases, SelfTune significantly improves cluster performance.

1 Introduction

Large cloud services depend upon cluster managers such as Protean [37], Borg [65], Twine [61], and Kubernetes [6] for job scheduling [32, 33, 39, 47, 53], virtual machine pre-provisioning [43], and resource autoscaling [42, 50, 51]. Cluster managers employ algorithms or heuristics to improve metrics such as throughput, latency, and resource utilization. Often, these algorithms rely on multiple configuration

parameters that critically influence their behavior, that we call *cluster manager parameters*. For instance, Kubernetes exposes parameters `cpu-histogram-decay-half-life` and `recommender-interval` to help the autoscaler [8] react promptly to changes in cluster utilization without reacting to extremely ephemeral changes in utilization.

Every cluster manager relies on developers¹ to manually set these configuration management parameters to “suitable” values. Table 1 gives examples of such parameters (not exhaustive) for different cluster managers. Typically, developers set these values using a combination of domain-knowledge and a limited set of manually-run tests or canaries [38, 60, 62]. While using domain knowledge is a step in the right direction, limited testing has many disadvantages. First, the tests may not widely explore different values of these parameters in different environments. Second, the search space of feasible values explodes exponentially when multiple interdependent parameters can be tweaked simultaneously. Third, cluster usage can change with time, and the best parameter values would therefore change with time as well. Consequently, clusters with manually tuned parameter values may result in reduced throughput, high request latencies or low resource utilization. For instance, we find that using the default values for `cpu-histogram-decay-half-life` and `pod-recommendation-min-cpu` parameters of the Kubernetes autoscaler drops the system throughput to nearly 50% when the workloads arrive in short, heavy bursts (Section 7).

To address this problem, we observe an interesting similarity between cluster manager algorithms and reinforcement learning (RL) algorithms. Cluster managers (Table 1) often use *state reconciliation*: periodically, they observe the current state of a cluster in terms of health and utilization metrics, compare it to a desired state, and take action to move the observed state closer to the desired state [27]. For instance, the Kubernetes autoscaler [8] continuously determines how to update container sizes, by maintaining a histogram of recent resource utilization values. RL algorithms are also iterative

¹For brevity, we refer to anyone developing, deploying or monitoring cluster managers – developers, operators, service engineers – as “developers”.

Cluster manager	Parameter	Description	Default
Kubernetes (Vertical Pod Autoscaler)	cpu-histogram-decay-half-life	How long to wait before halving the weights of past CPU measurements	24 hours
	recommendation-margin-fraction	Fraction of usage added as the safety margin to the recommended request	0.15
	pod-recommendation-min-cpu	Minimum CPU recommendation for a pod	25 millicores
	history-length	Window length for CPU utilization histogram	24 hours
	pod-recommendation-min-memory	Minimum memory recommendation for a pod	250 MB
	memory-histogram-decay-half-life	How long to wait before halving the weights of past memory measurements	24 hours
	memory-aggregation-interval recommender-interval	Window length for memory utilization histogram How often the resource utilization metrics should be fetched	24 hours 1 minute
Azure FaaS (App manager)	prewarm	Time to wait before pre-loading function code	5
	keepalive	Time to wait before retiring the loaded VM	99
Azure Protean (VM allocator)	num-aa	Number of rule-based VM allocation agents	
	k	k -highest quality clusters for VM placement	[8,16]

Table 1: Key numerical configuration parameters of popular cluster management frameworks.

in nature, and use “rewards” to periodically improve and converge a system to an optimal state. Hence we observe that cluster managers are naturally amenable to RL techniques for tuning configuration parameters.

In this paper, we propose SelfTune, a framework that automatically tunes such configuration parameters *in deployment*, rather than through testing. Three key aspects of our framework are: (i) SelfTune piggybacks *solely* on cluster manager’s periodic metric measurements, to help tune the cluster manager parameters, so that both tuning and the cluster state reconciliation can occur simultaneously with the same goal of moving the cluster *continuously* towards optimal state; (ii) SelfTune provides a light-weight API for the developers to augment the cluster manager code specifying which parameters to tune (as we illustrate with an example in Section 3), and an objective, e.g., average CPU utilization should be $\geq 60\%$ but $\leq 90\%$; and (iii) SelfTune uses a principled algorithm called Bluefin, based on theoretically-founded ideas for time-varying rewards [35, 52], to optimize the developer-specified objective; it gradually explores choices for the cluster manager parameters, observes the cluster state, and iteratively tunes the parameters to achieve the objective (Section 4).

We have deployed SelfTune on WLM, a scheduler which manages background job scheduling for many Microsoft M365 services including Exchange Online. WLM runs on hundreds of thousands of machines, of which about a third currently use SelfTune’s parameter tuning. Our deployment has been running for the last six months. We find that SelfTune has improved cluster throughput by 15%–20% in multiple clusters, while simultaneously improving the resource health in some cases. Based on this, operators are in the process of rolling out SelfTune on the entire fleet of machines.

Despite the simplicity of the Bluefin algorithm, SelfTune is successful *and* has low sample complexity (i.e., number of iterations to converge to the desired cluster state) across applications (Sections 5, 6, 7). This stems primarily from the fact that SelfTune does not learn a single complex model or “policy” for the various scenarios (e.g., high/low workloads) and states (e.g., resource utilization levels, failures) of the deployment environment, unlike standard RL techniques used in

systems [45], to tune parameters. Instead, SelfTune relies on pre-determined “scoping” of scenarios (by developers, which is easy in practice) to learn optimal parameters per scope (e.g., one model per machine in our WLM deployment). This scoping, along with light-weight parameter updates (Bluefin) within each scope, makes our solution sample efficient, requiring only about 20 iterations to converge in all our case-studies.

This paper makes the following contributions.

- (1) We present SelfTune, a framework that developers can use to automate parameter search for their cluster manager via a minimal interface (Section 3).
- (2) We use a novel algorithm, Bluefin, based on rigorously-studied ideas in online learning [35, 52], which allows multiple parameters to be tuned quickly and jointly (Section 4). SelfTune, with Bluefin, enables systems to converge to their objective, i.e., their most desired state faster than previous systems that use Bayesian Optimization [55] and standard RL algorithms [26] (Sections 2.1, 7). We have open-sourced an implementation of SelfTune with Bluefin [14].
- (3) We describe our deployment of SelfTune on WLM and show results from multiple clusters where SelfTune achieves up to 15%–20% improvement in the throughput (Section 5).
- (4) To the best of our knowledge, ours is the first developer-centric framework for automated tuning of parameters of online systems, not just cluster managers, with large-scale deployments. We show SelfTune’s generality in the contexts of (a) resource management for Azure FaaS with production workloads [54] (Section 6) yielding significant improvement in resource efficiency and (b) container rightsizing with Kubernetes and DeathStar benchmark [36] (Section 7), yielding significant improvements in tail latency and throughput.

2 Related Work

Optimally configuring systems is a long-studied research problem in both systems and machine learning [34, 40, 44, 63, 64, 68]. In this section, we describe how SelfTune improves upon previous work, in terms of both the core algorithm it uses, and the framework it provides to the developer.

2.1 Algorithm

Commonly-used techniques for tuning or learning system parameters are variants of Bayesian Optimization [25, 55], reinforcement learning [20, 67], and heuristic search [30].

Bayesian Optimization (BO): CherryPick [23] uses BO to pick the best cloud configuration for big data analytics while Metis [40] uses it to improve performance metrics like tail latency by tuning key system parameters. BO is meant for settings where one seeks global optima of a *fixed* reward function, and requires users to specify a model for the function. For example, CherryPick and Metis use Gaussian Processes to model the prior function. In contrast, Bluefin focuses on online settings where the reward function may change with time, and so does the optimal solution. Also, BO algorithms have high sample complexity, i.e., the number of parameter deployments needed to converge to an optimal solution is large, especially when the number of parameters is also large. Thus BO is not ideal for tuning parameters in deployment or online. Our evaluation in Section 7 confirms this.

Reinforcement learning (RL): RL solutions for tuning database systems [67] or learning scheduling algorithms [45] support continuous parameters but require the system to explicitly provide state information in addition to reward values. For instance, Decima [45] needs every node to specify state in terms of a feature vector consisting of average task duration, number of servers assigned to a node, etc. Defining and implementing states needs domain expertise and engineering effort which is hard to scale across diverse systems. In contrast, Bluefin works with just the reward values and does not need the system to explicitly define such state.

Heuristic search: Using branch-and-bound [30] based techniques for large combinatorial spaces, or domain-specific deductive search for high-dimensional spaces [68] are primarily meant for systems where the goal is to obtain the best configuration parameters for a fixed reward function, and a fixed set of workloads. Often, these techniques do not apply to online settings for the same reason as BO (discussed above); also, heuristic search space modeling lacks the generality of RL techniques like contextual bandits [20, 26] and Bluefin.

SelfTune’s Bluefin algorithm addresses the concerns in both BO and state-of-the-art RL techniques. It is a principled gradient-descent based algorithm which (a) needs no modeling, ML expertise, or non-trivial engineering effort, (b) works seamlessly with large real-valued and discrete parameter spaces, and (c) converges to local (or global) optima, with fewer samples than previous approaches.

2.2 Framework

MLOS [31] is a framework to automatically tune configuration parameters using BO; thus, its applicability is limited as discussed above. OpenTuner [24] provides a meta-framework using which domain-specific tuners can in turn be built. CG-

PTuner [29] considers contextual data, e.g., workload information, for DBMS tasks and uses BO to guide tuning. Best-Config [24] finds good configuration settings using heuristic search and sampling techniques. As discussed in Section 2.1, these techniques do not generalize to dynamic environments unlike SelfTune, where the rewards observed change with time, and in turn the optimal configurations themselves.

OtterTune [64, 66] is a framework for tuning DBMS configuration parameters. Though it also uses a variant of BO for tuning, it incorporates a novel technique to mitigate the risk of using stale configurations for new workloads. It builds ML models for selecting an appropriate workload (from a workload repository) that best represents the current workload, and uses the selected workload to estimate the effect of parameters on the current workload. In contrast, our online setting is much more dynamic, where it is extremely challenging to characterize and maintain such repositories.

AutoPilot [51] reduces resource wastage for containerized workloads using ML techniques for setting job-specific resource limits based on resource utilization. SelfTune is orthogonal to such cluster management frameworks and solutions — in fact, we show how SelfTune helps tune the key parameters of the open-source version of AutoPilot, called Vertical Pod Autoscaler [8], that is part of Kubernetes, in Section 7.

State-of-the-art RL frameworks, e.g., Microsoft’s Decision Service [21] are suited for settings where the parameter (“action”) space is discrete or categorical, as they rely on “multi-arm bandit” formulations [20]. Extending these techniques to multiple numerical parameters results in very large action spaces which makes it much more challenging to learn (as we see in Section 7). RL frameworks like SmartChoices [28] naturally support numerical parameters, but rely on providing explicit reward separately for each parameter. We, on the other hand, do not require such disambiguation — our problem formulation, and Bluefin, work with a single reward value (i.e., the desired system state objective) for tuning several, possibly inter-dependent, parameters together.

3 SelfTune Overview

We provide an overview of SelfTune and, using a simple example, explain how a developer uses it. Then we describe SelfTune’s main system components and their functions.

3.1 SelfTune Interface

To use SelfTune, a developer augments their cluster manager code in four ways. First, they specify the set of parameters SelfTune should tune. Second, they either initialize a fresh SelfTune instance or connect to an existing one. Third, they specify at what point in the code and at what frequency SelfTune should update the values of these parameters. Finally, they use the current state of the cluster to determine a *reward*, which captures the difference between the desired

state and the current state of the cluster. SelfTune’s algorithm (in our implementation this is Bluefin) uses this reward to set the parameter values in the next iteration. One of the main insights of this work is that the cluster manager already computes the current state of the cluster, and already has a notion of the desired state of the cluster. Hence SelfTune simply piggybacks on existing code to determine the reward, which is essential for any reinforcement learning platform. The example in Figure 1 shows how a simple token-based job scheduler uses SelfTune to tune the frequency with which it makes scheduling decisions. Using this example, we now describe the SelfTune-specific additions to code in detail.

```

1: public const double optLoad = 0.80;
2: // UpdateCycle = new TimeDelta("00:00:05");
3: Config UpdateCycle = new Config("UpdateCycle",
4: ① Specification           "TimeDelta",
5:                           "00:00:01-00:00:30",
6:                           "00:00:05");
7: SelfTune st = new SelfTune.Create(UpdateCycle);
8: st.Connect();           ② Creation
9: // This is the scheduler loop
10: var currentLoad = 0.0;
11: while(1)
12: {
13:     if (currentLoad < optLoad)
14:     {
15:         int numTokens = GenerateTokens(currentLoad);
16:         GrantTokensToJobs(numTokens);
17:     }
18:     Guid callId;        ③ Prediction
19:     UpdateCycle = st.Predict(callId, "UpdateCycle");
20:     sleep(UpdateCycle);
21:     currentLoad = CalculateLoad();    ④ Feedback
22:     st.SetReward(callId, currentLoad - optLoad);
23: }

```

Figure 1: Token-based scheduler augmented with SelfTune to tune the frequency with which its main algorithm runs — the highlighted lines show the three basic additions for SelfTune.

Specify Tunable Parameters: For each parameter, the developer specifies its data type, and optionally, initial value, a range of permissible values, and step-size (e.g., `TimeDelta` data type with values in multiples of 5 seconds). Line 3 in Figure 1 says that SelfTune should tune the `UpdateCycle` parameter, which determines the time between consecutive iterations of the main scheduler loop. Here, the developer has specified that this parameter can lie between 1 second and 30 seconds. They also specify 5 seconds as its initial value.

The developer has determined that `UpdateCycle` should be tuned because if the scheduler waits too long between iterations, it will not react fast enough to changes in cluster state, hence causing the cluster resources to be used sub-optimally. If, on the other hand, the scheduler iterations run

very frequently, the scheduler may react prematurely to extremely transient changes to system state, thereby causing sub-optimal resource usage. Note that though this example shows SelfTune tuning only one parameter, one instance of SelfTune can tune any number of parameters simultaneously.

Initialize and Connect to SelfTune Instance: Line 7 in Figure 1 starts a new SelfTune instance. In a cluster-wide deployment, the developer decides how many instances of SelfTune to set up. In our WLM deployment, each machine initializes a separate SelfTune instance. However, if needed, cluster managers can reuse the same instance of SelfTune across various machines, simply by connecting to an existing SelfTune instance (Line 8).

Get Parameter Values: Lines 11 to 23 show the main scheduler loop. Lines 13 to 17 capture the main algorithm of the scheduler. The developer measures the current cluster state as `currentLoad` (set to 0 in Line 10 and updated by the function `CalculateLoad()` in Line 21). The developer states the desired cluster state, i.e. `optLoad`, in Line 1. If the current load of the system `currentLoad` is less than the specified optimal load `optLoad`, it generates a number of tokens proportional to the difference between the optimal load and the current load.

After this, in Line 19, the scheduler invokes SelfTune’s **Predict** function to determine the value of `UpdateCycle`, and sleeps for `UpdateCycle` seconds. Without SelfTune, the scheduler loop would have slept for a fixed value of 5 seconds, as the commented Line 2 shows.

Set Reward Function: SelfTune needs the developer to specify a domain-specific function to determine the outcome of tuning the specified parameters. Note that the developer’s code already defined both `optLoad` and `currentLoad` since the core scheduling algorithm uses them both. The developer reuses this pre-existing code: in Line 22, the developer inputs the difference between `currentLoad` and `optLoad` to SelfTune’s **SetReward** function as the reward value.

Every reward is a result of a certain set of parameter values. So, the code associates the calls to **Predict** and **SetReward** using the same `callId`. The Data Collector stores this information for later use (details in Section 3.2).

3.2 SelfTune Components

We now describe the different components SelfTune needs to support the functions in Section 3.1. Figure 2 depicts the four main components: the Client API (which supports the **Predict** and **SetReward** functions), the Learning Engine, the Data Collector, and the Reward Tracker. Appendix A discusses the specifics of the client API. We describe the rest of the components here.

Learning Engine: The learning engine implements the necessary optimization algorithms such as Bluefin. While SelfTune primarily uses Bluefin, the framework itself is generic and can therefore include other algorithms, e.g., Azure Decision Service’s Contextual Bandits.

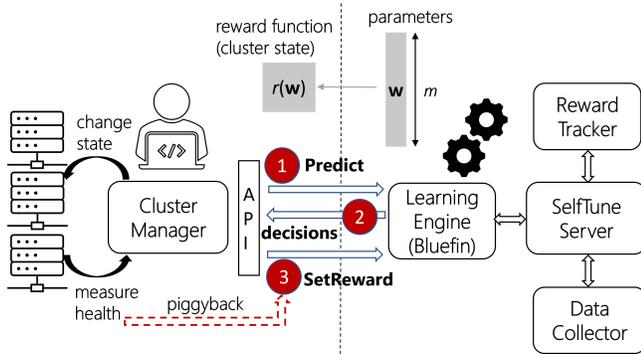

Figure 2: SelfTune architecture. The cluster manager interacts with the SelfTune server via client API. The learning happens on the server side, and it is transparent to the cluster manager.

Section 4 describes Bluefin algorithm that uses a variant of gradient descent. It determines the next value of the parameter based on how the cluster reacted to past parameter choices. For instance, in the example explained in Figure 1, Bluefin observes past values of `UpdateCycle` and the corresponding reward, and then determines the next value with the objective of getting the load as close as possible to `optLoad`.

Data Collector: The data collector is a background service that maintains the history of all parameter values and the corresponding reward for each SelfTune instance. In the example of Figure 1, whenever the client code makes a call to `Predict` and a subsequent call to `SetReward`, the data collector associates the parameter values and reward using the `callId` and stores this as the tuple $(callId, a, r)$ where a is the value for `UpdateCycle` that the client code obtained by calling `Predict()` and r is the resulting reward. The learning engine uses this data to set future parameter values as described in Section 4. The data collector also stores references to each SelfTune instance so that cluster managers can lookup existing SelfTune instances and connect to them. In our SelfTune implementation, since we use the Bluefin algorithm (Algorithm 1), the space requirement for Data Collector is negligible — it needs to persist only one $(callId, a, r)$ tuple (the most recent), per SelfTune instance (see Section 5).

Reward Tracker: In practical settings, the reward computation may have to happen asynchronously off the critical path; there may not be a natural place in the main control flow to call `SetReward`, unlike in the example of Figure 1. In fact, the actual implementation of WLM discussed in Section 5 is such a setting. To facilitate this scenario, SelfTune supports another background service, called the Reward Tracker, which computes rewards periodically, at a frequency determined by the developer, and pushes the values to the data collector.

4 The Bluefin Algorithm

This section describes the Bluefin algorithm used by SelfTune’s learning engine. We first define a “round”, that is essential to explaining the algorithm. Next, we describe two characteristics essential for making SelfTune generic as well as lightweight. Finally, we describe the algorithm in detail and explain how it achieves both the essential characteristics.

Definition of a round: Standard reinforcement learning (RL) proceeds sequentially in “rounds” between the learning engine and the system whose parameters are tuned. We define a round in the context of tuning deployed systems as the duration for which the system executes with a particular set of parameter values as returned by the calls to `Predict`. The client code terminates a round when it calls `SetReward`. In Figure 1’s example, the developer may introduce an `if` statement around Line 22, checking the last time the reward was set, and setting the reward only if more than a day has passed since. In this case, each day constitutes a round. Alternatively, the developer may share the same SelfTune instance across multiple machines and call `SetReward` only after all machines have had a chance to call `Predict`; here, a round completes only when all machines have called `Predict`.

Characteristic 1: Bluefin uses One-point Feedback. Cluster state is the result of a complex combination of parameter values and external factors such as sudden bursts in workloads and time-of-day effects. Therefore, the reward, which is a function of the cluster state, also changes with time. Modeling this behavior using a fixed function is extremely difficult, if not impossible.

Bluefin (like any other RL approach) uses rewards only at the parameter values that the cluster manager obtains by calling `Predict`. It does not assume any other information about the inherent, unknown function that determines the reward. In other words, following standard practice in RL literature [21, 56], Bluefin assumes only bandit-feedback or zeroth-order access to the reward function. This constraint is referred to as “one-point feedback” [35], as against multi-point feedback [22] in learning theory. Techniques such as Bayesian Optimization, branch-and-bound heuristics [30], and genetic algorithms [46, Chapter 1.6] need to compute the reward for multiple parameter values that may not have been deployed in the system. Hence they need a model to represent the potentially complex and unknown reward function. Thus, these techniques are much more suited to offline tuning than to our setting of tuning *in deployment* to optimize cumulative time-varying rewards.

Characteristic 2: Bluefin has Low Sample Complexity and Low Engineering Overhead. Our goal is to reach the optimal parameters that maximize the cumulative reward over

time. The metric of efficiency is *sample complexity*, i.e., the number of rounds it takes to converge to the optimal values. Each round can be very resource-intensive (as we discovered in SelfTune’s deployment on WLM, explained in Section 5), so the fewer the number of rounds the less the overhead of the parameter tuning framework itself. SelfTune reduces the engineering overhead and makes tuning highly sample efficient by letting developers statically identify suitable “scopes” for tuning. That is, rather than learning a single global model to account for all the complex behaviors of the underlying system being tuned, it allows developers to instantiate a SelfTune instance per scope (e.g., WLM uses machine as the scope, in Section 5). Each instance executes Bluefin to learn optimal parameters within its scope, thereby solving a relatively easier problem. Second, Bluefin algorithm (in each SelfTune instance) can be thought of as learning a model of size equal to the number of parameters tuned, unlike standard RL techniques that use sophisticated models with orders of magnitude more parameters to capture system states and behaviors. Thus, both the sample and the engineering complexities of Bluefin is much lower than the standard RL approaches.

Algorithm: We first define a few terms used to explain the algorithm. Say the developer wants to tune m parameters. In each round, the cluster manager receives an m -dimensional vector $\mathbf{a}^{(t)}$ when it calls **Predict**, and as a result of setting these values, it measures cluster state and reports back a reward value $r_t(\cdot) : \mathbf{a}^{(t)} \mapsto \mathbb{R}$. SelfTune then uses this reward to update the parameter values.

Algorithm 1 presents the core function of Bluefin, which leverages ideas from the rigorously-studied derivative-free online optimization [35, 52] in the machine learning theory community. There are two key challenges in our tuning setting. First, if we know the exact reward function, r_t , then we can apply the standard online gradient descent techniques [69]. However, in a deployed cluster, we do not have any information on r_t other than the one-point black-box access to it. Second, standard gradient-descent style updates are derived for real-valued parameters. However, cluster manager parameters can be discrete as well as real-valued.

To tackle the two challenges, we leverage the derivative-free optimization ideas studied in learning theory [35, 52]. They showed that we can reliably estimate the gradient of the black-box reward function by randomly perturbing the parameters *once*, albeit under some assumptions on the function. In particular, the theory requires that the problem be continuous, i.e., parameters are all real-valued. In practice, we often have to tune discrete-valued parameters. To this end, Bluefin introduces a function g , which it appropriately defines during the **Create** call, to map the real-valued parameters and the generic data-types that can be deployed in the system. In other words, Bluefin executes the well-studied online gradient descent updates in a suitably transformed parameter space. We discuss the details next.

Algorithm 1 Online tuning of parameters in SelfTune

```

1: procedure Bluefin (radius  $\delta > 0$ , learning rate  $\eta > 0$ )
2:   Initialize the parameters  $\mathbf{w}^{(0)} \in \mathbb{R}^m$  // Create
3:   Initialize  $g(\cdot)$  // Create
4:   for  $t = 0, 1, 2, \dots$  do
5:     Uniformly sample  $\mathbf{u} \in \mathbb{R}^m$  from  $\{\mathbf{u} : \|\mathbf{u}\|_2 = 1\}$ .
6:     Compute perturbed parameters  $\tilde{\mathbf{w}}^{(t)} := \mathbf{w}^{(t)} + \delta \mathbf{u}$ 
7:     Client receives perturbed decisions  $\mathbf{a}^{(t)} := g(\tilde{\mathbf{w}}^{(t)})$ 
// Predict calls
8:     Receive feedback  $r^{(t)} := r_t(\mathbf{a}^{(t)}) \in \mathbb{R}$  //
SetReward
9:     Do “one-point” gradient-ascent update (to maximize the reward):  $\mathbf{w}^{(t+1)} \leftarrow \mathbf{w}^{(t)} + \frac{1}{\delta} \cdot \eta \cdot r^{(t)} \cdot \mathbf{u}$ 

```

Initialization (Line 2). The algorithm works with a real-valued parameter vector $\mathbf{w} \in \mathbb{R}^m$, where m is the total number of parameters to tune. If the developer does not give an initial value for parameter i , the algorithm samples w_i uniformly at random from the specified range (suitably scaled, see below). If the developer has not provided a range, it initializes w_i to 0.

Defining g (Line 3). If the developer specified a step-size, g appropriately scales the corresponding components of \mathbf{w} . For instance, if the developer specifies that the i th parameter is an integer that needs to have a step-size of 5, then $g(w_i) = 5 * \text{round}(w_i)$, where w_i is the real value that the algorithm manipulates, and **round** is the round-to-the-nearest-integer function. Similarly, if the developer specified range constraints on the parameter, then g appropriately projects w_i to lie within the specified bounds. **Predict** applies the g function before returning the parameter values, as in Line 7 of the Algorithm.

Update parameters (Lines 5, 6, 9). To update \mathbf{w} , we use the technique of [35], where we estimate the gradient of r_t with respect to $\mathbf{w}^{(t)}$ by a random perturbation of $\mathbf{w}^{(t)}$. Line 6 effectively samples a vector $\tilde{\mathbf{w}}^{(t)}$ from the hyper-sphere centered at $\mathbf{w}^{(t)}$ with a radius δ (input to the algorithm, appropriately set as discussed below). Line 9 computes a gradient-*ascent* style update (to *maximize* the cumulative reward) in the direction of the random vector \mathbf{u} scaled appropriately by the learning rate η , and the observed reward value r_t at the perturbed vector. In some cases, such as in simulation settings, one may be able to perturb the vector more than once and make reward measurements. It turns out that with just two-point feedback, we can get a very accurate estimate of the gradient (in lieu of Line 9) as noted in the following remark.

Remark 1 (“Two-point feedback”). *The accuracy of gradient estimation, and in turn the sample complexity of Algorithm 1, can be further improved [57] in settings (e.g., simulations in Section 6) where it is possible to obtain reward $r_t(\cdot)$ at two*

different \mathbf{a} values. In that case, the gradient estimator in Line 9 of Algorithm 1 can be replaced with:

$$\mathbf{w}^{(t+1)} \leftarrow \mathbf{w}^{(t)} + \eta \frac{1}{2\delta} (r(g(\mathbf{w}^{(t)} + \delta\mathbf{u})) - r(g(\mathbf{w}^{(t)} - \delta\mathbf{u})))\mathbf{u}$$

Setting radius δ , learning rate η . In general, choosing a single real number δ can be tricky especially when the parameters have different scales. But, decoupling the deployed parameters \mathbf{a} (that may have very different scales) from the weights \mathbf{w} (that are in a normalized scale) via $g(\cdot)$ mitigates this issue in practice. Given $\|\mathbf{w}^{(t)}\|_2 = O(1)$ and $\|\mathbf{u}\|_2 = 1$, we set $\delta = O(1)$ and $\eta = O(\delta^2)$, so that $\mathbf{w}^{(t+1)}$ retains the scale after the update in Line 9 of Algorithm 1.

5 Large-scale Workload Scheduling System

In this section, we describe our experiences deploying SelfTune with WLM (short for “workload manager”), the background task scheduler for Substrate, a large data management engine used by many of Microsoft’s services. We first describe Substrate and WLM, and then the deployment of SelfTune with WLM, and finally present evaluation.

5.1 Substrate

Substrate is a large-scale data management engine at Microsoft which hosts data for several of Microsoft’s enterprise services such as Exchange Online, an enterprise email service, and SharePoint, an online collaboration platform. Substrate stores data in a local database on each machine. Substrate runs upon hundreds of thousands of machines worldwide and hosts billions of data items.

In Substrate, compute and storage are tightly coupled. Each machine runs many *user-facing* tasks, such as reading emails, writing documents, and searching through data. These tasks are latency-sensitive and need to complete within a few milliseconds. Simultaneously, Substrate runs a vast range of *background tasks* on the same machines such as data indexing, data analytics, machine learning, and data defragmentation. More than 70% of all tasks that run on Substrate are background tasks. An example background task analyses a customer’s mailbox to provide daily to-do lists [10]. Most tasks are defined to finish very quickly (e.g., process one mailbox and return), in the order of a few seconds.

5.2 WLM

To ensure that background tasks do not interfere with user-facing tasks, Substrate uses a background task scheduler called WLM which regulates these tasks’ access to disk,² CPU, memory, and network on that machine. WLM continuously polls the background task queues, granting the tasks

²majority of Substrate data is hosted on cost-effective HDD media

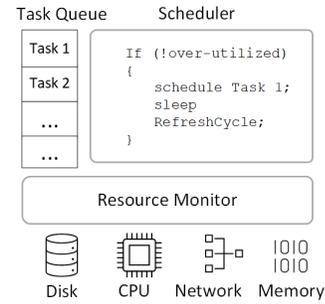

Figure 3: WLM service architecture.

access to resources when permissible (to ensure high throughput), while trying to keep resource utilization on the machine within a specified range (to ensure room for user-facing tasks).

Figure 3 depicts WLM’s scheduling algorithm. WLM’s resource monitor continuously tracks CPU, disk, network, and memory usage (IO latency for disk, utilization % for CPU and memory, and a function of bandwidth utilization and ping losses for network). For each resource, developers specify a lower and a higher usage threshold. If the resource’s utilization is under the lower threshold, the resource is said to be *under-utilized*. Similarly, if the resource’s utilization is over the higher threshold, WLM considers it to be *over-utilized*.

Configuring WLM: Every few seconds, determined by a configuration parameter called `RefreshCycle`, WLM updates a state variable called `MaxConcurrency`. `MaxConcurrency` determines the maximum number of background tasks that can run on a machine simultaneously. WLM operates an Additive Increase, Multiplicative Decrease (AIMD) algorithm to determine `MaxConcurrency`: every `RefreshCycle` seconds, it determines resource usage. If all four resources are under-utilized, WLM increments `MaxConcurrency` by 1. Even if even one of the resources is over-utilized, WLM cuts `MaxConcurrency` to half its current value. For instance, the developer may set the higher threshold for CPU usage to 60%, the idea being to reserve 40% for the more important user-facing tasks. If WLM observes that background tasks are using more than 60% CPU, it decreases `MaxConcurrency` to half the current value, thereby going into a mode of rejecting tasks until the usage comes down sufficiently. WLM thus gradually schedules more tasks and increases resource utilization, while also checking that no resource is over-utilized.

The ideal value of `RefreshCycle` depends on machine type and workload characteristics. A less powerful machine might benefit from a larger `RefreshCycle`. A smaller value of `RefreshCycle` may help machines with variable workloads. In the absence of an automated tuning framework, WLM’s developers have set up different versions of this parameter such as `CPU-RefreshCycle`, `machine-type-A-RefreshCycle`, etc. to control it in dif-

ferent contexts. This approach increases the number of configuration parameters, hence management overhead, as well as the developer burden to continuously check cluster state in these various contexts and manually tweak parameters.

Our deployment of SelfTune automatically and continuously tunes only one configuration parameter – `RefreshCycle` – for every machine independently, which is the scope identified by the domain experts. Developers can now stop using the context-specific `RefreshCycle` parameters, and also stop the continuous manual monitoring of the parameter value and its effect on cluster state.

Performance metrics: WLM measures its performance using two metrics, and hence SelfTune uses either one of these as its reward metric. The first, called a resource’s *Healthy Utilization Percent* (HUP), measures the fraction of time the resource is neither over-utilized nor under-utilized. The ideal value of HUP is 1. WLM usually calculates HUP for every hour and for every resource.

The second metric, *grant ratio* (GR), measures the ratio of the total number of tasks that WLM runs in a given time-period to the total number of tasks that were submitted to it in the same time-period. A grant-ratio of 1 implies that WLM did not reject any task. Thus ideally, WLM needs to drive the cluster to have HUP=1 and GR=1. We use the same metrics, aggregated over a day, as the reward function for SelfTune in our deployments.

While these are the two primary metrics that WLM directly exerts influence over, there are other workload-specific metrics, that are outside the scope of WLM, instrumented by the teams who rely on the scheduler. For instance, background task developers use a higher-level metric, i.e., *background task throughput*, to determine how promptly WLM schedules their tasks. This is measured as the total number of background tasks successfully completed within one day. While SelfTune does not use this as a reward metric, we use this metric to determine if SelfTune does indeed help improve the efficiency of the system (Section 5.3).

Integrating SelfTune: We integrate SelfTune with WLM to tune `RefreshCycle` separately for every machine. While the WLM code-base consists of tens of thousands of lines of code, we required less than 50 lines of code to integrate SelfTune, most of which is replacing parameter usage with `Predict`, and setting up the Reward Tracker service (to invoke `SetReward` asynchronously, as discussed in Section 3.2) with the appropriate reward function.

We look at aggregate metrics over a subset of machines for a month to set the scale of δ (which helps exploration) and η appropriately. We find that a single, fixed choice of δ and η works across clusters; we do not shrink these parameters to 0 with increasing iterations, which is needed in theory. This helps prevent stagnation when tuning in deployment.

Minimal overhead of running SelfTune: Each Substrate machine runs its own local SelfTune (i.e., its component services) instance; so `Predict` calls (executing Steps 5 and 6 of Bluefin) are just like any other local function calls in the WLM code-base. Parameter updates (Step 9 of Bluefin) are extremely light (at most 5 FLOPS) and are made once a day when the reward arrives. To enable debugging, the Data Collector (introduced in Section 3) persists a history of $(callId, a, r)$ tuples from the previous 30 days; this takes at most a few hundred KBs space per instance in production. Overall, there is minimal overhead to operationalizing SelfTune in production, in terms of both compute and space.

We enable parameter tuning with SelfTune on individual production servers via *flights*, a mechanism used for gradually deploying any code change in production. Deployment starts with a few hundred servers, and then slowly expands to more servers. This helps us perform controlled experiments.

5.3 Evaluation

In this section, we first describe our evaluation methodology. Then, we describe our experiments and results.

Evaluation Methodology: A significant challenge we faced while evaluating SelfTune is that resource HUP varies widely week over week in Substrate. Figure 4 shows the disk HUP over six weeks in Aug-Sep 2021 for two randomly chosen machine sets in a representative cluster in South America consisting of 450 servers. The sets contained 225 machines each, and were completely disjoint. The figure shows that, for the same machine set, utilization changes significantly from one week to the next. Hence we cannot evaluate the efficacy of SelfTune simply by observing HUP on the machine set before deploying SelfTune, and comparing it to HUP after deploying SelfTune. However, we also observe that the distributions of disk HUP computed on the two disjoint machine sets are very similar (e.g., relative difference between HUP P50 percentiles of the two sets was $\leq 0.5\%$ for all weeks). Therefore, to evaluate SelfTune, we deploy it on one machine set, called the *Treatment Group*, and compare this machine set’s HUP values after deployment to the HUP values on the other machine set within the same cluster, which is the *Control Group*. Similarly, we evaluate grant ratios across the two groups (for the same duration, the relative difference between GR P50 percentiles of the two sets was $\leq 3.0\%$).

Results: We ran three large-scale experiments to evaluate SelfTune. We chose three clusters with sub-optimal values of resource HUP and GR: (1) We chose Cluster 1 because, despite being under-utilized (and thus having low values of HUP), it also had low GR. Developers were submitting background tasks to WLM but a significant fraction of them were surprisingly getting rejected despite low resource utilization. Developers thus reported a trouble-ticket for Cluster 1, and

Cluster	Control Size	Treatment Size	Experiment Duration	Reward	Metric Improvement						RefreshCycle Value (minutes)		
					HUP			GR			P25	P50	P75
					P25	P50	P75	P25	P50	P75			
1	144	144	July 1–July 30	GR	SI	SI	SI	214%	178%	169%	5.05	6.00	6.08
2	1000	1000	Aug 25–Oct 12	GR	SI	SI	SI	34%	37%	25%	5.02	10.19	15.11
3	1950	1950	Oct 11–Nov 17	(CPU) HUP	2%	1%	3%	18%	18%	20%	0.016	0.043	0.071

Table 2: SelfTune experiment details, resulting performance improvement (SI=Statistically Insignificant) & RefreshCycle values.

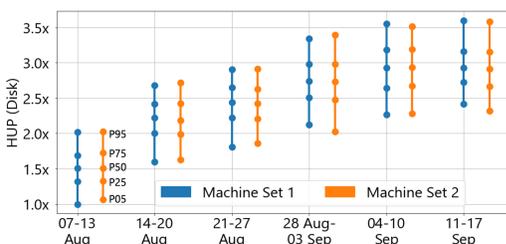

Figure 4: Disk HUP for a cluster in South America (of 450 servers) during Aug-Sep 2021: The (normalized) percentiles drift across weeks (1% – 32%) significantly; but they vary much less (1% – 2%) across the two disjoint server sets.

this made it a good candidate for SelfTune. (2) Cluster 2, with predominantly disk-intensive workloads, faced heavy disk throttling and consequently had poor GR. (3) Cluster 3, with predominantly CPU-intensive workloads, had low CPU HUP (CPUs were mostly in the over-utilized state), and consequently, low GR (recall that the CPU MaxConcurrency will quickly drop to 1, when it is in an over-utilized state for a short amount of time).

Our objective was to see if SelfTune, by tuning RefreshCycle on each machine in the cluster, could improve GR for Cluster 1 and Cluster 2, and CPU HUP for Cluster 3. Thus, in Cluster 1 and Cluster 2, we set up SelfTune with the Grant Ratio (GR measured over a period of one day) as the reward metric. For Cluster 3, we set up SelfTune with CPU HUP as the reward. In Cluster 1, we initialized RefreshCycle to 20 minutes since it was the default value used for the cluster. For Cluster 2 and Cluster 3, we initialized RefreshCycle to the default value of 6 seconds that was already in use.

(1) SelfTune improves utilization metrics in all three clusters significantly. Table 2 describes the duration of the experiments, sizes of the control group and treatment group, and the impact on the performance metrics using SelfTune. In particular, for each cluster, it shows the improvements in the resource HUP and the GR metrics. Given confidentiality requirements, we are unable to present absolute numbers, but present the percentage improvements. Since SelfTune separately tunes RefreshCycle on every machine, we present improvement in utilization in terms of 25th%-ile (P25), 50%-ile and 75%-ile of metric values across all machines in the treatment group relative to the corresponding percentile values in the control

group (during the deployment period). For all the results, we ensure statistical significance using the standard t -test, at a p -value of 0.05.

From Table 2, we observe significant improvements in GR, between 18% and 178% improvement in the median, across all three clusters. We see drastic improvements in the GR metric in Cluster 1, chiefly due to the sub-optimal and obsolete choice of RefreshCycle value used in this cluster (reflected in the Control Group). In Cluster 3, where SelfTune employed CPU HUP as the reward, the improvement in the median CPU HUP was around 2% (also see Figure 5 that shows relative values for confidentiality reasons). Even though the improvement in HUP is small (2%–3%), it is statistically significant; importantly, even a 2% improvement in the median HUP implies several minutes to an hour of better resource utilization per machine per day for at least 50% of the machine-days in the cluster. The actual impact is magnified manyfolds by the number of machines in the cluster over weeks and months. Furthermore, the small improvement in HUP led to significant improvements (18%–20%) in the GR metric.

(2) SelfTune has to tune RefreshCycle separately and continuously for each cluster. Table 2 gives the P25, P50 and P75 values of RefreshCycle that SelfTune converged to in each cluster. We find that Cluster 1’s RefreshCycle values converged to a median value of about 6 minutes, Cluster 2’s median value was about 10 minutes, whereas Cluster 3’s median value was much lower, i.e., 2.6 seconds. Additionally, in some cases, there is a significant spread of converged values within a cluster, as the P25 and P75 values show. Such differences in the ideal values of RefreshCycle are due to various reasons, such as varying workload characteristics and provisioned hardware even within the same cluster. Moreover, these workload and hardware characteristics also change with time, which means SelfTune should continuously run on every cluster for WLM to be able to react appropriately and quickly to such changes. Figures 11, 12, and 13 in Appendix B show how RefreshCycle converges differently for the three clusters over the course of deployment duration.

(3) SelfTune significantly improves background task throughput. SelfTune uses either resource HUP or GR as reward metrics since WLM already calculates these metrics. Ultimately, however, background task developers want a high background task throughput. We therefore evaluate how SelfTune improves this metric. Figure 6 shows the improvement in the task throughput when SelfTune was enabled in the

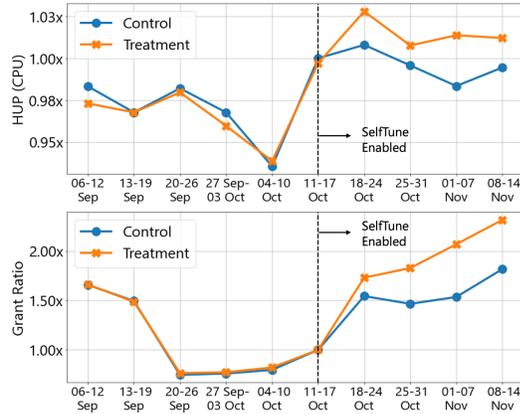

Figure 5: Both HUP (CPU) and GR (weekly P50 values) are significantly better after SelfTune was enabled in Cluster 3, with a 1% to 3% relative improvement over the control set in utilization and a 12% to 34% improvement in GR.

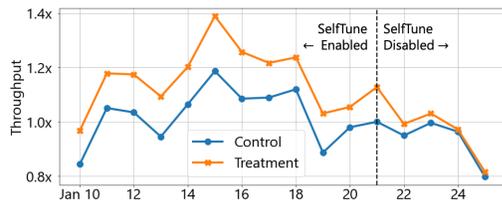

Figure 6: Background task throughput (normalized w.r.t. Jan 21st) clearly improved when SelfTune was enabled.

first week of Jan 2022, in a random half of a 750-machine cluster in the Asia-Pacific region. Before we enabled SelfTune, the throughput of both control and treatment groups were similar. Once enabled, SelfTune improves the background task throughput by as much as 17%. We disabled SelfTune on Jan 21, and the treatment group’s throughput went back to being the same as that of the control group. This shows that by improving resource HUP and/or GR, SelfTune significantly improves the background task throughput as well.

Since SelfTune has shown significant improvements in multiple metrics in our experiments, starting January 2022, we have enabled SelfTune in all Substrate clusters in North America, consisting of tens of thousands of machines.

6 Serverless Scheduling in the Cloud

Customers are increasingly using serverless computing, or “Functions as a Service” (FaaS), for deploying applications on the cloud [1, 3–5]. Previous work has proposed informed resource management strategies to use cluster resources efficiently for FaaS applications [54]. We evaluated SelfTune with this work and observed significantly improved resource usage with minimal to no performance loss. This section

describes the problem, experiments, and results.

6.1 FaaS Resource Usage

Cloud providers charge FaaS-based applications for the number of functions executed, and not for the resources that the applications use. Hence, to maximize their benefit, providers seek to offer good function performance to customers with the least resources assigned to run the customers’ functions.

To achieve good function performance, the provider should load the customer’s application into memory before the customer invokes the function (warm start), as opposed to loading it from persistent storage only after the customer invokes the function (cold start). However, keeping all applications in memory at all times is prohibitively expensive. Ideally, the provider should pre-load the customer code *just before* the function is invoked. This approach will minimize the resources that the provider assigns to this application and yet provide good performance.

To achieve this, Shahrads et al. [54] have proposed a policy that predicts two key parameters for a FaaS platform: 1) `prewarm`: The time the policy waits, since the last execution, before it loads the application image expecting the next function invocation. A large value of `prewarm` reduces resource usage but may cause cold starts. 2) `keepalive`: The time for which an application is kept in memory after it has been loaded in memory. A larger `keepalive` can reduce cold starts but will also waste resources. Therefore, the challenge is to predict suitable values of `prewarm` and `keepalive` that will provide good function performance and, at the same time, reduce resources used.

To determine these parameters, Shahrads et al. maintain a histogram of time between function invocations for each application, called the *Idle Time (IT) histogram*. Based on an empirical study, they suggest using `keepalive` = 99th percentile³ and `prewarm` = 5th percentile of the IT values in the histogram for all applications.

6.2 Evaluation Setup and Goals

We hypothesize that it may be sub-optimal to set `prewarm` and `keepalive` to the same value for all applications. Moreover, the IT histogram can change with time, and therefore these parameters should be set not once, but periodically. In this section, we seek answers to the following two questions:

1. Per-application Tuning: Can SelfTune set `prewarm` and `keepalive` for each application (i.e., use application as the scope for SelfTune instance) based on its invocation patterns, to achieve a better performance trade-off for the cloud provider? (Section 6.3)

2. Time-varying Tuning: Can SelfTune periodically tune these parameters to improve the trade-off, as the invocation patterns could change over time? (Section 6.4)

³henceforth, we write `keepalive` = 99, dropping the percentile

Simulation setup: We use the Python-based simulator used in [54] which replays real function invocation traces (obtained from Azure as described in Sections 6.3 and 6.4), and infers if each invocation creates a warm or cold start. The simulator also keeps track of when each application image is loaded in order to aggregate the wasted memory time for the application (i.e., the time the image is kept in memory without executing any functions). Following [54], we simulate (a) function execution times equal to 0 to quantify the worst-case wasted resource time, and (b) all applications use the same amount of memory (as memory data is only partially available).

Performance metrics: We focus on two metrics, following the analysis presented in [54]: (i) distribution (in particular, P75) of percentage of cold start invocations per application (i.e., what fraction of invocations of the app during the time period were cold starts), and (ii) wasted memory time (as defined above). We normalize (ii) w.r.t. a baseline policy of using *no* prewarm and a fixed 10-minute *keepalive* (absolute value, unlike the percentile values used throughout this section). We use the same metrics as reward for SelfTune.

6.3 Per-application Tuning

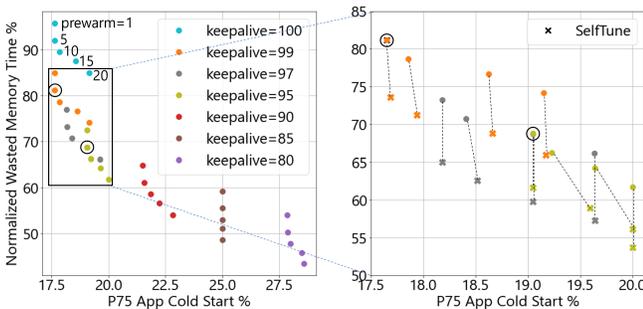

Figure 7: Performance of the VM management policy [54] on AzureFaaS data: (left) sweep of `prewarm` and `keepalive`, fixed for all apps; circled dots are the choices recommended in [54]; (right) with SelfTune for tuning the two parameters for each app, and memory wastage as reward; the dots are the starting points for SelfTune, and the corresponding crosses indicate the performance at convergence.

To answer the first question, we use the AzureFaaS dataset [2] consisting of 14 days of function invocation traces for about 22,000 applications running on Azure Functions.

Optimal global parameters: We first obtain the pareto-optimal trade-off frontier for the two parameters when they are fixed to the same value for all applications. To obtain this frontier, we did a simple grid-search with 7 `keepalive` values (100, 99, 97, 95, 90, 85, 80) and 5 `prewarm` values (1, 5, 10, 15, 20), i.e., we ran 35 simulations which took under three hours on a standard 64-core machine for this dataset (obviating the need for clever optimization/search algorithms). Fig-

ure 7 (left) plots normalized wasted memory time vs P75 app cold start percent. We see that one metric improves at the expense of the other metric, for various choices of `prewarm` and `keepalive` parameters. Our findings here align with [54], and the choices circled in black are indeed their recommendations: `prewarm` = 5, and `keepalive` = 99 that favors cold starts; or `keepalive` = 95 that reduces memory wastage by 15% at a small cost (< 9%) of cold starts, relative to `keepalive` = 99.

Optimal application-specific parameters: Doing a grid-search to determine application-specific parameters is very expensive since there are tens of thousands of applications. So we leverage SelfTune to determine *per-application* values of `keepalive` and `prewarm`. On one week of data, every time a function is invoked in the trace, we call **Predict** to determine the values of `keepalive` and `prewarm` for the application. The reward metric used is either wasted memory time or number of cold starts. We then evaluate the converged per-application parameter values on the second week of data.

Figure 7 (right) plots wasted memory time vs cold start percent when using SelfTune. We first observe that SelfTune, with memory wastage as the reward, reduces memory wastage by nearly 10% relative to the fixed optimal global choices (indicated in circled dots on both the right and left plots) *without* worsening cold starts. Second, application-specific tuning yields strictly better choices than the global frontier — the crosses (corresponding to the converged parameters) lie below the dots (initial values). We made similar observations when we used number of cold starts as the reward.

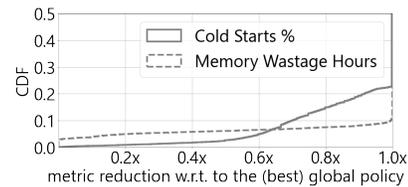

Figure 8: CDF of app-wise reduction in the cost metrics relative to the best global policy (circled in Figure 7) achieved via SelfTune on AzureFaaS. All improvements come from \lesssim 20% of the apps (axis curtailed for clarity).

Figure 8 shows that the overall cost reduction with SelfTune can be attributed to less than 20% of the apps. SelfTune is able to exploit the behavior of a fraction of apps to find better choices of parameter values, while for the other apps, the default global policy parameters already work quite well.

6.4 Time-varying Tuning

To answer the second question, i.e., whether SelfTune’s periodic parameter tuning helps reduce resource usage over time, we collected a much larger set of traces from the Azure FaaS

infrastructure between July 15 and Oct 31, 2019 and used them to drive the simulator. As in the previous section, in this large-scale study, we divide the traces into pairs of consecutive weeks, use SelfTune to tune parameters *per-application* on the first week, and evaluate the impact on the second week. Since we use 14 weeks of data, we have 7 such pairs.

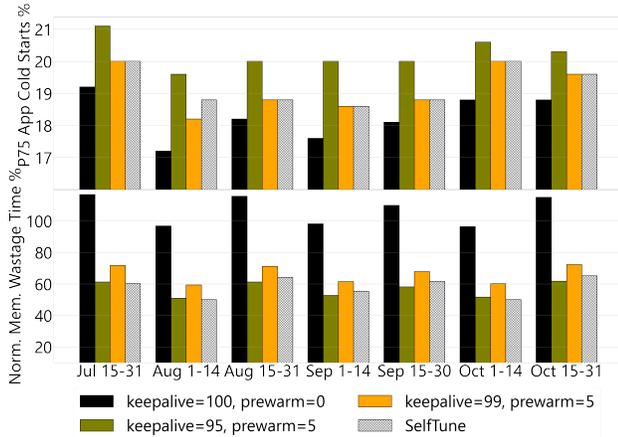

Figure 9: Performance of VM management policy [54] with app-specific tuning of parameters via SelfTune on the large Azure dataset: SelfTune is consistently superior or competitive w.r.t. the baselines along both the metrics, across weeks.

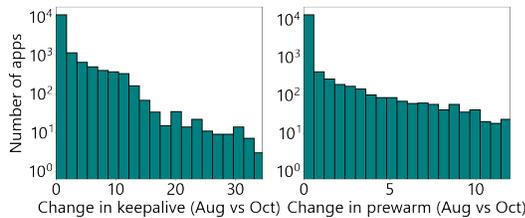

Figure 10: Distribution of differences in converged values, for the two parameters, over 3 months. SelfTune picked significantly different values in October vs. August, for over 25% apps, reflecting the temporal shift in the invocation patterns.

Figure 9 shows the value of P75 application cold starts and normalized wasted memory time with SelfTune and three baselines. We have included a baseline policy that achieves the best possible cold starts ($\text{prewarm} = 0$, $\text{keepalive} = 100$) for calibration. For SelfTune, we use multiple initial values as in Figure 7, and pick the best results obtained. Relative to the $\text{keepalive} = 95$ policy, on average, SelfTune reduces the cold starts by 5%, while incurring a 2.1% larger memory wastage. Also, relative to the $\text{keepalive} = 99$ policy, SelfTune yields 12.5% less memory wastage for a small (0.5%) increase in cold starts.

Figure 10 shows how SelfTune changes parameter values (for a random subset of apps) in October compared to August. SelfTune picks significantly different values, up to 300% relative change, for over 25% of the applications. This under-

scores the importance of continuously tuning the parameters.

7 Container Rightsizing

In this section, we show how SelfTune can be integrated with microservices architecture and Kubernetes to improve (a) cluster resource utilization, and (b) tail latencies of microservices-based cloud applications. We also present comparisons with BO and RL techniques.

Simulation setup: We use the social networking application in the DeathStar microservices benchmark [36]. We set up a cluster with 4 servers, each with 24 cores, 40GB of memory and 250GB of disk space. We restrict monitoring services to one server to avoid interference and deploy the microservices on the other three servers based on the functionality (e.g., all backend microservices are on one server). We simulate a diurnal workload, with short traffic bursts. Following [58], the workload generator [16] issues GET (read timeline), POST (create new post) requests continuously for 15 minutes at 500 requests per second, in the ratio 9 (GET):1 (POST).

Configuration parameters: We tune two types of parameters: (i) the first 4 CPU-related parameters listed in Table 1 for the Kubernetes VPA (Vertical Pod Autoscaler) [8], which impact the efficiency of autoscaling and throughput, and (ii) about 85 key numerical configuration parameters (2–5 parameters per microservice) for the 28 microservices in DeathStar (as identified in [58]), which impact the application latency.

Compared methods: We compare SelfTune’s Bluefin with three standard techniques: (i) Bayesian Optimization — the Gaussian Process (GP) method [25], implemented in [15], and used in [23, 58, 66], (ii) Contextual Bandits [26] RL technique — the ϵ -greedy algorithm implemented in [19], and used in [20, 21], and (iii) Deep Deterministic Policy Gradient (DDPG) [41], a popular deep RL technique for continuous action spaces used by prior works to tune system parameters [49, 67]. For all the experiments, we initialize Bluefin and BO (GP) with the default parameter values as well as random values, and report the best results. We note that, in this scenario, the initialization does not have a significant effect on the algorithms’ convergence. For both the algorithms, the difference in performances yielded by the best configurations obtained with either initialization is around 2%–4%. Each 15-minute peak workload constitutes a sample (a round). We fix a budget of 50 samples for all the methods for fair comparison. We configure the ϵ -greedy and DDPG algorithms to explore for the first 25 rounds and then exploit for 25 rounds.

7.1 Results

Optimizing throughput: We now demonstrate the significance of tuning Kubernetes VPA parameters. We set up a barebones version of DeathStar application, where Nginx microservice with two replicas serves static content for the GET requests. We use one of the servers in the cluster as

Metric	Bluefin	BO (GP)	ϵ -greedy	DDPG
Throughput %	86.1 \pm 2.2	83.9 \pm 3.1	71.2 \pm 4.3	73.4 \pm 5.4
# Samples	12	14	13	50

Table 3: Tuning key parameters of Kubernetes VPA.

the controller node and another as the worker node [7]. As the requests are light-weight, we ramp the workload up to 10000 rps, and see how quickly Kubernetes autoscales to catch up with the workload. In general, it has been found that default configuration for the Kubernetes VPA can hurt system performance [17]. For instance, with the default value of `recommendation-margin-fraction = 0.15`, Kubernetes will add a margin of $0.15 * \text{computed CPU recommendation}$ to allow the container to adapt to sudden changes in the workload. This ramp up can be quite slow at such high workloads. On the other hand, setting the parameter to a very large value might help quickly catch up with the heavy workload, but will lead to severe resource wastage once the peak dies.

A natural question is if we can tune the VPA parameters (the CPU parameters from Table 1) to help improve resource utilization. We use the throughput attained (over the 15-minute peak workload), with a penalty on the `cpu-histogram-decay-half-life` value as the reward function, to minimize wastage during off-peak hours.

Table 3 shows the best throughput achieved (mean and std. dev. over 5 deployments of the best parameters) and the number of samples needed by each of the methods to attain the best value. We find both BO and Bluefin converge, fairly quickly, yielding over 75% better throughput relative to the default configuration; Bluefin achieves the best throughput overall (statistically significant), an absolute improvement of 2.2% compared to BO. At convergence, Bluefin sets `recommendation-margin-fraction` to 1.5, and `pod-recommendation-min-cpu` to 850 millicores (see Table 1). This helps Kubernetes auto-scale the containers sufficiently quickly (compared to the default values of 0.15 and 250 millicores respectively) and serve the peak workload of 10000 rps. At the same time, Bluefin (and the other methods) converges to a small value (about 45 seconds) of `cpu-histogram-decay-half-life`, which is ideal for short bursts of workloads: Kubernetes evicts the worker containers right after the peak, thereby freeing up resources.

In what follows, we show how we can also tune the configuration parameters of microservices (running in containers) themselves, in order to improve application latency.

Optimizing tail latency: Microservices that are deployed in containers have multiple configuration parameters [9, 11–13, 18] that influence their performance. For instance, the number of threads of performance-critical microservices (e.g., `compose-post-service` in DeathStar) is known to significantly improve latency [58, 59]. We tuned 85 key numerical param-

Metric	Bluefin	BO (GP)	ϵ -greedy	DDPG
P95 latency (ms)	19.5	19.9	20.0	20.2
# Samples	8	41	30	50
P50 iter. cost (ms)	20.5	23.3	29.2	20.6
P75 iter. cost (ms)	21.1	33.0	33.2	22.1
P95 iter. cost (ms)	28.3	76541.9	67640.3	148543.1

Table 4: Tuning parameters of microservices in DeathStar: The second row indicates the number of samples (i.e., rounds) it took for each method to attain the best P95 latency reported in the first row. The last three rows show the spread of the latencies *while tuning* over 50 rounds.

eters of the microservices in DeathStar with P95 latency as the reward for all the methods.

Effectiveness of Bluefin in high dimensions: Table 4 shows the best tail (P95) latency attained by each of the methods and the number of samples they took to achieve the same. We deployed each parameter setting three times, and report the median number. This high-dimensional tuning setting clearly brings out the superiority of Bluefin over the popular techniques in terms of sample complexity. Even though there are 85 parameters, there are only a few parameters that critically influence the reward value. Indeed, Bluefin quickly converges to 19.5ms P95 latency (starting from 31.1ms, corresponding to the default values), with just 8 samples; in contrast, BO and ϵ -greedy algorithms take 3-5 times as many samples to attain similar latencies. The multi-arm bandits approach (ϵ -greedy) treats the parameter values as categorical choices and does not exploit continuity of the problem or correlations across the parameters. On the other hand, the deep RL method, DDPG, does exploit, but it has a much higher sample complexity.

We also show the *iteration cost*, i.e., the latency incurred through each round of tuning (which matters in deployments). The spread of the iteration costs for SelfTune indicates convergence close to 20ms. Even though all the compared algorithms eventually converge to statistically similar latency values, they incur several orders of magnitude worse P95 iteration costs than Bluefin. This is strong evidence of the effectiveness of Bluefin for tuning in live deployments, where the reward function can be highly ill-conditioned and can vary wildly in some regions of the explored parameter space.

8 Conclusion

This paper presents SelfTune, an RL-based framework using which cluster managers can tune parameters to improve cluster performance. We have deployed SelfTune with a large-scale task scheduler at Microsoft and show how it has improved overall system throughput. We show that SelfTune significantly improves system performance with experiments on Azure FaaS workloads, Kubernetes’s Vertical Pod Autoscaler, and the DeathStarBench microservice benchmark.

A SelfTune’s Client API Implementation

We now formally present the syntax and the semantics of SelfTune’s client API (introduced informally in Section 3, and in Figure 1).

Creation. The **Create** API creates an instance of the parameter learning problem for SelfTune. This API allows optional arguments that encode domain knowledge for tuning the parameters:

- (a) names for the parameters to learn,
- (b) (optional) initial values for the parameters,
- (c) (optional) constraints on the parameters to be tuned; the API supports range constraints (`min` and `max`), type constraints (e.g., `isInt = TRUE` if a parameter takes only integral values),
- (d) (optional) for user-defined types, one could specify step-size (e.g., memory sizes in multiples of 64MB), or scale (e.g., logarithmic or linear).

```
string Create(string[] params,
    Dictionary<string, double> initialValue,
    Dictionary<string, Constraints> constraints,
    Dictionary<string, Type> type)
```

Connection. The **Create** API sets up a data store instance in the back-end for tuning the specified parameters, initializes the necessary background services to maintain/update this store. A unique identifier to this store instance is returned by

the call to **Create**. The **Connect** API connects a parameter learning instance to a SelfTune object.

```
void Connect (int problemId)
```

Note that if a store already exists (for the parameter(s) of interest), then the client can directly connect to the instance, as the store instances are persistent. This also enables multiple clients (distributed spatially and/or temporally) to query the latest decisions for, as well as give feedback to, the same learning problem.

Prediction. With the **Predict** interface, the developer can query the *current* values for the parameters. These values are decided by the learning algorithm (presented subsequently).

```
(int, double[]) Predict (string[] params)
```

Note that **Predict** returns a pair of values – a unique identifier which identifies the particular invocation of **Predict**, and the predicted value.

Feedback. As shown in Figure 1, the **SetReward** interface allows the client to specify a reward value. More generally, it allows the client to associate the value with a particular invocation of **Predict**:

```
void SetReward(int invocationId, double reward)
```

The invocation id helps associate the reward to the parameters (and their values) returned by previous **Predict** calls — in particular, the reward value applies to all the parameters that were part of all the **Predict** calls since the last **SetReward** call.

B Parameter Convergence

In this section, we provide graphs to give the reader an idea of how long it takes for **RefreshCycle** to converge in our experiments with WLM (see Figure 11, Figure 12 and Figure 13)

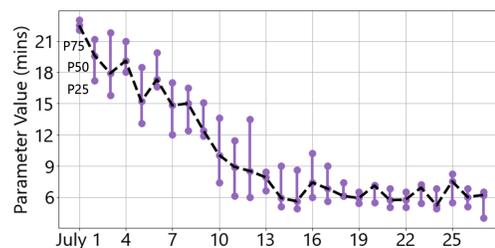

Figure 11: Convergence of **RefreshCycle** with SelfTune in the experiment using Cluster 1.

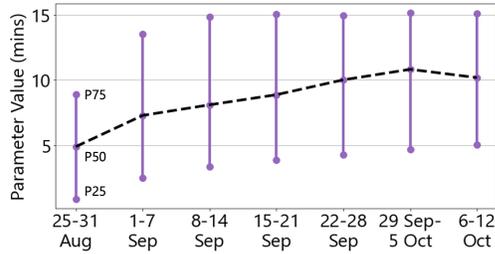

Figure 12: Convergence of RefreshCycle with SelfTune in the experiment using Cluster 2.

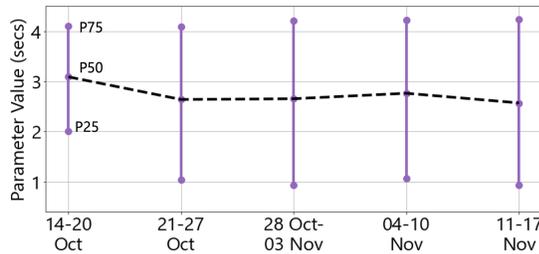

Figure 13: Convergence of RefreshCycle with SelfTune in the experiment using Cluster 3.

C Baselines

In this section, we discuss the implementation details of different baselines used in Section 7.

For Bayesian Optimization (BO), we used the `skopt` library [15] with `gp_hedge` as the acquisition function. The algorithm was initialized with the default configuration or with 3 random configurations (uniform sampling), and we reported the best results in Tables 3 and 4.

For Contextual Bandits (CB), we used the popular Vowpal Wabbit library [19]. Since the configuration space is too huge for the bandits formulation to handle, we restrict tuning to the four important parameters (memory limit parameter of the post-storage-memcached microservice, `worker_processes` and `worker_connections` parameters of the frontend microservice, memory limit of the post-storage-mongodb microser-

vice) based on empirical observations and recommendations from prior work [58]. Since the algorithm expects discrete actions spaces, we suitably quantize the configuration space of each parameter. We use a `step_factor` for each parameter which yields $(upper_limit - lower_limit) / step_factor$ number of quantized values per parameter. The value of `step_factor` is chosen such that the resulting (discrete) action space is not too large. After discretizing the four parameters in this fashion, we arrived at 24960 actions for the CB algorithm. We used the “explore first” strategy in the ϵ -greedy algorithm via the command `-cb_explore num_actions -first num_random`, which implies that the algorithm will (only) explore the action space with uniform probability for the first `num_random` iterations.

We implemented Deep Deterministic Policy Gradient (DDPG) [41] using PyTorch [48]. DDPG is a popular policy-based Reinforcement Learning algorithm used by prior works to tune system parameters [49,67]. We use the CPU and memory utilization of microservices on the nodes where microservices are running, workload volume (requests per second), number of clients, and request composition as state features. Both the actor and the critic networks consist of 1 hidden layer. The number of inputs to the actor layer is equal to the number of state features and the output is equal to the number of actions (i.e., parameters tuned). The input and the hidden layer use ReLU as the activation function while the output layer uses Tanh. For the critic network, the number of inputs is equal to the number of state features + the number of actions while the output is just 1-dimensional.

We use 1 step for each episode (to match how the iterations of the baselines and Bluefin proceed) and run the algorithm for 50 episodes. We let the algorithm explore random points for the first 25 episodes followed by 25 episodes where the explored configurations are chosen by the algorithm. To improve the algorithm’s ability to explore, we add a Gaussian noise to the action chosen which is controlled by a parameter γ ($\gamma = 0.1$ in our experiments). We update the model after every 5 steps. Once the 50 episodes are complete, we query the model to provide the best configuration for the initial state. We average the rewards over 5 such queries.

CausalSim: A Causal Framework for Unbiased Trace-Driven Simulation

Abstract

We present CausalSim, a causal framework for unbiased trace-driven simulation. Current trace-driven simulators assume that the interventions being simulated (e.g., a new algorithm) would not affect the validity of the traces. However, real-world traces are often biased by the choices algorithms make during trace collection, and hence replaying traces under an intervention may lead to incorrect results. CausalSim addresses this challenge by learning a causal model of the system dynamics and latent factors capturing the underlying system conditions during trace collection. It learns these models using an initial randomized control trial (RCT) under a fixed set of algorithms, and then applies them to remove biases from trace data when simulating new algorithms.

Key to CausalSim is mapping unbiased trace-driven simulation to a tensor completion problem with extremely sparse observations. By exploiting a basic distributional invariance property present in RCT data, CausalSim enables a novel tensor completion method despite the sparsity of observations. Our extensive evaluation of CausalSim on both real and synthetic datasets, including more than ten months of real data from the Puffer video streaming system shows it improves simulation accuracy, reducing errors by 53% and 61% on average compared to expert-designed and supervised learning baselines. Moreover, CausalSim provides markedly different insights about ABR algorithms compared to the biased baseline simulator, which we validate with a real deployment.

1 Introduction

Causa Latet Vis Est Notissima – The cause is hidden, but the result is known. (Ovid: Metamorphoses IV, 287)

Trace-driven simulation is a widely used method for evaluating new ideas in systems. In contrast to full-system simulation (e.g., NS3 [31]), which requires detailed knowledge of system characteristics (e.g., topology, traffic patterns, hardware details, etc.), trace-driven simulation does not model all components of a system. Instead, it focuses on simulating one (or a few) components of interest, where we wish to experiment with an *intervention*, e.g., a new design,

algorithm, or architectural choice. To account for the effect of the remaining components that are not simulated, we collect a trace capturing their behavior and replay it while simulating the component of interest with the proposed intervention.

The key assumption here is that the interventions would not affect the trace being replayed, which we refer to as the *exogenous trace* assumption. If this assumption does not hold, replaying the trace is invalid and could lead to incorrect simulation results. This problem has been referred to as *bias* in trace-driven (or data-driven) simulation [15, 37].

It is difficult to guarantee the exogenous trace assumption in traces collected from real-world systems. Consider, for example, trace-driven simulation of adaptive bitrate (ABR) algorithms [35, 50, 63, 75]. It is common to use network throughput traces from real video streaming sessions on Internet paths [38, 75]. However, the throughput achieved when the player downloads a video chunk is caused by certain *latent* properties of the network path (e.g., the underlying bottleneck capacity, the number and type of competing flows, etc.), as well as the particular choices made by the ABR algorithm (the bitrate chosen for each chunk). In other words, the trace data reflects the combined effect of these two causes and is biased by the ABR algorithms used during trace collection. To simulate a new algorithm, we need to tease apart the effect of the two causes, and predict how the trace would have changed under the decisions of the new algorithm.

We present CausalSim, a causal framework for unbiased trace-driven simulation. CausalSim relaxes the *exogenous trace* assumption by explicitly modeling the fact that interventions can affect trace data. Using traces collected from a *randomized control trial* (RCT) under a fixed set of algorithms, it infers both the latent factors capturing the underlying conditions of the system and a causal model of its dynamics, including the unknown relationship between latents, algorithm decisions, and observed trace data. To simulate a new algorithm, CausalSim first estimates the latent factors at every time step of each trace. Then, it uses the estimated latent factors to predict the alternate evolution of the trace, actions, and observed variables of the component of interest, under the same latent conditions that were present when the trace was collected. This two-step process allows CausalSim to remove the bias in the trace data when simulating new algorithms.

*Equal contribution

CausalSim provides two benefits: (i) it improves the accuracy of trace-driven simulation when the intervention could affect (in possibly subtle ways) the trace data; (ii) it enables trace-driven simulation of systems where defining an exogenous trace is not possible and therefore standard trace-driven simulation is not applicable. We evaluate both settings in this paper, by simulating ABR and heterogeneous server load balancing algorithms as examples for cases (i) and (ii) respectively.

CausalSim requires training data from an RCT. Large network operators have increasingly invested in RCT infrastructure to evaluate new ideas, but due to their low throughput and risk of disruptions or SLA violations [42], they can afford to evaluate only a fraction of proposed ideas in RCTs. CausalSim greatly extends the utility of RCT data by learning a model that can simulate a wide range of algorithms using traces from a fixed set of algorithms. Periodically or whenever an operator believes the underlying system characteristics have changed significantly, they can collect fresh data using an RCT (again, with the same fixed set of algorithms) to retrain CausalSim.

CausalSim’s design begins with the observation that unbiased trace-driven simulation can be viewed as a matrix (or tensor) completion problem [9, 14]. Consider a matrix M of traces (it is a tensor if traces are higher dimensional), with rows corresponding to possible actions and columns corresponding to different time steps in the trace data. For each column, the entry for one action is “revealed”; all other entries are missing. Our task can be viewed as recovering the missing entries.

A significant body of work has shown that it is possible to recover a matrix from sparse observations under certain assumptions about the matrix and the pattern of missing data. Roughly speaking, the typical assumptions that make recovery feasible are that the matrix has low rank, the entries revealed are chosen at random, and that enough entries are revealed. Low-rank structure is prevalent in many real-world problems [69] and has also been observed in network measurement data [16, 43, 44, 60]. But unfortunately the other two assumptions do not hold in our problem. As we detail in §4.3, one observed entry per column is below the information-theoretic bound for low-rank matrix completion (even for rank $r = 1$). Moreover, not only are the entries revealed in our problem not random, they depend on other entries of the matrix, since the actions are being taken by algorithms based on observed variables.

To overcome these challenges, CausalSim exploits two key insights. First, it assumes a causal model (§3) where the latent factors are exogenous and are not affected by the interventions we want to simulate in the component of interest. This *exogenous latent* assumption relaxes (and is therefore implied by) the exogenous trace assumption in standard trace-driven simulation. For example, in ABR, it says that underlying factors like the bottleneck link speed on a network path are not affected by a user’s ABR algorithm, whereas ABR decisions can impact the trace that user *observes* (i.e., the achieved throughput).

Second, CausalSim uses a basic property of trace data collected via an RCT. Since the assignment of an algorithm

to a trace is completely random in an RCT, the distribution of latent factors should be the same for the traces obtained using different algorithms, i.e., the latent distribution is *invariant* to the algorithm. We provide conditions on the RCT data (e.g., in terms of the number and diversity of algorithms) that guarantee recoverability of the low-rank matrix using this invariance property (§4.2), and we operationalize this idea in a practical learning method that exploits the invariance using an adversarial neural network training technique (§5).

We evaluate CausalSim on two use cases, ABR and server load balancing, with both real-world and synthetic datasets, and further verify CausalSim’s predictions with a test in the wild on the Puffer [71] video streaming testbed. Our main findings are:

1. We use CausalSim to debug and improve an ABR algorithm, BOLA1 [53, 63]. In a ten month experiment on Puffer [71], BOLA1 exhibited high stalling compared to BBA [35], with slightly better quality. Using CausalSim, we tune BOLA1’s parameters via Bayesian Optimization and deploy our improved version on Puffer. We show that it improves the stall rate of this well-known algorithm by $2.6\times$, achieving $0.7\times$ the stall rate of BBA with similar perceptual quality. The expert-designed baseline simulator that ignores bias predicts the exact opposite: that the new variant should stall $1.34\times$ the stall rate of BBA. This case study shows that removing bias is crucial to draw accurate conclusions from trace-driven simulation.
2. Evaluation of CausalSim on more than ten months of real data from Puffer shows that CausalSim’s error in stall rate prediction is bounded to 28%, while expert-designed and standard supervised learning baselines have errors in the range of 49–68% and 29–187% respectively. Similar observations are also made for perceptual quality metrics and buffer occupancy levels.
3. CausalSim opens up new avenues to apply trace-driven simulation to systems where the exogenous trace assumption is invalid. Using a synthetic environment modeling a heterogeneous server load balancing problem, we show how CausalSim reduces average simulation error by $5.1\times$, a stark improvement compared to a baseline simulator with a median error of 124.3%.

This work does not raise any ethical issues. Our code is available at <https://github.com/CausalSim/Unbiased-Trace-Driven-Simulation>.

2 Motivation

2.1 Bias in Trace-Driven Simulation

Trace-driven simulation is a widely used technique to design and evaluate systems. Unlike full-system simulation, it focuses on simulating one (or a few) components of the system while capturing the effect of remaining components by replaying a trace. For example, to simulate new ABR algorithms, it is common to replay network throughput traces from real Internet

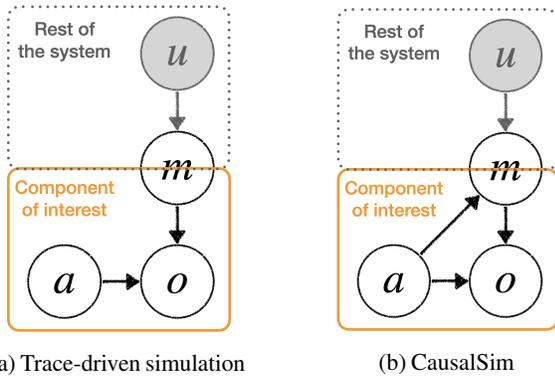

Figure 1: CausalSim relaxes the *exogenous trace* assumption in standard trace-driven simulation.¹

paths in a simulator modeling only the video player/server.

As we alluded to earlier, the key assumption here is that the interventions being simulated would not affect the trace being replayed; otherwise, replaying the trace would be invalid. We refer to this as the *exogenous trace* assumption, and it is central to standard trace-driven simulation. Figure 1a is a visual depiction of the exogenous trace assumption. In the figure, a represents the intervention we want to simulate; for example, the actions taken by a new algorithm. o is the observed state of the component being simulated. u represents the *latent* state of the rest of the system, which we do not observe or simulate. Finally, m is the trace, which captures the behavior of the other components.² The existence of each edge represents a causal effect. For example, the trace m and intervention a both affect o . Note the absence of the edge from a to m , which implies that the intervention cannot affect the trace (the exogenous trace assumption).

The simulator designer must define the trace carefully to meet this assumption. But what happens if it does not hold, i.e., there exists an edge from a to m (as in Figure 1b)? Ignoring the violation of *exogenous trace* assumption leads to biased simulation outcomes, as we will see next.

2.2 An Example Using Real-world Traces

In this section, we use more than ten months of real-world data from Puffer [71], a recently deployed system for experimenting with video streaming protocols, to illustrate the issue of bias in trace-driven simulation.

Puffer collects data from a continual Randomized Control Trial (RCT) that tests several Adaptive Bit Rate (ABR)

¹In general, a and u can be correlated. For example, they can both depend on prior latent conditions of the system. In ABR, for instance, recent latent path conditions are correlated with current path conditions (u), and also affect the action taken by the ABR algorithm (a). Correlation of a and u , however, does not imply a causal relationship between them. In particular, our model assumes *exogenous latents*, i.e. a does not affect u .

²Variables in Fig. 1a can be multidimensional and vary with time.

algorithms. In the period of interest (July 27, 2020 – June 2, 2021), the tested algorithms include Buffer-Based Algorithm (BBA) [35], two versions of BOLA-BASIC (henceforth called BOLA) [63]³, and two versions of an algorithm called Fugu developed by the Puffer authors. The dataset includes more than 56 million chunk downloads from more than 230 thousand streaming sessions, totaling 3.5 years of streamed videos. For each streaming session, it provides logs of the chosen chunk sizes, available chunk sizes, achieved chunk download throughputs, and playback buffer levels.⁴

Consider a typical trace-driven simulation scenario, where we wish to simulate a new ABR algorithm using traces from previous video streaming sessions. We define such a task on the Puffer data as follows. We let one of the algorithms, say BBA, be the algorithm that we wish to simulate. We leave out the data for this algorithm and ask whether it is possible to predict its performance using the other algorithms’ traces. In evaluating a new ABR algorithm, we may be interested in various performance measurements, e.g. buffer occupancy, rebuffering rate, chosen bitrates, etc. Here, we focus on predicting the behavior of playback buffer occupancy, which is one of the key indicators of an ABR algorithm’s behavior [35].

The goal of trace-driven simulation is to predict the trajectory of the system (e.g., buffer, bitrates, etc.) for one algorithm in *the same underlying conditions* that were present when a trace was collected using a different algorithm. When simulating algorithm B based on a trace collected using algorithm A , we will refer to A as the “source” algorithm and to B as the “target” algorithm.

It is generally not possible to evaluate the accuracy of individual simulated trajectories using real-world data, because we do not have ground truth trajectories for the target algorithm under the same exact network conditions that were present when running the source algorithm. However, since the Puffer data was obtained using an RCT, we can evaluate predictions about *distributional* properties of the target algorithm, such as the distribution of the buffer occupancy achieved by the algorithm over the population of network paths present in the RCT.

To summarize, our task is: *predict the distribution of the buffer occupancy for the users assigned to BBA (the target algorithm) in the Puffer dataset, using only the data from the other (source) algorithms.*

2.2.1 Simulation via Expert Modeling (ExpertSim)

As our first strawman, we build a simple trace-driven simulator (ExpertSim) using our knowledge of how an ABR system works. ExpertSim models the playback buffer dynamics for each *step*, where a step corresponds to one ABR decision and

³BOLA1 and BOLA2 are variations on BOLA adjusted to target the SSIM quality metric instead of bitrate [53]. They pursue different objective functions and use different principles for hyperparameter adjustment.

⁴We use ‘slow stream’ logs (by Puffer’s definition, streams with TCP delivery rates below 6Mbps) available on the Puffer website [1].

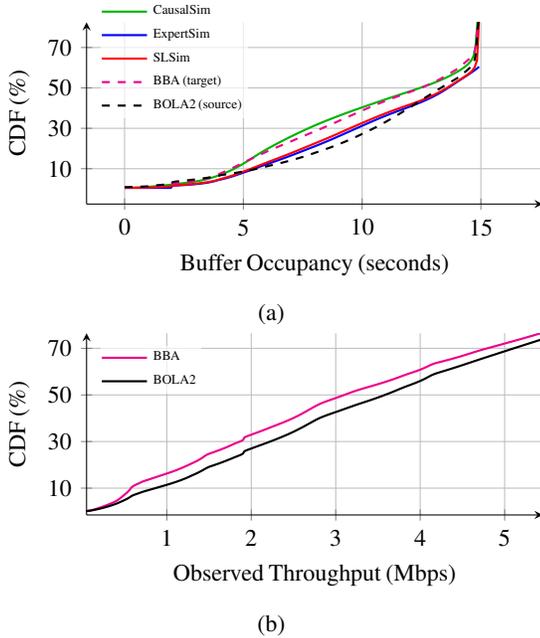

Figure 2: **(a)** CausalSim is accurate in predicting buffer level distribution of BBA users, while baseline simulators’ predictions are similar to BOLA2 users. **(b)** Distribution of achieved throughput is different in BBA and BOLA2 users.

the download of a single video chunk. Let \hat{c}_t be the throughput achieved in step t (for the t^{th} chunk) of a particular video streaming session using, say, the BOLA2 algorithm. To simulate BBA for the same user, ExpertSim assumes that the user would achieve the same throughput \hat{c}_t in each step under the BBA algorithm as well. In other words, it assumes that ABR decisions do not affect the observed network throughput (the exogenous trace assumption). Under this assumption, ExpertSim models the evolution of the video playback buffer as follows. Let b_t be the buffer level at the beginning of step t (before the download of chunk t), r_t be the bitrate chosen in step t , and s_t be the size of the t^{th} chunk implied by the chosen bitrate. Then the buffer at the end of step t is derived as: $b_{t+1} = \max(0, b_t - s_t / \hat{c}_t) + T$, where T is the chunk duration.⁵ Although simple, the assumption that throughput is an exogenous property of a network path is common in modelling ABR protocols. For example, both FastMPC [75] and FESTIVE [38] assume that the observed throughput does not depend on the chosen bitrate.

Figure 2a shows the true distribution of buffer level for BOLA2 and BBA users in the Puffer dataset (the two dashed lines), as well as the distribution *predicted* by running BBA on the traces collected from BOLA2 users using ExpertSim (solid blue line). The predictions are inaccurate: the buffer distribution generated by ExpertSim is more similar to the buffer distribution of BOLA2 users (the source algorithm) than the buffer distribution of BBA users (the target algorithm).

⁵The complete buffer dynamic equation is slightly more complex to handle cases with full buffers. Refer to §C.1 in the appendix for further clarification.

2.2.2 Simulation via Supervised Learning (SLSim)

Perhaps the simple model of buffer dynamics in ExpertSim does not accurately reflect the actual system behavior. As a next attempt, we turn to machine learning and try to learn the system dynamics from data. Specifically, we use supervised learning to train a Neural Network (NN) that models the step-wise dynamics of the system. This fully connected NN includes 2 hidden layers, each with 128 ReLU activated neurons. For each timestep t , the NN takes as input the buffer level before downloading the t^{th} chunk b_t , the achieved throughput \hat{c}_t for chunk t , and the chunk size s_t (which depends on the bitrate chosen by ABR). The NN outputs the download time of the t^{th} chunk, and the resulting buffer level b_{t+1} . We train the NN to minimize the prediction error on our dataset. To avoid information leaking, we exclude the logs for BBA from the training data.

Figure 2a shows the predicted buffer level distribution via this approach (SLSim) for BBA. As with ExpertSim, we use the traces collected from BOLA2 users as the source algorithm. The results are similar to ExpertSim; once again, the predicted buffer distribution is closer to that of BOLA2 than BBA.

2.2.3 What Went Wrong?

To understand the limitations of ExpertSim and SLSim, we plot the distribution of achieved per-chunk throughput for users assigned to BOLA2 and BBA in Figure 2b. Since algorithm selection is completely random, we would expect inherent network path properties such as bottleneck link capacity to have the same distribution for users assigned to different ABR algorithms. However, such an invariance should not be expected for achieved throughput, because even on the same path different ABR algorithms could achieve different throughput. For example, since congestion control protocols take time to discover available bandwidth (e.g., in slow start) or converge to their fair share rate when competing against other flows, an ABR algorithm that tends to choose lower bitrates (and hence download less data per chunk) may achieve less throughput than an ABR algorithm that picks higher bitrates [34, 64]. We can see this behavior in the Puffer dataset. The achieved throughput for BOLA2 and BBA is clearly different in Figure 2b.

This confirms that ABR algorithms cause a bias in the measured throughput traces, and the exogenous trace property does not hold. To perform accurate trace-driven simulation, we need to account for this bias when simulating new ABR algorithms.

2.3 Causal Inference to the Rescue!

If the traces were the *underlying network capacity* when each chunk was downloaded (rather than the achieved throughput), the exogenous trace assumption would hold and our problem would be simple. First, we would learn the relationship between network capacity and achieved throughput for different ABR actions using our data. Then, to simulate BBA for a given trace, we would start with the network capacity

at each step of the trace and predict the achieved throughput taking into account the bitrate chosen by BBA in that step. This would then allow us to predict how the buffer evolves. This works because unlike achieved throughput, underlying capacity is an exogenous property of a network path and is not affected by the ABR actions.

However, underlying network capacity is a *latent* quantity — we do not observe it in our traces. The key challenge is therefore to *infer* such latent quantities from observational data. Concretely, in our running example, we wish to estimate the latent factors like network capacity in each step of a trace, using observations such as the bitrate, the chunk size, the achieved throughput, etc.⁶

Inferring such *latent confounders* and using them for counterfactual prediction is the core issue in the field of causal inference [57, 58]. In this paper, we develop CausalSim, a causal framework for unbiased trace-driven simulation. CausalSim relaxes the exogenous trace assumption in trace-driven simulation. It explicitly models the fact that interventions can affect trace data (the edge from a to m in Figure 1b), and infers both the latent factors and a causal model of the system dynamics. This allows CausalSim to correct for the bias in trace data when simulating an intervention. As an illustration, Figure 2a shows the predicted buffer occupancy distribution when simulating BBA on the traces of users assigned to BOLA2, using CausalSim. CausalSim matches the ground-truth distribution for BBA much more accurately than the alternatives.

3 Model and Problem Statement

3.1 Causal Model

Consider the following discrete-time dynamical model⁷ corresponding to Figure 1b:

$$m_t = \mathcal{F}_{\text{trace}}(a_t, u_t), \quad (1)$$

$$o_{t+1} = \mathcal{F}_{\text{system}}(o_t, m_t, a_t). \quad (2)$$

Here, t denotes the time index, m_t is the trace, a_t is the intervention, u_t is the latent factor, and o_t is the observed state of the component of interest. The function $\mathcal{F}_{\text{trace}}$ models the effect of interventions on the trace (which traditional methods ignore), and $\mathcal{F}_{\text{system}}$ models the dynamics of the component of interest. When the intervention changes an algorithm in the component of interest, a_t can be viewed as the action taken by that algorithm at time t .

We assume that interventions do not affect the internal state of the rest of the system, i.e., that the latent factors are exogenous. This assumption is implicit in the dynamical system

⁶For simplicity, we only mention network capacity here, but other latent path conditions like the number of competing flows could also affect achieved throughput and the same reasoning applies to them.

⁷This model is similar to a special type of Partially Observable Markovian Decision Processes (POMDPs) in which the unobserved part of the state is exogenous [51].

equations, and also visualized in Figure 1b by the absence of the edge from a to u . Note that this is a strict relaxation of the exogenous trace assumption in standard trace-driven simulation. There, the trace itself is assumed to be unaffected by intervention, which also implies exogenous latent factors.

In our running ABR example, we want to simulate the video player and server (components of interest) without precisely modeling the entire network path (the rest of the system). Each time step t corresponds to the download of a new chunk, and u_t represents latent network conditions during that transmission, e.g., bottleneck link speed, number of flows sharing the same network path, type of congestion control used by competing flows, etc. At each time step, the ABR algorithm chooses a bitrate a_t , which together with u_t generate m_t , the *achieved* throughput when downloading a chunk. Typically, latent network conditions are exogenous factors, beyond the impact of a particular user’s actions. For instance, the bottleneck link speed and type of congestion control that competing flows use, are not affected by the actions of the ABR algorithm.

Note that the achieved throughput depends on the ABR action as well as the latent network conditions. Equation (1) captures this relationship and is the source of the bias induced by the ABR algorithm, which we demonstrated in §2.2.3.

When is the model applicable? The causal model applies in any trace-driven simulation setting where the trace may be impacted by interventions. Examples include:

- Job scheduling, where we wish to simulate a workload’s performance under different types of machines. The trace is the job performance (e.g., runtime), interventions are the scheduling decisions, and latent factors are intrinsic properties of each job (e.g., compute intensity) or latent aspects of the machines such as collocated interfering workloads.
- Network simulation, where we wish to simulate how some aspect of network’s design (e.g., congestion control, packet scheduling, traffic engineering, etc.) impacts application performance. The trace is an application’s traffic pattern, the intervention is the network design, and latent factors are the internals of the application that dictate its traffic demand.

In some cases, like our running ABR example, the exogenous trace assumption may not hold exactly but still be roughly valid.⁸ Here, CausalSim removes bias and improves simulation accuracy. But in certain problems, ignoring the effect of interventions is meaningless. For example, consider scheduling or load balancing on heterogeneous machines (e.g., with different hardware capabilities). Given a trace of job performance on specific machines, it isn’t possible to merely replay the trace for new machine assignments. In

⁸Even in these cases, these subtly biased simulations can produce entirely incorrect conclusions (§6.2).

such problems, CausalSim enables trace-driven simulation by explicitly modeling the effect of interventions on the trace.

When is the model invalid? Our causal model relaxes the exogenous trace assumption but still requires *exogenous latents*, i.e. that the latents are unaffected by the intervention. This won't hold in all systems. For example, we cannot model the effect of network routing policies (e.g., BGP) on observed video streaming throughput in this way, since changing the path would change the latent network conditions that impact a video stream. Another example is simulating the effect of a CPU feature like the branch predictor on instruction throughput. Here, we can't model the state of the instruction-/data caches as an exogenous latent factor, since changing the branch predictor can change their internal state significantly.

Overall, a simulation designer needs to reason about the causal structure of observed and latent quantities to define the appropriate model in the form of Equations (1) and (2). However, the designer does not need to precisely specify the meaning of the latents or the dynamics (the functions $\mathcal{F}_{\text{trace}}$ and $\mathcal{F}_{\text{system}}$). CausalSim learns both from observational data.

3.2 Problem Formulation

We are given N trajectories, collected using K specific policies.⁹ Let H_i be the length of trajectory $i \in \{1, \dots, N\}$. For trajectory i , we observe $(m_t^i, o_t^i, a_t^i)_{t=1}^{H_i}$. We assume that trajectories are generated using an RCT, i.e., that each trajectory is assigned to one of the K policies at random.

Our goal is to estimate the observations under an arbitrary given intervention (e.g., a new algorithm) for each of the N trajectories. Let $\{u_t^i\}_{t=1}^{H_i}$ be the exogenous latent factors for trajectory i . Formally, for any given trajectory i and given a sequence of actions $\{\tilde{a}_t^i\}_{t=1}^{H_i}$, starting with observation o_1^i and under the same sequence of latent factors $\{u_t^i\}_{t=1}^{H_i}$, we wish to estimate the counterfactual observations $\{\tilde{o}_t^i\}_{t=1}^{H_i}$ that are consistent with Equations (1) and (2).

This is a counterfactual estimation problem since it requires (i) estimating *latent* $\{u_t^i\}_{t=1}^{H_i}$ factors for observed trajectory i and using them along with the counterfactual actions $\{\tilde{a}_t^i\}_{t=1}^{H_i}$ to predict the counterfactual trace $\{\tilde{m}_t^i\}_{t=1}^{H_i}$ consistent with Equation (1), and then (ii) using the counterfactual trace and actions to predict counterfactual observations $\{\tilde{o}_t^i\}_{t=1}^{H_i}$ consistent with Equation (2).

For (ii), learning $\mathcal{F}_{\text{system}}$ is a supervised learning task because its inputs, (o_t^i, m_t^i, a_t^i) , and output, o_{t+1}^i , are fully observed. If $\{u_t^i\}_{t=1}^{H_i}$ was observed, then (i) would also boil down to learning $\mathcal{F}_{\text{trace}}$ in a supervised manner. *It is the lack of observability of $\{u_t^i\}_{t=1}^{H_i}$ that makes our simulation task extremely challenging. In short, we are left with (i), the task of estimating $\{\tilde{m}_t^i\}_{t=1}^{H_i}$ and learning $\mathcal{F}_{\text{trace}}$.*

⁹We use policy and algorithm interchangeably in this paper.

4 CausalSim: Theoretical Insights

This section describes the theory behind CausalSim. We discuss how to operationalize this theory in a practical learning algorithm in §5. We begin by casting counterfactual estimation as a challenging variant of the matrix completion problem [14]. We then formalize conditions that allow us to complete the matrix using a certain distributional invariance property that is present in data collected in an RCT.

4.1 Counterfactual Estimation as Matrix Completion

Recall from §3.2 the task of estimating the counterfactual trace $\{\tilde{m}_t^i\}_{t=1}^{H_i}$ consistent with Equation (1). In this section, we pose this task as a variant of the classical matrix completion problem. For simplicity, let action a_t^i be one of the finitely many options $\{1, \dots, A\}$ for some $A \geq 2$. Imagine an A by U matrix M , where rows correspond to A potential actions, and columns corresponds to $U = \sum_{i=1}^N H_i$ latent factors (u_t^i for different choices of i and t) in the dataset. To order the columns, we may index u_t^i as a tuple (i, t) and order these tuples in lexicographic order. The matrix M is called the potential outcome matrix in the causal inference literature [61].

At the t^{th} step of the i^{th} trajectory, we observe $m_t^i = \mathcal{F}_{\text{trace}}(a_t^i, u_t^i)$, which is the entry in M in the row corresponding to a_t^i and the column corresponding to u_t^i . The counterfactual quantities of interest, $\tilde{m}_t^i = \mathcal{F}_{\text{trace}}(\tilde{a}_t^i, u_t^i)$ for $\tilde{a}_t^i \neq a_t^i$, are the missing entries in M in the same column. In summary, we observe one entry per column of the matrix M and we wish to estimate the missing values in the matrix.

The task of filling missing values in a matrix based on its partially observed entries is known as *Matrix Completion* [19], a topic that has seen tremendous progress in the past two decades [18, 20, 47]. However, standard matrix completion methods do not apply to our problem (see §4.3 for details).

We use a distributional invariance property of data collected using an RCT to complete the potential outcome matrix M . The key observation is that, in an RCT, the latent factors for trajectories collected under each of the policies will have the same distribution. For example, in Puffer's RCT, incoming users are assigned to an ABR algorithm at random. Therefore each ABR algorithm will "experience" the same distribution of underlying latent network conditions, which is precisely why we can compare their performance in the RCT. The same property helps us recover the matrix M , as we show next.

4.2 Exploiting RCT for Matrix Completion

We use a minimal non-trivial example to give intuition about how we can exploit an RCT for matrix completion, before stating our main theoretical result.

Consider a simple example where $A = 2$ and $U = 2n$, and the rank of potential outcome matrix M is equal to 1. Rank 1

implies that $M = au^T$ for some $a \in \mathbb{R}^2$ and $u \in \mathbb{R}^{2n}$ with $M_{\alpha,\beta} = a_\alpha \cdot u_\beta$.¹⁰ Suppose we have $K = 2$ policies, where each policy always chooses only one of the two actions. Furthermore, we consider an RCT setting. That is, the distribution of latent factors across trajectories assigned to both policies should be the same.

Without loss of generality, we can re-order the columns of M so that the first n columns correspond to the latent factors of the trajectories assigned to policy 1, and the second n columns are those assigned to policy 2. Then the observed entries of matrix M appear as

$$\begin{bmatrix} M_{1,1} & M_{1,2} & \dots & M_{1,n} & \star & \dots & \star & \star \\ \star & \star & \dots & \star & M_{2,n+1} & \dots & M_{2,2n-1} & M_{1,2n} \end{bmatrix}$$

where \star represents the missing values.

Let us consider recovering the missing observation $M_{2,1}$. For column 1, we know the observation under the first action, i.e. $M_{1,1}$. Due to rank 1 structure, we have

$$\frac{M_{2,1}}{M_{1,1}} = \frac{a_2 u_1}{a_1 u_1} = \frac{a_2}{a_1}. \quad (3)$$

Therefore, to find $M_{2,1}$ (and by a similar argument, to find all missing entries of M), we need to estimate the ratio $\frac{a_2}{a_1}$.

Due to the distributional invariance induced by RCT, the samples u_1, \dots, u_n (which correspond to the latent factors encountered by policy 1) come from the same distribution as the samples u_{n+1}, \dots, u_{2n} (which correspond to the latent factors encountered by policy 2), for large enough n . Thus, their expected value should be equal:

$$\frac{1}{n} \sum_{\beta=1}^n u_\beta \approx \frac{1}{n} \sum_{\beta=n+1}^{2n} u_\beta \quad (4)$$

Equation (4) implies

$$\frac{\sum_{\beta=1}^n M_{1,\beta}}{\sum_{\beta=n+1}^{2n} M_{2,\beta}} = \frac{\sum_{\beta=1}^n a_1 \cdot u_\beta}{\sum_{\beta=n+1}^{2n} a_2 \cdot u_\beta} \approx \frac{a_1}{a_2}. \quad (5)$$

This provides precisely the quantity of interest in Equation (3) based on the observed entries, enabling us to complete the matrix.

Formal Result. This simple illustrative example relied on a convenient observational pattern (based on policies that always choose one action) and rank 1 structure. But the idea can be generalized. If the trace includes D measurements, $M_{\alpha,\beta,\gamma} \in \mathbb{R}^{A \times U \times D}$ becomes a tensor rather than a matrix, where α , β , and γ index the actions, latent factors, and measurements, respectively. The following theorem provides conditions where completion is possible for a rank r tensor. For more details and the proof, refer to Appendix A.

Theorem 4.1. *We can recover all entries of M by only observing one D -dimensional element in each column (corresponding to one latent and action) if the following is satisfied:*

¹⁰Note that for readability, we are abusing notation by overloading a and u to refer to both the action and latent, and their encodings in the factorization.

1. **(Low-Rank Factorization)** M is a low-rank tensor (rank = r), i.e., it admits the following factorization: $M_{\alpha,\beta,\gamma} = \sum_{\ell=1}^r a_{\alpha\ell} u_{\beta\ell} z_{\gamma\ell}$.
2. **(Invertibility)** The factorization implies existence of a linear mapping from latent encoding to trace for each action. This linear mapping is invertible.
3. **(Sufficient measurements)** $D \geq r$.
4. **(Sufficient, Diverse Policies)** The number of policies $K \geq Ar$, and the matrix $\mathbf{S} \in \mathbb{R}^{Ar \times K}$ is full-rank where $\mathbf{S}_{w,D:(w+1),D,x} = \mathbb{E}[m | \text{action_index} = w, \text{policy_index} = x] \mathbb{P}(\text{action_index} = w | \text{policy_index} = x)$. Linear independence of columns of \mathbf{S} can be interpreted as diversity among policies (Appendix A).

4.3 Discussion

Why not standard tensor completion? Tensor completion methods [26, 41, 48, 78] make several assumptions. First, the tensor M must be (approximately) low rank, which CausalSim also requires. Low-rank structure holds in many real-world problems [69] and has been observed in network measurements, e.g., in traffic matrices [16, 43, 44, 60] and network distance (i.e., RTT) [46, 52, 66]. As an example of how it emerges in the problems we study in this paper, we use a simple model of congestion control in Appendix C.4 to provide intuition about low-rank structure in ABR data.

Second, the pattern of missing entries should be *random*. If the missing patterns is not random and depends on latent factors or the entries themselves [8], standard approaches have difficulty recovering the tensor. This assumption does not hold in trace-driven simulation. Revealed entries are determined by the actions taken by the policies, which often use recent observations to make their decisions (e.g., an ABR policy may use recent throughput measurements). Hence the revealed/missing entries in a column are not random and depend on the entries in previous columns.

Third, a sufficient number of entries need to be revealed. For example, when $D = 1$ (i.e., when M is a matrix), the information theoretic lower bound to on the number of revealed entries needed to recover M is $4Ur - r^2$ [39, 70]. Thus even for rank $r = 1$, it requires 4 entries per column, whereas only one entry per column is revealed in trace-driven simulation.

Since the second and third assumptions do not necessarily hold in our setup, we cannot use *existing* tensor completion methods. However, as we argued in §4.2, exploiting the additional problem structure imposed by RCT data can make tensor completion feasible in certain conditions.

Limitations of Theorem 4.1. The proof of Theorem 4.1 (Appendix A) provides an analytical method for recovering the tensor M that generalizes the procedure described for the simple example in §4.2. While this provides a theoretical basis for why tensor recovery is possible, the analytical approach is not practical. First, it relies on M being exactly rank r ; if it is approximately rank r , we have found the calculation to be

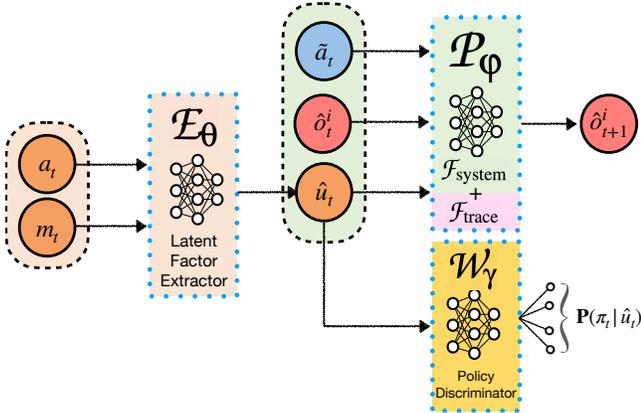

Figure 3: CausalSim Architecture

brittle. Second, it applies only to discrete action spaces. Third, it gives sufficient conditions for recovery, but they’re not all necessary. One reason is that the analytical method uses only *mean* invariance, i.e. the fact that the mean of the latent factors is the same across all policies (as in Eq. (4)), even though RCT data has the stronger property that the entire *distribution* of latents does not depend on the policy. In the next section, we describe our practical implementation of CausalSim that uses learning techniques and NNs to overcome these limitations (at the expense of theoretical guarantees).

5 CausalSim: Algorithm

CausalSim builds upon the insights presented earlier but replaces the factorized model with a learning algorithm based on NNs. For ease of notation, we will drop the trajectory index for all variables in the dataset, e.g. we will refer to the latent factor $u_t^i : t \leq H, i \leq N$ as $u_t : t \leq H$.

CausalSim architecture. As discussed, CausalSim aims to extract u_t and learn $\mathcal{F}_{\text{trace}}$ and $\mathcal{F}_{\text{system}}$ from observed trajectories $(o_{t+1}, o_t, m_t, a_t) : t < H$. Figure 3 summarizes CausalSim’s algorithmic structure.

To extract latent factors, we use a NN that takes in a_t and m_t , and computes \hat{u}_t (an estimate of u_t). To apply invariance on the extracted latents, i.e. distribution of u_t being the same regardless of the policy applied to it, we use a NN called the *Policy Discriminator*. This NN aims to predict the policy pertaining to that sample given \hat{u}_t , and if invariance is upheld, it will fail to do so. Unlike the analytical approach, the policy discriminator can enforce policy invariance on the entire latent distribution, potentially improving the accuracy of the estimate.

To calculate the counterfactual traces and observations, we need to learn $\mathcal{F}_{\text{trace}}$ and $\mathcal{F}_{\text{system}}$. However, we can simplify the learning problem by merging these two into one single combined function. Thus, we use a NN that takes in counterfactual actions \tilde{a}_t , observation o_t and estimated latent \hat{u}_t , and computes counterfactual observation \tilde{o}_{t+1} . Of course, we can explicitly use separate NNs for $\mathcal{F}_{\text{trace}}$ and $\mathcal{F}_{\text{system}}$ if we require

access to the simulated trace (\tilde{m}_t) values.

Overall, CausalSim uses three NNs for counterfactual simulation; \mathcal{E}_θ as the *latent factor extractor*, \mathcal{W}_γ as the *policy discriminator* and \mathcal{P}_φ as the combination of $\mathcal{F}_{\text{trace}}$ and $\mathcal{F}_{\text{system}}$. Figure 3 depicts the structure. Training these NNs is quick; on an A100 Nvidia GPU, CausalSim’s time to convergence on 56M data points (230K streams) was less than 10 minutes, and each simulation step in inference (on CPU) takes less than 150 μ s. A full inference run on the same volume of data takes less than 6 hours on a single CPU core and less than 20 minutes on 32 cores.

Training procedure. CausalSim’s training procedure alternates between: (i) training the policy discriminator using a discrimination loss $\mathcal{L}_{\text{disc}}$; and (ii) training other modules using an aggregated loss $\mathcal{L}_{\text{total}}$. Algorithm 1 provides a detailed pseudo code of this training procedure.

Training the policy discriminator (Lines 5–10 in Algorithm 1). Distributional invariance means restricting the distribution of latent factors u to be identical across policies. To that end, we first use \mathcal{E}_θ to extract latents \hat{u}_t , and then search for invariance violations via a *discriminator* NN, a standard approach in the paradigm of adversarial learning [29, 68]. Specifically, the policy discriminator aims to predict the policy π_t that took action a_t from the estimated latent factor \hat{u}_t (see Figure 3). Towards that, we use a cross-entropy loss to train the policy discriminator:

$$\mathcal{L}_{\text{disc}} = \mathbb{E}_B[-\log \mathcal{W}_\gamma(\pi | \hat{u})], \quad (6)$$

where the expectation is over the a sampled minibatch B from dataset D . We train the policy discriminator to minimize this loss, by repeating gradient decent num_disc_it times, as the

policy discriminator needs multiple iterations to catch up to changes in the latent factors.

Training simulation modules (Lines 11–17 in Algorithm 1).

In this step, we need to impose consistency with observations, all while preserving the distributional invariance. Thus, we compute latent factors \hat{u}_t with \mathcal{E}_θ and simulate the next step of the trajectory \hat{o}_{t+1} with \mathcal{P}_ϕ . We use an aggregated loss to enforce consistency and invariance. This loss combines the negated discriminator loss with a quadratic consistency loss using a mixing hyper-parameter κ .

$$\mathcal{L}_{\text{total}} = \mathbb{E}_B \left[(o_{t+1} - \hat{o}_{t+1})^2 \right] - \kappa \mathcal{L}_{\text{disc}}, \quad (7)$$

where the expectation is over the a sampled minibatch B from dataset D . Here, we used a quadratic loss function, but one could use any consistency loss fit to the specific type of variable (e.g. Huber loss, Cross entropy, ...).

Note the negative sign of discriminator loss, which means we train these NNs to maximize discriminator loss i.e., fool the discriminator to ensure policy invariance. If the extracted latent factors are policy invariant, the policy discriminator should do no better at its task than guessing at random.

Counterfactual estimation. To produce counterfactual estimates, as described above, the estimated latents \hat{u}_t are extracted from observed data. Using the extracted latents factors, along with the learned combined function \mathcal{P}_γ , we start with o_1 and predict counterfactual observations \hat{o}_{t+1} , one step at a time.

6 Evaluation

We evaluate CausalSim’s ability to do accurate counterfactual simulation (§6.1 and §6.3) using trace data from one real-world and one synthetic dataset. As a rigorous proof of concept, we debug and improve an ill-performing ABR policy with CausalSim (§6.2), and verify it through deployment on a public ABR testing infrastructure. Our baselines are as follows:

1. *ExpertSim*: Uses the analytical model described in §2.2.1.
2. *SLSim*: Uses a standard supervised-learning technique to learn system dynamics from data, as described in §2.2.2.

Finally, we show how CausalSim enables trace-driven simulation in problems where defining an *exogenous trace* is not straightforward and traditional trace-driven simulation is not applicable (§6.4). Further supporting experiments in the appendix provide more details about how CausalSim operates (§B.1, §B.2, §B.3, §B.4, §B.5, §B.7, §C.2, §C.3, §C.4 and §D.1).

6.1 Simulation Accuracy

We use CausalSim to predict the end performance of ABR policies, and compare them with ground truth data. We explore the same two metrics reported by Puffer to evaluate algorithms; 1) stall rate, which is the fraction of time a user spent rebuffering, i.e. paused and waiting for a new chunk

to download; 2) average Structural Similarity Index Measure (SSIM) in decibels, which is a perceptual quality metric. Our ground truth data comes from public logs of ‘slow streams’ on Puffer. Whenever a client initiates a video streaming session in Puffer’s website, a random ABR algorithm is chosen and assigned to that session. Sessions are logged (buffer levels, chunk sizes, timestamps, download times, etc) anonymously and the data is available for public use. Our dataset contains more than 230K trajectories from an RCT during July 2020 to June 2021, where five ABR algorithms (BBA, BOLA1, BOLA2, Fugu-CL, Fugu-2019) were evaluated. Exhaustive details of the setup and data can be found in §B.8.

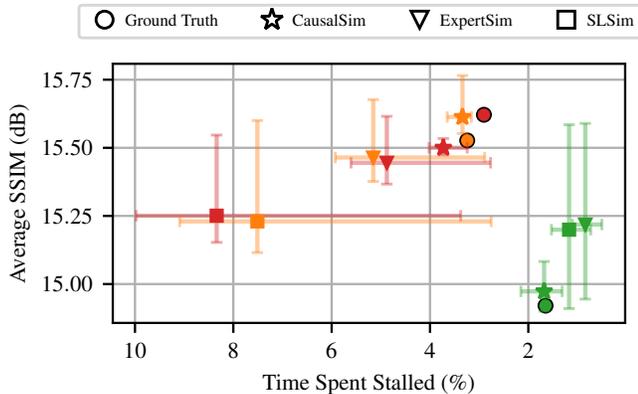

6.1.1 Can CausalSim simulate a policy it has not seen?

We choose one of BBA, BOLA1, and BOLA2¹¹ as the new policy that we want to simulate, and call it the *target* policy. The remaining four policies are called *source* policies. Traces assigned to the four source policies comprise our training dataset, which we use for training CausalSim and the two baselines. The goal is to simulate the outcome of applying the target policy on trajectories assigned to any of the source policies.

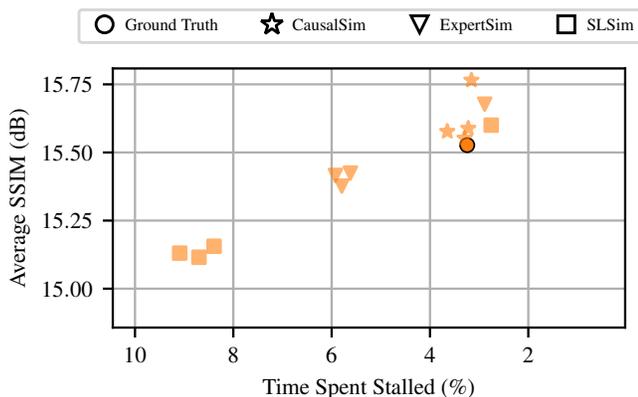

Figure 4a plots the stall rate and SSIM in the simulated trajectories and ground truth, denoting each target policy with a different color. Four source policies give us four separate predictions per target policy and simulator. Each point depicts the average of these four predictions, and the intervals show the minimum and maximum among the four. For either metric, CausalSim is the most faithful to ground truth among all simulators. For instance, in stall rate, CausalSim’s relative error spans 2 – 28%, while ExpertSim spans 49 – 68% and SLSim spans 29 – 187%. CausalSim may not always predict the correct relative ordering among policies with close performance. For example, BOLA1 and BOLA2 (shown in orange and red) have similar performance in both stall rate and SSIM. CausalSim predicts that these policies are similar but it infers their relative ordering incorrectly. However, CausalSim avoids the large errors made by the baseline simulators. In absolute terms, its predictions are close to the ground truth.

CausalSim also has the most consistent predictions across different **source** policies, because it removes the biases of the source policies. As an example, we investigate all four simulation results for BOLA1 in Figure 4b. SLSim and ExpertSim’s simulation results are only good when the source algorithm is BOLA2 (a similar algorithm to BOLA1 performance-wise). However, their predictions are far off from the ground truth for the other three source algorithms. CausalSim’s simulation results, on the other hand, are all close to the ground truth target. Appendix §B.7 demonstrates the same observation for other target algorithms, i.e. BBA and BOLA2.

¹¹We exclude Fugu as a test policy since we could not reproduce its logged actions (see §B.8).

(a)

(b)

Figure 4: **(a)** In a real-world dataset of live video streaming, CausalSim is the most faithful, compared to traditional trace-driven (ExpertSim) or data-driven (SLSim) simulators. Colors indicate different **target** ABR algorithms. **(b)** Predictions for BOLA1, separated by the source policy. Each point indicates a different **source** ABR algorithm. ExpertSim and SLSim predictions carry over biases of the source data, while CausalSim mitigates the bias.

6.2 Case Study: CausalSim in the Wild

An accurate simulator allows researchers to debug and improve protocols without repeated and invasive deployments. We shall demonstrate this with CausalSim, by improving a well-known ABR policy, and verifying our findings with a real-world deployment on Puffer.

Recall that in the particular RCT we used in §6.1, five ABR algorithms (BBA, BOLA1, BOLA2, Fugu-CL, Fugu-2019) were evaluated. Figure 5 shows the result of this evaluation for BBA, BOLA1 and BOLA2, across ‘slow streams’.¹² Similar to Figure 4a, the X-axis shows the stall rate, and the Y-axis is the average SSIM. BOLA1 exhibited 82% more rebuffering compared to BBA. A revised version of BOLA1, called BOLA2, was deployed alongside it, since the Puffer

¹²The data for this plot comes directly from Puffer [2, 3].

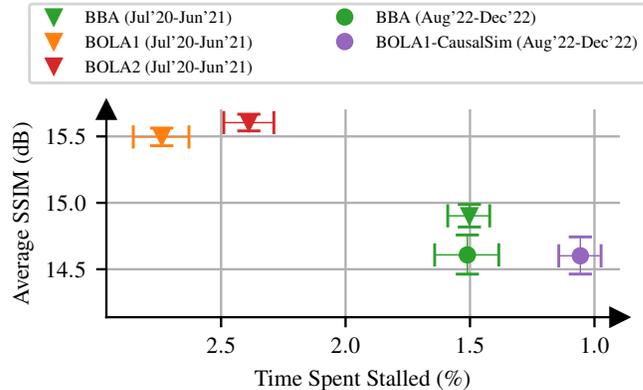

Figure 5: In an experiment preceding this work, BOLA1 exhibits high stalling. By deploying a BOLA1 variant in a later experiment CausalSim improved the stall rate by 2.6 \times , with comparable quality to BBA. User population is ‘slow streams’ and error bars denote 2.5%–97.5% confidence intervals.

team and the authors of BOLA believed the SSIM metric (in decibels) is incompatible with the protocol [53]. This new version had 12.8% less rebuffering and slightly higher quality, but still far too much stalling compared to BBA.

BOLA1 is an ABR policy with two hyperparameters, similar to BBA, and our hypothesis was that BOLA1 uses sub-optimal hyperparameters. To investigate this, we used the logged data pertaining to that plot along with CausalSim to exhaustively analyze the performance of BOLA1 and BBA for a range of hyperparameters. Using Bayesian Optimization¹³, we explored the parameter space and created a Pareto frontier curve for each policy. During this process, we evaluated over 150 different algorithms in two days, which is achievable only in a simulator. Each curve demonstrates the trade-off between quality and stall rate in that policy. Figure 6 presents the curves, where the left and right plots show CausalSim and ExpertSim predictions. For ease of comparison, we highlight where the original BOLA1 and BBA lie. CausalSim confirms our suspicion; the curve for BOLA1 is strictly better than that of BBA. We can revise the hyperparameters in BOLA1 for an improved BOLA1 variant, henceforth called ‘BOLA1-CausalSim’. We chose BOLA1-CausalSim, such that it would have better stall rate and marginally better SSIM compared to BBA.

Interestingly, ExpertSim predicts the complete opposite. It predicts that not only will BBA always improve on any BOLA1 variant in at least one metric, but also that any BOLA1 variant will stall more. This serves as a great opportunity to test CausalSim’s edge compared to traditional (biased) trace-driven simulation, which is used in prior work [38, 50, 75]. The results of BOLA1-CausalSim’s deployment can be seen in Figure 5. Considering confidence intervals, it is clear that it stalls less than BBA; in fact, BBA stalls 43% more than BOLA1-CausalSim on average. The confidence intervals for

¹³We use a Gaussian Process prior with a Matern Kernel [54].

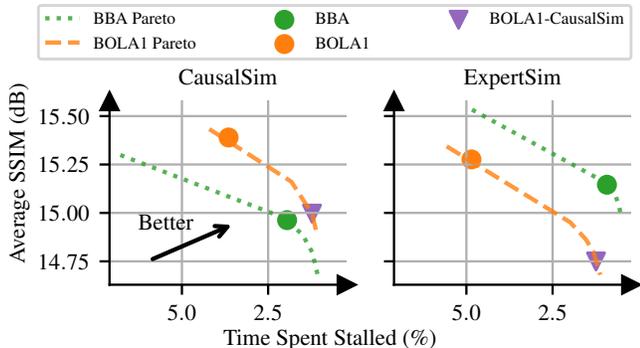

Figure 6: Pareto frontier curves for BOLA1 and BBA variants. **CausalSim correctly predicts BOLA1’s potential**, while ExpertSim fails to do so.

quality are wide and will need more data to be separable¹⁴, but based on the ongoing trend, BOLA1-CausalSim will have similar quality compared to BBA.

Our goal was to show CausalSim’s potential, and for that we targeted one of several plots on Puffer (‘slow streams’). We could have chosen a different plot to optimize on, but it would not affect the takeaway. Note that our opportunities for deployment on Puffer are limited, as other researchers use Puffer as well; hence we only deployed one BOLA1 variant. Furthermore, we hoped to also compare CausalSim’s prediction of stall rate and quality with the deployment results, but the client and network population has clearly changed; as shown in Figure 5, BBA achieves a different SSIM value for the two periods of time. Since CausalSim’s predictions are based on data from the previous RCT, directly comparing the predicted values to results from the new RCT isn’t meaningful. However, as our results show, the old RCT data allows us to compare different schemes. For example, CausalSim predicts BBA stalls 58% more than BOLA1-CausalSim on network distribution of the old RCT, which is reasonably close to the 43% observed in the new RCT (ignoring confidence intervals).

6.3 A Closer Look at Simulated Trajectories

For a deep dive in simulator accuracy, we focus on buffer occupancy level, a key indicator of ABR algorithm behavior. Ideally, we would like to compare simulated trajectories to ground truth. But this isn’t possible using real trace data, since it requires us to have multiple traces of different policies running under the exact same underlying path conditions. To overcome this issue, we resort to distributional evaluation. Puffer data is collected in an RCT setting; hence the characteristics of network paths assigned to each policy is the same. If we accurately simulate the target policy on traces assigned to one of the source policies, the distribution of each variable (e.g.

¹⁴Updated plots can be found on the ‘Experimental Results’ page of the Puffer website [1], under “Current experiment, full contiguous duration, slow streams only”.

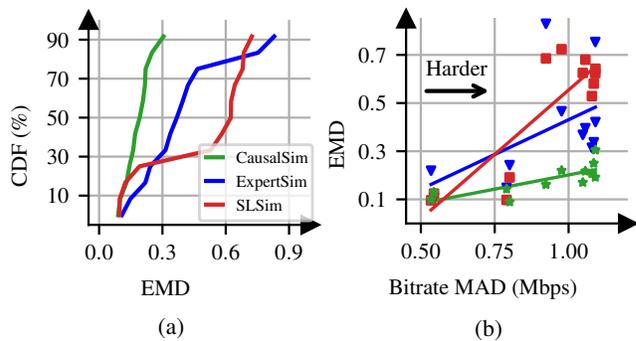

Figure 7: On average, CausalSim improves the EMD distance metric compared to ExpertSim and SLSim by 53% and 61% respectively. (a) Distribution of CausalSim, ExpertSim, and SLSim EMDs over all possible source/target choices. (b) Error (EMD) increases for baseline as simulation scenarios get harder, but CausalSim maintains good accuracy.

buffer level) must be similar in the simulated trajectory and ground truth trace assigned to the target policy. This motivates using distributional similarity as our performance metric.

To quantify the similarity of two distributions, we use the Earth Mover Distance (EMD) [62]. We can calculate EMD for one-dimensional distributions as $EMD(\mathcal{P}, \mathcal{Q}) = \int_{-\infty}^{+\infty} |\mathcal{P}(x) - \mathcal{Q}(x)| dx$, where \mathcal{P} and \mathcal{Q} are the Cumulative Distribution Function (CDF)s of p and q , respectively. A small EMD between two distributions implies that they are similar.

Figure 7a shows the CDF of the EMD (between actual and simulated buffer level distributions) for CausalSim and baselines, over all possible source/target policy pairs. EMD of CausalSim is smaller than EMD of baselines across almost all experiments. In terms of the average EMD across all experiments, CausalSim bests ExpertSim and SLSim by 53% and 61% respectively. Figure 2a visualized differences in buffer level distributions for the simulation scenario where BOLA2 and BBA are source and target policies, respectively. To observe buffer level distributions for all scenarios, refer to Figure 9.

In about 30% of cases, SLSim is slightly better than CausalSim. These cases are “easy” simulation scenarios where the source and target policies make similar actions (For more details see §B.3). In these cases, the EMD is low for both CausalSim and baseline simulators (< 0.15), and all perform well. For instance, Figure 9c (in the Appendix) shows source, target, and simulated buffer level distribution in an easy scenario, where BOLA2 and BOLA1 are the target and source policies respectively. In this example, all simulated distributions match the target distribution quite well.

Figure 7b shows where CausalSim most shines, i.e. hard simulation scenarios. The Y-axis is the error (EMD), and the X-axis is the mean absolute difference (MAD) between actions taken by the source policy and the target policy, in SLSim simulation. The larger the action difference, the harder the scenario (§B.3). As we move toward harder scenarios, the error increases

significantly for the baselines, while CausalSim is more robust.

6.3.1 Additional experiments

We perform further evaluations of CausalSim in the ABR environment. Due to space constraints, we summarize these results here and defer details to the appendix.

A more fine-grained evaluation. In the results above, we evaluated the performance of CausalSim and baselines using the distribution of buffer occupancy across the whole population. One way to further validate the results is to test whether they will hold on carefully partitioned sub-populations. In §B.4, we show that this is indeed the case when the sub-populations are partitioned according to the Min Round Trip Time (RTT), a network property that is independent of the selected ABR algorithm in Puffer.

Hyperparameters tuning. Counterfactual estimation (§3.2) is inherently an Out of Distribution (OOD) prediction task. Hence, typical supervised-learning hyper-parameter tuning methods do not work. In §B.5, we describe and evaluate CausalSim’s hyper-parameter tuning procedure.

Ground truth evaluation. Real data never comes with ground truth counterfactual labels. As a result, we cannot evaluate CausalSim’s simulations for each time step in real data, but we can do this in a reproducible synthetic environment. In §C.2, we evaluate CausalSim using ground truth counterfactual labels and show that it still outperforms baselines in the Mean Absolute Percentage Error (MAPE) metric.¹⁵ Specifically, CausalSim achieves an MAPE of ($\sim 5\%$), which is significantly lower than both ExpertSim’s and SLSim’s ($\sim 10\%$).

6.4 A Second Example: Server Load Balancing

We now focus on simulating load balancing policies with heterogeneous servers, where defining an exogenous trace is not possible and therefore standard trace-driven simulation is not applicable. This example shows how CausalSim opens up new avenues in trace-driven simulation.

We use a synthetic environment which consists of $N = 8$ servers (and a queue for each) with different processing powers, a load balancer, and a series of jobs that need to be processed on these servers. Each job has a specific size which is unknown to the load balancer. Each server can process jobs at a specific rate $\{r_i\}_{i=1}^N$, which is also unknown to the load balancer. The load balancer receives jobs and must assign them to one of N servers. Assuming the k^{th} arriving job has size S_k and gets assigned to server a_k , the job processing time will be S_k/r_{a_k} . If this job is not blocked by some other job being processed, its latency will equal its processing time. If it is blocked, and the jobs ahead of it in the queue take T_k to be processed, the incurred latency is $S_k/r_{a_k} + T_k$.

¹⁵Let $\hat{\mathbf{p}} = \{\hat{p}_i\}_{i=1}^N$ and $\mathbf{p} = \{p_i\}_{i=1}^N$ denotes the vectors of predicted and ground truth quantity of interest, respectively. Then, MAPE is defined as $\text{MAPE}(\mathbf{p}, \hat{\mathbf{p}}) = \frac{100}{N} \sum_{i=1}^N \frac{|\hat{p}_i - p_i|}{p_i}$.

We generate a collection of 5000 trajectories each with 1000 steps and use 16 policies in the load balancer. For a detailed explanation of the policies, job size generation process, and server processing rates, refer to §D.2.

6.4.1 Experiment setup

The aim of this experiment is to evaluate whether we can simulate new unseen server assignment policies in this environment, using traces collected with other policies. Recall that while we observe the processing time of each job, the actual size of the job is not observed, i.e., it acts as the latent factor in this problem. For all simulators, we assume access to $\mathcal{F}_{\text{system}}$ (the queue model) and focus on the more challenging task of learning $\mathcal{F}_{\text{trace}}$ and estimating the counterfactual traces \hat{m}_i^t for $i \leq 5000$, and $t \leq 1000$. Algorithmically, this translates to enforcing consistency for the observed traces (m_i), rather than the observations (o_i) (see §5). The trace we collect is the processing time when using a *source* server assignment policy. To simulate a *target* server assignment policy, we need to estimate the processing time of a job on servers other than the one where its processing time was measured (without knowing either the job size or the server processing rates).

Standard trace-driven simulation assumes an exogenous trace (job processing time), but this is the same as assuming servers have equal processing rates. This contradicts the problem setup, and standard trace-driven simulation (analogous to ExpertSim in ABR) is not applicable to this problem. Thus, we compare CausalSim with *SLSim* simulations. SLSim (realized by an NN) takes as input the observed processing time and the target server, and its output is the processing time under the targeted server. However, the observed and target processing time are always the same in training data, and hence it is impossible for SLSim to learn the true dynamics (e.g., the server’s underlying processing power). CausalSim sidesteps this problem by explicitly estimating latent factors. For details regarding the network architecture and training details for both SLSim and CausalSim, refer to Table 8 in the appendix.

Performance Metric. We compare CausalSim and SLSim with the underlying ground truth using the MAPE metric.

6.4.2 Can CausalSim Faithfully Simulate New Policies?

As is done in the ABR case studies, we train CausalSim and SLSim models based on a dataset generated using all policies except one, which will be the target policy. We use the same hyper-parameter tuning approaches explained in §B.5 for CausalSim and §B.6 for SLSim. We carry out this evaluation on eight target policies. We evaluate the performance for each pair of source-target policies, as was done in §6.1. In total, we have 120 different source/target policy pairs.

In Figure 8a and Figure 8b, we show the CDF of the MAPE of estimating the processing time and the latency, respectively, using both CausalSim and SLSim. As evident in these two figures, CausalSim’s error is significantly lower than that of

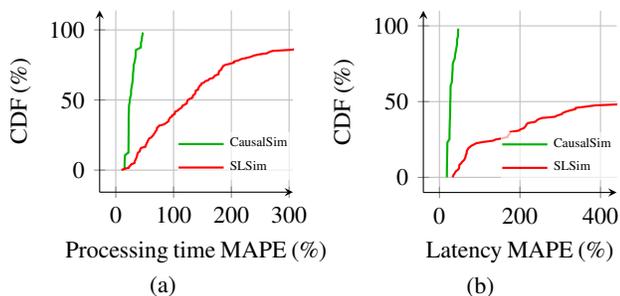

Figure 8: Distribution of CausalSim and SLSim MAPEs over all source target pairs.

SLSim for both the processing time and latency. In particular, the median MAPE when estimating processing time/latency is 24.4%/27.0% for CausalSim and 124.3%/467.8% for SLSim. For a complementary view, we compare the latent factors CausalSim extracts to the real latent job sizes and observe how closely they match, in §D.1 in the appendix.

7 Related-Work

Data-driven simulation. Traditional packet-level simulators [21, 31, 45] tend to sacrifice either scalability or accuracy when simulating large networks. MimicNet [77] and DeepQueueNet [73] use machine learning to improve simulation speed of datacenter networks. The aforementioned approaches are all full-system packet-level simulators, whereas CausalSim focuses on trace-driven simulation of a specific system component and must therefore deal with latent factors and biases present in trace data.

A very recent work, Veritas [17] (published on arXiv in Aug. 2022), models trace-driven simulation for ABR as a Hidden Markov Model (HMM) with a known emission process. This is equivalent to assuming that $\mathcal{F}_{\text{trace}}$ is known in our model (see Eq. (1)). Veritas uses the Viterbi algorithm to decode the latent factors, which are then used for counterfactual simulation. CausalSim solves a more general problem where $\mathcal{F}_{\text{trace}}$ is not known and must be learned. It therefore requires less knowledge of the system’s latents and underlying dynamics to apply. On the other hand, CausalSim requires RCT data whereas Veritas does not. Comparing the fidelity of these approaches using real-world ABR data would be interesting future work (Veritas evaluates its method in a network emulator).

Panthon’s calibrated emulators [72] model the end-to-end behaviour of a network path with a simple model including a handful of parameters, e.g., bottleneck link rate, constant propagation delay, etc., which are tuned to fit a collection of packet traces collected from this path using a variety of congestion control protocols. iBox [13] extends this approach by modeling cross-traffic. CausalSim does not assume any known model for the dynamics of the network. Furthermore, it has access to only a single trace from each network path.

Policy evaluation. Policy evaluation techniques such as

Inverse Propensity Scoring [33] and Doubly Robust [15] aim to predict population-level performance statistics for a given intervention. WISE [67] builds a Causal Bayesian Network from the data that is able to answer interventional (what-if) queries about the future, but the method requires absence of latent confounding variables. Sage [25] uses a Causal Bayesian Network model with latent factors to diagnose performance issues in microservice applications. It answers what-if questions about how interventions like changing the resources allocated to a microservice impacts the end-to-end application latency. Trace-driven simulation is distinct from all these methods, in that it requires counterfactual predictions of how an intervention would have changed specific previously-measured trajectories rather than how it changes population-level statistics.¹⁶

8 Concluding Remarks

The exogenous trace assumption is central to traditional trace-driven simulation. CausalSim relaxes this key assumption, by modeling the intervention effect on the trace and learning to replay the trace in an unbiased manner. We showed how this improves the accuracy of trace-driven simulation using real-world ABR data, and how CausalSim provides insights for algorithm improvement that are in contrast with standard trace-driven simulators’ predictions, which we validated in a real-world deployment. Furthermore, we showed how this expands the applicability of trace-driven simulation to problems where defining an exogenous trace is not possible by applying it to heterogeneous server load balancing. We believe CausalSim could be applied to many other system simulation tasks.

CausalSim opens up several interesting paths for future work. First, evaluating CausalSim in problems with a higher-dimensional latent factors would be interesting. Second, it is a natural next step to use CausalSim for more complex policy optimization methods, e.g., using reinforcement learning. Last, as discussed in §4.3, our theoretical analysis of CausalSim’s approach, i.e. exploiting the policy invariance of latent factors distributions, is not tight, and improving it could potentially relax the assumptions of our analytical method.

9 Acknowledgement

We thank our shepherd Keith Winstein for in-depth suggestions, and our reviewers for insightful comments. We thank the Puffer team, specifically Emily Marx and Francis Y. Yan for providing us with the data we used in §6.1 and the algorithm deployment in §6.2. This work was supported by NSF grants 1751009 and 1955370, an award from the SystemsThatLearn@CSAIL program, and a gift from Intel as part of the MIT Data Systems and AI Lab (DSAIL). A. Alomar and D. Shah were supported in part by DSO-Singapore project, MIT-IBM project on Causal representation learning and NSF FODSI project.

¹⁶Appendix E provides a broader overview of the causal inference literature.

Appendix A Tensor Completion with policy invariance

Here, we discuss a more generic version of the problem considered in §4.2 from the lens of tensor completion. Specifically, in §4 we considered the simplified setting where the trace was considered to be one-dimensional. Here, we shall consider higher dimensional traces. This, naturally suggests using the lens of Tensor instead of Matrix completion. We will also discuss how higher dimensional trace can enable recovery of more complex system dynamics or models compared to the simple solution we discussed in §4 for rank 1 setup.

Potential Outcomes Tensor. As considered in §4 let all possible actions be denoted as $[A] = \{1, \dots, A\}$ for some $A \geq 2$. Let the trace be of D dimension. As before, we have N trajectories of interest with trajectory $i \in [N]$ being of length $H_i \geq 1$ time steps. As before, let $U = \sum_{i=1}^N H_i$.

Consider an order-3 tensor M of dimension $A \times U \times D$, where $M = [m_{\alpha\beta\gamma} : \alpha \in [A], \beta \in [U], \gamma \in [D]]$ with $m_{\alpha\beta\gamma}$ corresponds to the γ th co-ordinate of the D -dimensional trace corresponding to action $a_t = \alpha \in [A]$ when latent factor is $u_{i,t}$ with β corresponding to enumeration of (i,t) for some $i \in [N]$ and $t \leq H_i$. Recall that, as explained in Section 4, all possible $(i,t) : t \leq H_i, i \in [N]$ are mapped to an integer in $[U]$. We call this tensor M as the Potential Outcomes Tensor.

Indeed, if we know M completely, then we can answer the task of simulation or counterfactual estimation well since we will be able to estimate the mediator for each trajectory under a given possible sequence of counterfactual actions, and subsequently estimate the counterfactual observation (assuming we could learn the $\mathcal{F}_{\text{systems}}$).

We shall assume that there are $P \geq 1$ policies under which these traces were observed. In particular, each trajectory was observed under one of these P policies and the assignment of policy to the trajectory was done uniformly at random. Define $\Pi_p \subset [U]$ as collection of indices corresponding to trajectories $i \in [N]$ and their times $t \leq H_i$ where trajectory i was assigned policy p for $p \in [P]$. Let $U_p = |\Pi_p|$.

Tensor factorization, low CP-rank. The tensor M admits (not necessarily unique) factorization of the form: for any $\alpha \in [A], \beta \in [U], \gamma \in [D]$

$$m_{\alpha\beta\gamma} = \sum_{\ell=1}^r x_{\alpha\ell} y_{\beta\ell} z_{\gamma\ell}, \quad (8)$$

for some $r \geq 1$. For any tensor, such a factorization exists with r at most $\text{poly}(A, U, D)$.

Assumption 1 (low-rank factorization). We shall make an assumption that r is *small*, i.e. does not scale with A, U, D and specifically a small constant.

Assumption 2 (sufficient measurements). We shall assume that number of measurements per instance, D , is at least as large as the underlying rank r of the tensor M , i.e. $D \geq r$.

Distributional invariance and RCT. As before, we shall assume that the distribution of latent factors is the same across different policies due to random assignment of policies to trajectories in the setup of RCT. In the context of the tensor M , this corresponds to the distribution invariance of factors $y_{\beta\ell} \in \mathbb{R}^r$ over $\beta \in \Pi_p$ for any $p \in [P]$. Concretely, for any $p \neq p' \in [P]$ and $\ell \in [r]$, we have

$$\frac{1}{U_p} \sum_{\beta \in \Pi_p} y_{\beta\ell} \approx \frac{1}{U_{p'}} \sum_{\beta' \in \Pi_{p'}} y_{\beta'\ell}. \quad (9)$$

More generally, any finite moment (not just first moment or average) of latent factors should be empirically invariant across policies. As in §4, we would like to utilize property (9) to estimate the tensor M .

A Simple Estimation Method and When It Works. We describe a simple method that can recover entire tensor as long as rank $r \leq D$. For simplicity, we shall assume $r = D$ (the largest possible rank for which method will work). By (8), for a given fixed $\alpha \in [A]$ and across $\beta \in [U], \gamma \in [D]$,

$$m_{\alpha\beta\gamma} = \sum_{\ell=1}^r y_{\beta\ell} \tilde{z}_{\gamma\ell}^{\alpha}, \quad (10)$$

where $\tilde{z}_{\gamma\ell}^{\alpha} = x_{\alpha\ell} z_{\gamma\ell}$. Since $D = r$, the matrix $\tilde{Z}^{\alpha} = [\tilde{z}_{\gamma\ell}^{\alpha} : \gamma \in [D], \ell \in [r]]$ is a square matrix. With this notation, we have that for any fixed $\alpha \in [A]$, the matrix $M^{\alpha} = [m_{\alpha\beta\gamma} : \beta \in [U], \gamma \in [D]] \in \mathbb{R}^{U \times D}$ (or $\mathbb{R}^{U \times r}$ since $r = D$) can be represented as

$$M^{\alpha} = Y \tilde{Z}^{\alpha,T}, \quad (11)$$

where $Y = [y_{\beta\ell} : \beta \in [U], \ell \in [r]] \in \mathbb{R}^{U \times r}$.

Assumption 3 (invertibility). We shall assume that the $D \times D$ (i.e. $r \times r$) square matrices \tilde{Z}^{α} for each $\alpha \in [A]$ are full rank and hence invertible.

The Assumption 3 implies that $Y = M^{\alpha} (\tilde{Z}^{\alpha,T})^{-1}$ for all $\alpha \in [A]$.

For policy $p \in [P]$, indices $\beta \in \Pi_p$ are relevant. For a given $\beta \in \Pi_p$, if the policy p utilized action $\alpha \in [A]$, $m_{\alpha\beta} \in \mathbb{R}^D$ is observed. To that end, let $\Pi_{p,\alpha} = \{\beta \in \Pi_p : \text{policy utilized action } \alpha\}$. Let $U_{p,\alpha} = |\Pi_{p,\alpha}|$ for any $\alpha \in [A]$. Then, define $Y^{p,\alpha} = [y_{\beta\ell} : \beta \in \Pi_{p,\alpha}, \ell \in [r]] \in \mathbb{R}^{U_{p,\alpha} \times r}$, $M^{\alpha,p} = [m_{\alpha\beta\gamma} : \beta \in \Pi_{p,\alpha}, \gamma \in [D]]$. Then we have $Y^{p,\alpha} = M^{\alpha,p} (\tilde{Z}^{\alpha,T})^{-1}$.

Therefore, for any $\ell \in [r = D]$,

$$\begin{aligned} \sum_{\beta \in \Pi_{p,\alpha}} y_{\beta\ell} &= \mathbf{1}^{p,\alpha,T} Y^{p,\alpha} \mathbf{e}_{\ell} \\ &= \mathbf{e}_{\ell}^T Y^{p,\alpha,T} \mathbf{1}^{p,\alpha} \\ &= \mathbf{e}_{\ell}^T (\tilde{Z}^{\alpha})^{-1} M^{\alpha,p,T} \mathbf{1}^{p,\alpha}, \end{aligned} \quad (12)$$

where $\mathbf{1}^{p,\alpha} \in \mathbb{R}^{U_{p,\alpha}}$ is vector of all 1s, and $\mathbf{e}_{\ell} \in \mathbb{R}^r$ be vector with all entries 0 but the $\ell \in [r]$ th co-ordinate 1.

Then, for any $\ell \in [r]$ and $p \in [P]$,

$$\begin{aligned}
\frac{1}{U_p} \sum_{\beta \in \Pi_p} y_{\beta\ell} &= \frac{1}{U_p} \sum_{\alpha \in [A]} \sum_{\beta \in \Pi_{p,\alpha}} y_{\beta\ell} \\
&= \frac{1}{U_p} \sum_{\alpha \in [A]} \mathbf{e}_\ell^T (\tilde{\mathbf{Z}}^\alpha)^{-1} M^{\alpha,p,T} \mathbf{1}^{p,\alpha} \\
&= \sum_{\alpha \in [A]} \mathbf{e}_\ell^T (\tilde{\mathbf{Z}}^\alpha)^{-1} \left(\frac{1}{U_p} M^{\alpha,p,T} \mathbf{1}^{p,\alpha} \right) \\
&= \sum_{\alpha \in [A]} \mathbf{e}_\ell^T (\tilde{\mathbf{Z}}^\alpha)^{-1} \mathcal{M}^{\alpha,p}, \tag{13}
\end{aligned}$$

where $\mathcal{M}^{\alpha,p} = \frac{1}{U_p} M^{\alpha,p,T} \mathbf{1}^{p,\alpha} \in \mathbb{R}^{r,1}$ is an observed quantity, while $\tilde{\mathbf{Z}}^{\alpha,T}$ is unknown. Using (13) and (9), we obtain that for any $\ell \in [r]$ and $p \neq p' \in [P]$,

$$\sum_{\alpha \in [A]} \mathbf{e}_\ell^T (\tilde{\mathbf{Z}}^\alpha)^{-1} \mathcal{M}^{\alpha,p} \approx \sum_{\alpha \in [A]} \mathbf{e}_\ell^T (\tilde{\mathbf{Z}}^\alpha)^{-1} \mathcal{M}^{\alpha,p'}. \tag{14}$$

Let $\tilde{z}^{\alpha,\ell} = \mathbf{e}_\ell^T (\tilde{\mathbf{Z}}^\alpha)^{-1} \in \mathbb{R}^{1,r}$ be the ℓ th row the of $r \times r$ matrix $(\tilde{\mathbf{Z}}^\alpha)^{-1}$. Then (14) implies that for any $\ell \in [r]$ and $p \neq p' \in [P]$,

$$\sum_{\alpha \in [A]} \tilde{z}^{\alpha,\ell} (\mathcal{M}^{\alpha,p} - \mathcal{M}^{\alpha,p'}) \approx 0. \tag{15}$$

Which can be written in matrix form as

$$[\tilde{z}^{1,\ell} \quad \tilde{z}^{2,\ell} \quad \dots \quad \tilde{z}^{A,\ell}] \begin{bmatrix} \mathcal{M}^{1,p} - \mathcal{M}^{1,p'} \\ \mathcal{M}^{2,p} - \mathcal{M}^{2,p'} \\ \vdots \\ \mathcal{M}^{A,p} - \mathcal{M}^{A,p'} \end{bmatrix} = 0 \tag{16}$$

By noting that that this hold for all $\ell \in [r]$, and recalling that $\tilde{z}^{\alpha,\ell}$ is the ℓ -th row the of the $r \times r$ matrix $(\tilde{\mathbf{Z}}^\alpha)^{-1}$, we get,

$$\left[(\tilde{\mathbf{Z}}^1)^{-1} \quad (\tilde{\mathbf{Z}}^2)^{-1} \quad \dots \quad (\tilde{\mathbf{Z}}^A)^{-1} \right] \begin{bmatrix} \mathcal{M}^{1,p} - \mathcal{M}^{1,p'} \\ \mathcal{M}^{2,p} - \mathcal{M}^{2,p'} \\ \vdots \\ \mathcal{M}^{A,p} - \mathcal{M}^{A,p'} \end{bmatrix} = \mathbf{0}, \tag{17}$$

where $\mathbf{0}$ is a vector of zeros of size r . Note that the above is a system of r linear equations, with Ar^2 unknowns (recall that the $r \times r$ matrices $(\tilde{\mathbf{Z}}^\alpha)^{-1}$ are unknown for $\alpha \in [A]$). Let $\mathbf{Z} \in \mathbb{R}^{r \times Ar}$ and $\mathbf{v}^{p,p'} \in \mathbb{R}^{Ar}$ denote the first and second matrix in the left hand side, respectively, then (17) can be re-written as,

$$\mathbf{Z} \mathbf{v}^{p,p'} \approx \mathbf{0}. \tag{18}$$

By definition, $\mathbf{v}^{p,p'}$ is observed quantity for each $p \neq p' \in [P]$. Now if we consider $P-1$ equations produced by considering pair of policies $(1,2), (1,3), \dots, (1,P)$ in (18), by design they are

non-redundant linear equations. Let matrix $\mathbf{V} \in \mathbb{R}^{Ar \times P-1}$ be formed by stacking $\mathbf{v}^{1,2}, \dots, \mathbf{v}^{1,P}$ column-wise.

Furthermore, let us define $\mathbf{s}^p \in \mathbb{R}^{Ar}$ as $[\mathcal{M}^{1,p}, \dots, \mathcal{M}^{A,p}]^\top$. Define $\mathbf{S} \in \mathbb{R}^{Ar \times P}$ by stacking $\mathbf{s}^1, \dots, \mathbf{s}^P$ column-wise.

Assumption 4 (Sufficient, Diverse Policies). Let $P \geq Ar$ and the rank of $\mathbf{S} = Ar$.

Note that we can derive \mathbf{V} from \mathbf{S} by subtracting the first column from all other columns, and removing the first column. Thus, Under Assumption 4, the $+$ rank of \mathbf{V} is at least $Ar-1$. Further, given Assumption 3 which excludes the scenario $\mathbf{Z} = \mathbf{0}$, it follows that the rank of \mathbf{V} is $Ar-1$. As rank of \mathbf{V} is $Ar-1$, we can uniquely (up to scaling) recover \mathbf{Z} by solving for system of linear equation $\mathbf{Z}\mathbf{V} = \mathbf{0}$ as the null space of \mathbf{V} is of dimension 1.

Once we know \mathbf{z} , i.e. by undoing flattening, we obtain $(\tilde{\mathbf{Z}}^{\alpha,T})^{-1}$ for each $\alpha \in [A]$. Since for each policy $p \in [P]$ and $\alpha \in [A]$, $Y^{p,\alpha} = M^{\alpha,p} (\tilde{\mathbf{Z}}^{\alpha,T})^{-1}$ and we observe $M^{\alpha,p}$, we can recover $Y^{p,\alpha}$ and hence subsequently $Y \in \mathbb{R}^{U \times r}$.

By (11), we can now recover slice of tensor M , the M^α for each $\alpha \in [A]$, and hence we can recover entire tensor M as desired.

Interpretation of Assumption 4. Consider β^{th} Column of the matrix \mathbf{S} , i.e., $[\mathbb{E}[m^\top | i=1, \pi_\beta] \mathbb{P}(i=1 | \pi_\beta), \dots, \mathbb{E}[m^\top | i=A, \pi_\beta] \mathbb{P}(i=A | \pi_\beta)]^\top$ where i denotes the action index and β the policy index. This column is a vector of statistics associated with traces collected using policy β . Each element in this vector consists of two components: the first component is the conditional mean of the trace given a specific action, and the second element is the probability of taking this action. We interpret linear independence of each of these components for different policy vectors as policy diversity. For instance, think of the second component which captures probability vectors of different actions for each policy. Its linear independence across different policies roughly means that each policy should assign new probability vectors to different actions, and not a probability vector similar (linearly dependent) to that of previous policies. Also note that this assumption is not satisfied if an action is not taken by any of the policies which makes all elements of the corresponding row equal to zero.

Appendix B Real-world ABR

B.1 Comprehensive results

In Figure 7a, we presented a concise view of simulator fidelity, for an internal variable in ABR sessions called buffer occupancy level. Specifically, we considered the simulation of a target policy, given trajectories collected using a different source policy. We measured the error between buffer simulations and ground truth through EMD, a similarity index for distributions. For a complementary view, we provide the full distributions in Figure 9, for all simulators and ground truth for target and source policies. Below each plot, we also report the EMD of CausalSim predictions.

B.2 Policy Discriminator and Latent Invariance

The policy discriminator (\mathcal{W}_γ in Figure 3) described in §5 has the goal of predicting the source policy, given a latent factor generated by the latent factor extractor (\mathcal{E}_θ in Figure 3). Since our data is collected with an RCT, the true latent factor distribution should be indifferent to the source policy. Therefore, if the latent factor extractor generates the ground truth latent factors, the policy discriminator should not be able to predict the source policy accurately. In fact, even the optimal policy discriminator outputs the population share of each source policy (e.g. what fraction of the data comes from BBA) in the training data [28]. To assess this statement, we present the confusion matrix and population share of source data, for three left-out policies in Table 1. Each row corresponds to one source policy, and each column corresponds to the policy discriminator’s prediction of the source policy. We observe that predictions do not change noticeably with different source policies, and that they closely match the population share for each left-out policy. This demonstrates that the extracted latent features were indeed invariant to the source policy.

B.3 What makes a simulation scenario easy/hard?

In §6.3, we compared the accuracy of CausalSim, ExpertSim and SLSim, in a simulation task on real ABR data. We observed that in about 30% of scenarios, which we call *easy* scenarios, all simulators perform well. However, in about 70% of the source/target scenarios, which we call *hard* simulation scenarios, baseline predictions are highly biased towards the source distributions. In these hard scenarios, CausalSim is able to de-bias the trajectories and its predictions match the target distribution well, as observable in Figure 9.

So it is natural to wonder what makes a simulation scenario easy/hard? An easy simulation scenario happens when source and target policies take similar actions. Similar action means that the factual achieved throughput (of the source policy)

Table 1: Confusion matrix and population statistics for the policy discriminator with three left out policies.

is similar to the counterfactual achieved throughput (of the target policy). This is what both ExpertSim (explicitly) and SLSim (implicitly) assume for doing simulation. Making this assumption is the core reason their simulations are biased in hard cases, where source and target policies take different actions, as we discussed in detail in §2.2.3.

Figure 10 validates our reasoning for what makes a simulation scenario difficult. The X axis shows the Mean Absolute Difference (MAD) between source and simulation actions (bitrates) when simulating with SLSim in a specific

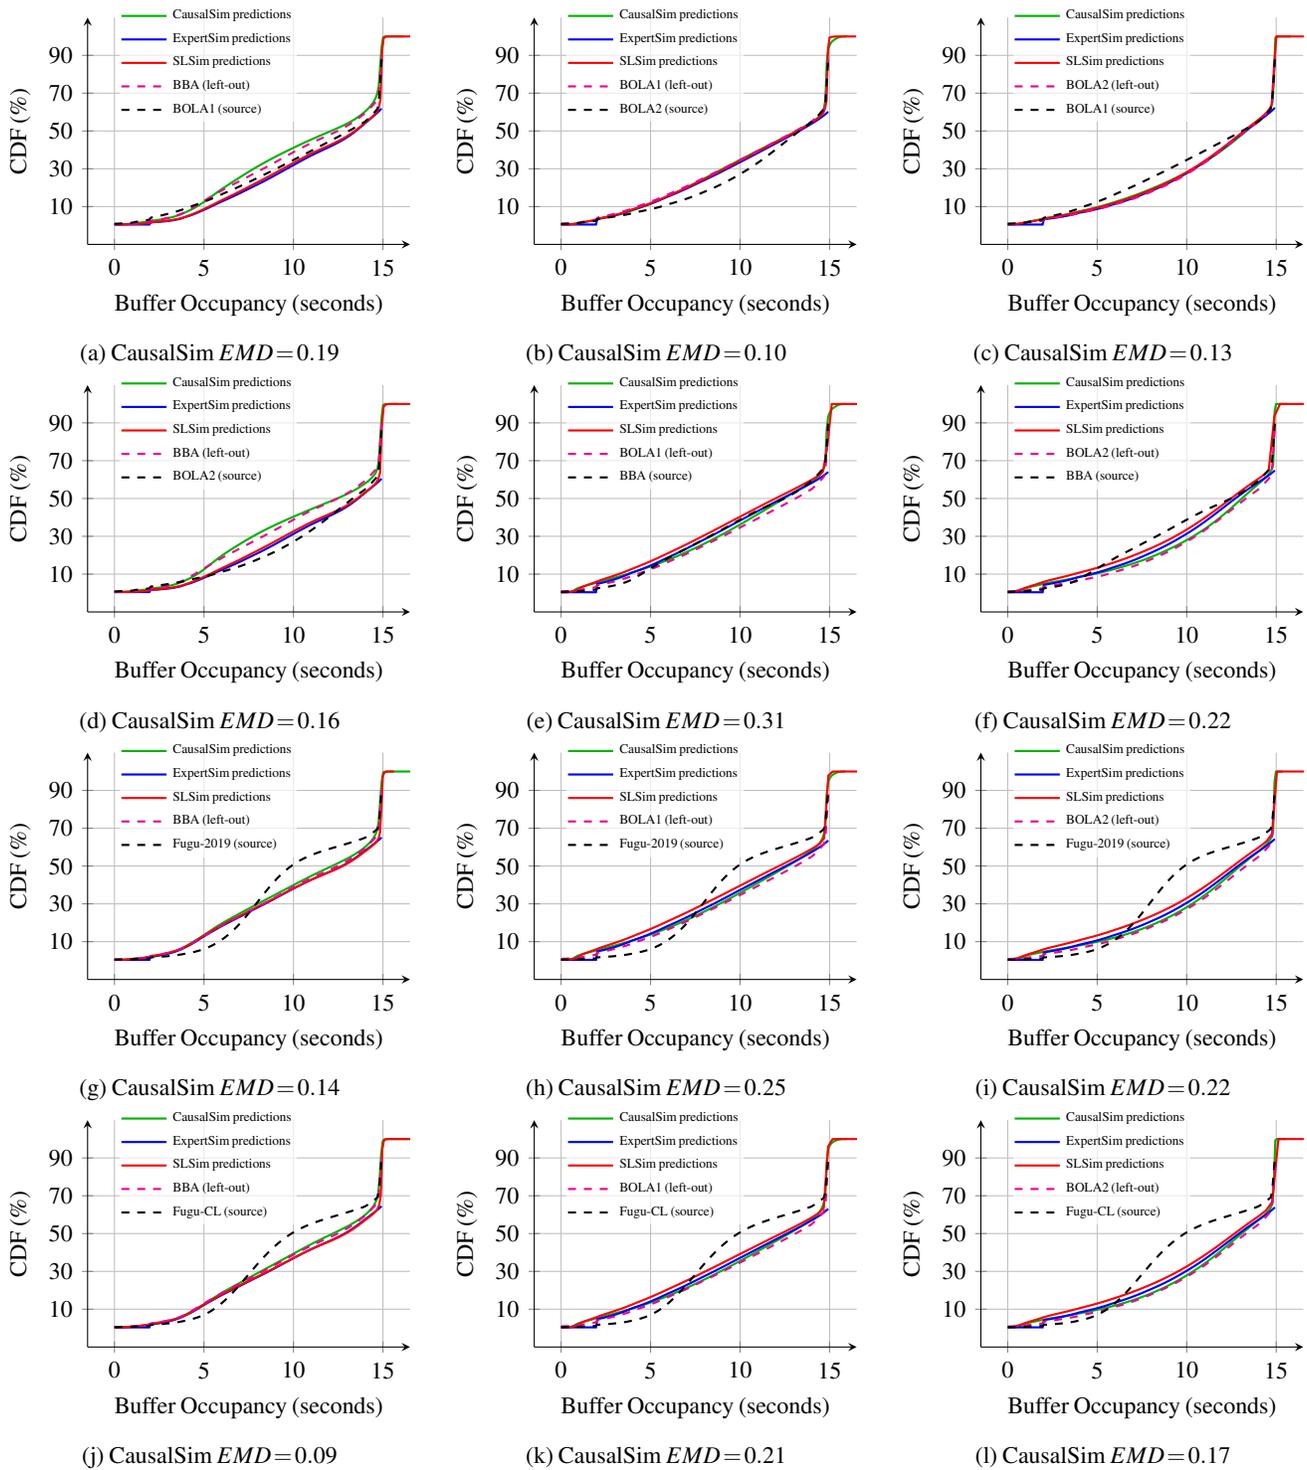

Figure 9: Buffer level distribution of source, target, CausalSim predictions, and baseline predictions across all source/target scenarios.

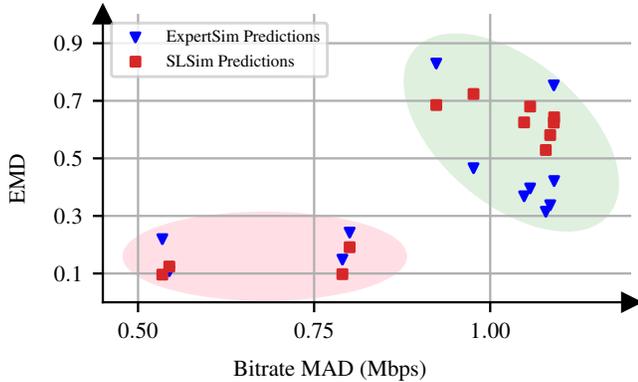

Figure 10: Simulation difficulty is related to how different counterfactual actions are from factual ones. This figure shows scatterplot of EMD versus mean absolute bitrate difference, for ExpertSim and SLSim, over all possible source left-out pairs. The pink cluster signifies the ‘easy’ scenarios and the green cluster signifies ‘hard’ ones.

source/target scenario. Y axis shows EMD (Our performance metric for simulation, smaller is better) of both baselines in that specific scenario.

Two main cluster of points are clearly visible in this figure. The pink cluster on the bottom left corresponds to easy simulations. It includes all source/target simulation scenarios where baselines perform well (bottom), and at the same time, source and target actions are quite similar (left).

The green cluster at the top right corresponds to the hard simulations. It includes all source/target simulation scenarios where baselines fail to perform an unbiased simulation (top), and at the same time, source and target actions are quite different (right).

B.4 A More Fine-grained Evaluation

Ideally, we would like to evaluate CausalSim’s simulation to ground truth on a step-by-step basis for a given trajectory. But as discussed in §6.3, this is not possible in real-world data, as we only see the outcome of one ABR algorithm’s chosen action for a single step. In other words, there is no way to get ground truth for individual steps in the observational data, which is referred to as the fundamental problem of Causal Inference [32]. This is the reason we evaluated predictions on a distributional level.

However, there is a way to evaluate CausalSim’s predictions at a more fine-grained level. Instead of evaluating the predicted distribution of buffer occupancy across the whole population, we can evaluate on certain *sub-populations* of users. The only requirement is that the way we select these sub-populations should be statistically independent of the ABR algorithm. For example, we can partition users by a metric such as Min RTT, which is independent of the policy chosen for each user in the

RCT. Min RTT is an inherent property of a network path¹⁷, and we would expect Min RTT distribution to be the same for users assigned to different ABR policies.

We use the MinRTT to create the following four sub-populations:

1. Sub1: users with $\text{Min RTT} < 35^{ms}$
2. Sub2: users with $35^{ms} \leq \text{Min RTT} < 70^{ms}$
3. Sub3: users with $70^{ms} \leq \text{Min RTT} < 100^{ms}$
4. Sub4: users with $100^{ms} \leq \text{Min RTT}$

Now, we can ask question of the following type: *had the users in sub-population two, who were assigned the source ABR algorithm, instead used the left-out ABR algorithm, what would the distribution of their buffer level look like?* As the ground truth answer to this question, we can use the buffer level distribution of users in sub-population two assigned to the left-out policy.

Figure 11a shows the CDF of CausalSim’s EMD when simulating the left-out ABR algorithm over each of the above sub-populations. We can see that CausalSim maintains a superior EMD CDF compared to ExpertSim and SLSim, and remains accurate across different sub-populations. This further suggests that even at surgically small subpopulations, CausalSim maintains accuracy, and does not overfit to the whole distribution.

B.5 How to Tune CausalSim’s Hyper-parameters?

Counterfactual prediction is not a standard supervised learning task that optimizes in-distribution generalization. Rather, it is always an OOD generalization problem, i.e., we collect data from a training policy (distribution 1), and want to accurately simulate data under a different policy (distribution 2). Since we do not use data from the test policy when we train CausalSim, we use the following natural proxy for tuning hyper-parameters: *Simulating ABR algorithms in the training data using trajectories of other ABR algorithms in the training data*. This of course can be viewed as an OOD problem as well. We claim that if a choice of hyper-parameters results in a robust model that performs well OOD across all validation ABR algorithms in the training data, it should work well for the actual left-out test policy as well.

We verify this hyper-parameter tuning procedure empirically. For each choice of the three left-out ABR algorithms (hence training dataset), we train eleven different CausalSim models with different choices of κ (defined in Equation (7)). We consider two metrics: (i) *Test EMD*, defined as the average EMD when simulating the left-out ABR algorithm with trajectories in the training dataset. This is our main performance objective. (ii) *Validation EMD*, defined as the average EMD when

¹⁷This is true to a first order approximation, if we ignore the possibility that a video streaming session drives up queueing delays throughout the course of a video, thereby inflating the observed Min RTT.

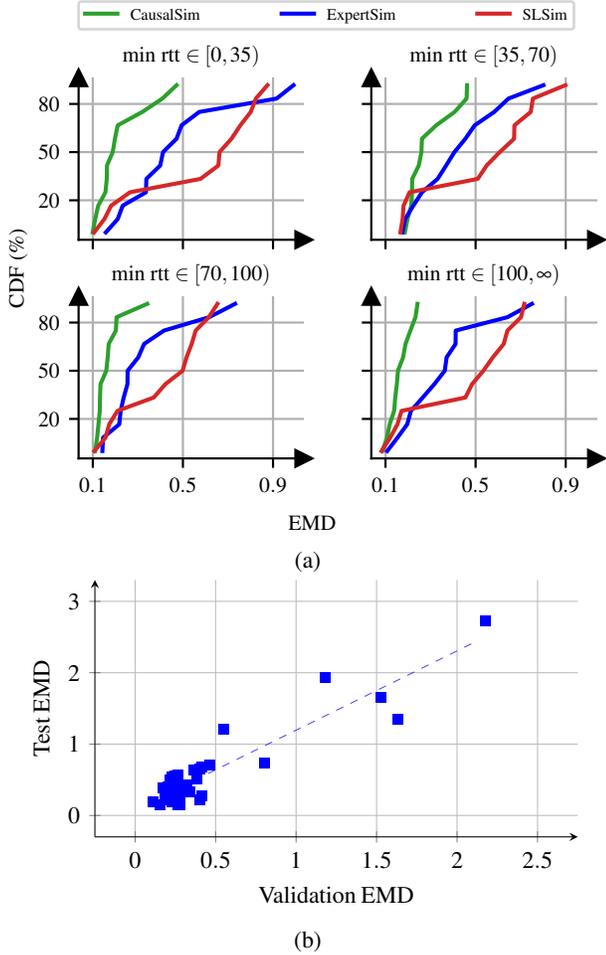

Figure 11: **(a)** Comparing the distribution of CausalSim EMDs with ExpertSim and SLSim over different sub-populations. **(b)** Validation EMD and test EMD are highly correlated. This justifies our hyper-parameter tuning strategy.

simulating ABR algorithms in the training dataset with trajectories in the training data that were collected with other ABR algorithms. This is our proxy objective for hyper-parameter tuning.

For each model (33 in all: 3 datasets, 11 example hyper-parameters), we calculate both Test EMD and Validation EMD, which results in one (Validation EMD, Test EMD) point in Figure 11b. The Pearson Correlation Coefficient (PCC) between Valid EMD and Test EMD is 0.92, which shows high linear correlation. Hence, though CausalSim might not always perform well (i.e., Test EMD is not low for some combinations of training dataset and hyper-parameters), we can have a very good idea of how well it works by measuring Validation EMD.

B.6 How to Tune SLSim’s Hyper-parameters?

SLSim takes as input the current buffer value, selected chunk size and observed throughput, and similar to CausalSim, predicts the next buffer \hat{b}_{t+1} and download time \hat{d}_t . We add two knobs to tune while training SLSim: **(1)** The loss function $\mathcal{L}_\xi(\cdot, \cdot)$ used to steer the NN output to the ground truth output, and **(2)** The relative weighting of the loss function for download time with respect to that of the buffer occupancy, η . Concretely, we use the following total loss:

$$\mathcal{L}_{\text{slsim}} = \mathbb{E}_B \left[\frac{1}{\eta+1} \cdot \mathcal{L}_\xi(\hat{b}_{t+1}, b_{t+1}) + \frac{\eta}{\eta+1} \cdot \mathcal{L}_\xi(\hat{d}_t, d_t) \right] \quad (19)$$

where the expectation is over the a sampled minibatch B from dataset D , and b_{t+1} and d_t denote the ground truth values for next buffer level and chunk download time. Table 3 lists the loss functions and η values considered.

To tune these values, we use ground truth data from all policies except a left out policy. We then proceed with the proxy tuning objective used in §B.5, i.e. we look for the configuration with the highest accuracy at simulating algorithms in the training data using trajectories of other algorithms in the training data. We then use the resulting configuration (and model) to simulate the left-out policy on the training data.

From the perspective of tuning, this methodology puts SLSim on equal ground with respect to CausalSim, and makes for a fair comparison. Note that we do not tune loss function type or η with CausalSim due to limited computational resources, but tuning those as well could potentially improve CausalSim’s accuracy.

B.7 Simulation Accuracy: Continued

In §6.1.1, we stated that ExpertSim and SLSim predictions are significantly affected by the source data they are simulating on, and demonstrated the effect of source policies on BOLA1 predictions in Figure 4b. Here, we demonstrate the same figure for BBA in Figure 12a and BOLA2 in Figure 12b. CausalSim is designed to remove the bias of the algorithm used for collecting source data when simulating a target policy and its predictions remains unaffected by the performance of that source policy. ExpertSim and SLSim however, due to the violation of the exogenous trace assumption, will predict different metrics when using different source traces.

B.8 Dataset & Algorithms

Our trajectories in the real-world (Puffer) data come from ‘slow streams’ in the time span of July 27, 2020 until June 2, 2021. In this period of time, 5 ABR algorithms appear consistently and are listed in Table 2. Each trajectory is an active client session streaming a live TV channel. We follow Puffer’s definition of

Policies	Hyperparameter	Value	Used as source	Used as left out
BBA	Cushion	3 (as used in puffer)	✓	✓
	Reservoir	10.5 (as used in puffer)		
BOLA-BASIC v1	V	0.67 (As computed in puffer)

	Minimum utility	0 (As used in puffer)		
	Maximum utility	1 (As used in puffer)		
Fugu-CL	-	-	✓	×
Fugu-2019	-	-	✓	×

Table 2: ABR algorithms used in the real-world dataset and experiments

‘slow streams’; streams with TCP delivery rates below 6 Mbps. We use ‘slow streams’ data, since the highest quality chunks rarely surpass 6–7 Mbps, and paths with higher bandwidth will always stream the highest quality chunks under all policies. Puffer uses the same reasoning and evaluates algorithms at two population levels; ‘slow streams’ and ‘all streams’.

In aggregating ‘slow stream’ logs, we met several difficulties that we outline here for reproducibility. Data without these difficulties would potentially improve CausalSim’s accuracy. Note that this does not affect Figure 5, as the data for that figure is reported directly on Puffer [2, 3].

Puffer logs are reported as three separate event groups; 1) ‘video_sent’: the first packet of a chunk is sent, 2) ‘video_acked’: The last packet of a chunk is acknowledged, 3) ‘client’: The client sent a message. Stall rate is computed using the ‘client’ logs and quality is computed using the ‘video_sent’ logs.

1. To compute download time, we have to merge ‘video_sent’ and ‘video_acked’, and ensure that merged logs are consecutive in timestamps, i.e. no chunk is missing in between two other chunks. However, in the current data this removes all chunks that have been sent but not acknowledged, usually the last chunk. Puffer uses these chunks in measuring quality level, but we can’t. This did not have any measurable impact, however.
2. To compute stall rate, both total stall time and total watch time are computed with ‘client’ logs. For this, the latest

report that obeys a set of rules is used. We, however, have to compute stall time and watch time using our merged logs (merged logs are also what we get out of simulation). This would be easy on the original data, if ‘client’ logs and ‘video_sent’ were in sync, but they are not; whenever a rebuffering is reported by the client, ‘client’ log is updated but ‘video_sent’ is updated in the next few chunks. To circumvent this, we recompute rebuffering as $t_r = \max(0, t_d - b)$, where t_r is rebuffering, b is buffer occupancy and t_d is download time. This formula is off by half of an RTT, and empirically inflates stall rates by 1.26–1.31x, for all policies. In the absence of synchronized data, this is the best we can recover, but it does not affect the comparison among policies. Hence, we believe simulating with this data should lead to similar trends as with clean unperturbed data.

3. We cannot calculate watch time as Puffer does, since we have to use the merged log. We tried several simple formulas that should calculate watch time, but oddly most turn out to be inaccurate. One reason is that in some streams, buffer playback rate is not 1, i.e. one second of buffer is not depleted per second. These streams are likely due to browser tabs put in background, and throttled by the browser threading system. As a workaround, we use the original watch time minus the original stall time that Puffer computed for a stream, and offset it by the total stall time in the simulation.

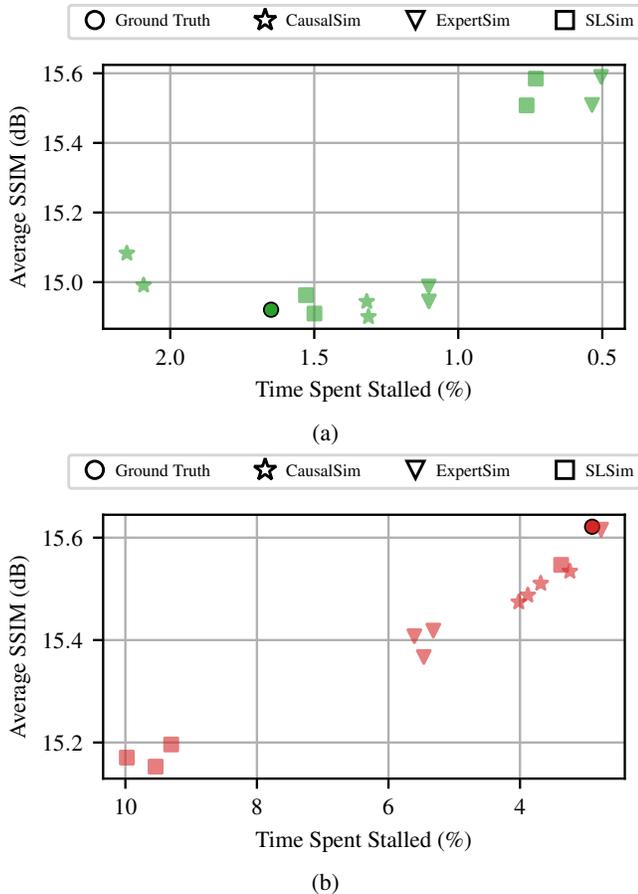

Figure 12: Predictions for (a) BBA and (b) BOLA2, separated by the ABR algorithm source data was collected with. Each point indicates a specific **source** ABR algorithm.

4. At each step, the buffer should not increase by more than a single chunk, 2.002 seconds, but it does (sometimes by as much as 14 seconds). We filter such data out.
5. When we are about to send a chunk, our last reported buffer value must never dip below 2.002 (except in the beginning). When buffer is below 15 seconds, the next chunk must be sent immediately after the last one. If rebuffering occurs, the next buffer value will be exactly 2.002 and if it doesn't, it will be larger than 2.002. We frequently (more than one million instances) observe buffer values below 2.002. We do not filter them out, as this would invalidate most logs.

To test out CausalSim, we need to simulate the streaming session using a different algorithm than the one that was actually used in that session. This requires implementation of the ABR algorithms. To ensure our implementations are correct, we attempt to reconstruct the choices made at runtime by each policy, and compare them to the logged choices. We expect our reproduction to match 100% when

our implementation is faithful and logs match runtime inputs. For the logs in July 27th, 2020, we observe 100% matching for BOLA1 and BOLA2 and 99.993% for BBA. For the latter, there are rare cases where two encodings are seemingly equal in SSIM up to the 6 logged decimal places, but were likely slightly different in double precision format at runtime. These instances are rare enough that we can ignore them.

For Fugu-2019 or Fugu-CL however, our reproductions did not match in 6% and 19% of cases, whether we used the original C implementation or our own Python port. The Puffer team informed us of a use-after-free issue regarding the Transmission Control Protocol (TCP) info struct that was fixed in March 7th, 2022. Hence we retried this process for the logs pertaining to July 27th, 2022 and the error rate shrank to 0.53% and 0.64%. Unfortunately, a 0.5% error rate is still too high and even if we ignore that, limits us to RCT logs after March 7th. Therefore, we do not consider Fugu-2019 or Fugu-CL as candidates for left-out algorithms.

B.9 Training setup

We use Multi Layer Perceptrons (MLPs) as the NN structures for CausalSim models and the SLSim model. All implementations use the Pytorch [56] library. Table 3 is a comprehensive list of all hyperparameters used in training.

Appendix C Synthetic ABR

As explained in §6.3.1, we also evaluate CausalSim in a synthetic ABR environment, in which we can obtain ground truth for individual counterfactual predictions on a step-by-step basis for a trajectory. In these experiments, we also use a larger set of policies than available in the real data.

C.1 Simulation Dynamics

In each simulated training session, we start with an empty playback buffer and a latent network path characterized by an RTT and a capacity trace. In each step, an ABR algorithm chooses a chunk size, which is transported over this network path to the client as the buffer is depleting. Once the user receives the chunk, the buffer level increases by the chunk duration. This simple system can be modeled as follows:

$$b_{t+1} = \min(b_t - d_t, 0) + c \quad (20)$$

where b_t , d_t and c refer to the buffer level at time step t , the download time of the chunk at time step t , and the chunk video length in seconds, respectively. Streaming the next chunk is started immediately following receiving the previous one, except when the buffer level surpasses a certain value (in our case, 10 seconds to mimic a live-stream ABR setting). To compute d_t , we model the transport as a TCP session with an Additive Increase - Multiplicative Decrease (AIMD)

Model	Hyperparameter	Value
SLSim (1 network), CausalSim (3 networks)	Hidden layers	(128, 128)
	Hidden layer Activation function	Rectified Linear Unit (ReLU)
	Output layer Activation function	Identity mapping
	Optimizer	Adam [40]
	Learning rate	0.001
	β_1	0.9
	β_2	0.999
	ϵ	10^{-8}
CausalSim	Batch size	2^{17}
	κ	{0.05, 0.1, 0.5, 1, 5, 10, 15, 20, 25, 30, 40}
	Training iterations (num_train_it)	5000
	num_disc_it	10
	Loss function	Huber($\delta=0.2$)
SLSim	η (download time weight wrt buffer)	1
	Training iterations	10000
	Loss function	{Huber($\delta=0.2$), L1, MSE}
	η (download time weight wrt buffer)	{0.5, 1, 10}

Table 3: Training setup and hyperparameters for the real-world ABR experiment

congestion control mechanism with slow start. For every chunk, the TCP connection starts from the minimum window size of 2 packets and increases the window according to slow start. Therefore, it takes the transport some time to begin fully utilizing the available network capacity. The overhead incurred by slow start depends on the RTT and bandwidth-delay product of the path. When downloading chunks with large sizes, the probing overhead is minimal but it can be significant for small chunks. Therefore, as we observed in the Puffer data, the throughput achieved for a given chunk in this synthetic simulation depends on the size of the chunk.

Performance Metric: We compare CausalSim predictions with ground truth counterfactual trajectories, via the Mean Squared Error (MSE) distance between the two time series:

$$MSE(\mathbf{p}, \mathbf{q}) = \|\mathbf{p} - \mathbf{q}\|_2^2 \quad (21)$$

Here, $\mathbf{p} = \{p_t\}_{t=1}^N$ and $\mathbf{q} = \{q_t\}_{t=1}^N$ are time series vectors. Better predictions yield smaller MSE values, where an ideal MSE is 0.

C.1.1 Data & Algorithms

Simulating a trajectory in our synthetic ABR environment needs three components:

- A video, with several bit-rates available. We use "Envivio-Dash3" from the DASH-246 JavaScript reference client [22].
- An ABR algorithm. We have a set of 9 policies to choose from, presented in Table 4.
- A network path, which is characterized by the latent network capacity and the path RTT.

We use random generative processes to generate 5000 network traces and RTTs. The RTT for a streaming session is sampled randomly, according to a uniform distribution:

$$rtt \sim Unif(10\text{ ms}, 500\text{ ms})$$

Our trace generator is a bounded Gaussian distribution, whose mean comes from a Markov chain. Prior work shows Markov chains are appropriate models for TCP throughput [65], and Gaussian distributions can model throughputs in stationary segments of TCP flows [49].

Concretely, at the start of the trace, the following parameters

Policies	Hyperparameter	Value	Used as source	Used as left out

 &\text{s.t. } \frac{h-l}{h+l} > 0.3 \\
 s_0 &\sim \text{Unif}(l, h) \\
 c_\sigma &\sim \text{Unif}(0.05, 0.3)
 \end{aligned}$$

At each time step, the state remains unchanged with probability $1-p$ and changes otherwise. When changing, the next state is sampled from a double exponential distribution centered around the previous state:

$$\begin{aligned}
 \lambda &= \text{solve}_{x \in \mathbb{R}^+} (1 - e^{x(h-s_{t-1})} - e^{x(s_{t-1}-l)} = 0) \\
 s_t &= \text{DoubleExp}(s_{t-1}, \lambda)
 \end{aligned}$$

The point for this specific transition kernel is that small changes in network capacity should be more likely than drastic changes.

Finally, the network capacity c_t in each step is sampled from a Gaussian distribution, defined by these parameters:

$$c_t \sim \text{Normal}(s_t, s_t \cdot c_\sigma)$$

C.1.2 Training setup

Similar to the real-world ABR experiment, we use MLPs as the NN structures for CausalSim models and the SLSim model. We tune all the hyperparameters of both baselines as is done in the real-world ABR experiment (see §B.5 and §B.6). Table 5 comprehensively lists all hyperparameters used in training.

C.2 Can CausalSim Faithfully Simulate New Policies?

Similar to our real-data evaluations, we train models based on training data generated using all policies except a left-out policy, for which the model does not observe any data. Although

Model	Hyperparameter	Value
CausalSim (4 networks)	Hidden layers (SLSim)	(128, 128)

SLSim	Training iterations	20000
	Loss function	{Huber($\delta=1.0$), L1, MSE}

Table 5: Training setup and hyperparameters for the synthetic ABR experiments.

traces come from the same generative process, no two trajectories in the dataset collected with different policies share the exact same trace, as this would be an unrealistic data collection scenario. Given that we have 9 possible policies to leave out, we have 9 possible datasets and models. There are 8 possible groups of trajectories to choose as sources, based on the policy that generated them. In total this leaves 72 different combinations and scenarios. We use the same hyper-parameter tuning approach examined in §B.5. Figure 13a compares the CDF of MSE values resulting from CausalSim and the two baselines. As evident, both baselines suffer from inaccurate predictions and in some cases are catastrophically inaccurate. On the contrary, CausalSim maintains favorable performance, even in the tail of its MSE distribution. Figure 13b gives a closer look at the CDF curves. We see CausalSim dominates at every scale.

Figure 13c is a heatmap of the two dimensional histogram of CausalSim predictions and ground truths. A fully accurate prediction scheme would perfectly match the ground truth and only the diagonal of this histogram would be populated. CausalSim almost achieves that, indicating it produces accurate trajectories on a step-by-step basis.

Further, in Figure 14, we compare the the Mean Absolute Percentage Error (MAPE) of CausalSim, ExpertSim and SLSim predictions across all trajectories at each time step for the first 35 steps. Note that the error naturally accumulates

for all three methods as we move forward in time. However, CausalSim maintains a MAPE of ($\sim 5.1\%$) which significantly lower than both ExpertSim’s and SLSim’s ($\sim 10\%$).

C.3 Learning ABR policies with CausalSim

We observed how CausalSim can be used to design an improved policy in §6.2, and verified this through deployment in the wild. We would like to take these experiments one step further and ask *can CausalSim be used to design learning-based policies, such as with Reinforcement Learning (RL)?*

Recent work has shown that RL algorithms can learn strong ABR policies by learning through interactions with the environment [50]. Could we use a CausalSim model to train high-performance ABR policies without direct environment interaction? As a first step, we decided to carry out an initial experiment in the synthetic ABR environment. We build a CausalSim model using traces from a “simulated RCT” on the synthetic environment.

Performance Metric. ABR algorithms are typically evaluated through QoE metrics [75]. Assuming the chosen bitrate at step t was q_t , the download time was d_t and the buffer was b_t , we use the following QoE definition:

$$QoE_t = q_t - |q_t - q_{t-1}| - \mu \cdot \max(0, d_t - b_{t-1})$$

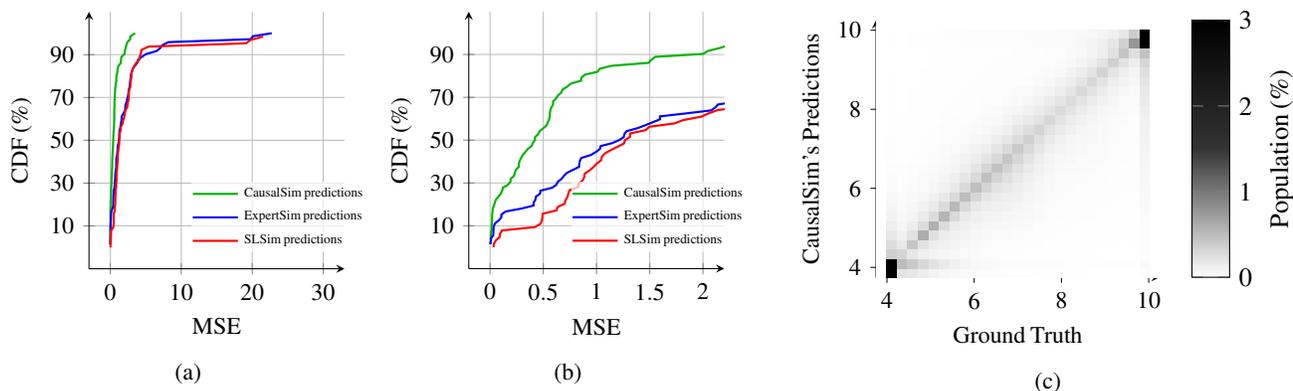

Figure 13: (a) Distribution of CausalSim, ExpertSim, and SLSim MSEs over all possible source left-out pairs. (b) The same figure with a smaller MSE range. In this magnified view, CausalSim clearly outperforms the baselines. (c) Two-dimensional histogram heatmap of CausalSim predictions vs. ground truth.

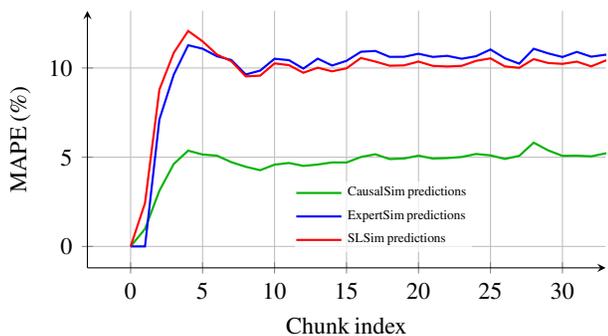

Figure 14: A time series plot of the Mean Absolute Percentage Error (MAPE) across all trajectories, for CausalSim, ExpertSim and SLSim predictions. Notice how errors accumulate in trajectory simulation.

This QoE metric captures three goals (in succession): 1) Stream in high quality, 2) Maintain a stable quality, 3) Avoid rebuffering. Better policies yield higher QoE values, where an ideal QoE is equal to the max bitrate.

C.3.1 How to train policies via simulators?

To train the RL agent, we take a set of logged trajectories where the source policy was MPC and feed them to CausalSim. In each step, CausalSim will predict the next counterfactual observation and reward, and the RL agent will choose the next counterfactual action based on that observation. This process repeats until this simulated session is over, after which the counterfactual trajectory is used to train the RL agent. For the RL algorithm, we utilize the Advantage Actor Critic (A2C) method, a prominent on-policy algorithm, along with Generalized Advantage Estimation (GAE). Table 6 lists all hyperparameters for the RL training.

C.3.2 Does CausalSim train better policies?

Figure 15a plots the CDF of average session QoE that each policy attains. Here, *Real Environment* refers to training directly with the synthetic ABR environment, and CausalSim, ExpertSim and SLSim refer to policies trained by using each of these simulators. CausalSim trains policies nearly as well as training directly on the environment, while ExpertSim and SLSim fail to provide robust policies across all sessions. Figure 15b plots the CDFs for the high RTT (above 300 ms) clients, where the gap between CausalSim and the baseline simulators is even larger.

In this environment, chunk are downloaded according to the slow start model, where congestion control must ramp up its window size over several RTTs before the download rate can reach the available bandwidth. As a result, downloads of smaller chunks (with lower bitrates) incur a noticeable overhead, particularly on high-RTT paths. This overhead becomes less apparent as chosen bitrates become larger. Biased simulators such as SLSim and ExpertSim, which assume all actions lead to the same observed bandwidth, overestimate the achieved rate when counterfactual bitrates are smaller than factual ones (chosen by the source policy) and underestimate it when the counterfactual bitrates are larger. Since the source policy is conservative and tends to choose low bitrates, ExpertSim and SLSim find larger bitrates to be undesirable in the QoE trade-off. This can be seen in Figure 15c, which visualizes the 3 aspects of QoE in terms of the rebuffering rate and the smoothed bitrate, i.e the chosen bitrates with the smoothness penalty. Notice how policies trained on the real environment and CausalSim utilize the network by 200 kbps more than other policies. The extra rebuffering that CausalSim incurs is negligible compared to the extra bitrate: 5.9 seconds every hour.

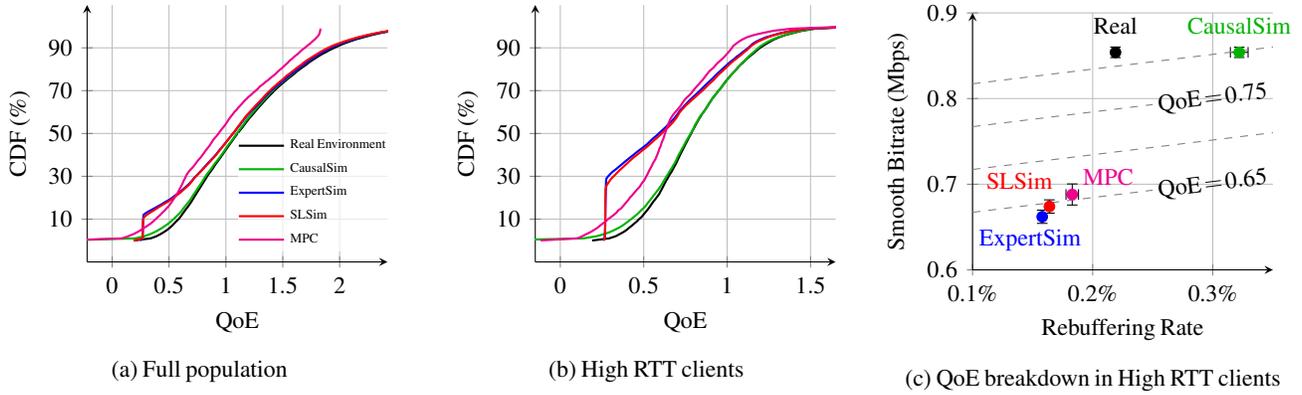

Figure 15: CausalSim trained policies perform well, only marginally behind training on the real environment. Distribution of Quality of Experience (QoE) in policies trained with the real environment, CausalSim, ExpertSim, and the MPC policy. CausalSim does not underestimate bandwidth in high RTT clients and trains policies that strike the best balance in QoE goals.

Group	Hyperparameter	Value

C.4 Low-rank structure

As discussed in §4.1, we can formulate the counterfactual estimation problem in the context of matrix completion. For each time step, we know the chosen bitrate (action) and the achieved throughput (trace). We also know the trace is computed using a latent factor and the action. Suppose the

latent factor is the network bottleneck capacity c_t ¹⁸. $\mathcal{F}_{\text{trace}}$ describes how the achieved throughput (the trace) relates to this latent factor. Intuitively, this should be a close-to-linear function, $m_t \approx c_t$. But it's not exactly linear; for example, congestion control may under-utilize the network capacity for

¹⁸There may be other latent factors but bottleneck capacity is likely to have the strongest influence on the achieved throughput.

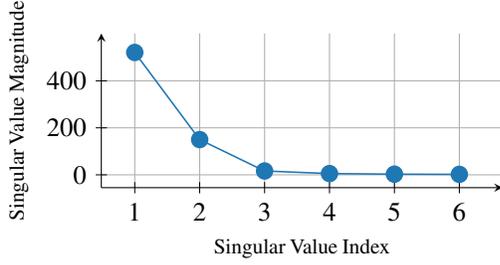

Figure 16: Singular values of matrix M in synthetic ABR suggest that M is approximately rank 2.

small transfers on high-RTT paths.

We form a matrix M , where the rows denote actions $a_t \in [A]$ and the columns denote the latent factors u_t^i for each trajectory. The ‘factual’ data we have are single observed trace values in each column, i.e. for each step and each latent, we have observed the trace from a single action. To estimate counterfactuals, we must complete the matrix. We have no way of knowing the true $\mathcal{F}_{\text{trace}}$ in the Puffer dataset. But to get a sense for what it might look like and whether it’s plausible that M is low rank, we can investigate this in the synthetic ABR environment instead.

For the TCP slow start model this environment uses, $\mathcal{F}_{\text{trace}}$ takes the following form:

$$\text{Let } R\hat{T}T := \frac{RTT}{\ln(2)} \quad (22)$$

$$m_t = \begin{cases} \frac{c_t}{1 + \frac{R\hat{T}T \cdot (\ln(c_t/\dot{c}) - c_t + \dot{c})}{s_t}} & \text{if } s_t \geq R\hat{T}T \cdot (c_t - \dot{c}) \\ \frac{s_t}{R\hat{T}T \cdot \ln(\frac{s_t}{R\hat{T}T \cdot \dot{c}} + 1)} & \text{otherwise} \end{cases} \quad (23)$$

where s_t is the chunk size (which itself is determined by the bitrate chosen by ABR) and \dot{c} is the starting download rate in the slow start algorithm (in our case, equal to 2 MTUs). We use this model to generate a version of M with $A = 6$ actions and $U = 49000$ latent network conditions. We compute the singular value decomposition with the 6 singular values represented in non-increasing order ($\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_6$). The total ‘energy’ of matrix is given by sum of squares of these singular values. It turns out that $\frac{\sigma_1^2 + \sigma_2^2}{\text{total energy}}$ is more than 0.999. This suggests that most of the matrix is captured by its rank-2 approximation, as depicted in Figure 16. In other words, M is approximately low (=2) rank.

Appendix D Load Balancing

D.1 Does CausalSim Faithfully Infer Latent States?

We test the claim that estimating the exogenous latent state and using it to predict the next state was indeed the key to pro-

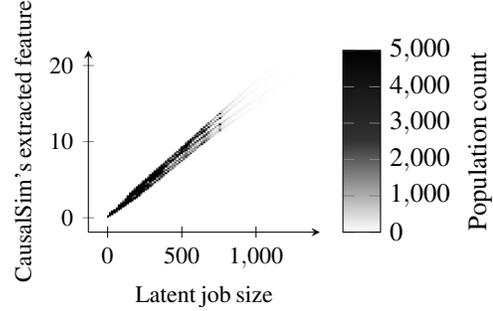

Figure 17: Two-dimensional histogram heatmap of CausalSim extracted latent state vs. latent job sizes.

ducing accurate counterfactual predictions, as the architecture of CausalSim suggests. To do so, we compare CausalSim’s estimated latent state with the underlying job sizes—the job size is indeed the latent state that dictates the dynamics in the load balancing environment. We find that the estimated latent states and the job sizes are highly correlated, as illustrated in Figure 17, with a PCC of 0.994. This demonstrates that CausalSim can learn faithful representations of true latent states.

D.2 Data & Algorithms

To simulate the load balancing problem described in §6.4.1, we need to set the server processing rates $\{r_i\}_{i=1}^N$, and arriving job sizes S_k . Server rates are generated randomly, as follows:

$$r_i = e^{u_i} \quad (24)$$

$$\text{where } u_i \sim \text{Unif}(-\ln(5), \ln(5)) \quad (25)$$

We generate job sizes using a time-varying Gaussian distribution. At step k of the trajectory, job size S_k is sampled as follows:

$$S_k \sim \text{Normal}(\mu_k, \sigma_k)$$

where μ_k and σ_k signify the mean and variance of the generative distribution at time step k . At each time step, with a probability of $p = 1/12000$, the mean and variance change and with a probability of $1 - p$, they remain the same. The mean and variance values are drawn from random distributions, both at the start of a trajectory and when a change occurs, in the following manner:

If $k=0$ (start of trace) or, mean and variance must change:

$$\mu_k \sim \text{Pareto}(\alpha = 1, L = 10^1, H = 10^{2.5}) \quad (26)$$

$$\sigma_k \sim \text{Unif}(0, 0.5\mu_k) \quad (27)$$

Else:

$$\mu_k = \mu_{k-1} \quad (28)$$

$$\sigma_k = \sigma_{k-1} \quad (29)$$

Jobs generated according to this process are temporally correlated, and therefore not independent and identically distributed. Training data consists of 5000 trajectories of length 1000, each of which was randomly assigned a policy from a set of 16 policies, described in Table 7.

Policies	Description	Used as source	Used as left out
Server limited policy (8 variations)	Randomly assign to only two servers	✓	×
Shortest queue	Assign to server with smallest queue	✓	✓
Power of k ($k \in \{2,3,4,5\}$)	Poll queue lengths of k server and assign to shortest queue	✓	✓
Oracle optimal	Normalize queue sizes with server rates and assign to shortest normalized queue	✓	✓
Tracker optimal	Similar to oracle, but estimates server rates with historical observations of processing times	✓	✓

Table 7: Scheduling policies used in the load balancing experiment.

D.3 Training setup

As before, we use MLPs as the NN structures for CausalSim models and the SLSim model and Table 8 is a comprehensive list of all hyperparameters used in training. We tune the parameter κ for CausalSim and the loss function in SLSim in a similar fashion to what is described in §B.5 and §B.6. Note that, as mentioned in §6.4.1, we assume access to $\mathcal{F}_{\text{system}}$ and focus on the more challenging task of estimating the trace quantities, for both CausalSim and SLSim. Therefore, in training, there are no observations and hence $\mathcal{L}_{\text{total}}$ consist of two terms: the squared loss of the trace quantities and the discriminator loss.

Appendix E Causal Inference Related Work

Identifying causal relationships from observational data is a critical problem in many domains [30], including medicine [55], epidemiology [59], economics [36], and education [23]. Indeed, identifying causal structure and answering causal inference queries is an emerging theme in different machine learning tasks recently, including computer vision [74, 76], reinforcement learning [6, 24], fairness [27], and time-series analysis [7] to name a few. One important aspect about causal inference is its ability to answer counterfactual queries. For such queries, many methods were developed; where some approaches are motivated by Pearl’s structural causal model [57], and by Rubin’s potential outcome framework [61]. We refer the interested reader to recent surveys such as [30] and references there in for an overview of recent advances in our ability to infer causal relationships from observational data.

Another related line of work within this literature is synthetic controls and its extension synthetic interventions, which aims to build synthetic trajectories of different units (e.g. individuals, geographic locations) under unseen interventions by appropriately learning across observed trajectories [4, 5, 9–12]. However, these approaches assume a static set of intervention and do not apply to our setting.

HALP: Heuristic Aided Learned Preference Eviction Policy for YouTube Content Delivery Network

Zhenyu Song^{*†}, Kevin Chen^{*}, Nikhil Sarda^{*}, Deniz Altınbüken, Eugene Brevdo, Jimmy Coleman, Xiao Ju, Pawel Jurczyk, Richard Schooler, Ramki Gummadi^{*}

Google

Abstract

Video streaming services are among the largest web applications in production, and a large source of downstream internet traffic. A large-scale video streaming service at Google, YouTube, leverages a Content Delivery Network (CDN) to serve its users. A key consideration in providing a seamless service is cache efficiency. In this work, we demonstrate machine learning techniques to improve the efficiency of YouTube’s CDN DRAM cache. While many recently proposed learning-based caching algorithms show promising results, we identify and address three challenges blocking deployment of such techniques in a large-scale production environment: computation overhead for learning, robust byte miss ratio improvement, and measuring impact under production noise. We propose a novel caching algorithm, HALP, which achieves low CPU overhead and robust byte miss ratio improvement by augmenting a heuristic policy with machine learning. We also propose a production measurement method, impact distribution analysis, that can accurately measure the impact distribution of a new caching algorithm deployment in a noisy production environment.

HALP has been running in YouTube CDN production as a DRAM level eviction algorithm since early 2022 and has reliably reduced the byte miss during peak by an average of 9.1% while expending a modest CPU overhead of 1.8%.

1 Introduction

YouTube is one of the largest sources of downstream internet traffic, accounting for 15% of global application traffic in 2021 [27]. It leverages a Content Delivery Network with a presence in more than 200 countries and territories to serve videos to over 2 billion users [30]. Caching in CDNs is done by storing content, such as videos, in proxy servers that are distributed closer to end users instead of delivering content from the origin servers. A CDN uses multiple levels of caches

^{*}Equal technical contributions. The corresponding author is Pawel Jurczyk (pawelj@google.com).

[†]Zhenyu is affiliated with Princeton University, but this work was done during his internship in Google.

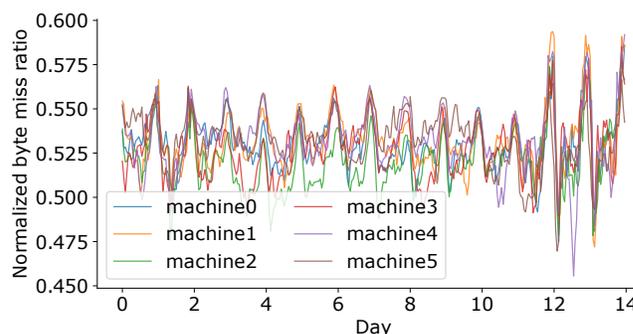

Figure 1: Byte miss ratios over time for six machines on a rack, normalized by dividing with a reference constant to hide the proprietary absolute values. The substantial differences across machines and over time make it hard to measure a new cache algorithm’s production impact accurately.

to reduce the cost of content distribution and access latency for end users. A key metric to optimize in CDN caches is byte miss ratio, i.e., the portion of user-requested bytes missed in the CDN cache.

Recently, machine learning techniques have been used to improve cache eviction and admission policies (e.g., [32, 34]). Caching algorithms can benefit from learning patterns from existing workloads, predicting which byte is more likely to be accessed in the future, and using this information to improve caching decisions.

In this paper, we present a new cache eviction algorithm called Heuristic-Augmented Learned Preferences (HALP), and share our experience in deploying HALP at a large scale. From our experience, while reducing the byte miss ratio is important to improve cache efficiency, it is not the sole criterion for deployment. For a solution that uses machine learning to be deployed in a large-scale production environment, there are three main challenges that need to be tackled:

- **Computation overhead for learning.** Learning-based cache algorithms can be more computationally expensive to run compared to heuristic-based algorithms. The model training and prediction cost is high compared to

normal cache operation such as LRU eviction. Using LRB [32] as an example, for each eviction it needs to run predictions for 64 objects, which makes deployment cost-prohibitive ($\approx 19.2\%$ additional CPU overhead)

- **Robust byte miss ratio improvement.** Learning-based cache algorithms can introduce regressions if their design does not include a regression prevention mechanism. For large-scale systems, bounding regression of byte miss ratio is crucial. YouTube CDN contains a large number of locations, and byte miss ratio regressions in even a few locations could result in degraded user experience. In addition, having a robust algorithm also increases our confidence in the design.
- **Measuring impact under production noise.** It is challenging to accurately measure the impact of a new eviction algorithm in a large-scale deployment. We cannot solely rely on simulations as they are imperfect proxies for production behavior. It is also impractical to replicate user requests and test different algorithms at every location. Therefore, current production practice uses A/B testing. An example is to compare different machines on a rack because machines on a rack share the same hardware/software configurations, and the request mix they receive should be similar. However, in practice, the behaviors of machines are never identical. Figure 1 shows byte miss ratios over time for six machines on a rack. The substantial differences across machines and over time make it hard to measure the production impact of a new algorithm accurately.

To tackle the first two challenges, we develop a novel approach, the HALP policy, to perform eviction decisions with low-overhead and to generalize over the whole production system with limited regressions. It achieves this by augmenting a heuristic policy with machine learning instead of learning a policy end-to-end. The HALP eviction policy uses the heuristic policy to select eviction candidates and the learning policy to pick the final object to evict from those candidates.

To address the third challenge, we developed an impact distribution analysis that evaluates the impact of a new caching algorithm deployment in a noisy production environment.

HALP has been deployed in YouTube’s CDN as a DRAM level eviction algorithm since early 2022. It has robustly reduced the byte miss by an average of 9.1%. In addition, these improvements were achieved with a modest 1.8% CPU overhead.

In this paper we make the following three contributions:

- We present Heuristic Augmented Learned Preferences (HALP), a learned cache eviction algorithm with low computation overhead and robust byte miss ratio improvement by augmenting a heuristic policy with a learnable scoring function.
- We propose an impact distribution analysis to measure

the impact of a caching algorithm in the presence of production noise.

- We evaluate HALP in YouTube’s large-scale production environment and provide a detailed analysis on how it improves the cache efficiency of YouTube CDNs.¹

The paper is structured as follows: §2 describes the background of the problem. §3 covers the design of HALP. §4 introduces our impact distribution analysis design, and §5 shows the evaluation results.

2 Background

In this section, we give an overview of the YouTube CDN architecture. We then describe heuristic-based caching algorithms and learning-based caching algorithms. Lastly, we describe the key ideas for deploying a learned cache algorithm in a large-scale production environment.

2.1 YouTube CDN Edge Cluster Architecture

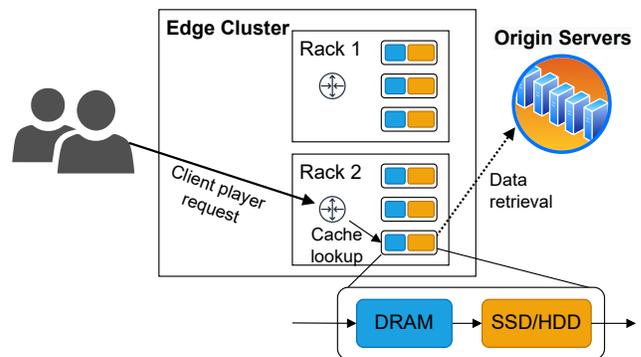

Figure 2: A YouTube CDN edge cluster contains multiple racks of servers. Machines in a rack are of the same type.

YouTube CDN [4, 11] contains edge clusters spreading more than 200 countries and territories globally. As shown in Figure 2, an edge cluster consists of multiple racks. Each rack contains multiple cache servers configured homogeneously using the same type of machines. Servers from different racks may have hardware from different generations. Each cache server is equipped with DRAM, SSDs and HDDs used for caching data chunks. A video is stored in these data chunks on the cache server.

Client player requests are sharded amongst machines in an edge cluster. A request includes a key and a byte range of a data chunk. Because a video is played sequentially, video range requests are issued sequentially as well. On the arrival of a request, the server checks if the requested data chunk is

¹Two traces from a developed market region and an emerging market region (§5.2) can be shared with interested parties, but a signed data sharing agreement between Google and the outside institutions is required.

in its DRAM. If it is not present (a.k.a. is missed), the data will be fetched from other cache layers such as local SSDs and HDDs, with the remote origin server being the last resort. When the DRAM cache is full and a miss occurs, an eviction algorithm is used to remove data chunks from the cache to insert new data chunks.

As the first caching tier, the DRAM cache serves an important role in reducing traffic for subsequent tiers. It also contributes to the overall storage costs of the YouTube CDN. A better DRAM eviction algorithm with a lower byte miss ratio would require less DRAM to be provisioned while keeping a similar traffic reduction on subsequent tiers. This saves the overall resource cost as long as the computation overhead is modest (which requires additional CPU resources). We focus on the byte miss ratio during the peak hours. This is because during peak hours, large numbers of videos are concurrently accessed, causing the byte miss ratio peaks, which could degrade Quality of Experience (QoE). We therefore focus on reducing the 95th percentile byte miss ratio: **P95 byte miss ratio**. We choose to not directly optimize QoE because it is too noisy as feedback for each cache eviction. §5.3 and §5.4 list other metrics related to cache performance.

The previous eviction algorithm used in production [28] uses heuristic to rank chunks. A score is computed for each chunk by summing its request rate score and end of chunk score, and the chunk with lowest score would be evicted. The request rate score is calculated based on the chunk’s past request rate, which captures the temporal locality. The end of chunk score is a binary score indicating whether the previous range request hits the chunk end. Since range requests for a chunk are issued sequentially, after a client requests the last byte of a video chunk, the same chunk is less likely to be fetched again. This score captures the spatial locality.

2.2 Heuristic and Learned Cache Algorithms

Many heuristic cache algorithms maintain a priority queue for objects in the cache and select the lowest priority object to evict when a miss occurs. For example, A Least Recently Used (LRU) policy uses the latest time of access for an object to determine evictions. This ordering is good for workloads where objects that have been accessed recently are more likely to be accessed repeatedly. A First In First Out (FIFO) policy uses the order in which items were inserted into the cache for determining evictions. This ordering performs well for workloads where objects are accessed sequentially. Managing priority queues is efficient, which makes these algorithms efficient as well. However, these algorithms work well in some workloads, but not in others. Caching policies that can self-tune and balance between different features, recency and frequency in Adaptive Replacement Cache (ARC) [25] or object size and frequency in Greedy-Dual-Size-Frequency (GDSF) [12, 13], can cover a wider range of workloads but only adapt to specific features [21], limiting their performance

for changing workloads.

Learning-based algorithms like LRB [32] achieve better performance than heuristic algorithms, because they train a model to learn the cache access pattern directly from the trace instead of assuming a static workload behavior. As an example, LRB maintains features for objects that are both currently, and historically present in the cache, and trains a regression model to predict an object’s time to next access. When an eviction is required, it randomly samples 64 objects and runs this predictive model on them and evicts the object which is predicted to be accessed furthest in the future.

When optimizing the byte miss ratio for variable-size objects, the eviction methodology is similar to optimizing the miss ratio for uni-size objects. This is because in the variable-size object scenario, we can treat each eviction decision as a group of decisions, which evicts each byte of an object individually.

3 HALP Eviction Policy Design

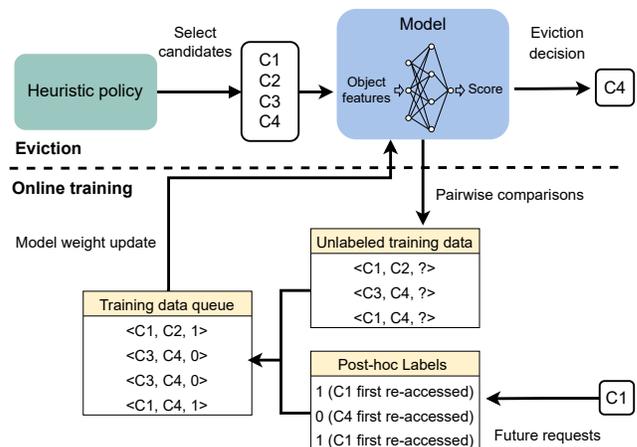

Figure 3: The architecture of HALP. A key component of HALP is a neural network based *score function*, whose inputs correspond to the features for a single eviction candidate, and whose output is a real valued score which tracks the likelihood of a quick re-access to the same object. When an eviction is required, a heuristic policy (e.g., LRU) is used to propose a small set of eviction candidates. Then a neural network-based model ranks the eviction candidates and selects the final eviction decision by pairwise comparisons. The same pairwise comparisons are also used to generate training data for online training.

This section describes the design of HALP, which is illustrated in Figure 3. A key component of HALP is a neural network based *score function*, whose inputs correspond to the features for a single eviction candidate, and whose output is a real valued score which tracks the likelihood of a quick re-access to the same object. When an eviction is required, a

heuristic policy is first used to propose a small set of eviction candidates. Then, a neural network score function is used to re-rank this small set of candidates, to identify the final eviction decision. A key design challenge involves how to learn the scoring function, which involves both generating the training data and adjusting the weights of the neural network. As part of its design, HALP also includes the steps required to efficiently update this score function, starting with randomly initialized weights.

Because of these design choices, HALP can be deployed without the operational overhead of having to separately manage the labeled examples, training procedure and the model versions in separate offline pipelines. Therefore, HALP has minimal extra overhead for operation similar to other heuristic policies, but has the added benefit of being able to take advantage of additional features to make its eviction decisions and continuously adapt to a changing access patterns.

To learn the score function efficiently, we convert the ranking problem into a small set of pairwise preference queries, which is a general and robust framework for learning to rank [9, 29] multiple items from a list. As a result, HALP makes repeated use of pairwise comparisons during decision making to simultaneously generate training data for online training. One challenge in efficiently managing the training data is that the time required to identify the labels is non-deterministic and depends on the future re-accesses to items. HALP snapshots the features generated for pairwise comparisons used at eviction decision time saved as unlabeled training data tuples (see Figure 3). In parallel, HALP continuously observes incoming requests to resolve any pending labels for prior comparisons and generate training data that continuously updates the model.

3.1 Heuristic-based Candidate Selection

A key insight for ensuring a low overhead is that many objects can be easily excluded from eviction consideration without the need to use expensive computations, ML or otherwise. For example, objects near the head of an LRU priority queue are less likely to be good eviction candidates as opposed to objects near the tail. Therefore, we can appropriately bias our learned eviction towards only the tail instead of considering the entire cache, saving overhead on training and inference.

The goal of using a heuristic policy for candidate selection is to reduce the ML computational overhead. It also provides a lower limit on decision quality. This heuristic algorithm can be selected as LRU, LFU, or other heuristic policies. We find in practice LRU policy is sufficient to achieve good performance.

The number of eviction candidates is a hyperparameter. If too many candidates are selected, the ML pipeline overhead will be too high. But too few candidates may lead to not a single good candidate to evict. We find empirically selecting four candidates achieves a good balance between the recall of

good candidates and the incurred CPU overhead.

3.2 Ranking-based Learned Eviction

HALP is designed to provide better eviction decisions than the heuristic algorithm in the general case. To achieve this, the pairwise comparisons should pick the eviction decision that is the best for improving cache efficiency. Since the goal of cache eviction is to use the limited size of the cache to receive as many hits as possible, finding the best eviction decision is equivalent to ranking the candidate that will be accessed furthest in the future (or not at all) highest, in effect evicting it before other candidates.

After four eviction candidates are selected from the heuristic, the best candidate is selected based on three pairwise comparisons done in tournament style. The deselected candidates are re-inserted into the heuristic policy. In the case for LRU, those deselected candidates are re-inserted into the head of LRU queue.

To have a theoretical intuition that the combination of a heuristic and a learning policy can increase the robustness of eviction candidate selection, we analyze a simple Gaussian model for the benefits of re-ranking in Appendix B. This analysis underlines the conditions under which such re-ranking might generate more utility than the baseline heuristic.

Online Training. As shown in Figure 3, when a pairwise comparison is done, the same pair of candidates is selected to generate training data. However, at the time of prediction, the required label (i.e., which of these two candidates will be accessed further in the future) is not available. Therefore, an initial feature snapshot is taken at the pairwise comparison during eviction and is buffered in an unlabeled state with a label placeholder until one of the candidates is accessed again, making the label available. Accordingly, HALP maintains a collection of pending comparisons. This collection of pending comparisons continuously observes all incoming requests, and upon the first access to either candidate, a binary label is assigned to construct the training example.

HALP keeps the feature metadata of objects in a “ghost cache”. For our application of video caching, this metadata is lightweight relative to the sizes of the objects being cached, therefore the information continues to be stored for keys that are evicted from the cache up to a limit. This limit is set to be a multiple of the number of elements in the actual cache to track enough history. Evictions from the ghost cache are performed using LRU when the size exceeds this set limit. When a key is removed from the ghost cache, pending comparisons associated with the key are also deleted.

The training data generated from the above procedure is stored in an in-memory replay buffer. When the replay buffer accumulates 1024 training entries, it creates a mini-batch to update the ML model. The retrain batch size is a hyperparameter of HALP and was chosen empirically. Theoretically, a

pathological workload could have access pattern shifts aligning with the retraining period, causing HALP performance degradation. However, we didn't observe this in our production workloads.

The online training framework and the model itself are written using XLA [2] and carefully crafted C++ code to ensure low overhead. We also leverage uncommon synchronization primitives such as user space per CPU spinlocks and RCU's to ensure maximum performance without sacrificing scalability and thread safety in highly concurrent environments.

ML Model. The model is trained as a binary classification task (which of a pair gets re-accessed first) with cross entropy loss. It is a simple neural network model with one hidden layer. We found that increasing the number of layers did not help improve the model further. With this simple model, we are able to run a pairwise prediction in 720 ns, and each training in several ms. And HALP implementation is based on Google's SmartChoices service [10]. Details about the loss function and the model weight updates are provided in Appendix A.

Feature name	Dimension
<u>Access-based</u>	
Time between accesses	32
Exponential decay counters	10
Number of accesses	1
Average time between accesses	1
Time since last access	1
<u>Video-specific</u>	
End of chunk	1

Table 1: Features used by HALP.

Features. Table 1 shows the features HALP uses. Of these features, time since last access, time between accesses, and exponential decay counters are the same as the features used in [32]. Time since last access and time between accesses capture short-term access patterns while they retain information about at most 32 accesses. Exponential decay counters (EDCs) capture longer term trends. The end of chunk score is identical to the previous production algorithm (§2.1).

4 Impact Distribution Analysis

Comparing cache algorithms may seem like a straightforward hypothesis test (e.g., t-test or z-test) over an A/B testing experiment. A new algorithm with lower byte miss ratio that passes the hypothesis test would generally be considered as an improvement. However, the operating conditions in a large-scale system could be very diverse, and understanding the

robustness of an improvement is critical to decision making in practice.

To illustrate the risk of solely relying on mean-shift estimates, consider a scenario where a new algorithm is beneficial for most machines but performs extremely poorly for some small set of machines. In that case, applying the new algorithm everywhere could be sub-optimal. Any algorithms without a theoretical performance lower-bound (relative to an optimal solution) have these risks, but the concern is exacerbated for learning algorithms that are prone to over-fitting.

A naive approach to the diversity problem is to enumerate all configurations and perform separate A/B tests (e.g., one test for each rack where workload and hardware is assumed to be similar). However, this severely limits the number of data points, and the signal to noise ratio for each configuration could be very poor in a production setting. Figure 1 is a typical example of byte miss ratio variation for production machines on the same rack with identical setting.

We propose a novel impact distribution analysis to get a more holistic picture of how a new algorithm is affecting the fleet. Specifically, instead of estimating the average performance change, we try to estimate the *distribution* of performance changes across different conditions.

4.1 Model of Measurements

We model the measured relative improvement as

$$M = I + N \quad (1)$$

where I represents actual impact and N represents the noise. In other words, we model the PDF of M as a convolution between I and N .

The core idea is that we could directly sample M by A/B tests, and sample N by A/A tests (performance difference measured in no-op experiment), and once we have those two distributions, we can get to I by deconvolution.

4.2 Measurement Setup

The environment we want to measure the effect of using HALP comprises of racks from hundreds of locations. In our experiment setup, we randomly split machines in a rack into three different configurations:

- **Experiment Machines:** Experiment machines use the HALP algorithm.
- **No-op Machines:** No-op machines use the baseline caching algorithm. They are used to measure the production environment noise.
- **Control Machines:** Control machines also use the baseline caching algorithm. They are selected as the baseline to compare with the experiment group and no-op group.

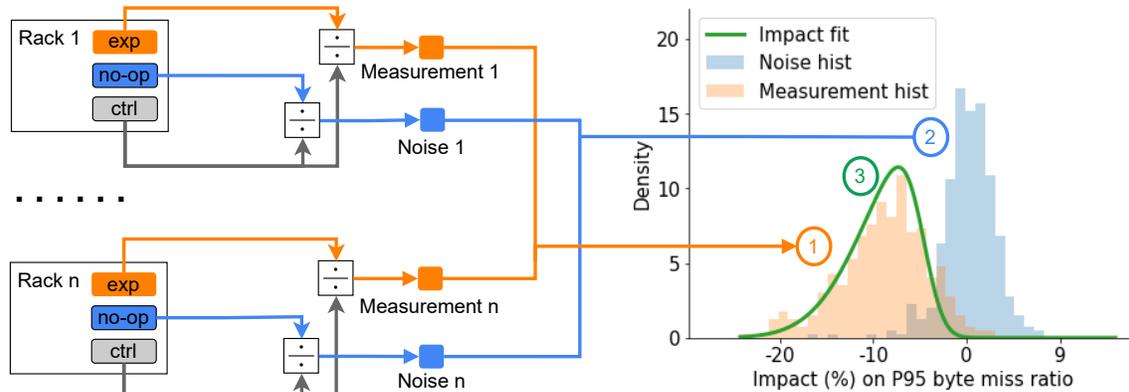

Figure 4: Impact distribution analysis procedure: 1. Estimate measurement distribution. 2. Estimate noise distribution. 3. Fit impact distribution.

Figure 4 shows how the measurements from these three groups are used to calculate the impact distribution. We first collect the relative values (e.g., relative byte miss ratios) of experiment machines over control machines as measurement samples (Measurement M). Then we collect the relative values of no-op machines over control machines as an estimation of the environment noise (Noise N). Finally, we fit an impact distribution from the measurement distribution and noise distribution using each comparison as a data point, as we describe in the next subsection.

4.3 Fitting Impact Distribution

Algorithm 1 Algorithm for fitting impact distribution

Input: measurement samples M , noise samples N , and distribution candidates.

Output: measurement distribution P_M , impact distribution P_I , noise distribution P_N .

- 1: $P_N = \text{FitByMLE}(\text{dist}=\text{"t-dist"}, N)$
 - 2: **for** candidate_dist in candidate_distributions **do**
 - 3: // Approximate P_M by discretized grid G .
 - 4: $P_I = \text{FitByMLE}(\text{dist}=\text{candidate_dist}, M, P_N)$, with $P_M(m) \approx \sum_{v \in G} P_N(v) P_I(m - v)$
 - 5: **end for**
 - 6: **return** P_I with the highest likelihood
-

Algorithm 1 describes our algorithm to fit the impact distribution given sample M and N . We first fit the noise distribution P_N using noise samples with maximum likelihood estimation (MLE) (Line 1). We assume the noise has zero mean and follows a t-distribution. We choose a t-distribution because we expect noise to exhibit a symmetric and bell-shaped behavior like the normal distribution but allow fitting

to have more degrees of freedom.

Next, we fit the impact distribution (Lines 2-5). This is done in two steps. First, a distribution type for impact needs to be chosen (Line 2). Since this depends on the setting, several well-known distributions could be reasonable candidates. Therefore, we iterate over a list of common distributions (beta, non-central student, and skewed normal) and pick the one that best fits our data. Second, we estimate the measurement distribution by discretizing the distribution into a fine-grained grid G . Then we use the maximum likelihood estimation to fit the chosen distribution candidate to find the measurement distribution that is the best fit (Line 4).

Note that this method is only feasible because we have machine data from more than 200 countries and territories. Without enough samples the fitting will not be able to recover impact accurately from the noise.

5 Evaluation

In this section, our goal is to answer the following questions for HALP and our impact distribution analysis:

- Can HALP improve cache performance without causing regression in production? (§5.3)?
- What is the computation overhead of HALP compared to the previous production algorithm (§5.4)?
- How does HALP compare to other learned and heuristic algorithms (§5.5)?
- What are the effects when changing HALP’s hyperparameters (§5.6)?

5.1 Deployment Setup

Deployment HALP was rolled out in production in early 2022. The rollout was done in stages, and the impact of the new algorithm was monitored using the impact distribution

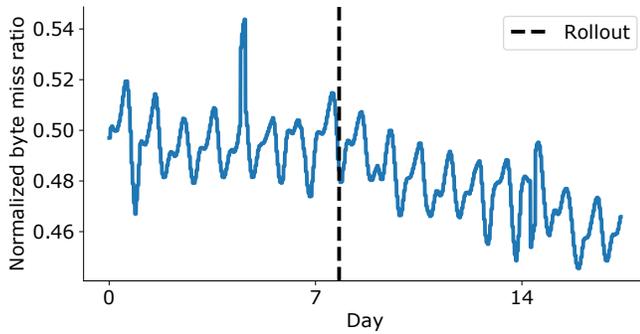

Figure 5: YouTube fleet normalized byte miss ratio for the DRAM level, before and after rollout.

analysis on the changes in DRAM byte miss ratio. Figure 5 shows the DRAM byte miss ratio changes in the fleet before and after the rollout, which shows a fleet-wide drop.

Release Process HALP has an online design to make sure that the model does not degrade over time. As a result, the online model does not require new releases. While the model does not need to go through production releases, code changes and any improvements in HALP design go into production through releases that happen periodically. HALP is integrated into the existing YouTube release process, which guarantees that during rollout, HALP goes through the release tests and any code changes are released in a safe manner.

Monitoring As part of maintaining stable performance, HALP is integrated into the monitoring setup used for monitoring YouTube deployment. In addition to existing metrics that monitor cache efficiency, two new metrics were added to monitor HALP performance: 1) model accuracy, and 2) the byte miss ratio difference between HALP and a holdout previous production algorithm. For model accuracy, we monitor model loss which is an indicator of how good the model decisions are. For the byte miss ratio difference, we keep 1% of the machines running with previous production algorithm and alert if the byte miss ratio for machines using HALP become worse than the heuristic algorithm. We do not use the impact distribution analysis here as our goal is to detect abnormal behaviors with a low false positive ratio.

5.2 Experimental Methodology

Production experiments. To measure reduction in the byte miss ratio and overhead, we used production experiments and our impact distribution analysis. To use the impact distribution analysis, we randomly selected a small percentage of racks from all locations. For each rack, we selected one experiment machine, one no-op machine, and the rest as control machines (§4). We use one day of data for our measurement after observing HALP training is stable.

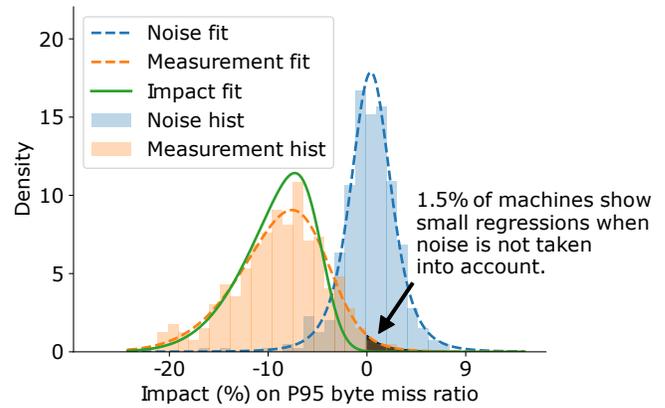

Figure 6: Our impact distribution analysis can “denoise” the experiment measurements from the no-op measurements and reveals HALP’s clear average 9.1% byte miss ratio reduction with negligible regression. When noise is not taken into account, the measurements show 1.5% of racks that were impacted negatively, where some machines showed up to 4% byte miss ratio increase.

Simulation experiments. We use simulation to measure how HALP compares to other cache algorithms and how the changes in hyperparameters effect the performance of HALP. Because simulation does not have production noise and is deterministic, and direct comparisons can be set up reliably, we compare the byte miss ratio from simulations directly instead of using our impact distribution analysis.

For simulation experiments (except two experiments in §5.5), we use traces from a small percentage of randomly selected locations. For each location selected, we choose four traces, each three days long, with each trace coming from different quarters in the calendar year of 2021 (except the retrain interval experiment uses six days long trace). Using a diverse set of traces helps reduce seasonal/weekly noise. For each simulation, the first day of the trace is used as a warm-up, and we measure the P95 byte miss ratio of the next two days.

5.3 HALP Improvements in Production

P95 byte miss ratio. This experiment measures the impact of HALP on the byte miss ratio, disk latency, and joint latency during production. To measure the improvement, we collected byte miss ratios from machines on randomly selected racks and applied our impact distribution analysis. Figure 6 shows the relative change in the byte miss ratio distribution. The regions and lines are the P95 byte miss ratio distribution relative to the control groups.

The blue region is the no-op group relative change distribution. Although the no-op group uses the same configuration as the control group, the noise can cause up to 10% difference in P95 byte miss ratio. The blue dash line shows the fitted t-distribution of the noise. The orange region is the mea-

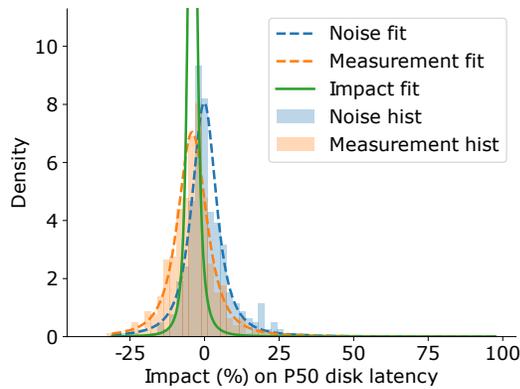

Figure 7: Compared with the previous production algorithm, HALP reduces disk first byte latency by an average of 3.8%.

surement distribution. The orange dash line shows the measurement fitted gamma distribution, which was picked as the best distribution for this specific measurement. When noise is not taken into account, as shown by the orange dash line there is 1.5% of racks that were impacted negatively, where some machines showed up to 4% byte miss ratio increase. However, just looking at the measurement fit, we do not know whether the negative impact is because of the algorithm or the production noise.

Our impact distribution analysis (Section 4) can “denoise” the experiment measurements from the no-op measurements, and the result is the green curve showing a clean byte miss ratio reduction up to 24% with negligible regression, with an average reduction of 9.1%. This shows HALP can not only improve the average byte miss ratio, but also has negligible regression. In addition, the variance of improvements also shows different locations have different access patterns which have different difficulty for learning.

Disk first byte latency. Disk first byte latency is the time between a disk cache receives a request and returns the first byte. It is a good indicator of DRAM cache efficiency because a better DRAM eviction algorithm reduces the number of requests to the disk layer, thus reducing the disk request queue length. Figure 7 shows the disk first byte latency impact of HALP. Compared with the previous production algorithm, the change in latency ranges from a 13% reduction to a 5% increase, with an average reduction of 3.8%.

The tail increase (the part of the impact fit that is above 0) is likely to come from the object miss ratio increase, which is more correlated with disk first byte latency than the byte miss ratio. Different from the byte miss ratio, the object miss ratio is the fraction of user requests missed in the cache. These two metrics may conflict with each other. Since HALP’s primary goal is to reduce the byte miss ratio, it may slightly increase the object miss ratio in certain cases.

Join latency. Join latency is the time taken to start video playback after the user hits “play”, and one of the most im-

portant metrics of streaming. Since join latency is a playback metric that involves both clients and servers instead of servers only, we are unable to use our impact distribution analysis to measure it. We set up an experiment that distributes playbacks from clients to server machines with and without HALP and compares latency on clients. HALP reduces join latency from 1.03% to 1.41%, with an average reduction of 1.22%. This shows that the improvement of the memory cache has a strong impact on the end-to-end user experience.

5.4 HALP Computation Overhead

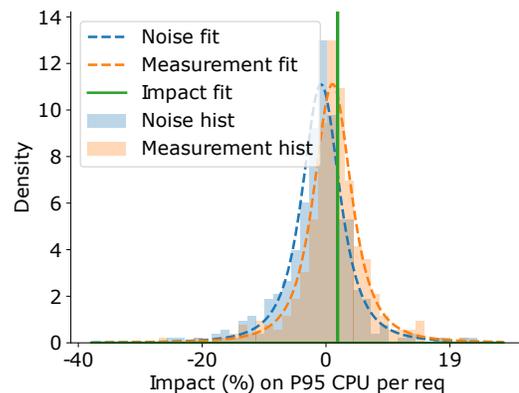

Figure 8: The CPU overhead of HALP is 1.8% per request with low variance. This implies the additional CPU cost is roughly linear to the number of requests.

Learning comes with overheads, so it is important to measure these overheads and underline the trade-offs. In this section, we show the computation overhead associated with using HALP for cache eviction decisions, including prediction and online training.

We have analyzed the extra CPU overhead that is incurred while using HALP using our impact distribution analysis, and Figure 8 shows the impact of P95 CPU normalized per request. The CPU impact is consistently at 1.8% with low variance, meaning the additional CPU cost is roughly linear to the number of requests. This is because both training and prediction costs are roughly linear to the number of requests. For training, the cost is roughly linear to the amount of training data, and on average each prediction generates a single pair of training data. In addition, each eviction requires three pairwise comparisons. Finally, since all locations have similar byte miss ratios, the number of evictions (misses) is roughly linear in the number of requests. To conclude, the computation overhead is small compared to the byte miss ratio improvement.

5.5 HALP vs. Other Cache Algorithms

To further evaluate HALP, we ran simulation experiments to compare it with other cache eviction algorithms.

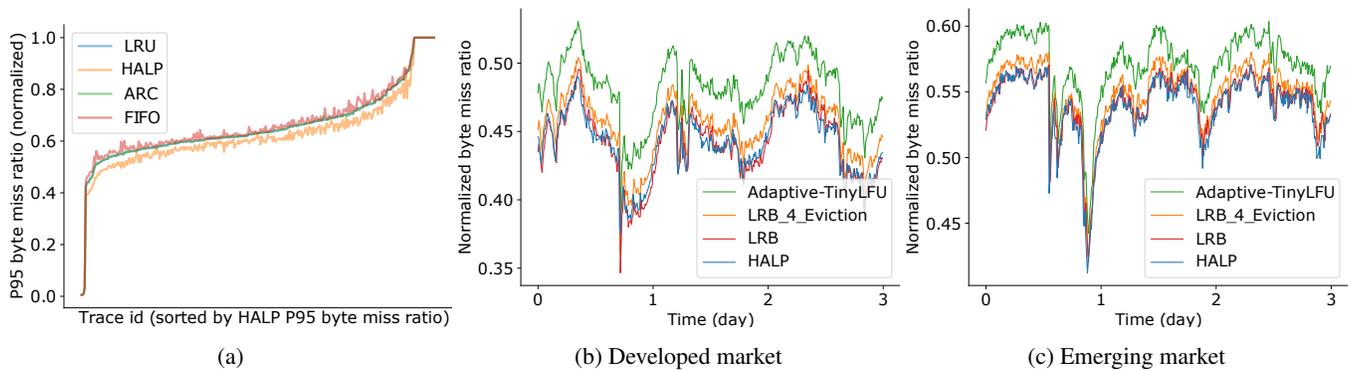

Figure 9: (Fig. 9a) P95 byte miss ratios for different cache algorithms over a variety of traces in simulation. HALP achieves a strictly better performance than all other algorithms on 92.6% of traces, and achieves the same performance as the best of the other algorithms on 7% of traces, in effect performing worse than the best algorithm on only 0.4% of traces. (Figs. 9b and 9c) Normalized byte miss ratio over time for HALP and LRB [32] on production traces from a developed market region, and an emerging market region. HALP achieves a similar byte miss ratio, but only needs 4 eviction candidates compared to 64 for LRB. Tuning LRB’s eviction candidates from 64 to 4 would increase P95 byte miss by about 2%.

Comparison with classic cache algorithms

We compared HALP with three heuristic cache algorithms: LRU, FIFO, and ARC [25]. Figure 9a shows the normalized P95 byte miss ratios for different traces, sorted by HALP P95 byte miss ratio. HALP achieves a strictly better performance than all other algorithms on 92.6% of traces, and achieves the same performance as the best of the other algorithms on 7% of traces, in effect performing worse than the best algorithm on only 0.4% of traces.

Comparison with advanced cache algorithms

We compared HALP with a state-of-the-art learned cache algorithm LRB [32] and heuristic cache algorithm Adaptive-

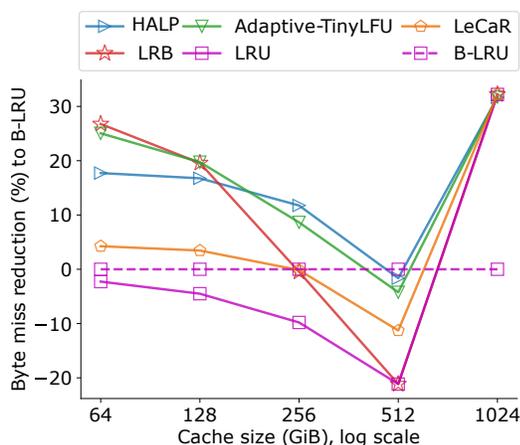

Figure 10: The byte miss reduction of different algorithms compared to B-LRU on a public trace from a Wikipedia CDN node. LRB, Adaptive-TinyLFU, HALP, and B-LRU achieve the best performance individually at cache size 64 GiB, 128 GiB, 256 GiB, 512 GiB. At 1024 GiB, the cache is big enough that all cache algorithms converge.

TinyLFU [15]. We use two YouTube production traces from a developed market region and an emerging market region in 2020 to get robust results. These traces are four days long. Our implementation of LRB and Adaptive-TinyLFU is based on LRB’s open-source simulator [1]. For a fair comparison, we extended LRB’s features to be identical as HALP. We tuned LRB’s major hyperparameter (memory window) using its public implementation. In addition to using LRB’s original 64 eviction candidates, we also tested using 4 eviction candidates identical as HALP. Figure 9b and 9c show normalized byte miss ratios over time for Adaptive-TinyLFU, LRB with 4/64 eviction candidates, and LRB. We use the first day of each trace as a warm-up, and exclude it from the figures.

Adaptive-TinyLFU achieves P95 byte miss ratios of 0.515 and 0.598 on two traces. Compared to it, LRB and HALP achieve smaller ratios (0.479/0.565 for LRB, 0.475/0.564 for HALP). HALP achieves similar P95 byte miss ratios compared to LRB (0.17%/0.83% less byte misses) with less than an order of magnitude computation overhead. For each eviction it only compares 4 eviction candidates instead of 64 for LRB. As a result, HALP computes a prediction for each eviction in 2.1 μ s in comparison to 60 μ s that is required by LRB [32]. Tuning LRB’s eviction candidates from 64 to 4 would increase P95 byte misses by about 2% (to 0.489/0.575). And this increase would be higher with larger cache sizes given there are more number of objects in cache. In addition, LRB’s performance is sensitive to the selection of its memory window, which requires extensive tuning.

Comparison on a public general CDN trace

To test HALP’s performance on a general CDN workload, we evaluated HALP on a trace from a Wikipedia CDN node [32]. We mimic LRB evaluation settings in cache sizes, the warmup length, and the byte miss reduction metric (Figure 9(a) in LRB), but we converted the object sizes into uni-size. We

select the uni-size to be 32 KiB to match the average request size of the original trace. We compare HALP with the best-performing cache algorithms in LRB evaluations, i.e., LRB, Adaptive-TinyLFU, LeCaR, B-LRU, and LRU. We ran HALP by our simulator, and baseline algorithms by LRB public simulator. For LRB, we use the hyperparameter values described in the paper and its website. Compared to LRB, HALP does not use the additional categorical feature in the trace.

Figure 10 shows the byte miss reduction of different algorithms compared to an industry standard algorithm B-LRU (LRU-eviction policy using a Bloom filter as admission control [24]). None of the algorithms achieves the best performance across all cache sizes. LRB, Adaptive-TinyLFU, HALP, and B-LRU achieve the best performance individually at cache size 64 GiB, 128 GiB, 256 GiB, 512 GiB. At 1024 GiB, the cache is big enough that all cache algorithms converge. At such cache size B-LRU suffers from its admission control. Our observation for this trace is the frequency of objects remains stable over time, making past frequency a reliable indicator of future frequency and allowing the frequency-based heuristic algorithms such as Adaptive-TinyLFU to perform well. In contrast, the workload on YouTube exhibits strong spatial locality, which means that past frequency is less indicative of future frequency, resulting in a lower performance of the frequency-based heuristic algorithms. Note the differences between these results and Figure 9(a) in LRB are likely due to the uni-size object transformation.

5.6 Hyperparameter Selection

We validate the effect of different hyperparameters. This includes different numbers of eviction candidates, different neural network architectures, and different retrain intervals.

Neural network architecture

HALP uses a simple neural network with one hidden layer. Here we vary the number of hidden neurons in the hidden layers and measure the byte miss ratio.

Fig. 11a shows the relationship between the geometric mean of P95 normalized byte miss ratio of all traces as the number of neurons in the hidden layers increase logarithmic from 1 to 256. We see a marginal benefit by increasing the number of neurons up to 8. Beyond this point, more hidden representations do not help. To keep a safe margin, we select the number of hidden neurons in our deployment to be 20.

Number of eviction candidates

HALP uses this parameter in training and prediction. After candidates are selected by the heuristic policy, it iteratively does pairwise ranking to select the final chunk to evict, and later uses these comparisons to generate training data. We vary the number of eviction candidates in the simulation, and measure the byte miss ratio. Note that this changes training and prediction distributions in lock-step.

Fig. 11b shows the relationship between the geometric

mean of P95 normalized byte miss ratio of all traces and the number of candidates selected by the heuristic algorithm varying from 2 to 16. As the number of eviction candidates increases from 2 to 4, the byte miss ratio reduces from 60.4% to 59.3%. Further increasing the number of eviction candidates has a marginal effect. Large numbers of eviction candidates have a marginal benefit of the byte miss ratio, but too large a number may harm the byte miss ratio if the other training hyperparameters are not adjusted accordingly.

The number of pairwise comparisons per eviction increases from 3 to 7 when the number of eviction candidates increases from 4 to 8. This increase in CPU does not justify the less than 1% relative byte miss ratio reduction, as a result HALP uses four eviction candidates and does three pairwise comparisons.

Retrain interval

HALP trains online as new requests are processed. We conduct simulation experiments to test different retrain intervals. In order to only test the difference in updating the model online, we increase the trace length to be 6 days from 3 days. We use the first 3 days to train the model in the same retrain interval, and validate that the training loss has been stable. After that, we vary the retrain intervals in the next 3 days, and only measure the byte miss ratio during the latter 3 days.

Fig. 11c shows the relationship between the geometric mean of P95 normalized byte miss ratio of all traces and the retrain intervals. As the retrain intervals increases from processing every 1 new training data input to every 10^8 new training data input, the byte miss ratio slightly increases by less than 0.2%. Our hypothesis is that the traffic pattern change is slow in most traces. But to increase the algorithm robustness, we keep the retrain interval to be every 1024 training data input. This is acceptable in production given the CPU increase is only 1.8% and enables the model to adjust to unpredictable quick workload changes.

6 Related Work

Heuristic-based cache algorithm. Many heuristic-based cache algorithms have been proposed in the past six decades, and from them the most impactful ones include LRU, FIFO, CLOCK [3], SLRU [19], 2Q [18], ARC [25], and TinyLFU [15,16]. Many heuristic algorithms have low computation overhead and provable competitive ratios. But because they are not adaptive enough, they work well in some traces but not in others.

Learned cache eviction. Recently, many learning-based cache algorithms have been proposed to make cache eviction decisions. Table 2 summarizes the state-of-the-art learned cache eviction and admission algorithms. We list four properties of learning-based cache algorithms: target application, whether they are used to make admission or eviction decisions, if they employ online learning, and which underlying machine learning algorithm they employ.

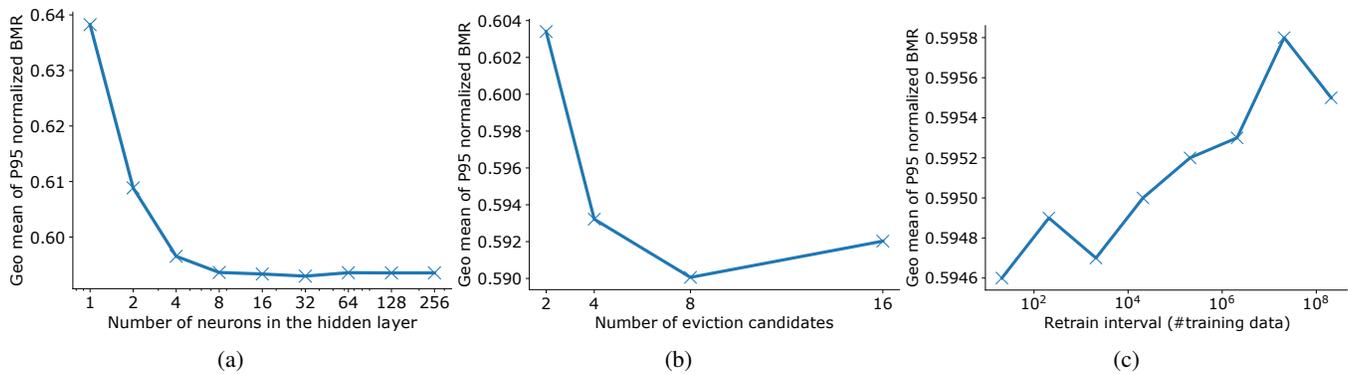

Figure 11: Geometric mean of P95 normalized byte miss ratio of all traces (a) as the number of neurons in the hidden layers increases logarithmically from 1 to 256. We see a marginal benefit by increasing the number of neurons up to 8. (b) as the number of candidates selected by the heuristic algorithm varies from 2 to 16. As the number of eviction candidates increases from 2 to 4, the byte miss ratio reduces from 60.4% to 59.3%. Further increasing the number of eviction candidates has a marginal effect. (c) as the retrain interval increases by how much training data is processed. As the retrain interval increases from processing every 1 new training data input to every 10^8 new training data input, the byte miss ratio slightly increases by less than 0.2%.

CACHEUS [26] proposes two new heuristic algorithms: SR-LRU, a scan-resistant version of LRU, and CR-LFU, a churn-resistant version of LFU. Then it proposes a regret minimization algorithm to switch between these two experts. As a limitation, the overall algorithm cannot adapt to a new workload if neither of the two experts can adapt to it. In addition, the metadata overhead scales linearly with the number of experts because each one needs to maintain its priority queue. [36] learns next request distribution from tags collected by a distributed tracing framework. It combines a lookup table, a K-Nearest Neighbor approach, and a Transformer model to achieve low overhead and high accuracy. But it has a high learning overhead. LRB [32] uses a regression model to approximate Relaxed Belady, a relaxed oracle algorithm. It uses random sampling to generate eviction candidates and training data. Because of a large number (64) of candidates are needed, the eviction has a high computation overhead. In addition, generating training data with enough critical objects is costly due to the uniform sampling process. And LRB’s performance is sensitive to the selection of the memory window (its major hyperparameter).

Parrot [22] and LFO [8] use imitation learning to mimic the oracle algorithm. The objective is to achieve an end-to-end design, but they suffer from a distribution shift. This is because they train their models in an offline fashion, and in practice learning-based cache algorithms have a substantial gap from an oracle, and the objects in the cache as a result differ from a cache that would use an oracle algorithm.

AVic [5] is designed for a video streaming CDN, leveraging the constant speed sequential access patterns, and predicts the time to the next access for the following chunks. However, it has a high implementation overhead because of the complex synchronization between video sessions. Glider [31] targets an eviction policy for CPU caches, and uses an LSTM model

for offline analysis. It uses a fast SVM model for an online policy heavily leveraging the program counter (PC) address feature, which is unavailable in the CDN domain.

LHD [6] estimates the hit density of an object between admission and eviction using Bayesian approaches. But it cannot scale with increasing number of features since it does not have a general model for prediction. Predictive Marker [23] is a theoretical work using learning to augment a cache using the Marker algorithm. This idea inspires the design of HALP.

Another line of works [14,20] use reinforcement learning to directly optimize an eviction policy with the target objective. But because cache feedback (hit) can take tens of millions of steps, reinforcement learning approaches suffer from such long feedback and currently have lower performance than supervised learning approaches in practice.

Learned cache admission. In addition to learned eviction policies, many recent research proposed to use learning in cache admission. Cache admission is helpful when a cache has a bottleneck in write constraints (e.g. SSD write amplification and endurance), or a large portion of objects are never reaccessed. The prominent papers include Flashfield [17], CacheLib [7], and CacheSack [35]. Because their decision space is more limited than that of eviction algorithms, they have worse performance. HALP’s eviction policy can be used jointly with a learned admission policy.

Statistical hypothesis test. Many statistical hypothesis tests have been proposed. But they often focus on using small data, and not on measuring the distribution change. For example, a standard t-test [33] measures the change of mean value.

Algorithm	Year	Target application	Learned admission or eviction	Online learning?	Algorithm
HALP (ours)	2022	CDN	Eviction	Yes	1-hidden-layer MLP, Heuristic + pairwise preference ranking from re-accesses.
CacheSack [35]	2022	Flash cache	Admission	Yes	Greedy optimization
CACHEUS [26]	2021	Storage	Eviction	Yes	Heuristic algorithms w. regret minimization
Learning on distributed traces [36]	2021	Storage	Eviction	No	Lookup Table, K-Nearest Neighbors, Transformers
LRB [32]	2020	CDN	Eviction	Yes	Decision trees
Parrot [22]	2020	CPU	Eviction	No	Transformers
CacheLib [7]	2020	Multipurpose	Admission	No	<i>Private</i>
AViC [5]	2019	CDN	Both	No	Decision trees
Glider [31]	2019	CPU	Eviction	Yes	SVM
Flashield [17]	2019	Flash cache	Admission	No	SVM
LHD [6]	2018	KV store	Eviction	Yes	Probability model
LFO [8]	2018	CDN	Eviction	No	Decision trees
Predictive Marker [23]	2018	/	Eviction	/	Learning + Marker algorithm
Harvesting randomness [20]	2017	KV store	Eviction	Yes	Reinforcement learning

Table 2: A summary of state-of-the-art learned cache eviction and admission algorithms

7 Future Work

For future work, we aim to expand HALP to the SSD and HDD caching tiers of the YouTube CDN. We also seek to jointly optimize eviction and admission policies. Another line of future work we plan to explore is to redesign the features and model architecture leveraging existing hardware accelerators. Right now, HALP uses only CPUs and the pairwise comparisons that use the model to pick candidates are subject to the CPU overhead limits acceptable in production. With accelerators like GPUs or TPUs we will be able to explore a larger design space of features and model architectures. One challenge here is how to design an asynchronous batched eviction algorithm to achieve a high utilization of accelerators while preventing it on path of cache operations that require a low latency.

8 Conclusion

This work describes the design, implementation, and evaluation of HALP, a learned caching algorithm that has been deployed to a large-scale production CDN. We also describe an impact distribution analysis method that allows us to measure the impact of deploying a new cache algorithm in a

production setting with significant measurement noise. The key insight of HALP is to augment a preexisting heuristic caching policy with machine learning, using the heuristic policy to pick candidates for eviction and the ML model to decide which candidate to evict. The key insight of our impact distribution analysis is modeling machine level measurement noise by comparing machines with HALP deployed against no-op machines.

These design decisions enable HALP’s robust byte miss reduction by an average of 9.1%. In addition, these improvements were achieved with a modest CPU overhead of 1.8%.

A Details about the loss function and model weight updates

To explain why we use a cross entropy loss: let w denote the neural network weight parameters and $s_w(f(k, t))$ denote the score output of the neural network for features corresponding to cache key k at time t . Assume that the feedback generation process for the pairwise comparison orders the cache key k_1 ahead of k_2 while querying for the first access to either after time t (i.e. k_1 arrives before k_2 for the first access to either of them after time t). In this case, the cross entropy loss penalizes the loss according to how much the predicted score for k_2 exceeds that of k_1 . Specifically, with $\Delta = s_w(f(k_2, t)) - s_w(f(k_1, t))$, as the difference in scores, the neural network weight parameters w are adjusted based on the gradient of the loss function $\log(1 + e^\Delta)$. When $\Delta \ll 0$, the loss is close to 0, but when $\Delta \gg 0$, the loss is linear in Δ and varies smoothly around 0.

B Analysis of a simple model for reranking

Let (U, H, L) be a triple of jointly distributed random variables. Let

$$(U_1, H_1, L_1), \dots, (U_n, H_n, L_n)$$

be iid samples $\sim (U, H, L)$. The value H_i corresponds to the score for item i predicted by some (heuristic) ranking policy and similarly, L_i corresponds to the score predicted by, (say a learned) ranking policy L . U_i denotes the true utility from object i , but this is a latent variable. The problem is to choose an index i such that U_i is as large as possible. Define the expected utility of a policy $X \in \{U, H, L\}$ as follows:

$$\mathcal{U}(X) = \mathbb{E}[U_{\arg \max_i (X_i)}]$$

We’d like to pick $i^* \triangleq \arg \max_i (U_i)$, which achieves the optimal utility $\mathcal{U}(U)$, but we only observe (H, L) with U being a latent variable. Given two ranking policies H and L , define an aggregate selection policy on them, $\pi(H, L)$ as a map ², $\pi : \mathbb{R}^{2n} \mapsto [n]$, and the resulting expected utility as $\mathcal{U}(\pi) \triangleq \mathbb{E}[U_{\pi(H, L)}]$. Next, we describe and analyze a simple aggregation strategy that we’ve discovered to be useful in learned caching. Let $\lambda_X(i)$ be defined as the item with ranked

² $[n]$ denotes the set $\{1, \dots, n\}$

order³ i when using the ranking policy X for $X \in \{U, H, L\}$. For each $k \in [n]$, define $\pi_k(H, L)$ as the item chosen when re-ranking the top k items in the heuristic H according to L .

$$\pi_k(H, L) \triangleq \lambda_H(j), \text{ where } j = \arg \max_{i \in [k]} L_{\lambda_H(i)}$$

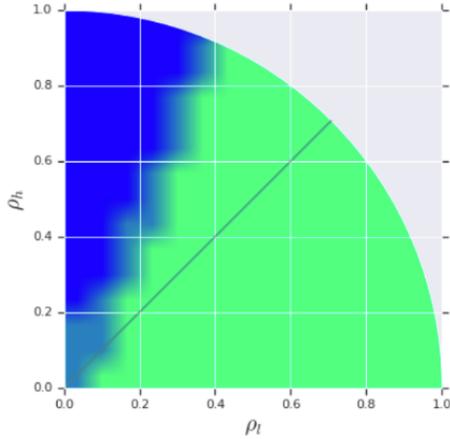

Figure 12: The benefit of rank aggregation evaluated over various configurations for the correlation coefficients based on a sample of $N = 20$ items. The diagonal line indicates points at which $\rho_H = \rho_L$. The green region indicates configurations where $\mathcal{U}(\pi_2(H, L)) > \mathcal{U}(H)$ based on a 95% confidence interval generated from bootstrap estimates of the sample mean. The blue region indicates areas where $\mathcal{U}(\pi_2(H, L)) > \mathcal{U}(H)$ with at least a 95% CI. The grey areas are where the confidence interval overlaps with 0. Interestingly, even when $\rho_H > \rho_L$, it could be advantageous to switch to the lightweight reranking of just the top two items despite having a poor (e.g., learned) policy L . Our experiments indicate that as we increase n , it is better to uniformly switch from H to $\pi_2(H, L)$ for all configurations.

The notation implies $\pi_1(H, L) = \lambda_H(1)$ and $\pi_n(H, L) = \lambda_L(1)$. In other words, $\mathcal{U}(\pi_1(H, L)) = \mathcal{U}(H)$ and $\mathcal{U}(\pi_n(H, L)) = \mathcal{U}(L)$. To understand precisely when the proposed aggregation might help, we now make some assumptions to help with mathematical tractability, analysis and visualization. Let $\rho_H \geq 0, \rho_L \geq 0$ be such that $\rho_H^2 + \rho_L^2 \leq 1$, and consider the jointly Gaussian distribution,

$$(U, H, L) \sim \mathcal{N} \left(\mathbf{0}, \begin{bmatrix} 1 & \rho_H & \rho_L \\ \rho_H & 1 & 0 \\ \rho_L & 0 & 1 \end{bmatrix} \right)$$

It is clear that $\mathcal{U}(H)$ and $\mathcal{U}(L)$ are monotone in ρ_H, ρ_L respectively under the above assumptions. To map the above model

³order 1 is the largest item.

to a motivating practical scenario, think of H as an efficient heuristic strategy (e.g. LRU). L could be imagined to be a learned policy that is (1) expensive to evaluate (2) not always safe, i.e. we can end up with $\rho_L < \rho_H$. The proposed mechanism addresses both of these issues simultaneously. For (1) we only need to invoke L on at most e.g. $k = 2$ items, and for (2) the below claim argues that we get an improved outcome, $\mathcal{U}(\pi_2(H, L))$ compared to the baseline strategy $\mathcal{U}(H)$ (which is also naturally greater than $\mathcal{U}(L)$, when $\rho_H > \rho_L$). Based on numerical analysis, we observe, and hypothesize more generally, that as $n \rightarrow \infty$, the re-ranking strategy improves over the pure heuristic policy, i.e. $\mathcal{U}(\pi_2(H, L)) > \mathcal{U}(H)$. The above hypothesis applies to arbitrary positive values of ρ_H and ρ_L . It says that we can improve on H even with a worse alternate policy L . This helps give some evidence for why such a strategy appears to be “safe” in terms of improvement over the baseline. In Figure 12, we plot the situation numerically for $N = 20$, for all possible problem configurations of ρ_H, ρ_L .

OpenLoRa: Validating LoRa Implementations through an Extensible and Open-sourced Framework

Abstract

LoRa is one of the most widely used LPWAN communication techniques operating in the unlicensed sub-GHz ISM bands. Its long range however also results in increased interference from other LoRa and non-LoRa networks, undermining network throughput due to packet collisions. This has motivated extensive research in the area of collision resolution techniques for concurrent LoRa transmissions and continues to be a topic of interest. In this paper, we verify the implementation and efficacy of four of the most recent works on LoRa packet collisions, in addition to standard LoRa. We implement *OpenLoRa*, an open-source, unified platform to evaluate these works and extensible for future researchers to compare against existing works. We implement each of the four techniques in Python as well as separate the demodulator and decoder to provide benchmarks for future demodulators that can be plugged into the framework for fair and easy comparison against existing works. Our evaluation indicates that existing contention resolution techniques fall short in their throughput performance in practical deployments, especially due to poor packet detection in low and ultra-low SNR regimes.

1 Introduction

LoRa is one of the most widely used Low Power Wide Area Network (LPWAN) technologies for IoT applications such as smart cities [1, 2], smart agriculture [3, 4], and industrial IoT [5, 6]. LoRa’s popularity stems from its long operating range, low power consumption, low-cost, and ease of deployment [7–10]. Its long range however, is a double-edged sword as it also results in increased interference from other independently deployed LoRa networks, leading to poor network throughput due to packet collisions [11, 12]. Ghena et.al [13] show that LoRa falls short of meeting the requirements for a large variety of IoT applications due to two key reasons : (a) under-utilization of the network capacity and (b) lack of co-existence between networks.

Recently, a large number of *LoRa collision resolution* techniques have been proposed to address the above chal-

lenges: Choir [14], FTrack [15], NScale [16], CoLoRa [17], mLoRa [18], CIC [19], Pyramid [20], and AlignTrack [21]. These techniques develop novel LoRa de-modulation algorithms that can simultaneously decode multiple colliding LoRa packets to improve network throughput and address scalability challenge faced by LoRa networks.

In this paper, we seek to compare and verify the efficacy of state-of-the-art in LoRa collision resolution algorithms and ask the question, “*How effective are state-of-the-art collision resolution techniques in improving network throughput?*”. Our goal is to evaluate and analyze various existing techniques in a variety of important scenarios such as indoor/outdoor and low/high-SNR networks. Towards this evaluation, we have developed *OpenLoRa*, an extensible, open-source framework using Python to implement each of the demodulators and design an evaluation pipeline, along with extensive datasets that can be used for benchmarking future works in LoRa receiver designs. To this end, we pick four recent techniques, (i) FTrack [15], (ii) NScale [16], (iii) CoLoRa [17], and (iv) CIC [19] that provide public implementations.

The motivation for our paper stems from several key gaps in the available implementations and evaluations.

Lack of throughput evaluations. While increasing network throughput (in kilo bits per second) is their key goal, most LoRa packet collision resolution literature evaluates the performance of the demodulator only, which outputs data symbols rather than bits; this can perhaps be attributed to the difficult task of recreating LoRa’s encoder and decoder. In the absence of the decoder, one can only evaluate the average symbol error rate, but not bit or packet error rates and hence network throughput in kbps. As we demonstrate in Section §5.1, lower symbol error rates do not necessarily translate to lower packet error rates and corresponding higher network throughput. In fact, seemingly lower symbol error rates compared to standard LoRa might still result in lower throughput!

Lack of co-existence evaluation. Although co-existence of LoRa networks has been identified as a key challenge [11–13], to the best of our knowledge existing literature has not studied the impact of interference due to other LoRa and non-LoRa

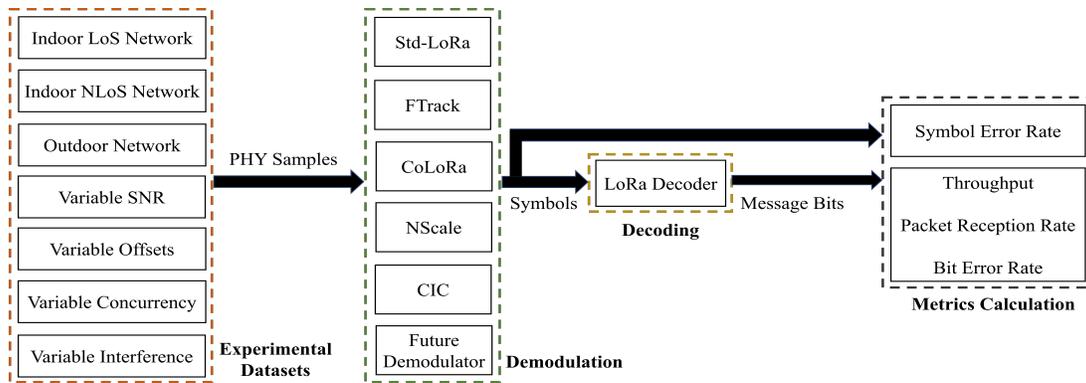

Figure 1: Overview of *OpenLoRa*, the proposed open-source framework

networks on the efficiency of collision resolution. In this paper, we design and perform a new set of experiments to measure the impact of LoRa interference from networks with different SF and non-LoRa interference such as FSK on the network throughput performance.

Lack of a uniform evaluation and a benchmark datasets.

Understanding and analyzing the performance of various techniques in different settings is crucial to future research. Existing evaluations differ in terms of evaluation metrics, methodology, scenarios that impact performance such as signal-to-noise-ratio (SNR), indoor/outdoor settings, nature of traffic, effect of bursts etc. In some cases, these have only been studied using simulations. In this paper, we create a set of benchmark datasets spanning various important LoRa scenarios that can be used to evaluate uniformly. In our experiments we find that existing techniques under-perform compared to standard LoRa in very low SNR scenarios.

Implementation variability. Current implementations do not use a common tool: Python, GNURadio, and MATLAB are some of the tools used. Additionally, each of the implementations have a different data preprocessing methodology, making it a challenging task to input a sample file and determine the metrics of interest. Therefore, despite the availability of public code repository, it is a challenging task to input a new file and obtain the performance of the demodulator.

In order to address the above gaps, we have implemented an evaluation framework (depicted in Figure 1) with the goal of providing a common framework to benchmark existing methods. We believe that our extensible framework will help future researchers evaluate LoRa collision resolution techniques uniformly against prior works with common datasets, and analyze them. *OpenLoRa* includes a pipeline of four key stages. First, a suite of experimental datasets comprising received raw samples of LoRa transmissions obtained from various experimental deployments, specifically designed to evaluate various important aspects of collision resolution algorithms. Second, a uniform Python based interface to interact with each demodulator. A future LoRa demodulator algorithm can be simply plugged into this framework and compared against other implementations on the metrics of interest for

real-world deployments. Third, a standard LoRa decoder that can convert symbols generated by any demodulator into packets, so that we can measure bit error rates, packet error rates, and throughput. Last but not the least we provide a suite of important metrics such as bit error rate, packet reception rate, and network throughput.

In summary, we make the following contributions towards our verification of state-of-the-art LoRa demodulators:

- We present *OpenLoRa*, an extensible, open-source framework to evaluate and compare different techniques that we hope future researchers will be able to use (provided in GitHub repository¹ as well as in a Docker container² enabling environment-independence to run the demodulators locally). Our framework comprises benchmark datasets, a standard interface to plug in various demodulators, a LoRa decoder that outputs bits and a suite of relevant metrics.
- We implement and verify the performance of four state-of-the-art LoRa collision resolution demodulators and standard LoRa, comparing their throughput (in kbps) improvements. We find a surprising fact that even though many techniques decode more symbols on average than standard LoRa, this does not necessarily translate to throughput improvements. As the network traffic increases in long-range outdoor scenarios, standard LoRa outperforms all existing techniques.
- In order to cross-validate the results reported in original works, we recreate the key experimental scenarios presented by each and compare the results. Our results are in line with the results in the respective papers evaluated. This extra effort validates the fidelity of our framework and implementation of various demodulators.
- We develop a web interface³ for users to easily add new custom demodulation techniques for benchmarking and analyze the performance of implemented techniques.

¹ <https://github.com/UW-CONNECT/OpenLora>

² Linked in OpenLoRa Github page.

³ <https://openlora.wisc.edu>

- We implement and validate the standard LoRa decoder in Python, allowing the comparison of different demodulation techniques based on end-to-end metrics such as throughput (in kbps) and the number of successfully received packets after error correction. We hope this openly accessible implementation enables future researchers to evaluate their works based on similar end-user metrics.
- We design new experiments to study the effects of collisions under extremely-low SNR, interference from LoRa networks with different spreading factor and non-LoRa interference such as Frequency-Shift-Keying from other networks on the throughput performance.

2 LoRa Demodulators Validated

In LoRa, data is modulated using a Chirp Spread Spectrum (CSS) scheme which confers it long range and sub-noise decoding ability. We present details on LoRa’s modulation/demodulation and effects of collision on network throughput in Appendix A. Choir [14] is a pioneering work in LoRa collision resolution with the goal of improving network throughput. It leverages the inherent hardware imperfections in the radio of LoRa transmitters and distinguishes colliding packets by uniquely mapping their imperfections to the transmitters. mLoRa [18] leverages Successive Interference Cancellation to iteratively decode the symbols with the highest power and remove them from consideration. In this paper, we implement four demodulator algorithms that improve upon Choir and mLoRa to decode multi-packet collisions. We discuss these demodulators in the rest of the section.

2.1 FTrack [15]

FTrack is one of the first approaches to use time and frequency domain features to resolve LoRa collisions. FTrack relies on Short Time Fourier Transform (STFT) to obtain time and frequency features. FTrack proposes to apply STFT on the dechirped LoRa symbol to leverage the spread spectrum gain as well as to remove the linear change in frequency with time. Appendix B.1 explains how FTrack chooses an appropriately sized window and leverages time-frequency resolution to resolve collisions.

2.2 CoLoRa [17]

CoLoRa, similar to FTrack, leverages time offsets and frequency features to resolve collisions. CoLoRa observes that collided packets are misaligned in time and therefore have different lengths of symbol segments appearing in the demodulation window. This results in FFT peaks with heights proportional to the length of the symbol in the current demodulation window. CoLoRa also observes that the ratio of FFT peak between two consecutive windows remains the same

throughout a packet. It uses these key insights to translate time offsets to frequency features and differentiate colliding packets. Details on CoLoRa’s demodulation window choice and the use of peak ratios can be found in Appendix B.2.

2.3 NScale [16]

As the range increases, the SNR of LoRa packets decreases and the relative performance improvement of FTrack and CoLoRa degrades. NScale [16] focuses on decoding packet collisions at SNRs as low as -10dB. Similar to CoLoRa, it translates the timing offsets to frequency features and further amplifies the time offsets by non-stationary signal scaling. NScale’s strength lies in its ability to decode and resolve LoRa packet collisions at SNRs below -10 dB. In Appendix B.3, we explain how NScale achieves sub-noise decodability.

2.4 Concurrent Interference Cancellation [19]

Concurrent Interference Cancellation (CIC) also leverages time and frequency domain analysis to decode multi-packet collisions. CIC identifies that due to Heisenberg’s Time Frequency Uncertainty Principle, one can achieve either the best frequency resolution or best time resolution, not both. CIC attempts at getting the best of both resolutions by accumulating multiple windows of varying lengths, resulting in varying time and frequency resolutions. Appendix B.4 explains CIC’s technique to resolve packet collisions.

3 Framework Implementation

We implement *OpenLoRa* and evaluate standard LoRa, FTrack, CoLoRa, NScale, and CIC in a uniform framework using Python as illustrated in Fig. 1. The extensible framework also provides the ability to add a new demodulator and evaluate its performance against the implemented techniques over the datasets collected over a range of scenarios.

We have built an easy-to-use web interface to help users analyze the implemented demodulators’ performance in more detail. We also provide the option to plug-in one’s own new demodulator for benchmarking, with a few simple steps. Some screenshots to walk through the web page are provided in Fig. 2. The homepage asks for user selection to either add a new demodulator or run existing techniques as shown in Fig. 2(a). Fig 2(b-c) show the flow to add a new custom demodulator with the user downloading the existing framework, adding their files, testing on a sample dataset and uploading to run and compare against already implemented techniques. Similarly, Fig 2(d-f) show the flow to analyze the existing demodulators in detail by choosing a scenario and configuration among those presented in Section §5 and presenting detailed data points as well as plots.

OpenLoRa has a pipeline of four major blocks: datasets, interface to the demodulators, decoder, and metrics. We describe each one of these blocks in detail below.

3.1 Datasets : Experimental setup for data collection

For a thorough and fair evaluation of the demodulation algorithms, a uniform set of data sample files is necessary. We deployed practical networks of LoRa nodes in varying configurations (SF and BW) and scenarios (Line-of-Sight, SNR) as shown in Fig. 3. We believe the presented evaluation accounts for a comprehensive (but not exhaustive) set of conditions to assess the feasibility of real-world usage, and serve as a benchmark to gauge the performance of future work in this domain. We will make the datasets, along with the ground truth, publicly available for reproducibility. We believe this will help other researchers to evaluate their work on a variety of scenarios as well.

We used 20 battery-powered Adafruit Feather M0 with RFM95 [22] as LoRa transmitters deployed in the following settings, with a USRP B200 as the receiver. Unless otherwise mentioned, by default, each transmitter sends a known message, while the duty cycle and the load follows a Poisson distribution. The arduino code flashed onto Adafruit Feather M0 boards and the circuit diagram to setup the boards can be found in the github repository⁴ under the folder `Experiment_Setup`. At each of the locations (red dots in Fig. 3), the individual transmitters were verified to be reachable from the receiver i.e., in the absence of collisions, LoRa packets from each of the transmitters were successfully received using the standard LoRa demodulator. Each data point in the evaluation results was averaged over multiple iterations of data transmissions (ranging from a minimum of 200 packets to over 6000 packets depending on the scenario). The details on each experimental setup and the methodology specific to each experiment can be found in the Appendix E. The three settings used in our experiments are:

1. **Indoor Line-of-Sight (LoS)** : This setting serves as a high-SNR scenario in our experiments. Twenty LoRa nodes were deployed in a 15m x 10m room, distributed uniformly in LoS with the receiver as shown in Fig. 3 (a). This setting emulates a deployment similar to a smart home, with IoT nodes distributed in a small space, many of which have LoS to the receiver. In this setup, we performed experiments which required precise control over collision parameters, parametric analysis with controlled time offset between colliding packets, concurrent collisions, and high SNR collisions.
2. **Indoor Non-Line-of-Sight (NLoS)** : This setting serves as a low-SNR setting inside a building spanning an area of

150 m x 75 m (per floor) over two floors. The transmitters were deployed as per Fig. 3 (c) and (d), showing the distribution of nodes on first and second floor respectively. The nodes were distributed in NLoS setting, separated from the receiver by multiple concrete walls, elevator shafts, and metal obstructions. This setting emulates a typical deployment of IoT nodes in an indoor office or factory building, with human movement as well as wireless traffic interfering with active transmissions. This setup was used to collect datasets for collisions with increasing aggregate transmission rate. We also performed controlled interference experiments here.

3. **Long-range outdoor** : This setting serves as an extremely low-SNR setting with nodes at distances of 1 to 8.25 km from the receiver. The nodes were distributed across urban areas and along a lake shore as seen in Fig. 3 (b). This setting emulates applications which particularly benefit the use of LoRa modulation where communication over long distances is necessary, such as city monitoring applications or sensor deployment across huge agricultural fields. We collected datasets for various transmission rates in extremely low-SNR conditions.

3.2 Demodulators Block

Fig. 13 in Appendix C.1 shows an overview of the Python implementation and how the demodulators were integrated into the overall flow of the framework. Appendix C.2 also describes the organization of the implementation code into Python modules. We thank the authors of each of the works presented here for sharing their implementations with us. In addition to re-implementing the code in Python, the following refinements were made to accept and pre-process a variety of datasets, as well as to reduce the computation time of demodulation using parallel processes:

FTrack : FTrack processes the entire input data file at once. While it is feasible for slices with a few packets, it is computationally intensive for real-life data capture with tens of million of samples. This also posed a challenge in the memory constraints for practical datasets such as those from our experiments. To mitigate this, we built a pre-processing block that separates out the active data transmission from silence periods based on energy thresholds of the signal and passes only the valid transmission data to the demodulator. FTrack's demodulator algorithm uses a number of threshold parameters for separating collisions such as peak power ratio, noise floor power, and ratio of stronger to weaker peaks, among others. These parameters need to be modified based on the input dataset for accurate functioning of the algorithm. We set these parameters based on our datasets empirically, however a formal procedure for the derivation of these thresholds would be highly beneficial for any user.

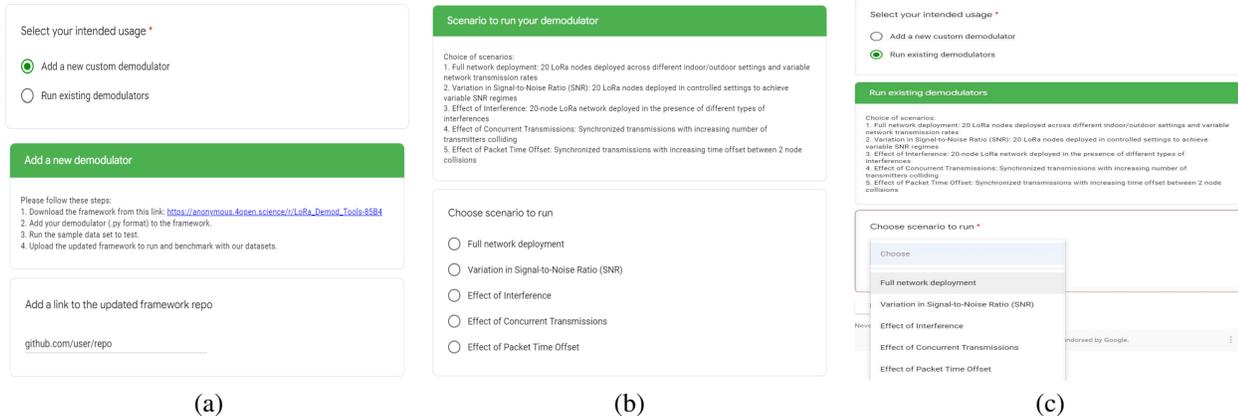

Figure 2: Screenshots from the system interface web page : (a) Flow to add a new demodulator (b) choose a scenario to benchmark (c) Flow to run an existing demodulator for analysis with network setting and SF configuration

NScale : In addition to re-implementing in Python, we parameterized NScale implementation to accept datasets with different LoRa configurations. Various parameters and thresholds for recognizing sync words, clustering packets from the same transmitters together, and choosing the correct demodulation window were generalized to get the optimal demodulation results. The original implementation resulted in missed or repeated symbols when any of the collided packets was split approximately in half by the demodulation window due to ambiguity in length and peak ratios. We implemented an up-chirp correlation-based packet identification, as described in the paper, and aligned the demodulation window appropriately to avoid this corner case.

CoLoRa : We implemented an up-chirp correlation based strategy to process the input file parallelly using Python multiprocessing. This enabled us to identify the start of packets and choose a reception window, ensuring any symbol's split ratio to be between 1/3 and 3 as derived in the paper. We implemented the Akaike Information Criterion based algorithm to detect the onset of the received packet.

CIC : CIC iteratively decodes packets and hence stores the entire data transmission session. At higher data rates, frequent transmissions can lead to very long packet transmissions that can overflow the memory. We overcome this challenge by splitting active data transmissions longer than a threshold into multiple sessions and process them separately.

Std-LoRa Demodulator : For the implementation of the standard LoRa demodulator, we used *rpp0/gr-LoRa* [23], an open source GNURadio block for decoding LoRa packets. *gr-LoRa* has demodulator and decoder integrated as a single block. We split the two into separate blocks and used the demodulator as part of our std-LoRa demodulator implementation. It looks for the strongest peak in each demodulation window and tries to find consecutive occurrences of the same symbol to detect preambles. Once all the preambles are detected and the preamble indices saved, it continues finding the strongest

peak in every demodulation window of the detected packet and outputs the corresponding symbols.

3.3 Standard LoRa Decoder Block

Majority of the existing works focus on demodulator performance as a function of the symbols received. A LoRa receiver consists of a demodulator followed by a decoder. The decoder maps received symbols to message. LoRa decoder (and encoder) is responsible for performing forward error correction using Hamming codes, interleaving, whitening, and gray coding to decode symbols to bits and then message. LoRa supports four coding rates ranging from 4/5 having the least redundancy to 4/8 having the highest. This redundancy allows the LoRa signal to endure interferences and correct small errors. While the demodulated symbols provide some understanding of the receiver, the output of the decoder is required to obtain metrics such as throughput, bit error rate, and number of packets successfully received. Additionally, the number of symbol errors that can be corrected by the receiver depends on the coding rate used by the LoRa transmitter.

In order to evaluate the throughput performances of the demodulators, we implemented LoRa decoder in Python. We used an open-source LoRa receiver framework [23] that jointly demodulates and decodes LoRa samples and separated the decoder and demodulator modules. We then implemented the decoder module separately in Python such that the output of any demodulator can be decoded. This allows for a modular implementation of a LoRa receiver pipeline. Our decoder implementation first extracts the symbols corresponding to LoRa header from the demodulator output. It infers the payload CRC and payload length information by reversing the process of Gray encoding, interleaving, shuffling, and Hamming encoding. Finally, these operations are performed on the symbols corresponding to the payload and the final message is displayed as the output. This process is repeated for

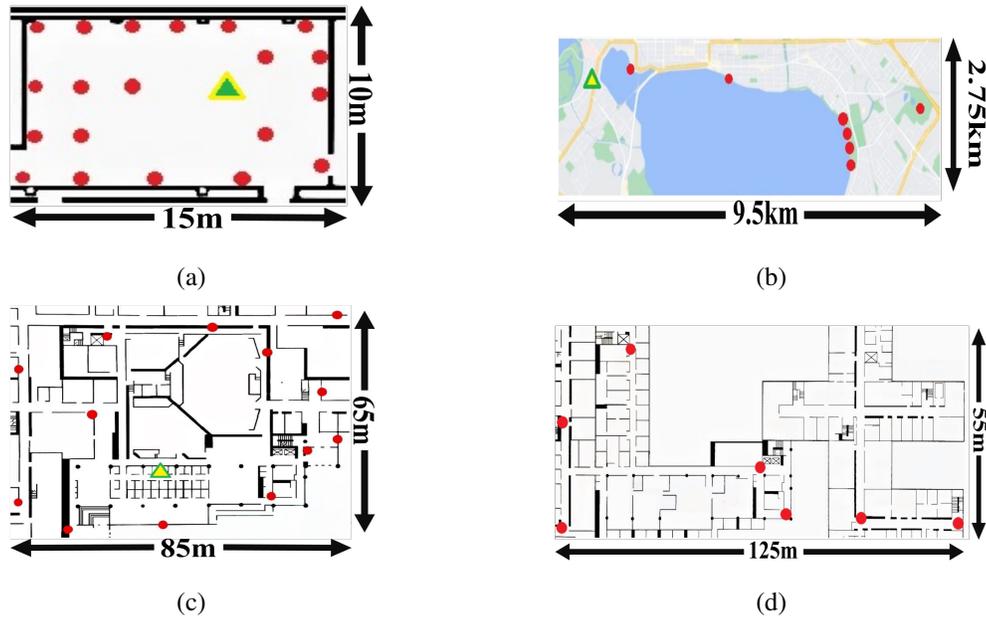

Figure 3: Experimental Setup for LoRa deployments. (a) Indoor LoS, (b) Outdoor, (c) 1st and (d) 2nd Floor Indoor NLoS. Triangle:Base Station, Circles:Transmitters

each demodulator’s symbols and the final output is used to calculate the metrics. We validate this Python implementation of the standard LoRa decoder in Section §4. As shown in Fig. 13 in Appendix C.1, the implemented decoder is independent of the demodulators and thus can be integrated with any other demodulator in the pipeline. This openly accessible implementation we have made available, can be used by other researchers to evaluate their demodulator on end-user metrics.

3.4 Metrics

The final module of *OpenLoRa* is the set of metrics that evaluate the end-to-end-performance. This module takes in the demodulated symbols and decoded bits and outputs the calculated metrics. We use the following definitions for the metrics exposed by our framework:

1. Symbol Error Rate (SER): SER is calculated as the ratio of number of incorrect symbols to the total number of transmitted symbols. This metric evaluates the efficiency of demodulator algorithms. With prior knowledge of the transmitted symbols, a one-to-one comparison is used to determine the number of incorrect symbols per packet.
2. Packet Reception Rate (PRR): PRR is calculated as the ratio of number of correct packets received to the total number of transmitted packets. A packet is considered correct if and only if the received message (after error correction) is equal to the transmitted message. Thus, PRR is determined from the output of the decoder.

3. Throughput: This is the one of the most important metrics from an end-to-end workflow perspective. Throughput is defined as the number of correct bits received per second. Towards calculating throughput, we only consider correct packets i.e., packets where all the received bits are correct.

Calculating metrics from the decoded bits provides a holistic evaluation of the receiver performance of the demodulator algorithms, which we believe is critical in practical LoRa deployments. We will use the metrics used in the papers being validated first, in order to cross-validate our implementation in Section §4. Then, we will present our evaluations using the end-to-end metrics of Packet Reception Rate and Throughput obtained from the output of decoder in Section §5 under varying settings, configurations, and scenarios.

4 Cross Validation of the Demodulators

In order to validate the fidelity of our framework and implementation of the various demodulators, we recreate a representative result from each of the four papers considered. As mentioned in Section §2, each existing work proposes unique techniques to resolve multi-packet collisions. Existing works compare their performance against standard LoRa and a few other existing state-of-the-art. However, each one of them uses a dataset that has been captured in different experimental scenarios, using different configurations for Spreading Factor, Bandwidth, duty cycle and concurrency.

In this section, we recreate the experimental setup as discussed in the original papers to the best of our knowledge and

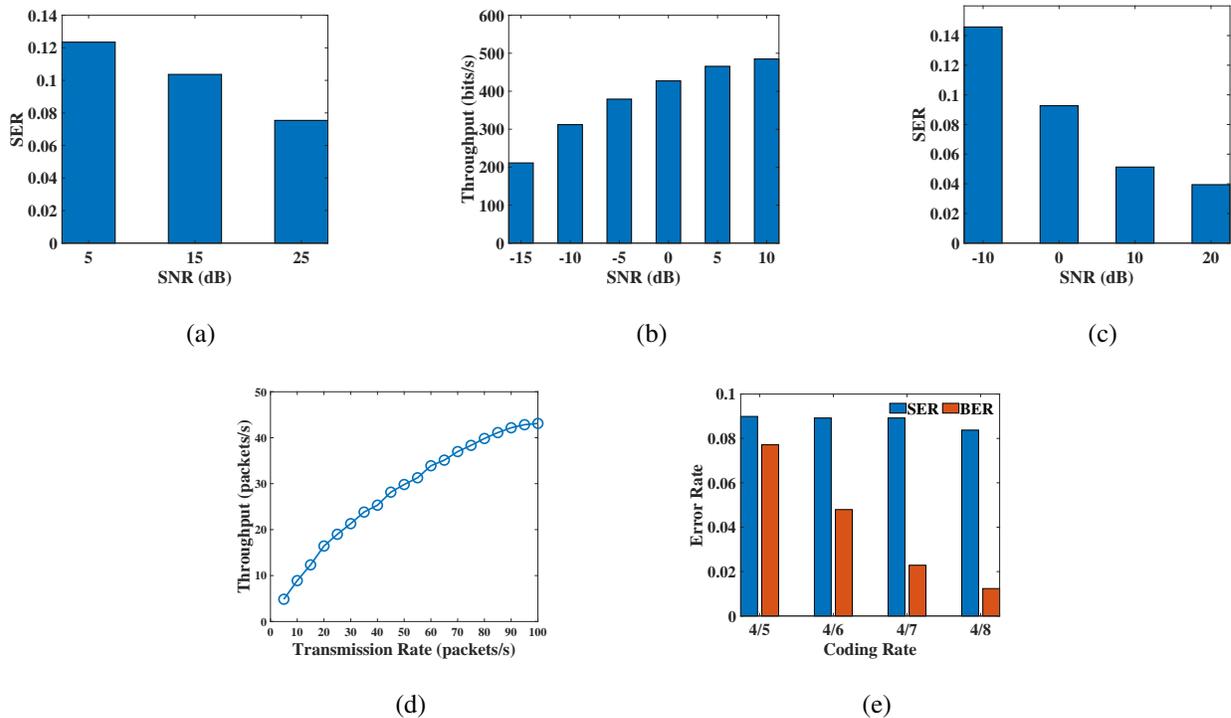

Figure 4: Cross-validation of results from original papers : (a) FTrack: SER vs SNR (b) CoLoRa: Network Throughput vs SNR (c) NScale: SER vs SNR (d) CIC: Throughput vs Aggregate rate (e) Cross-validation of Std-LoRa Decoder : SER and BER for varying coding rates of a single transmitter

report the same result metrics. The goal of this exercise is two-fold : 1) To validate our implementation by recreating the original reported results in each of the papers considered 2) To provide a module in our framework for future works to recreate the existing works and their results.

We have selected the following results to recreate :

1. FTrack’s Fig. 14 : SER vs SNR
2. CoLoRa’s Fig. 12 : Throughput vs SNR
3. NScale’s Fig. 11a : SER vs SER
4. CIC’s Fig. 28 : Throughput vs transmission rate

FTrack: Following FTrack’s setup, we created the two-node collisions initiated by beacon packets. Upon listening to the beacon packets, the two LoRa nodes send packets with a random delay within a packet duration ensuring collisions. Each node transmitted packets of fixed length with SF8 and BW 250kHz. To achieve the SNR ranges of low (<5dB), medium (5 – 20 dB) and high (>20dB) as mentioned in the paper, we installed nodes at appropriate distances to achieve SNRs of 5, 15 and 25dB respectively. Fig. 4 (a) shows that the SER decreases with increasing SNR, implying better collision resolution at high SNRs by FTrack. SER of ≈ 0.1 is in complete agreement with the results presented in the original work.

CoLoRa: We design the experiment with a 20-node architec-

ture that closely follows the description in the original paper. Each node transmitted SF10, BW 250kHz packets at a fixed rate of 1 packet per second. As mentioned in the paper, we captured data for high SNR packets and then added Additive White Gaussian Noise (AWGN) on the captured data to vary its SNR in a controlled manner. Fig. 4 (b) shows the throughput that we obtain for varying levels of emulated SNR. As the SNR increases from -15dB to 10dB, the network throughput increases from 200 bits/s to over 400 bits/s. This result is in complete agreement with the original work.

NScale: For NScale, we generated beacon-initiated collisions with the responding nodes transmitting packets with SF10 and BW 125kHz, following the experimental setup of NScale. We installed nodes at distances that ensured SNRs of -10, 0, 10, and 20 dB. As shown in Fig. 4 (c), lower SER of 0.04 at 20dB SNR indicates strong collision resolution capability of NScale. SER increases slightly for -10dB SNR to approximately 0.1, close to the results presented in NScale. This trend is similar to the original results presented and verifies that NScale is able to achieve low SER even at -10dB SNR.

CIC: In order to recreate the result in CIC, we used the open source data-set provided by CIC in the GitHub repo instead of designing a new experiment. The results, as shown in Fig. 4

(d) are in complete agreement with actual results presented in the paper. CIC's throughput improves from 5 packets per second to over 40 packets per second as the aggregate rate increases, indicating its ability to resolve collisions.

Std-LoRa Decoder : We also validate the correctness of our decoder implementation, since it forms the basis of throughput in Section §5. To validate the decoder, we designed an experiment to study the impact of Forward Error Correction (FEC) over raw symbols. LoRa offers 4 coding rates : 4/5, 4/6, 4/7, 4/8 where 4/8 implies twice as many redundant bits as data bits. Therefore, higher coding rates lead to better reliability and resilience to bit errors, but lowers effective data-rate. We placed a LoRa transmitter in a NLoS setting from the receiver to ensure low SNR of approximately -15dB. We transmit SF8 packets with 250 kHz BW and vary the coding rate of the transmitter for the same message. Fig 4 (e) shows SER and BER for varying coding rates. We can observe that the SER remains almost constant, since SER is unaffected by the coding rate and only depends on the SNR. However as the coding rate varies from 4/5 to 4/8, redundancy increases and as expected, the decoder is able to correct more errors such that the Bit Error Rate decreases from 7.7% to 1.2%. This result establishes the expected decoder operation and validates our implementation of the standard LoRa decoder. This reliability comes at the cost of longer packet time with the coding rate of 4/8 needing 64 ms to transmit the same data as compared to 49 ms for 4/5 coding rate.

To summarize, we recreated one representative result from each of the papers being validated to verify the correctness of our implementation as well as validate the results with the exact same experimental setup described in the respective papers. We show that the results recreated are in complete agreement with that in the original papers. We also validated the decoder block implemented by comparing the SER and BER performance for varying coding rates. In the next section, we design new experiments to further test the throughput performance of each of these demodulators integrated with our LoRa decoder block.

5 Experimental Evaluation

We evaluate the performance of the five demodulators on several metrics and configurations. We aim to answer the following questions in this section through our experiments:

- Do collision resolution techniques improve the overall network throughput in the presence of collisions?
- What is the impact of variations in the SNR for different transmitters on decoding multi-packet collisions?
- What is the impact of LoRa and other non-LoRa narrow-band interferers in decoding concurrent transmissions?

- How many concurrent transmissions can be successfully decoded from the cumulative signal?
- How does the time offset between two colliding packets affect the demodulation and throughput performance?

In the rest of this section, we describe the experiments performed and the results observed to answer these questions. Most of the experiments were repeated for two different configurations: SF8, BW 125kHz and SF10, BW 250kHz, to represent low and high air-times respectively. Unless otherwise mentioned, the default configuration is the larger packet airtime with SF10, BW 250kHz, and a coding rate of 4/5.

5.1 Impact of transmission rate on Network Throughput

In this section we evaluate the overall network throughput achieved by various techniques for *Indoor LoS*, *Indoor NLoS* and *Outdoor* data sets for a 20-node network. The transmission rate of each node is varied from 1 packet/s to 5 packets/s, resulting in an aggregate network rate of 20 packets/s to 100 packets/s as the x-axis. Packets were generated with inter-arrival times following an exponential distribution. We collected upto 6000 packets for each iteration of this experiment for different transmission rates, repeated for both SF, BW configurations. Each data point in the figures presented is averaged over all these packets.

Indoor LoS: In this scenario, packets from almost all the nodes are captured at high SNR therefore, all techniques perform at their best. We present the results and analysis of this scenario in Appendix D.1.

Indoor NLoS: At low-SNR indoor NLoS scenario, where 20 nodes are deployed across two floors in an office building, a trend similar to indoor-LoS can be observed with increasing Transmission Rate. As shown in Fig. 5 (a) and (b), at low SNR, the average network throughput is lower than that of higher SNR for most demodulators. All the demodulators achieve their peak throughput at 40 packets/s in case of SF8 transmissions, beyond which it decreases with an increase in the aggregate transmission rate. In case of SF10 transmissions, a much sharper descent in the throughput curve can be seen due to the compounding of the lower SNR with more severe collisions. As noted by the authors themselves in [15], FTrack fails to detect packets at SNRs lower than 10dB. Since majority of the nodes operated near the noise floor (0dB SNR) in this setting, FTrack failed to detect any packets and is not shown in the corresponding Fig. 5.

Long Range Outdoor: To test the long-range capability of LoRa and the demodulators, we deployed LoRa nodes in outdoor environments at distances as far as 8 km from the receiver. Transmissions from these devices were received at SNRs as low as -15dBm. At this low SNR, even schemes that are specifically designed for low-SNR such as NScale were unable to detect any packets. While only CIC was able to

○ CIC * NScale ✕ Std-LoRa □ CoLoRa

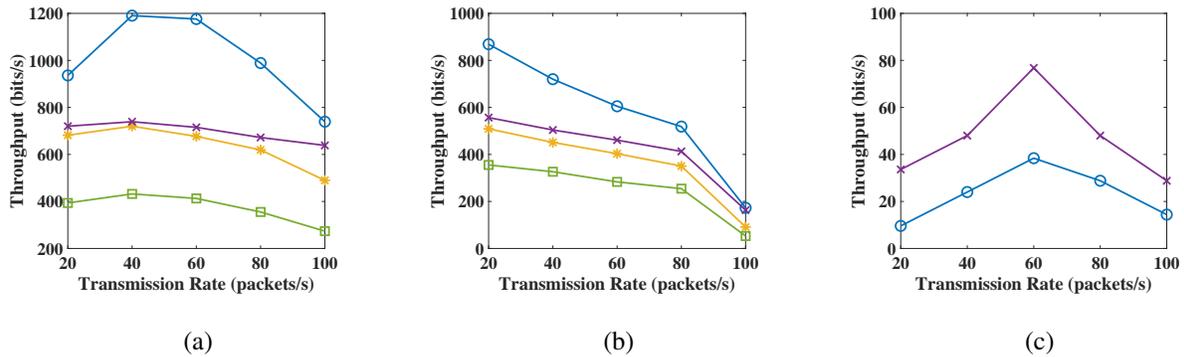

Figure 5: Throughput of a 20-node indoor NLoS network with increasing aggregate transmission rates
 (a) SF8, 125kHz bandwidth (b) SF10, 250 kHz bandwidth
 (c) Throughput of a 20-node outdoor network with SF10, 250 kHz bandwidth

receive packets, its network throughput is worse than that of standard LoRa as seen in Fig. 5 (c).

Summary: In summary we arrive at the following conclusions : on an average, the network throughput is higher for SF8/125kHz than that of SF10/250kHz for every demodulator. This is because, for the same message, SF10/250kHz packets have twice the duration of SF8/125kHz, which leads to a higher probability of collisions. As the aggregate rate increases, the network throughput peaks due to higher traffic. Further increments lead to an increased number of collisions, thus reducing network throughput. Extreme combination of configuration parameters: NLoS, SF10, 100 packets/s (Fig. 5 (b)), leads to comparable throughput for all demodulators, with excessive collisions nullifying any gains from the elaborate demodulation techniques as compared to the simplistic Std-LoRa. CIC demonstrates significant throughput gains over Std-LoRa in both high (>10dB) and low SNR (around 0dB) settings, followed by FTrack (in high SNR scenario) and NScale. CoLoRa despite performing better on the metrics of SER and BER, falls short of matching Std-LoRa’s throughput. FTrack fails to demodulate any packets in the low SNR settings. Most techniques perform poorly at extremely low SNRs (around -15dB) as their preamble detection fails and is not as robust as Std-LoRa. Based on our experiments we believe that further study and *novel techniques for packet detection and collision resolution, especially in low-SNR regimes is needed.*

5.2 Impact of Signal to Noise Ratio (SNR) on Network Throughput

We note from the network throughput in the long-range outdoor settings above that none of the existing techniques perform better than Std-LoRa at extremely low SNR scenarios. To study the impact of SNR on the throughput performance of each demodulator, we design a new controlled experiment.

In the Indoor setup, we deploy 20 LoRa nodes and accurately control their transmit power and physical placement such that all the nodes have comparable SNR that falls under one of the following categories. We repeat the experiment such that all the nodes are in High, Medium, Low, and Extremely-low SNR categories, as defined below :

- **High SNR** : >10 dB
- **Medium SNR** : 5 to 10 dB
- **Low SNR** : -5 to 5 dB
- **Extremely Low SNR** : <-5 dB

Each transmitter was configured at SF10, BW 250kHz; we collected upto 3000 colliding packets for each combination of SNR and transmission rate. Fig. 6 shows the throughput of the network as a function of decreasing SNR regime defined above, repeated for aggregate transmission rates of 20, 60 and 100 packets/s respectively. Due to the controlled setting needed for this experiment, it was not performed in the outdoor setting.

Summary: The results corroborate the earlier observations in indoor and outdoor experiments. CIC, NScale, and FTrack outperform Std-LoRa in high SNR, low traffic scenarios (Fig. 6 (a)) because of lesser collisions. However, as the SNR drops below noise floor, the throughput gains delivered by these demodulators decline sharply. FTrack fails to detect packets in lower SNR settings, whereas the throughput for other demodulators drop as we move towards lower SNR and higher transmission rates (Figs. 6 (b) and (c)). As stated in NScale, its performance is comparable to FTrack at high and medium SNR, and outperforms FTrack at lower SNRs. CIC improves the most over Std-LoRa in most of the scenarios, NScale also performs well in medium and low SNR regimes, not

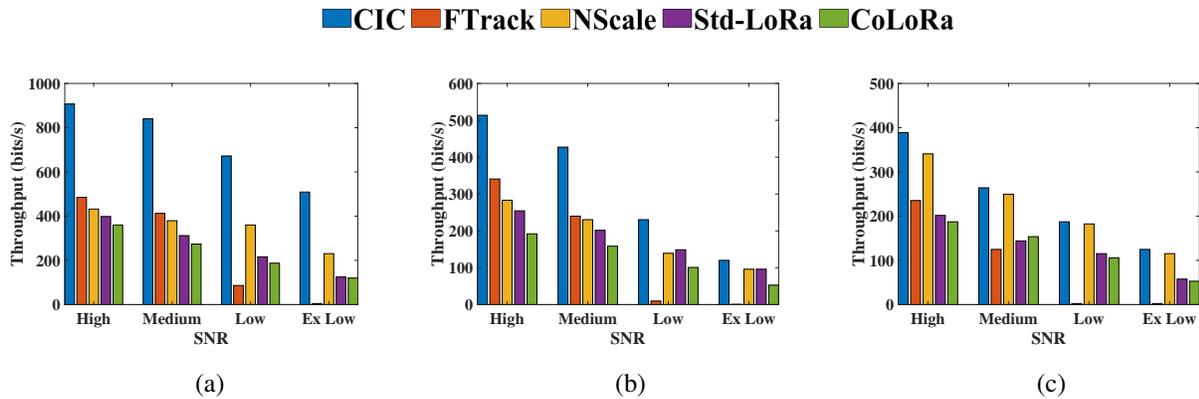

Figure 6: Throughput of a 20-node SF10 network with varying SNR and aggregate transmission rates (a) 20 packets/s (b) 60 packets/s (c) 100 packets/s

suffering excessive drop in throughput with lower SNR. At extremely-low SNR settings, all these techniques fail to demodulate most of the packets, which is further worsened at higher traffic rate. Similar to our earlier observations, the SER analysis of CoLoRa indicates that even though it has low SER, at low and extremely low SNRs, the overall throughput is worse than that of Std-LoRa. From these experiments, we conclude that further research is required to achieve significant throughput gains over standard LoRa in extremely-low SNR and/or dense deployments, that are typical scenarios for LoRa applications.

5.3 Impact of Interference on Network Throughput

In addition to underutilized network capacity, co-existence of multiple LoRa networks as well as across technologies was identified as a bottleneck for scalability [11, 13]. In this experiment, we evaluate the throughput performance of the five demodulators in the presence of LoRa transmissions from neighboring LoRa networks as well as non-LoRa, Gaussian Frequency Shift Keying (GFSK) narrow-band transmissions, representing other LPWANs operating in the same band. To the best of our knowledge, this is the first work to design an experiment and evaluate the impact of interference on the demodulator performance.

The primary LoRa network in this setup consists of 20 nodes, configured at SF10, BW 250kHz setting. We study the impact of the following three interfering nodes, each placed within few meters from the receiver; the interfering signal transmits at a duty cycle of 50% with an SNR of approximately 7 dB at the receiver.

- i SF8, BW 125kHz LoRa node sending 93 ms packets
- ii SF12, BW 500kHz LoRa node sending 290 ms packets
- iii GFSK node sending 50 ms packets

Summary: Fig 7 shows the network throughput under these three types of interference. *Ambient* shows the results with no added interference. Due to the orthogonality of CSS, we expected no impact from SF8, BW 125kHz node. However, it does have a very minor impact on the performance of SF10 nodes for most demodulators. Although LoRa signals with different SFs are typically assumed to be perfectly orthogonal, this result attests to the Quasi-Orthogonality of different SFs (discussed in [24]). This quasi-orthogonality leads to residual interference even after dechirping which raises the noise floor and consequently reduces the SINR (Signal to Interference + Noise Ratio). GFSK interference has a minimal impact on the throughput performance, with a minor drop attributed to SINR. This showcases the inherent robustness of CSS to other narrow-band interference. SF12, BW 500kHz interference however notably reduces the throughput of all demodulator algorithms by almost 50%. This is primarily due to the longer packet duration of SF12 which has higher probability of interfering with complete SF10 packets whereas shorter duration of SF8 packets are less likely to interfere complete SF10 packets. Thus, higher SFs have more impact on lower SF transmissions due to the increased probability of collision. This is critical to notice in practical deployments where multiple LoRa networks, each operating at a different SF would co-exist. Additionally, SF-based MAC protocols have been proposed as a way to improve LoRa’s scalability. Thus, we believe that collision resolution techniques that consider the impact of interference from other LoRa networks with multiple SFs remains to be developed.

5.4 Impact of concurrent transmissions on Packet Reception Rate

In the experiments so far, the nodes transmitted packets randomly at a predetermined rate. As the rate increased, packet collisions increased, affecting network throughput. To understand the efficacy and limitations of each algorithm in decod-

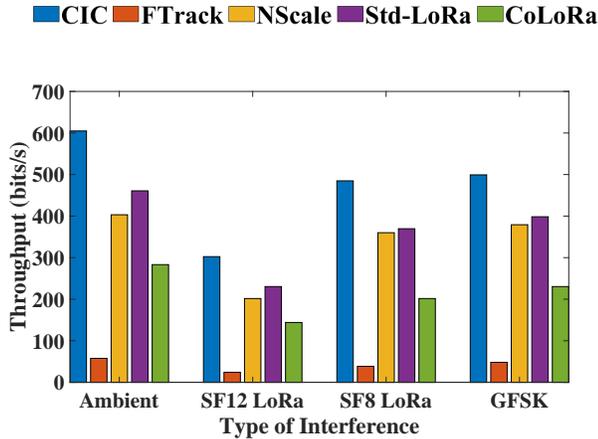

Figure 7: Throughput of a 20-node SF10 network in the presence of various interference signals

ing concurrent collisions, we performed controlled collision experiments. We synchronized all the nodes with a beacon packet: on receiving a beacon, each sender transmits a single packet with a random delay between 0 and packet duration. We define concurrency to be the number of colliding packets within one packet duration i.e., each packet partially overlaps with every other packet.

We evaluate the number of colliding packets that can be resolved by each demodulator using the metric Packet Reception Rate (PRR). We measure PRR as we increase the number of concurrent packets from 2 to 12 in indoor LoS setup. We define PRR as the ratio of fully correct packets decoded at the receiver to the total number of packets transmitted from the transmitters. We collect upto 180 such colliding packets for each iteration of the experiment and present the metrics averaged over this dataset. Figs. 8 (a) and (b) show the PRR for SF8/125kHz and SF10/250kHz.

As the number of concurrent transmissions increases, PRR decreases for every demodulator. As expected, Std-LoRa has a sharp decrease in PRR since it demodulates at most one packet at a given time. We notice that irrespective of the number of nodes, Std-LoRa aligns with the strongest signal and successfully demodulates symbols corresponding to that packet. CoLoRa intentionally misaligns its demodulation window to detect more packets. Although CoLoRa detects most of the packets, it fails to demodulate when the majority of a packet overlaps with other packets. This is because of errors in finding peak ratios accurately. NScale builds on CoLoRa and improves demodulation; PRR using NScale is higher than that of CoLoRa. However, it suffers from not recognizing frequency bins of the detected peaks in presence of collisions, often leading to small offsets in the demodulated symbols. FTrack’s use of time and frequency domain features to create frequency tracks and separate out collisions enables it to infer more number of colliding packets. FTrack is able to correctly

output 3% to 5% more packets as compared to Std-LoRa. CIC, which improves on FTrack has the highest PRR. CIC’s use of interference cancellation and spectral intersection features to demodulate enables it to demodulate most number of colliding packets. Beyond 8 concurrent collisions, PRR of all the approaches is below 0.2.

Summary: We observe a sharp decrease in PRR with increasing concurrency for all techniques because increasing concurrency reduces SINR. In this controlled collision setting, we see that SF10 transmissions result in a higher PRR, in contrast to the observations for scenarios with random collisions. This is because higher packet air-time with SF10 works in favor of demodulators here as there is more leeway in how closely in time the transmitters can collide. As the network scale of LoRa deployments increases, we expect concurrent collisions to occur with higher probability. We study the impact of the time between two colliding transmissions in more detail in the following section. *We believe that there is still room to improve in decoding collisions with more than two concurrent transmissions.*

5.5 Impact of Packet Time Offset (PTO) on Packet Reception Rate

It is evident from the concurrent transmission experiments that as the number of concurrent transmissions increases, the packet reception rate and hence network throughput decreases. Prior work [15] has also observed that the relative time (and frequency) offsets between two colliding packets plays a critical role in the throughput performance. Therefore, the impact of concurrent transmissions on throughput is a function of the time offset between the colliding packets. To understand the impact of time offsets, we design the following experiment: two LoRa nodes are connected to an Arduino microcontroller (MCU). The MCU, using a hardware interrupt, triggers the LoRa nodes such that the difference in the start of their packet transmission is configurable, thus controlling time offsets. Both the nodes transmit the same data. We repeat the experiment 20 times for each offset value and present the PRR metric averaged over the whole data.

Summary: Figs 9 (a) and (b) show the PRR as a function of increasing time offsets between two LoRa nodes. NScale and CoLoRa depend heavily on packet offsets and peak ratios to demodulate symbols and to group symbols from each transmitter together. As the packet time offset increases, their PRR performance improves as accuracy in peak estimation and peak ratio will increase. So, these show significantly better performance as the packet offset time increases, with NScale improving its PRR from 0 to 0.9 when changing collision time offset from 5% to 30% for SF8 packets. Similarly, CoLoRa shows a notable improvement in PRR over the same range, going from 0 to 0.4. Std-LoRa is unaffected by the time offsets since it always decodes the strongest signal. CIC and FTrack demodulate packets iteratively and use time and

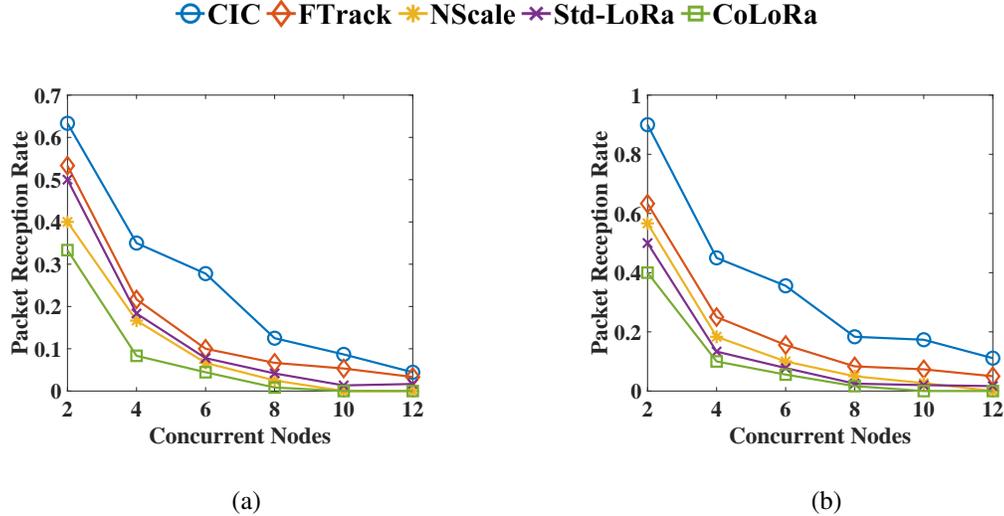

Figure 8: Reception rate of fully correct packets with increasing concurrent transmissions
(a) SF8, 125kHz bandwidth (b) SF10, 250 kHz bandwidth

frequency information to separate collisions. The impact of time offsets on FTrack and CIC is also therefore negligible. We conclude that although most demodulators focus on improving network throughput by resolving collisions, some are better suited for collisions with a higher overlap in time than others. We observe that demodulation techniques that utilize both time and frequency resolutions are more resilient to PTO. *Therefore, more study is needed on improving time-frequency resolution when multiple concurrent nodes collide within short time offsets.*

6 Discussions and Limitations

Our results shows that packet decobability and hence network throughput differs significantly under varying network conditions. Therefore, rigorous evaluation of the existing and future LoRa demodulators over a wide variety of network conditions, as described in Section 5. We have made the datasets of the various network conditions and scenarios evaluated publicly available. Although this is an extensive set of scenarios, it certainly is not an exhaustive list. We strongly encourage the community to share new scenarios and datasets.

In *OpenLoRa*, we focused on network throughput comparisons across multiple demodulators. However, we did not compare the computational complexity of existing techniques. Since we relied on accurate recreation of existing works, optimizing each technique’s implementation was not the focus. In order to evaluate the practical usability of a demodulator, computational complexity is critical. For example, Std-LoRa and CoLoRa rely on dechirping followed by FFT for packet detection and demodulation and cost the least in terms of number of computations, but also have the lowest throughput improvements, i.e., the computational complexity for both

is $N \log(N)$ where N is the number of samples per symbol and is typically the size of the FFT window as well. On the other hand, FTrack, NScale, and CIC use auto-correlation to detect the start of packets and therefore their packet detection cost these schemes N^2 computations. FTrack computes the spectrogram for the whole received buffer using a sliding window and tracks the frequencies in each window of the spectrogram; therefore, its demodulation block has $N^2 \log(N)$ complexity per window. CIC computes spectrogram for a fixed number of sliding windows regardless of SF as opposed to sliding over whole demodulation window and therefore has computation cost of $cN \log(N)$ where c is a constant that depends on the number of fixed sliding windows. NScale performs multiple dechirpings followed by FFT to translate timing offsets to frequency features and have a computation cost of $kN \log(N)$ where k is the number of multiple dechirpings. The computation cost for CIC and NScale is therefore lower than that of FTrack and more than standard LoRa’s and CoLoRa’s computation cost. Thus, further evaluations on the network throughput improvements along with their computational complexity is needed to identify the practical challenges in deploying the demodulators.

In this work, we focused on novel demodulators that receive from commercially available LoRa transmitters. More recent works such as CurvingLoRa [25] and NetScatter [26] have proposed changes to the transmitter to improve resilience to packet collisions, communication range, and network throughput. Although our framework cannot be used for non-standard LoRa transmitters, the new techniques can still use our experimental scenarios to test their performance in different network conditions and compare against standard LoRa.

7 Conclusions

In this work, we implement and validate four state-of-the-art collision resolution techniques for LoRa on a variety of system configurations and scenarios. We developed *OpenLoRa*, a Python framework that provides a uniform platform to evaluate existing works over the same datasets and metrics. We also design a standard LoRa decoder in order to study the end-to-end performance. This platform will allow future researchers to plug-in their demodulator and benchmark against existing works. We observe that metrics such as network throughput are more meaningful for practical deployments. We study the impact of interference and variations in SNR on the network throughput performance. We perform a wide range of experiments to emulate practical deployment settings, showcasing the strengths and challenges of existing LoRa demodulators. Our evaluations show that there are open challenges in the low-SNR, long-range regime, with more room for innovations in LoRa packet collision resolution.

A Appendix: LoRa Primer

LoRa Modulation. In LoRa, data is modulated using a Chirp Spread Spectrum (CSS) scheme. In CSS, symbols are chirp signals whose instantaneous frequency increases linearly with time as shown in Figure 10 (a). A base chirp starts from a frequency of $-\frac{BW}{2}$ and increases linearly to $\frac{BW}{2}$ over a symbol duration of T_s where BW is the bandwidth of transmission and T_s can be defined as $T_s = \frac{2^{SF}}{BW}$. $SF \in \{7, 8, 9, 10, 11, 12\}$ defines a packet's Spreading Factor, a value that dictates the data-rate, resistance to interference and range of transmission.

Every symbol $S(t, f_{sym})$ is derived by cyclically shifting a base chirp $C(t)$, as shown in Equation 1. For example in Figure 10 (b) and (c), $S(t, f_1)$ and $S(t, f_2)$ are obtained by introducing a frequency offset of f_1 and f_2 to the base chirp. The data to be transmitted modulated these starting frequencies viz., f_1 and f_2 .

$$C(t) = e^{j2\pi(0.5\frac{BW}{2^{SF}}t - \frac{BW}{2})t}, 0 \leq t \leq T_s \quad (1)$$

$$S(t, f_{sym}) = C(t) \cdot e^{j2\pi f_{sym}t} \quad (2)$$

LoRa Demodulation. To demodulate a symbol, a LoRa receiver aligns and multiplies a down-chirp $C^{-1}(t)$ (the complex conjugate of $C(t)$) with the received symbol $S(t, f_{sym})$ (Equation 3). Dechirping transforms the chirp signal to a sinusoid with a constant frequency equal to the start frequency f_{sym} . This frequency is located by finding the peak in the FFT of the dechirped signal. The operation of dechirping followed by FFT concentrates the symbol's energy into a single frequency, thus providing the spread spectrum gain necessary to decode symbols in sub-noise conditions.

$$C^{-1}(t) \cdot S(t, f_{sym}) = e^{j2\pi f_{sym}t} \quad (3)$$

Since dechirping requires the downchirp to align with the received symbol, a LoRa receiver determines the onset of a new packet by searching for its preamble and uses it to identify the symbol boundaries of symbols. LoRa preamble comprises of a sequence of $N = 6$ to 65535 consecutive $C(t)$ symbols, followed by two SYNC symbols $S(t, s_1), S(t, s_2)$ ($s_1 \neq 0, s_2 = s_1 + 8$) and 2.25 down-chirps $C^{-1}(t)$. To detect a new packet, the receiver continuously de-chirps and performs an FFT until it finds N consecutive peaks with the same frequency. The SYNC words and down-chirps then help locate the symbol boundaries. In CSS, time offsets are equivalent to frequency offsets. For example, as shown in Figure 11 time shifting a chirp symbol by τ will introduce an equivalent frequency offset in the starting frequency. Therefore, frequency offsets in LoRa can easily be compensated by identifying the equivalent time shifts during preamble detection.

Effect of collisions on demodulation. Standard LoRa is incapable of demodulating data symbols in case if multiple packets collide. Should multiple LoRa packets arrive simultaneously at the receiver, there will be multiple f_{sym} values to

detect for any given symbol window, making it difficult for standard LoRa to choose one. Standard LoRa assumes that the maximum peak in the FFT always corresponds to the data value of the packet of interest. Whereas, in case of packet collision, multiple peaks from interfering packets show up in the FFT as shown in Figure 12 and the assumption of maximum peak's link to the packet of interest is not guaranteed anymore since height of interfering peaks may surpass the height of true peak.

B Appendix: LoRa Demodulators Validated

B.1 FTrack [15]

FTrack [15] relies on Short Time Fourier Transform (STFT) to obtain time and frequency features. Applying STFT to the LoRa symbols would result in frequency tracks that increases linearly with time. An appropriate STFT window size that offers good frequency resolution to identify the frequency and good time resolution to follow the progression of a chirp is challenging to determine. FTrack proposes to apply STFT on the dechirped LoRa symbol to leverage the spread spectrum gain as well as to remove the linear change in frequency with time. Dechirping the received buffer results in a sinusoid whose frequency remains constant throughout the symbol duration. This allows FTrack to choose a window size of a symbol length that yields a good frequency resolution (of upto 1 bin) if perfectly aligned with the symbol boundaries. Dechirping allows STFT to have the least possible frequency variation with time (single frequency over a symbol duration) and therefore yields the best possible frequency resolution. It yields a constant frequency track over a symbol duration, rendering it simpler to track the frequency of a packet of interest. FTrack, thus, employs dechirping followed by STFT to extract the longest frequency tracks to detect preamble as well as data symbols. Typical LoRa preambles consists of 8 base upchirps, that promise a constant frequency track for a duration of 8 symbols in the final spectrum. FTrack extracts symbol edges from preambles and uses this time information to detect the symbol boundaries of payload. FTrack builds on the observation that all the interfering packets are misaligned in time and hence their symbol boundaries are misaligned in time. FTrack detects the preambles of all colliding packets and leverages the time offset between colliding packets to differentiate transmitters. The receiver aligns itself with the boundaries of a packet of interest : once aligned, it observes the frequency tracks of current packet as well as that of the interfering tracks. The frequency track of the packet of interest will be continuous in the given window whereas all the interfering tracks will change abruptly. Therefore, after detecting all the LoRa packets in a received buffer, FTrack iteratively demodulates each packet. While demodulating a specific packet, FTrack cancels out interfering symbols by tracking the frequency continuity. At the end of this itera-

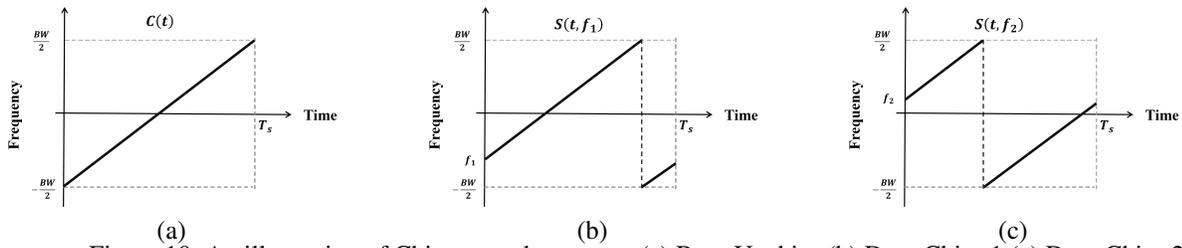

Figure 10: An illustration of Chirp spread spectrum (a) Base Upchirp (b) Data-Chirp 1 (c) Data-Chirp 2

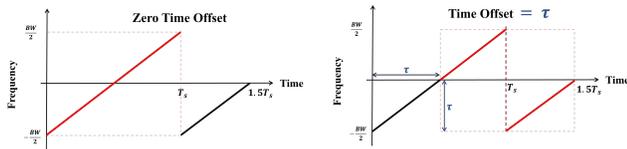

Figure 11: Time offsets in LoRa symbols translates to Frequency offsets

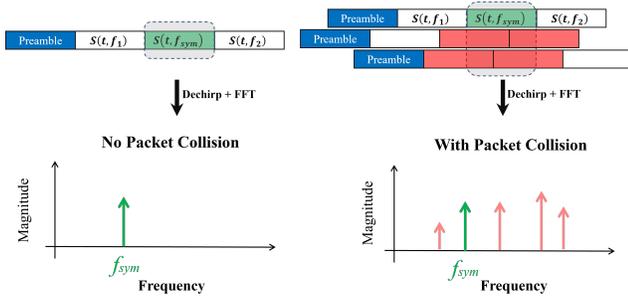

Figure 12: Symbol spectrum with and without collisions

tive process, FTrack receiver detects and demodulates data symbols from multiple transmitters that collided with each other. FTrack’s performance suffers in low-SNR conditions. At SNRs below 5 dB, energy of the frequency tracks corresponding to preamble and data symbols are not high enough and hence are buried in the noise floor and is not decoded. Thus, it fails to detect and/or demodulate LoRa packets at SNRs below 5 dB.

B.2 CoLoRa [17]

CoLoRa [17] proposes a novel technique to translate time offsets to frequency features, in turn using that to resolve packet collisions at low-SNR regimes. CoLoRa starts with a misaligned window size of one symbol length. It determines the presence of interference based on the number of peaks appearing in the FFT obtained after dechirping; since multiple peaks imply packet collisions as discussed in Appendix A. Once collisions are confirmed, CoLoRa proposes an interleaved window selection strategy. It chooses a misaligned window such that no chirp is covered fully by the window i.e., each chirp is segmented and thus falls into two consecu-

tive windows such that the normalized FFT peak is bounded within $[1/3, 3]$ in each window. It then jumps the window over received buffer and performs dechirping followed by FFT at each point. The resulting spectrum contains peaks whose height is proportional to the segment of chirp appearing in the current window. CoLoRa observes that when a chirp is split into 2 windows, the frequency at which the peaks appear in the FFT remains the same across the 2 windows. However, the energy and hence the height of the FFT peak at the corresponding frequency in each window is proportional to the duration of the chirp segment within that window.

CoLoRa proposes *Peak Ratio*, which is defined as the ratio of peak heights of a chirp appearing in two consecutive windows; it captures time misalignment through frequency features. It proves that the peak ratio is identical for all chirps of the same packet since the in-window distribution of chirps is identical for all the symbols of the same packet. Additionally, peak ratios differ across packets since the in-window distribution of chirps is different due to misalignment of interfering packets. Since CoLoRa relies on accurate estimation of Peak ratio, it proposes an iterative peak recovery algorithm to estimate the heights of strong peaks first and cancel their contribution while estimating the low-SNR peaks. Since the chirps are segmented, wide side lobes appear around peaks that may bury low SNR peaks. CoLoRa uses k-means clustering (where k is the number of packets detected) to classify the packets of different clients. Peaks with identical peak ratios are clustered together, following the observation that the symbols of the same packet have the same peak ratio. Each cluster represents a unique packet, thus decoding multiple packets from the collided signal.

B.3 NScale [16]

While FTrack and CoLoRa focus on decoding multi-packet collisions, their performance improvements over standard LoRa demodulator is noticeable at high SNR. NScale [16] focuses on decoding packet collisions at SNRs as low as -10dB where the relative performance improvement of FTrack and CoLoRa degrades. Similar to CoLoRa, NScale translates the timing offsets to frequency features and further amplifies the time offsets by non-stationary signal scaling. NScale’s strength lies in its ability to decode and resolve collisions of LoRa packets below -10 dB SNR. Instead of sliding the window as FTrack does, NScale jumps the window of size

that promises maximum frequency resolution i.e., duration of a symbol. To retain sub-noise decodability, NScale relies on dechirping to accumulate energy at the single frequency. While jumping the window across the received buffer, NScale observe that, for a specific LoRa packet, all the symbols of interest will have same in-window distribution in consecutive windows whereas in-window distribution for interfering symbols will be different. Simply put, the location of symbol edges where the symbols transition to next symbol is same across all the windows of a given packet but across different packets, these symbol edges are different. This essentially stems from the fact that collisions are misaligned in time. Similar to CoLoRa, NScale translates symbol edge offsets to the peak heights.

NScale introduces a novel non-stationary scaled window as opposed to conventional rectangular window of FTrack and CoLoRa. Non-stationary scaling across the windows amplifies the timing misalignment of symbols of interfering packets. The linear amplitude scaled window scales the amplitude of peaks with respect to their in-window distribution and therefore amplifies the misalignment of different packets. This amplification helps estimate the time offsets for very low SNR packets. Consequently, different packets get a unique fingerprint in terms of peak heights while symbols of a specific packet share the same fingerprint. NScale detects the number of packets and their corresponding start and end indices using correlation and then performs k-means clustering to classify symbols based on their fingerprint.

B.4 Concurrent Interference Cancellation [19]

Concurrent Interference Cancellation (CIC) [19], similar to FTrack, leverages time and frequency domain analysis to decode multi-packet collisions. CIC introduces the concept of sub-windows, which are a portion of the demodulation window. It observes that, for a given packet of interest, symbols from the packet appear in all the sub-windows; symbols from interfering packets appear only in a subset of the sub-windows. Therefore, the intersection of FFT of all the sub-windows would result in the symbol of interest. CIC proposes a sub-window selection algorithm that maximizes interference cancellation.

CIC looks for the best sub-window which promises an acceptable time resolution while compromising the least on frequency resolution. It uses packet detection to determine the start of all the colliding packets in order to select the best set of sub-windows. Unlike standard LoRa, CIC uses downchirp correlation to detect the start of a packet. With prior knowledge of symbol duration, CIC determines symbol boundaries within each of the colliding packet. The sub-windows are chosen such that it contains the most of each interfering symbol, using CIC's knowledge of the symbol boundaries of interfering packets. Spectral intersection of the FFT of the demodulating window and the optimum set of sub-windows selected results

in a single FFT peak that corresponds to the symbol of interest. It iteratively demodulates the rest of the packets in the collided signal. CIC also proposes fractional frequency offset to filter out interfering peaks that were not cancelled in the spectral intersection. Additionally, it uses power-filtering to estimate received power of each packet from its preamble and discards symbols which do not qualify a certain power threshold. Finally Spectral Edge Difference, filters interfering peaks further and chooses one peak to be the final demodulated peak.

B.5 Other recent works on LoRa demodulation

In addition to the works presented above, other papers have focused on LoRa demodulator design. The modular design of our proposed framework renders it simple to integrate them. Pyramid [20] is one such work which tries to resolve LoRa collisions by tracking the change in FFT peak heights corresponding to different interfering symbols. AlignTrack [21] tracks and translates time offsets to frequency features, i.e. peak heights, similar to CoLoRa. AlignTrack chooses a window which completely overlaps the packet of interest instead of a misaligned window used by CoLoRa. AlignTrack's complete overlap gives highest peaks in FFT and therefore, has least SNR loss. NeLoRa [27] is another work which tries to push the limit of LoRa's range by using deep-neural-network. Their results show that its ability to decode packets with SNR as low as -30dB.

C Appendix: Implementation Overview

C.1 Python Implementation

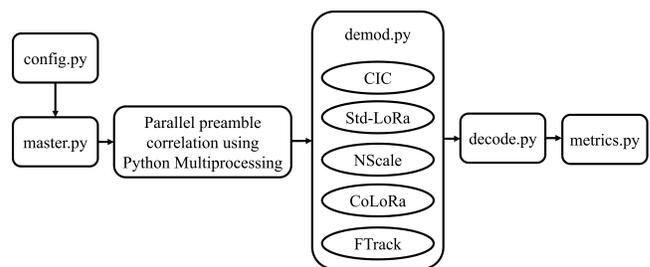

Figure 13: Flowchart of the Python implementation of the proposed framework

C.2 Code Organization

The implementation has been organized into the following major Python modules:

- *config.py*: Configures demodulation parameters such as SF, BW, sampling rate to pass to the demodulators as

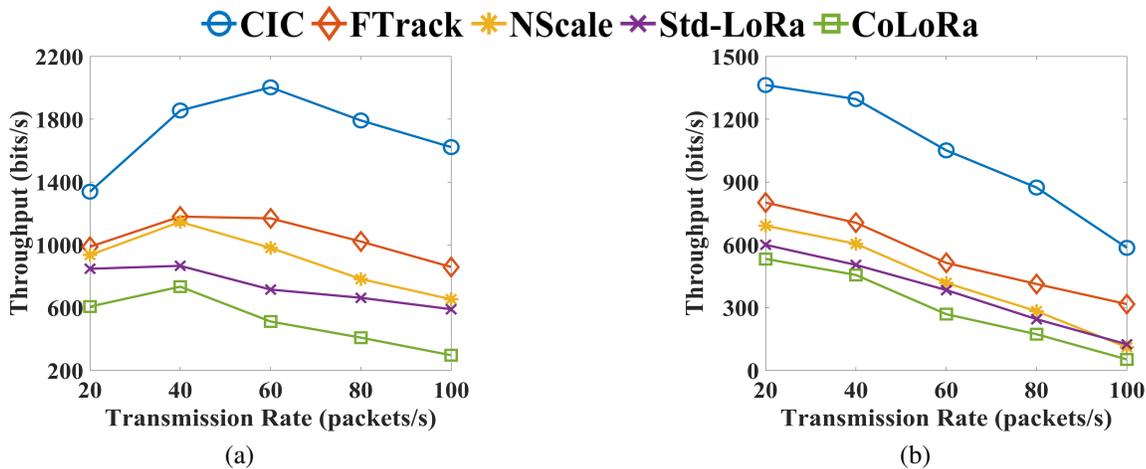

Figure 14: Throughput of a 20-node Indoor LoS network with increasing aggregate transmission rates
(a) SF8, 125kHz bandwidth (b) SF10, 250 kHz bandwidth

well as the transmitted symbols and bits to compare against and evaluate the desired metrics.

- *master.py*: Performs the highest level tasks and interfaces with other modules. Reads in the input file, calls each demodulator module to get the symbols and gets calculated metrics after decoding. Also implements parallel upchirp-based preamble detection using Python multiprocessing capabilities.
- *demod.py*: Imports each demodulator implementation and interfaces with each block to pass the data and parameters in appropriate format. Returns demodulated symbols to the *master* block.
- *decode.py*: Implements the standard LoRa decoder as described in the following subsection. Returns decoded bits to the *master* block.
- *metrics.py*: Takes in the demodulated symbols, decoded bits, and the configuration information to calculate all the relevant metrics and saves then in the specified output file.

D Appendix: Additional Results

D.1 Impact of transmission rate on Network Throughput

Indoor LoS: Figs. 14 (a) and (b) depict the average network throughput as a function of aggregate transmission rate in indoor LoS setting. Network throughput is calculated as the sum of the bits of successfully decoded packets per unit time. In case of SF8 transmissions, the network throughput increases with increasing aggregate rate upto the rate of 40 packets/s for most demodulators, due to increase in traffic. However,

beyond a threshold, packet collisions are too high for a demodulator to resolve, leading to a drop in throughput. CIC achieves its peak throughput at 60 packets/s because of its power filtering and down-chirp based preamble detection features. FTrack and NScale perform considerably well in this high SNR scenario giving significant gains over Std-LoRa. Even though Std-LoRa is unable to demodulate concurrent transmissions, it latches on to the strongest signal due to capture effect and often correctly demodulates the packet from the strongest transmission. This results in throughput numbers of Std-LoRa being comparable to other demodulators at higher transmission rates when they suffer from abundance of collisions. Another interesting observation is CoLoRa's throughput being slightly lesser than that of Std-LoRa despite having a lower Symbol Error Rate (SER) and Bit Error Rate (BER). Our analysis indicates that the reason is its erroneous identification of peak frequencies and calculation of peak ratios in the presence of high amount of collisions. CoLoRa detects and correctly demodulates larger number of symbols on average but the symbol errors are distributed across all concurrent transmissions. It consistently makes errors in a few of the bits in packets, which result in those packets being discounted from throughput calculation.

This result is an important observation we make in noticing the significance of end-to-end metrics such as Throughput and Packet Reception Rate over Symbol Error Rate, which could be misleading for end users. For SF10 transmissions, due to its longer air-time, the impact of collisions lead to a decreasing network throughput for all demodulators even at transmission rates as low as 1 packet/second per node.

E Appendix: Experimental Setup & Methodology

E.1 Network Experiments

All the network experiments and SNR experiments were performed using 20 transmitting nodes T_1 through T_{20} , a roll-call node R , as well as a beacon node B . R helped in setting up the parameters for each experimental setup without manually changing the setting at each location serially. Each transmitter node (T_1 through T_{20}) would reply only to their specific roll-call message from R . The roll-call messages were sent at a predefined SF and BW. Therefore, all the nodes reset to this SF and BW to listen and respond to the roll-call message. These replies were also used for calculating node-specific SNR at the USRP B200 (serving as a base station for each experiment). Using the received SNR for each node T_i , we could ensure every T_i would hear broadcasts from B . Similarly, B transmits a broadcast to inform the nodes about the settings such as SF, BW, transmission rate for the upcoming experiment. After setup, B would broadcast control messages to all 20 nodes telling each to begin transmitting messages randomly. The beacon information about transmission rates that each node T_i had to follow with a random time offset. The time offsets were generated through Poisson distribution. Each node transmitted to the base station for approximately 30 seconds. All network and SNR experiments were repeated following the aforementioned roll-call and beacon process to ensure no nodes were lost.

E.2 Interference Experiments

Interference tests utilized a similar setup to the Network Experiments, however interfering transmitters were deployed near (<10m) the receiving USRP B200. Interfering nodes included a LoRa transmitter with varying SF's and BW's as well as a GFSK transmitter. Network and interference experiment Arduino code can be located within the Experiment_Setup/Random_Network directory on the OpenLoRa Github page⁵.

E.3 Concurrent Transmissions Experiment

Concurrent transmission experiments were performed using a separate beacon node B to continually synchronize up to 12 transmitting nodes T_1 through T_{12} . B would broadcast a short message instructing all nodes T_i to respond within a pre-determined time. These time-limits were determined by recording transmissions from a USRP B200 and measuring total transmit time. Offsets followed a uniform distribution within these time limits thus ensuring random transmission overlaps. The concurrent transmission experiment's Arduino code can be located within the Exper-

iment_Setup/Random_Offset directory on the OpenLoRa Github page⁵.

E.4 Packet Time Offset Experiment

To achieve reliable, and precise collisions with microsecond accuracy, we relied on interrupt-driven transmissions. Two transmitting nodes T_1 and T_2 (Adafruit Feather M0 boards), were connected to a third driving node D periodically triggering interrupts via a pin tied on T_1 and T_2 . Upon receiving the interrupt, T_1 immediately transmitted its LoRa packet. Node T_2 however utilized a pre-determined delay before transmitting. Delays on T_2 were experimentally gathered ahead of time by measuring packet transmission times on a USRP B200. These delays were then calculated as some fraction of the total transmit time for a single packet, and then flashed onto T_2 . Both transmitting nodes were connected to the same breadboard with similarly oriented antennas thus ensuring similar SINR at the receiver. The packet time offset experiment's Arduino code can be located within the Experiment_Setup/Precise_Offset directory on the OpenLoRa Github page⁵.

[†]Tsinghua University

{zhangyithss@gmail.com, wyhou@cs.hku.hk, hmilyyz@gmail.com, chenshu@cs.hku.hk}

Abstract

On average, every 10 days a child dies from in-vehicle heat-stroke. The life-threatening situation calls for an automatic Child Presence Detection (CPD) solution to prevent these tragedies. In this paper, we present VECARE, the first CPD system that leverages existing in-car audio without any hardware changes. To achieve so, we explore the fundamental properties of acoustic reflection signals and develop a novel paradigm of *statistical acoustic sensing*, which allows to detect motion, track breathing, and estimate speed in a unified model. Based on this, we build an accurate and robust CPD system by introducing a set of techniques that overcome multiple challenges concerning sound interference and sensing coverage. We implement VECARE using commodity speakers and a single microphone and conduct experiments with infant simulators and adults, as well as 15 young children for the real-world in-car study. The results demonstrate that VECARE achieves an average detection rate of 98.8% with a false alarm rate of 2.1% for 15 children in various cars, boosting the coverage by over $2.3\times$ compared to state-of-the-art and achieving whole-car detection with no blind spot.

1 Introduction

The ability of cars to sense, and save lives, inside a car remains to be improved. One life-critical feature that is widely missing is in-vehicle *Child Presence Detection* (CPD). Every year, many children have been unintentionally and unknowingly left in parked cars, or have got stuck into a car independently. As the temperature inside a car can rise rapidly¹, especially in hot months, serious injuries or heatstroke deaths could happen to children being left alone inside a car. It takes only a matter of minutes before the heat can overwhelm a child's ability to regulate his/her internal temperature and cause injuries/deaths

¹This work was done when Yi Zhang was a Research Assistant at HKU.

¹A car can heat up by 19 degrees in just 10 minutes. Even on a mild day, the temperature in a parked car can rise to extremely dangerous and potentially fatal levels for infants and toddlers. As reported, heatstroke can occur even when outside temperatures are just 57°F [3].

Figure 1: Application scenario of VECARE. It detects an unattended child using in-car audio and alert registered parties for immediate responses and/or activate the air conditioner to keep the child safe automatically.

as a child's core temperatures increase three to five times faster than an adult's [3]. On average, around 40 children dying from hot cars have been witnessed each year (about one every 10 days), leading to over 900 pediatric vehicular heatstroke (PVH) deaths on record since 1998 in the US alone [50]. Despite remarkable advances in automobiles in recent years, unfortunately, the cases of hot car deaths are only increasing, with 2018 and 2019 being the record years of 54 and 53 deaths each [50]. All of these deaths could have been prevented, if the car can detect the unattended child timely and responsively alert concerned parties or take prompt actions to keep the car cool and the child safe (as depicted in Fig. 1).

The widespread and tragic problem has driven governments and the auto industry to take initiatives to make CPD a compulsion for future cars [49, 76], which fosters an expected market of \$400 million by 2025 [27]. Existing solutions include early systems using special sensors such as optical/weight/pressure/ultrasonic sensors [4, 20, 21, 54], cameras [10, 13, 85], as well as recent efforts with Ultra-Wideband (UWB) or millimeter-wave (mmWave) radars [26, 28, 66], WiFi [45, 81], etc. These solutions, however, suffer from different limitations. Many works focus on adult passenger monitoring, and cannot generalize well to infants and toddlers. And the sensing coverage is mostly limited to only the seats (for special seat sensors) or a certain Field-of-View (FoV) (for

cameras/UWB/mmWave radars), leading to degraded accuracy in Non-Line-Of-Sight (NLOS) scenarios and blind spots, e.g., when a child is in a rear-facing car seat, blocked by a seat, or on the car floor. More importantly, these techniques require extra hardware that is not standard offerings in today's cars to be precisely installed². This not only introduces additional hardware and manufacturing costs, which are huge considering more than 80 million new cars annually, but is also backward-incompatible with most of the over one billion existing cars in the world. A truly pervasive system that requires no extra hardware and works for all cars still lacks.

In this paper, we ask the following question: *Can we build an accurate and robust in-cabin monitoring system by using only readily available in-car modules without any hardware modifications?* We present the design and implementation of such a system, named VECARE, by leveraging in-car audio systems, which are widely available in most, if not all, modern cars. As illustrated in Fig. 1, it operates by transmitting sound signals from the speakers and analyzing their reflections recorded on a microphone, which have interacted with the human body, if present. VECARE accurately and responsively detects tiny motions and extremely weak breathing of young children including newborns. It can reliably detect the presence of a child in a car, achieving whole-car detection with no blind spots. Importantly, it can be readily deployed in existing and emerging car models, offering the best ubiquity superior to the aforementioned other solutions.

Albeit acoustic sensing has been extensively studied, VECARE introduces a novel paradigm of *Statistical Acoustic Sensing* (SAS). The mainstream practice in the literature mostly focuses on *geometrical* parameters, e.g., Time of Flight (ToF) and Doppler Frequency Shift (DFS), of a few multipath reflections around the range where a target presents. Differently, inspired by recent advances in WiFi sensing [79, 88, 89], we propose to analyze the *statistical* characteristics of acoustic signals by leveraging *all* multipath reflections, which can be all affected by the target and therefore can contribute to sensing if utilized properly. Towards that end, we explore unseen properties of acoustic multipath signals and accordingly develop a novel SAS model that underpins a unified pipeline for detecting motion, estimating breathing rates, and even measuring moving speeds. The proposed SAS model truly embraces all the reflections and favors complex multipath environments, while requiring only a single microphone rather than a microphone array.

Based on the SAS model, we develop a set of techniques that overcome multiple challenges in translating SAS into a practical CPD system. First, effective acoustic channel estimation is non-trivial, mainly because of ambient sound noises, limited frequency band (up to 24kHz) on commodity devices, and multiple concurrently-transmitting speakers. In VECARE, we adopt Kasami Sequence, a pseudo-noise or

thogonal sequence for channel measurement, which provides resilience to environmental noises as well as orthogonality for multi-speaker sensing. Second, acoustic sensing is known to suffer from limited coverage, e.g., typically within 1-meter range [53, 71], mainly because sound reflections off the human body are considerably weak. The problem is aggravated for young children who have even weaker motion/breathing. We boost the sensing coverage by statistically leveraging all multipaths (time diversity), optimally combining multiple sub-carriers (frequency diversity), and opportunistically exploiting multiple speakers (space diversity), which ultimately allows comprehensive detection in a car. Last, CPD is a time-critical mission requiring fast response (e.g., detection within 10 seconds [49]). We design an instantaneous motion/breathing detector for CPD based on a time-domain approach, which can detect child presence rapidly (motion in a few seconds and breathing with a minimum delay slightly exceeding one breathing cycle).

We prototype an end-to-end system using commodity off-the-shelf (COTS) microphones and speakers, including car speakers and microphones. We first use infant simulators and recruit adults to systematically evaluate VECARE under various conditions both in buildings and in cars. Then we conduct a real-world study with 15 children, aged 0 to 6 except for one 10-year-old, for testing in various cars. Our results show that VECARE achieves an overall detection rate of 98.8% with a false alarm rate of 2.1%, using a single microphone. It can detect motion accurately up to 5 m, and estimate breathing at a distance of 4.5 m for an adult and 1.6 m for an infant, outperforming the state-of-the-art by 2.3 \times . Using in-car audio without any hardware changes, VECARE holds great potential to be widely adopted for practical CPD.

Contributions: In summary, our goal is to enable a ubiquitous solution to accurate and robust in-car CPD to prevent PVH deaths. To this end, we make three key contributions to delivering the first CPD system using accessible in-car audio: (1) We introduce a novel statistical acoustic sensing model that can detect motion, track breathing, and estimate speed by leveraging all the reflections. (2) We present a pipeline of techniques to detect motion, speed, and breathing based on the SAS model accurately and robustly, with a significantly enlarged coverage. (3) We design and implement a prototype CPD system VECARE on COTS devices and conduct extensive experiments in the real world with infant simulators and young children. Not only is VECARE a promising solution to the critical application of CPD, we also believe the proposed SAS opens a new paradigm in acoustic sensing for various applications in smart homes, healthcare, and beyond.

2 Design Space

Design Scope: Among over 900 deaths reported since 1998 [50], the primary circumstances resulting in PVH deaths include a caregiver forgetting a child in a vehicle (about 55% of

²WiFi is becoming popular in modern cars, but still many do not have it.

the cases), someone knowingly leaving a child in the vehicle (~20%, e.g., running a quick errand), and the child gaining access to and getting stuck in the vehicle (about 25%). For all of these circumstances, if the car can detect the child left behind and remind/alert parents and caregivers promptly, immediate actions can be taken, by caregivers or by the car, to end these entirely preventable tragedies.

CPD systems are designed for this purpose. Typically, a CPD system is expected to run, for a short period of time, after the driver turns the engine off and locks the doors. Therefore, we mainly focus on in-cabin monitoring of a parked, closed car and do not consider a driving car. The system should then detect a child presenting anywhere inside the car quickly (e.g., within 10s [49]), and take registered actions responsively, such as alerting corresponding parties (e.g., car owners, parents, caregivers) via horn alarms and/or messages, activating the air conditioner automatically if the temperature goes high, etc. Yet how a CPD system exactly reacts is not our focus in this paper. For example, questions like how a CPD system integrates into the car system and responds to child presence (which depends on auto manufacturers, car owners, parents and caregivers), and whether the system should be a built-in component or a standalone module are out of our scope.

Why Acoustics? Although presence detection is not a new topic, existing works mostly focus on adult subjects in buildings. In-car CPD is particularly challenging because it demands a very high detection rate (any miss detection can lead to a potential tragedy) and it requires such a high accuracy for extremely tiny motion/breathing from an infant, which prior methods cannot achieve. Different modalities can be used for CPD, such as WiFi, UWB, mmWave, cameras, etc. In VECARE, we choose audio modules mainly because of the best ubiquity: Audio systems have been standard components in modern cars, which are nowadays commonly equipped with two, four, or more speakers plus *one microphone*. These speakers are most commonly installed around the dashboard, the front/back doors, and/or the rear deck, while the microphone is usually installed on the dashboard, around the rear-view mirror, or behind the steering wheel. They are placed in such a way primarily for high sound quality, which also turns out to support a good whole-car coverage for sensing.

While acoustic sensing is usually vulnerable to ambient sounds, vehicles today are designed and manufactured to provide the necessary level of safety and to muffle as much road noise as possible. Therefore, in the CPD application, the impact from the noise outside a closed car is insignificant. On the other hand, embedding sensing signals in the audible frequency band may result in shrill noises that are intrusive to human ears. Previous work has nicely modulated sensing signals into white noise [71] or on only the inaudible frequency band [9] to solve the problem. In our case, VECARE can work on either the full bandwidth (e.g., up to 24kHz) or only the inaudible band (e.g., above 18kHz), depending on practical choices. While existing works like BreathJunior [71] also

monitor infants' vital signs, they are not suitable for in-car CPD as they rely on a large microphone array that is unavailable in commercial cars. Overall, acoustic signals appear to be an attractive choice for ubiquitous and practical in-car CPD, yet it entails numerous challenges to build an accurate and robust system using a single microphone.

3 Statistical Acoustic Sensing

We first present a novel statistical acoustic sensing paradigm. Our model is inspired by the success of statistical approaches in WiFi sensing [78, 79, 88, 89]. To put it briefly, this line of work treats each multipath component as a scatterer and investigates the spatial-temporal statistical properties of WiFi Channel State Information (CSI), which have been shown to imply important information such as motion [89], speed [79, 88], as well as breathing [90]. These approaches show superiority in complex environments and have been commercialized as real-world products on commercial WiFi devices [24, 25, 39]. In below, we first present our new observations on multipath propagation of acoustic signals, and then show that similar statistical properties also hold for acoustics.

Acoustic Multipaths: Unlike WiFi signals, one can effectively resolve multipath signals due to the high range resolution of acoustic signals. As a result, previous works mostly only focus on reflections from the range of interest and segment others out. However, our measurements show that a target at a certain range not only alters the reflection around that range, but also distorts multipath signals arriving later to a considerable extent. As shown in Fig. 2, while a human target contributes the strongest reflection at the Channel Impulse Response (CIR) taps corresponding to her/his range (i.e., 1.25 m), the CIR taps up to 7 m after that range are also altered remarkably. In comparison, the CIR taps are mostly noises in the empty case without human presence. Our key insight is that all these multipath distortions, if aggregated properly, can contribute useful information for sensing. The problem is, how can we truly leverage these weak and noisy multipaths? **SAS Model:** CSI, a.k.a Channel Frequency Response (CFR), is the frequency-domain counterpart of CIR. CSI for an acoustic multipath channel of frequency f at time t is denoted as

$$H(f, t) = \sum_{r=1}^R a_r(t) \exp(-j2\pi f \tau_r(t)), \quad (1)$$

where $a_r(t)$ and $\tau_r(t)$ are the complex amplitude and propagation delay of the r -th reflection path, respectively, while R denotes the total number of paths. From a rich-scattering perspective, each reflection path can be treated as a scatterer that scatters the incoming energy back to the receiver (i.e., microphone) [22, 33, 89]. Thus, we have

$$H(f, t) = \sum_{i \in R_D} H_i(f, t) + \sum_{j \in R_S} H_j(f, t) + N(f, t), \quad (2)$$

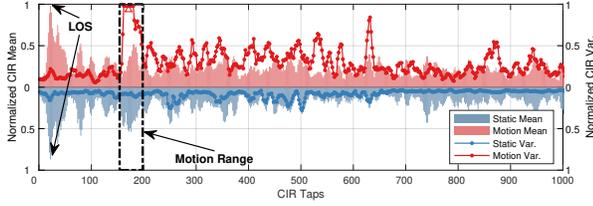

Figure 2: CIR measurements with and without human motion. The large CIR values at the motion range are truncated for the sake of visualization.

where $H_i(f, t)$ denotes the component contributed by the i -th scatterer, $N(f, t)$ is the noise term with variance σ_N^2 , and R_S and R_D denote the set of static and dynamic scatterers, respectively. Assuming all scatterers are statistically independent of each other, each with the same variance $\sigma_i^2(f)$ and approximately zero means, it has been established in the context of WiFi signals [22, 79, 88], that the Autocorrelation Function (ACF) of $H(f, t)$ obeys the 0th-order Bessel function of the first kind. That is, denoting $\rho_i(f, \tau)$ as the ACF of $H_i(f, t)$ with time lag τ , we have $\rho_i(f, \tau) = J_0(kv_i\tau)$, where $J_0(x) = \frac{1}{2\pi} \int_0^{2\pi} \exp(-jx\cos(\theta))d\theta$, v_i is the moving speed of $H_i(f, t)$, and k is the wavenumber. Suppose there is one single moving target, and thus all dynamic scatterers have approximately the same speed v , $v_i \approx v, \forall i \in R_D$. This assumption is realistic because, for human subjects, the torso scatterers dominate others and have a similar speed. Then the ACF $\rho(f, \tau)$ of $H(f, t)$ can be associated with the target's moving speed v as follows [79, 88]: For $\tau \neq 0$,

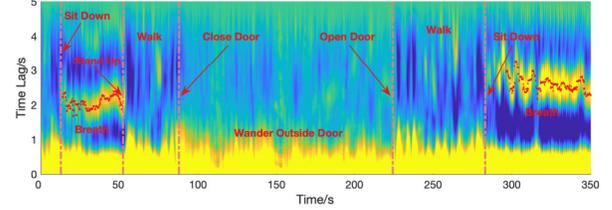

$$\rho(f, \tau) = \frac{\sum_{i \in R_D} 2\pi\sigma_i^2(f) + \sigma_N^2(f)\delta(\tau)}{\sum_{i \in R_D} 2\pi\sigma_i^2(f) + \sigma_N^2(f)} J_0(kv\tau) \triangleq g(f)J_0(kv\tau), \quad (3)$$

where $\delta(\cdot)$ is the Dirac's delta function and $g(f)$ is defined as the channel gain of $H(f, t)$. Eq. (3) bridges the ACF of the CSI with the target's moving speed. In practice, we can calculate the sample ACF, $\tilde{\rho}(f, \tau) = \rho(f, \tau) + n(f, \tau)$, from a time series of CSI measurements with a noise term $n(f, \tau)$.

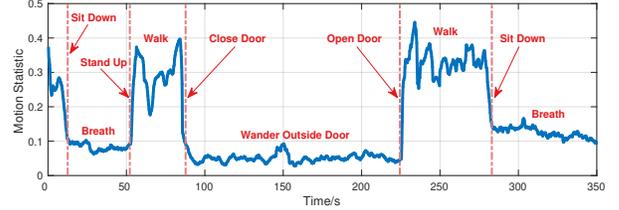

While statistical approaches in WiFi sensing [79, 88–90] have demonstrated success for practical solutions and commercialized products [25, 39, 60, 67], they have not been previously explored in acoustic sensing. VECARE brings statistical sensing approaches to acoustic sensing. In the following, we perform real-world measurements to demonstrate the properties of acoustic CSI and explain how to derive motion, speed, and breathing based on the SAS model.

1) *Detecting Motion*: Similar to the *motion statistic* defined in [89] for WiFi CSI, we find that the defined channel gain $g(f)$ in Eq. (3) is a sensitive and robust indicator for acoustic motion detection. From Eq. (3), we have $g(f) = \lim_{\tau \rightarrow 0} \rho(f, \tau)$ since $\lim_{\tau \rightarrow 0} J_0(kv\tau) = 1$. Hence, given a sufficient CSI sampling rate F_s , we can approximate $g(f)$ as the value of the first tap of the ACF, i.e.,

$$g(f) = \tilde{\rho}(f, \tau = 1/F_s). \quad (4)$$

(a) The ACF matrix. Each column indicates an ACF.

(b) The extracted motion level

Figure 3: Human motion and breathing in a bedroom.

If any motion presents, the value of $g(f)$ is greater than zero; otherwise $g(f) \rightarrow 0$. Fig. 3 shows an example of $g(f)$ in the case of human presence and absence, respectively. As seen, there is a clear gap between the empty level and the values for motion. Additionally, $g(f)$ exhibits larger values when the motion is stronger/closer, implying that it also indicates motion strengths.

2) *Tracking Breathing*: ACF itself is a time-domain approach to identifying periodic signals. Therefore, we can also detect breathing signals from the ACF, which are periodic signals induced by repeated chest movements. If a breathing signal is captured by CSI, the ACF will observe a prominent peak at the time lag τ_b corresponding to the cycle time, as in Fig. 3(a). Thus, by finding time lags of these peaks over time, we can track one's breathing rates as $60/\tau_b$ BPM (breath per minute). Note that as a time-domain approach, ACF in principle is faster for breathing estimation compared to spectrum-based approaches, which usually require a much longer window to yield better frequency resolution.

3) *Estimating Speed*: As indicated by Eq. (3), the ACF of CSI is a function of speed v , which underpins a statistical approach entirely different from the Doppler effect for speed estimation [88]. Specifically, as shown in Fig. 4b, the shape of the ACF $\rho(f, \tau)$ resembles the Bessel function $J_0(x)$ with $x = kv\tau$, meaning that we can estimate the speed by aligning $\rho(f, \tau)$ with $J_0(x)$. Assuming x_0 is the constant value corresponding to the first peak of $J_0(x)$, then the moving speed v can be calculated as [79, 88]: $\hat{v} = \frac{x_0}{k\tau_s} = \frac{x_0\lambda(f)}{2\pi\tau_s}$, where τ_s is the time lag corresponding to the first local peak of the ACF $\rho(f, \tau)$ and $\lambda(f)$ is the wavelength of subcarrier f . Fig. 4 illustrates an example of speed estimation with the setup in Fig. 8(c), which shows that the ACF reacts to the moving speed faithfully as the above equation implies.

Remark: As seen, a peak in the ACF can either indicate a speed signal or a periodic signal. However, we notice that the peak locations for breathing (e.g., 1-5s for breathing rates

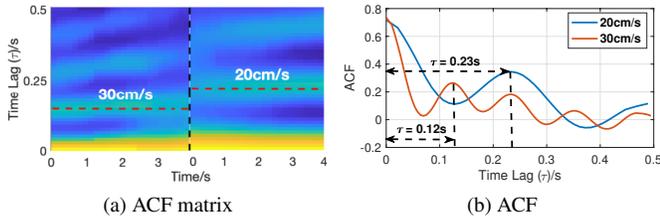

Figure 4: Speed estimation. A plate moves along a track programmed with different speeds (frequency @ 10 kHz).

60-12 BPM) are usually of magnitude longer than those for speed (e.g., <0.5s for 0.5 m/s using 10 kHz sound, and the faster the speed, the smaller the delay), a sufficient difference to determine whether to estimate breathing or speed. We do not involve speed in the current VECARE for CPD as motion and breathing will be sufficient. Yet we still present a brief description here, with an analysis of a few more issues in Appendix A.1, to show a unique approach offered by the SAS model. We keep the exploration of the full potential of SAS speed estimation for future work.

4 VECARE Design

Translating the proposed SAS model into a practical CPD system on commodity speakers and microphones still entails multiple challenges. In this section, we overcome these practical challenges and present the design of VECARE.

4.1 Acoustic Channel Estimation

The proposed SAS model leverages acoustic CSI, which demands effective channel estimation. Several unique characteristics of sound waves make it particularly challenging. First, the sound wave speed is orders of magnitude slower than that of light and EM waves, which imposes limitations on the max possible CSI sampling rate of the acoustic channel. For example, given the in-air sound speed of around 343 m/s, the propagation delay of a path of 7 meters in length will be greater than 20 ms, requiring a minimum channel measurement interval larger than 20 ms to avoid signal mixture. Second, acoustic sensing is vulnerable to environmental sound interference, especially when it is limited to a frequency band under 24 kHz on commodity devices. Ambient interference like the human voice, music, and natural sounds, can smear channel measurements for certain frequency bands. Moreover, concurrent sensing signals transmitted on multiple speakers, if used, may also interfere with each other.

In VECARE, we investigate Pseudo-Noise (PN) sequence [57] for CIR measurements. PN sequence is a set of noise-like signals and can be effectively distinguished from both a time-shifted version of itself (a.k.a, excellent auto-correlation properties) and every other signal in the set (a.k.a, excellent cross-correlation properties), which have been used in spread-spectrum communications, radar sensing, etc [52]. Among

different types of PN sequences such as m-sequence [58], Golay sequence [64], GSM training sequence [86], and Zadoff-Chu (ZC) [63], we choose Kasami sequence [31] for CSI estimation because of its superior properties of orthogonality and noise tolerance. Fig. 5a shows the auto-correlation and cross-correlation of a pair of example Kasami sequences with period $2^6 - 1$. The auto-correlation produces an impulse-like signal with minor side lobes, while the cross-correlation only produces minor values that are much smaller than the impulse of auto-correlation. Note that our approach is not limited to a particular channel estimation technique, but can work with any approach, including the widely used FMCW, that provides effective CSI.

CIR estimation with Kasami sequence: Fig. 6 shows the channel estimation process in VECARE, with two speakers as an example. We generate two orthogonal Kasami sequences s_1 and s_2 with the same length and periodically transmit them on both speakers simultaneously. The transmitted sequences undergo different time delays and attenuation before being captured by the microphone. On the receiver side, we correlate the microphone recordings with s_1 and s_2 separately to get CIR streams of the two channels, and slice them into segments with the same length as s_1 and s_2 , resulting in the CIR estimates $h_1(t)$ and $h_2(t)$. We can then convert $h_1(t)$ and $h_2(t)$ into the frequency domain by performing Fourier transform and obtaining the CSI $H_1(f, t)$ and $H_2(f, t)$.

Since a correlation operation is equivalent to a conjugate multiplication in the frequency domain, the measured CSI $\tilde{H}(f)$ using Kasami sequence can be represented as

$$\begin{aligned} \tilde{H}(f) &= [S(f) \cdot H(f) + N(f)] \cdot S^*(f) \\ &= \|S(f)\|_2 \cdot H(f) + N(f) \cdot S^*(f), \end{aligned} \quad (5)$$

where $H(f)$ denotes the ideal CSI, and $S(f)$ and $N(f)$ are the frequency-domain representations of Kasami sequence and sound noises respectively. $S(f)$ is a wideband signal spanning over the whole spectrum, and $S^*(f)$ is its conjugate. The term $\|S(f)\|_2 \cdot H(f)$ approximates to a scaled version of $H(f)$. An example of the measured CIR is shown in Fig. 2.

We generate Pulse Coded Modulation (PCM) samples from the Kasami sequence and play them on the speaker without an extra modulation process. Several previous works have exploited more complicated signal modulation techniques to improve measurement performance including Orthogonal Frequency-Division Multiplexing (OFDM) [48] and BPSK [86], which is not necessary for VECARE.

Audibility and Interference: There are two issues with the above channel estimation process. First, the Kasami sequences composed of 1's and -1's with sharp transitions in between can be intrusive to human ears. Second, by transforming CIR, the obtained CSI spans the full spectrum, which might be polluted by the ambient sound noises, especially on the audible frequency band. To circumvent these problems, we apply a high-pass filter (HPF) on both the transmitted and received signals. The passband can be set flexibly, and

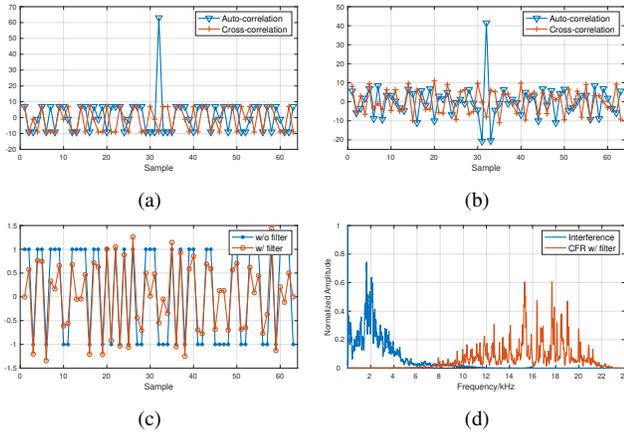

Figure 5: Kasami sequence. The auto-correlation and cross-correlation of (a) Kasami sequence and (b) Kasami sequence after applying a 10 kHz high-pass filter. (c) The Kasami sequence before and after a 10 kHz high-pass filter. (d) The spectrum of background traffic interference and CSI after the 10 kHz high-pass filter. The sound sampling rate is 48 kHz.

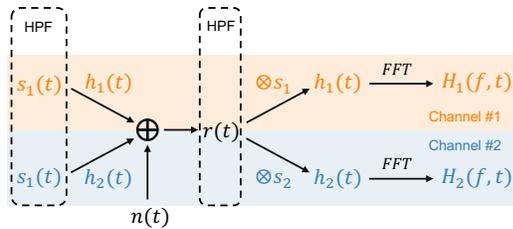

Figure 6: CSI estimation process with Kasami sequence.

VECARE can work reliably even with only the inaudible pseudo-ultrasound band, e.g., above 18kHz. Here we use an empirical passband of 10 kHz as an example for illustration and will evaluate difference choices extensively in §6.

Transmitter Filtering: When we apply the filter on the transmitter side, as shown in Fig. 5c, the binary values on the time domain signal are softened, and the output sound contains fewer intrusive bursts. The major concern is whether this filter operation breaks the auto-correlation and cross-correlation properties of Kasami sequences or not. To validate, we plot the auto-correlation and cross-correlation between the original and filtered Kasami sequence in Fig. 5b. It can be seen that, after applying the filter, the auto-correlation still observes an impulse (with a decrease in SNR) while the cross-correlation approximates the noise.

Receiver Filtering: On the receiver side, the term $N(f) \cdot S^*(f)$ in Eq. 5 is eliminated by high-pass filtering. This is because typical daily sound interference, such as traffic and human voice, mostly occurs in the frequency band below 10 kHz. Fig. 5d shows the spectrum of traffic noise and the measured CSI after applying the HPF. As seen, the noise is successfully removed. Meanwhile, we are left with fewer subcarriers for sensing because of the filtering, motivating us to maximize the sensing signals (§4.2).

Resilience to asynchronization: The speakers and microphones are connected to the same controller in our prototype and in cars as well. Due to hardware imperfections and software latency, however, they are not perfectly synchronized, which makes it difficult to measure accurate channel response. Fortunately, synchronization errors only introduce phase offsets in CSI, which does not affect VECARE because CSI is measured consecutively without blanks in between and we only use the amplitude. We will experimentally verify this in §6 and show that VECARE even works with separate speaker and microphone, while providing proof in Appendix A.2.

4.2 Sensing Signal Enhancement

Sound reflection off human bodies is considerably weak, a major reason confining the coverage of human-centric acoustic sensing [71, 74]. The problem is aggravated when the target is an infant/toddler in CPD applications. Our SAS model utilizes all multipaths for better coverage. We now present an effective technique to exploit subcarrier diversity which further boosts the sensing signals, particularly for breathing.

Subcarrier diversity is attributed to frequency selective fading, a well-known phenomenon in wireless communications. Fig. 7 demonstrates a breathing example, with the calculated ACF matrix on different subcarriers in Fig. 7a and the raw amplitude of good subcarriers (manually selected) in Fig. 7b. Some subcarriers capture dominant breathing signals, while others merely observe noises, even in such an example with strong breathing signals. We also notice that, because of the complex multipath propagation, the most sensitive subcarriers can vary over time randomly. Therefore, it is critical to dynamically find the best subsets of subcarriers and effectively combine them to maximize the signal SNR.

Like in WiFi sensing works [79, 90], we employ Maximal Ratio Combining (MRC) [6], a classical diversity combining method in wireless communications which optimizes the receiving SNR, to combine multiple subcarriers optimally. Since the noise terms on different subcarriers are statistically independent, we can maximize the signal SNR by MRC as

$$\hat{\rho}(\tau) = \sum_{f \in F} w(f) \tilde{\rho}(f, \tau), \quad (6)$$

where $\hat{\rho}(\tau)$ is the combined ACF, $w(f)$ denotes the normalized weight for combining subcarrier f (i.e., $\sum_{f \in F} w(f) = 1$), and F is the set of all subcarriers. The optimal weight $w(f)$ should be linearly proportional to the gain on each subcarrier. Following [90], we adopt the normalized $g(f)$, defined in Eq. (4), as the weight $w(f)$ in VECARE. Note that, some intuitive criteria commonly used like mean/variance of CSI amplitude cannot serve as the optimal weights for MRC, as they are not linearly proportional to the gain $g(f)$ and subcarriers with higher amplitude means/variances do not necessarily better capture the sensing signals, as shown by Fig. 7a.

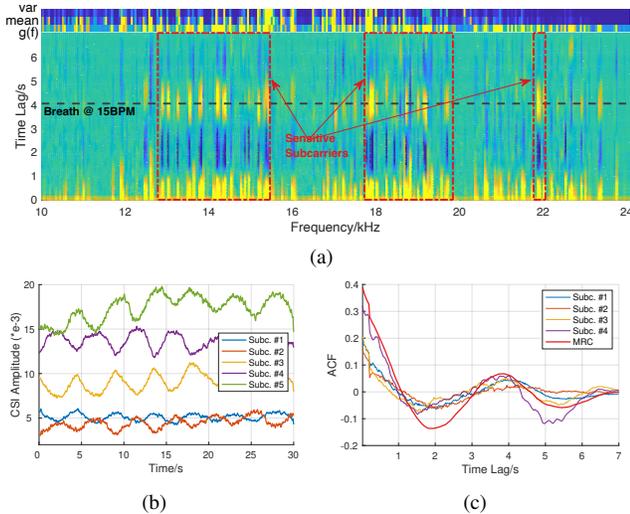

Figure 7: Breathing signals. (a) The ACF over all the subcarriers, with gain $g(f)$, mean and variance of CSI amplitude marked on the top. (b) The CSI amplitude on different subcarriers. (c) ACF on subcarriers and after MRC.

We can combine multiple subcarriers here because, by taking the ACF, the sensing signals (either breathing or speed) are synchronized across different subcarriers (Fig. 7c). It cannot be done directly on the raw amplitude due to the considerable phase offsets of breathing/speed signals on different subcarriers, as demonstrated by Fig. 7b. In case multiple speakers are available, the subcarriers on different speakers can be combined similarly, and again, asynchronization among different speakers is not an issue. By combining them, we can further boost the SNR and extend the sensing coverage.

4.3 Child Presence Detection

VECARE combines motion and breathing detection for CPD. **Motion detection:** It is straightforward to detect motion. We first average the gains $g(f)$ across all subcarriers and obtain $\bar{g} = \frac{1}{|F|} \sum_{f \in F} g(f)$. Then given a preset motion threshold ϵ , the system detects motion at any given time t if $\bar{g}(t) > \epsilon$; otherwise no motion presents. We use equally averaged \bar{g} instead of using MRC because the averaged values across all subcarriers with equal gains will approximate zero in absence of motion, allowing us to find a generic threshold ϵ for different environments and cars.

Breathing Detection: To estimate the breathing rate, we first need to find whether there exists a dominant peak in the enhanced sensing signal $\hat{p}(\tau)$. To achieve so, we adopt similar criteria in [90] for peak finding. Basically, we first examine the peak prominence, width, and amplitude to identify potential peaks. Then we further check the peak location to sift out those beyond the typical range of human breathing rates, e.g., 10-60 BPM. We also compare the motion level \bar{g} against the peak value as there will be unlikely breathing if the motion level is way larger than the peak value. Once we find the

peaks corresponding to breathing, we will estimate the peak location τ_b and accordingly derive the breathing rate.

Real-time CPD: In real-time, we employ a sliding window on the continuous CSI to calculate the ACF. We employ a shorter window of CSI (e.g., 1s) for calculating the ACF for motion detection to make it more responsive while saving computation. While for breathing, a minimum window larger than a typical breathing cycle (e.g., 6s, which can be shorter for children who usually have higher breathing rates) is desired. As motion is more common and the computation is more efficient, we will only further perform breathing estimation when no motion can be detected. Note that the system can output detection decisions as fast as every CSI sample, or at a predefined lower rate, e.g., every 1 second, to save energy. Once we have the time series of motion/breathing decisions, we check them within a certain window, e.g., 5s, and child presence is claimed if there is a certain amount of motion/breathing detection, e.g., >30% of the window.

5 Implementation

Hardware: We implement VECARE using a programming audio prototype, which consists of a MiniDSP UMA-8-SP USB microphone array [44] with 7 built-in Knowles SPH1668LM4H microphones (we use only one of them) and PUI Audio AS07104PO-R speakers [5] connected to the MiniDSP board via cables. As in Fig. 8(g), we also evaluate the performance on a variety of commodity devices used in consumer electronics and cars, including JBL Stage1 621 car speaker [29] and Linhuipad car microphone [38], JBL Clip 4 speaker, Sony SRS-XB23 speaker, Razer Seiren Mini Mic, and speakers and microphones on Macbook and iPhone, etc. Again, we always use *only one single microphone* throughout our experiments, even if more are available. We connect this prototype to either a computer or Raspberry PI 3 Model B+.

Software: We implement signal generation and transmission as well as all our algorithms using MATLAB mainly for benchmark analysis. We also build an end-to-end prototype of our system running in real-time using Python3.9, which can run on embedded devices (Raspberry PI in our case).

Kasami Sequence: A longer period of Kasami Sequence allows higher SNR for channel estimation, which, however, creates an immediate conflict with sampling rates. To trade-off, we use a sequence of period $2^{10} - 1$ modulated into 0.02 s, which allows a desired sampling rate of 50 Hz to use in VECARE. By default, we use 3 seconds of CSI for motion calculation and use 8 seconds for breathing rate estimation.

Handling Sharp Interference: By applying a high-pass filter, we successfully get rid of most of the daily environmental noises. However, if there are sharp and short impulse-like noises (e.g., horn honk/beep), the impacts may go above 10 kHz and cause false motion detection. We notice that these kinds of sharp noises will impose a sudden change in the CSI amplitudes, which translates into a special ACF pattern,

which linearly decreases first and then linearly increases (See Appendix A.3 for more details). Therefore, we design a detector to identify this linear decrease-then-increase pattern and skip CPD during the interfered period. By doing so, VECARE becomes immune to sharp noise like horn beep, an important feature making it more practical. Although this would reduce the effective protection time (the system is not working in presence of such noises), we argue the impact is minimal because these noises are usually short (~ 1 s) while VECARE detects so rapidly that it can find a period for detection.

6 Evaluation

6.1 Experimental Setup

We conduct experiments both in office environments and in cars, as Fig. 8 illustrates, which mainly consist of three parts: 1) Indoor experiments with adults to evaluate the performance in large space against various parameters. 2) Indoor and in-car experiments with infant simulators. Our evaluation involves two infant simulators. One is Laerdal SimNewB (Fig. 8(b)), a high-end model (retail price around \$30,000) offered by the clinical facility in our university’s medical school, which is co-created by the American Academy of Pediatrics and allows to set the breathing rate as well as move various body parts. The second one comes with a breathing motor and does not support body movements. 3) Real-world in-car experiments with children. We recruit 15 young children and perform CPD in 7 different cars including sedan and SUV.

Ground truth for adult breathing is measured by Plux piezo-electric Respiration (PZT) sensor [7]. Infant simulators have a preset fixed breathing rate. We did not record the ground truth breathing rate of children participants as it is difficult to have their cooperation. Motion and presence ground truths are manually labelled. This work does not raise any ethical issues and has been approved by our university’s IRB. No sensitive data like personal identifiers were collected.

To show our performance under extreme responsiveness constraints, by default we use a 2-second window for the decision below. A higher detection rate is expected if a longer decision window is applied. Also, we use only one speaker for evaluation unless otherwise specified. Using more speakers is expected to provide larger coverage. We mainly use detection rate (DR) and false alarm rate (FAR) as the evaluation metrics for motion, breathing, and overall presence detection, while we also evaluate the mean absolute breathing rate error.

6.2 Indoor Performance

We first evaluate with comprehensive indoor experiments to validate motion detection and breathing estimation.

Motion Detection: We first evaluate the motion detection performance in a $7\text{m} \times 5\text{m}$ conference room. We set up one microphone and one speaker in the corner. The room is in an

Figure 8: Experimental setups

office building, with constant noise from the central fan and occasional footstep sounds when people pass by the outside corridor. An adult is asked to sit in a chair, at various distances from 1m to 5 m, and only move his one hand slowly to mimic the tiny motion of a child. We also test with the speaker facing different angles with respect to the subject. As shown in Fig. 9, VECARE achieves an average detection rate of 98.1%, which maintains 94.1% even when the user is 4~5 m away from the speaker and microphone, while the false alarm rate is only 1.1%. The performance degrades slightly when the subject is at a distance and at an angle of 60° . Note that the motion detection rate is almost 100% when the user is within 3.5 m, a sufficient distance to cover a typical car.

Breath Estimation: Now we evaluate the breathing estimation performance in the same environment. First, we also test with an adult subject at different distances, sitting still in a chair. As shown in Fig. 10, we achieve a mean absolute error of 0.88 BPM within the distance of 3 m, including all orientations. More importantly, VECARE can detect breathing rate at a range as far as 4.5 m, with a slight increase in breathing rate error. We also evaluate the case when there is no Line-Of-Sight (LOS) between the speaker and the subject, as well as the case when the user wears a thick down jacket. As portrayed in Fig. 11, even when a user is wearing a thick coat, VECARE can still pick up the breathing rate at distance up to 4 m. When the speaker is blocked, the maximum range of breathing estimation decreases to 2.5 m, still more than enough to cover an entire car. Note that the accuracy under occlusion is not necessarily lower than that for LOS cases since VECARE embraces all multipath reflections to significantly enhance the NLOS scenarios, which may experience richer multipath effects.

Evaluation with SimNewB: Now we carry out a feasibility study with the SimNewB newborn simulator in a clinical facility, which features tens of beds and has continuous machinery and HVAC noises. The experimental setup is illustrated in Fig. 8(a). During the tests, the laboratory technician randomly set the breathing rate of the newborn simulator. As shown in Fig. 13, VECARE can detect the newborn simulator’s very weak breathing reliably, achieving an average detection rate of 87.8% with a mean error of 3.43 BPM, which decreases to 78.0% with an increased mean error of 8.6 BPM when the newborn is covered with a blanket. Note that we didn’t exhaust various breathing rates due to limited access to the fa-

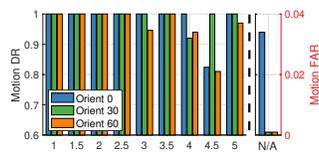

Figure 9: Indoor motion detection performance.

cility and SimNewB during the pandemic time, yet we believe the results already show the capability to detect a newborn’s breathing at a distance. We will further study the impact of breathing rates later. In another test case, we configure the neonatal simulator to move her forearms, for which we detect the motion for 100%.

Speed Estimation: We also conduct a preliminary evaluation of our speed estimation by moving a plate back and forth at speeds from 15 cm/s to 25 cm/s along a 1.8m long straight programming track, as in Fig. 8(c). As shown in Fig. 12, VECARE achieves a considerable 80%ile accuracy of 5 cm/s. Errors mainly occur around the turning points when the plate slows to stop and starts moving again. We believe the results are encouraging and plan to further investigate statistical acoustic speed estimation for other applications in the future.

6.3 Real-World CPD Study

We conduct a real-world study with young children in different cars and parking scenarios, such as parking lots, roadside parking, garage, etc. For each child, we test different locations, with either forward-facing or rear-facing car seats as regulated. For older children who can sit/crawl independently, we also test seats without the baby car seat. All the children wear their regular winter coats. We test motion (awake) cases for every child and evaluate breathing for children who are able to get asleep (or stay very quiet) during the test. The data collection for each child lasts about 30-60 minutes. During tests, the car is parked and locked with windows closed, the typical scenario that hot-car deaths may occur. There are cars parking around and/or passing by, and parents and our experimenters talking/standing/walking around the car. There are frequent traffic noises during most of the tests, done in central downtown Hong Kong. In total, we have 15 children (aged 7 months, 12 months, 18 months, 2 (2×), 3 (4×), 4 (2×), 5 (3×), and 10 years old, respectively) tested in 7 different cars, including Lexus LS430, BMW 330, Mercedes-Benz C200, Mercedes-Benz S320, Tesla Model 3, Honda Jazz, Nissan Serena. We use one or two speakers for the real-world study, considering not all cars have four or more, and always use one single microphone. In most cases, the LOS condition is occluded, provided that the devices are installed in the front row while the kids are seated in the back. Example setups are shown in Fig. 8(d) and (e).

We mainly focus on the overall presence detection rate for this CPD test. Fig. 14 shows that VECARE achieves an

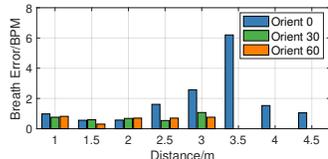

Figure 10: Indoor breath estimation performance.

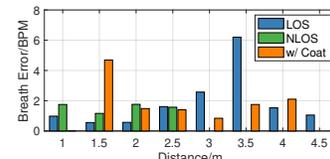

Figure 11: Breath estimation in NLOS and with coat.

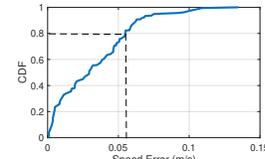

Figure 12: Speed estimation performance.

average detection rate of 98.8% with an average false alarm rate of 2.1% for all age groups of children. As expected, the detection rate for infants (one 7-month-old and one 12-month-old in our experiments) is relatively lower than older kids, but is still around 90%. The high performance is consistently achieved across different cars, varying from 95% to 100% with marginal differences, as portrayed in Fig. 15. The FARs in Fig. 14 vary slightly because different kids are tested in different cars that have different enclosure materials and in-car noise levels. False negatives are most likely to occur when there is a lack of awake motion and the infant’s breathing is extremely weak.

Furthermore, we analyze the performance at different in-car locations. As shown in Fig. 16, we group the results based on where the child seats, i.e., driver seat (L-F), passenger seat (L-R), two back seats (L-B and R-B), as well as the case when the child is on the back row floor (B-G). As seen, VECARE maintains a consistently high detection rate and low false alarm rate across different locations. Overall, the results demonstrate VECARE’s remarkable performance in real-world scenarios, promising its potential for practical adoption.

To further understand the detection coverage in a car, we use a small toy car, as shown in Fig. 8(f), to simulate tiny motions at nine different on-seat and on-floor locations. Two speakers are installed on the left and right front doors, respectively. As depicted in Fig. 17(a), VECARE achieves a 100% detection rate for all the 9 testing locations, using either two speakers or only one single speaker on the left or the right.

Long-term Study: Besides the high accuracy, it is also critical to study false alarms, especially over a long period in diverse noisy environments like busy streets, noisy garages, etc. We first note that the above real-world experiments were conducted in noisy urban areas (including noisy garages, busy streets, parking lots next to highways, etc) in downtown Hong Kong in the presence of cars, sirens, pedestrians, etc. To further understand the performance in different environments, we carry out a relatively long-term evaluation in the busy Beijing City. We park the car, without kids inside, in a busy garage and a crowded street for about 10 hours, respectively. We report a false alarm if motion is detected for over 10% of the time for a sliding window of 2s. Our results show that VECARE observes a false alarm rate of 0.12% in the garage and 0.28% for the roadside parking case. In practice, a CPD system may not need to run for a long time, but perhaps only for a few minutes after the car is parked and locked, which will further reduce the chance of observing false alarms.

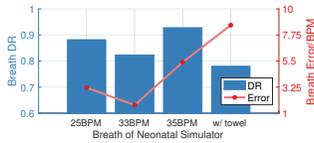

Figure 13: Evaluation with a neonatal simulator.

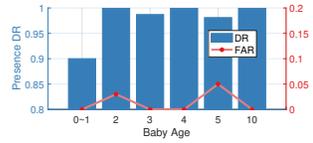

Figure 14: VECARE for children at different ages.

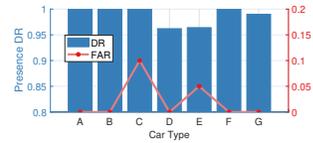

Figure 15: VECARE for children in different cars.

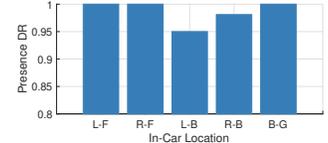

Figure 16: VECARE for different in-car locations.

System Latency: As a time-critical task, we now analyze the detection latency of VECARE. To do so, we evaluate the delay of the first decision for each test. We use a 3s window for ACF calculation for motion and an 8s window for breathing, and then use another 2s window for presence detection. Hence, the minimum delay will be 5s if motion is detected and 10s if there is no motion but breathing. With this configuration, the results show that VECARE can output the first detection within 5.7s for 81.9% of the time, 11.2s for 95.2%, and 15.2s for 98.8%. The minimum delays and thus the overall latency can be reduced by using a shorter window (e.g., 1s) for motion detection, the most common case for CPD.

6.4 Comparative Study

Baseline Comparison: We compare VECARE with the state-of-the-art approach BreathJunior [71], the closest to our work which successfully uses white noise for infant breathing monitoring. We implement BreathJunior and perform comparison experiments using an infant simulator. The results demonstrate that VECARE outperforms BreathJunior in both accuracy and coverage. As shown in Fig. 18, the maximum distance BreathJunior achieved is 70 cm (with a considerable error of 8 BPM), while VECARE goes to 1.6 meters under the same condition, which is 2.3× improvement. In addition, while BreathJunior is accurate within 0.5 m, the breathing estimation error quickly increases at a distance of 70 cm. In comparison, VECARE maintains a breathing rate error below 2 BPM at a distance of 90 cm, smaller than the error BreathJunior experiences at 60 cm.

Channel Estimation Methods: As said, VECARE can work with any channel estimation methods that output CIR. We now compare the performance of using Kasami Sequence against using different CIR estimation methods, including chirp signals (FMCW) [15], Golay Sequence [64], MLS [59], Gold Sequence [19]. As shown in Fig. 19, while all these methods produce a high detection rate above 90%, Kasami Sequence demonstrates its superior performance with the lowest breathing rate error and the highest detection rate.

Device Diversity: We now examine VECARE’s performance on different devices. We are most interested in how it works on commodity car speakers and microphones. We thus evaluate it using JBL Stage1 621 car speaker and LinhuiPAD car microphone, both adopted in existing automobile audio systems. As shown in Fig. 20, VECARE maintains high performance and large coverage. We further test motion detection at 2m on various speaker/microphone combinations as summarized in Fig.

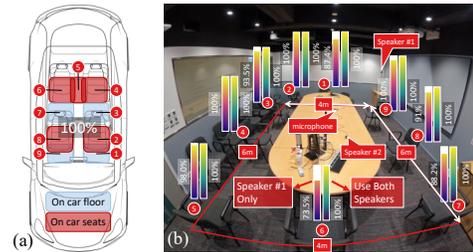

Figure 17: Motion coverage (a) in a car and (b) in a room.

21, which indeed show device diversity yet good performance retains in most cases.

6.5 Benchmark Study

In this section, we evaluate the impacts of various factors and validate the robustness of VECARE. For more controllable data collection, we use the infant simulator instead of real babies for this study, and focus more on breathing estimation.

Background Interference Type: We first study the impact of background sound interference of different types, including human voices, traffic noise, rain sound, wind sound, hail-stone sound, and music. To better control the experiments, we download sound files of these noises and play them through a loudspeaker around 50 dB next to the VECARE system. As shown in Fig. 22, VECARE maintains high accuracy regardless of different types of natural sound interference, with only marginal differences among them. This has also been partly verified in our real-world testing in §6.3 where we tested under real environments with all different ambient noises.

Background Interference Level: We also evaluate the performance under various background noise levels. We mainly focus on traffic noise and human voices for this test. We play sound files of noise through a loudspeaker at various powers and distances and record the actual sound level received at the microphone. As shown in Fig. 23, the BPM error increases with higher surrounding noises, especially over 50 dB level.

Transmitter Sound Level: The transmitting power of the speaker can affect performance. To verify this, we vary the transmitted sound from 46 dB to 53 dB and evaluate the breathing estimation error accordingly. As seen in Fig. 24, the breathing rate error quickly drops from about 7 BPM to below 2 BPM when the sound level exceeds 49 dB. Sensing sound at this level is perceived acceptable, according to our observations of the response of children participants and their parents’ feedback, and users outside the car can barely hear the sound. Also, note that previous works [71] use higher sound levels (reportedly 56 dB [71] and 75 dB [70]) than

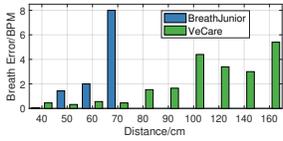

Figure 18: Performance comparison with baseline.

Figure 21: Motion detection on various devices.

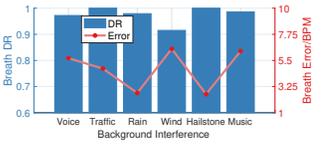

Figure 22: Impact of background interference.

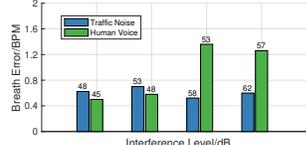

Figure 23: Impact of background interference level.

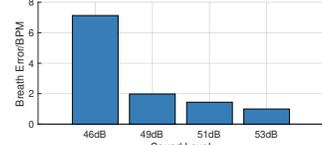

Figure 24: Impact of transmitting sound level.

VECARE. Nevertheless, a higher sound level is more favored in VECARE as a relatively high sound level could benefit CPD applications since it promises a better chance to wake up a sleeping baby for more reliable detection via awake motion. As research [16, 51] reports that a sound level higher than 75 dB will disturb the infants, we set the default sound level as 50 dB. Based on our real-world experiments with children, such a sound level appears to be tolerable to kids including infants and toddlers: We received no cases to complain about the sound intrusiveness and annoyance.

Frequency Bandwidth: We use the band above 10 kHz by default in our experiments, which may still be intrusive to human ears. We now study the performance with narrower and higher frequency bands. To do so, we adapt the passband of the high-pass filter from 10 kHz to 22 kHz with a 2 kHz step. Fig. 25 shows that VECARE retains a good performance until the passband exceeds 20 kHz. Larger bandwidths allow better performance, while VECARE still performs well using 18-24 kHz, the commonly used inaudible band in the literature. Commodity devices like Google Nest start to support acoustic frequencies up to 30 kHz [70], which we believe will become more common in the future. Such devices allow a sufficiently large and truly inaudible band across the age spectrum for non-intrusive acoustic sensing.

Impact of Temperature: As sound speed depends on temperature, we are curious how VECARE works under high temperatures. To do so, we heat up the surrounding air to about 120°F and then let it naturally cool down in a warm room of about 70°F. We keep the system running during the process and show the breathing estimation results in Fig. 26. As seen, VECARE failed to work when the devices overheat, but resumes excellent performance when they slightly cool down (after 30 seconds). We argue that a CPD system is expected to work *before* rather than *after* the car has heated up, as intervention actions are most effective right after the car is parked and locked. Therefore, we believe VECARE’s CPD effectiveness will not be affected even though its performance degrades under overly high temperatures.

Multiple Speakers: Multiple speakers, if available, can further increase the sensing coverage. We present a case study with two speakers in a meeting room, where an adult sits in a chair moving one hand. As portrayed in Fig. 17(b), while the coverage with a single speaker is already good, by adding one speaker, we achieve a 100% motion detection rate through the 6m×4m area. We didn’t continue with more speakers as the system already covers the entire room using two.

Synchronization Errors: We manually introduce large synchronization errors to show that VECARE is resilient to phase offsets. Particularly, we shift the starting point of the received signals by an amount of time ranging from 0 to 1 second with a step of 0.1 s. As shown in Fig. 27, VECARE maintains similar accuracy without being affected by the time offsets, which confirms our theoretical analysis.

Breath Intensity: Infants and toddlers usually have higher breathing rates than adults. We evaluate the performance of VECARE with respect to a range of breathing rates from 30 BPM to 60 BPM. We fix the breathing rate for each run by controlling the motor of our infant simulator. The results show insignificant differences for various breathing rates.

System Overhead: We benchmark the system overhead on a desktop (Intel i7-11700 @ 4.9GHz CPU), a MacBook Air M1, and a Raspberry Pi 3 Model B+, on which VECARE use 0.52s, 0.73s, and 3.97s respectively to process 10s of the data stream. The results show that VECARE can run in real-time on embedded devices, promising its integration into existing car control systems. The current prototype of VECARE using MiniDSP microphones introduces an extra power consumption of about 3W on Raspberry PI 3 B+, resulting in a total of 6W. The energy consumption can be optimized by improved hardware and software implementation. Additionally, the power usage is overall negligible as, again, we believe the CPD system can run only for minutes after a car is parked.

7 Discussions and Limitations

VECARE takes an important and promising step towards a ubiquitous solution to accurate and robust in-car CPD, an

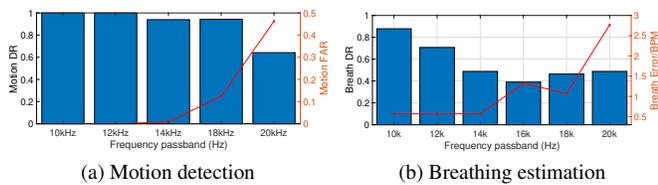

Figure 25: Impact of frequency band

extremely challenging task. However, there is certainly room for improvement and more to explore.

First, we cannot differentiate between an adult, a child, or a pet. Neither do we distinguish a single subject from multiple ones, as the proposed SAS currently is limited to one single user. A CPD system is expected to detect the presence of one or more children or pets, and the case of an adult being locked in a car is uncommon. While it is possible to distinguish between a child and an adult, to some extent, by examining the range of the breathing rates, we leave this task as an open challenge for the community. Second, although the proposed SAS model presents a new approach to speed estimation, the capability to estimate high speed is limited by the sampling rate of acoustic CSI. It is worth exploring how to break down this limit and enable speed tracking for normal walking speed, which will foster many applications. Third, there are more applications of the proposed SAS model in smart homes and non-contact healthcare to be explored. Towards that, one particular problem is to further improve the sound audibility, including reducing transmit sound level and shifting more to the inaudible frequency bands, e.g., 20-30 kHz used in commercial smart speakers like Amazon Echo and Google Home. Fourth, while a universal threshold ϵ applies to different environments and cars, we notice one-time calibration is needed for different devices due to hardware diversity (Fig. 21). Future work explores to relax it. Last, current evaluation is limited to children older than 7 months. Although we have experimented with the neonatal simulator, evaluation with real newborns is a worthwhile exploration.

VECARE can be deployed without any hardware modification: It works with legacy in-car audio systems, and we can leverage existing car control units for the computation and necessary alert functions. Alternatively, it can also be deployed as a standalone system to promote rapid adoption. Additionally, system integration with other available sensing modalities, such as seat sensors, radar, or WiFi, would promise a more reliable CPD system, but at a higher cost and lower ubiquity. These issues are, however, out of the scope of this work, and we seek to learn more about real deployment with industrial collaborations.

8 Related Work

Car Occupancy Sensing: CPD, or car occupancy detection in general, has recently gained tremendous attention with various technologies being explored. Early systems install special

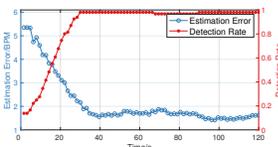

Figure 26: Impact of temperature (cooling from 120 °F)

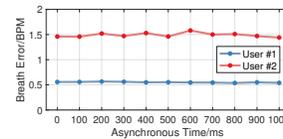

Figure 27: Impact of synchronization errors

sensors, such as optical/weight/pressure sensors [12, 32] as well as capacitive sensors [4, 18, 54], on passenger seats/baby car seats for detection (e.g., for seat belt reminder). These systems cannot detect a left-in-car child not in a designated seat. Nor can they reliably differentiate animate targets from inanimate objects. PIR sensors [21, 55, 87] can extend the range beyond the seats, but are limited to the LOS view and sensitive to temperature changes. Camera-based systems [10, 13, 85] can be accurate given good lighting conditions³, but cannot see through seats, in addition to being privacy-invasive and computation hungry. Radio-based systems have been recently popular. The radar industry is promoting radar systems for CPD in new car models [26, 28, 66]. UWB and mmWave radars [8, 14, 34] feature high sensing resolution, yet the coverage is limited to the FoV and the performance degrades for NLOS scenarios. Moreover, they need precise installation with wire/cable harnesses, usually on the roof of a car, to provide good coverage. With WiFi becoming prevalent for in-car connectivity, it has been exploited by the industry for CPD [45, 81]. Yet due to the innate limitations, it is challenging to detect vital signs of little infants using WiFi. Ultrasonic motion sensors have been used, e.g., in Hyundai cars [20], yet only report low detection accuracy and are being replaced [20]. Most importantly, all these solutions will incur additional dedicated hardware and/or costly installation as being non-standard offerings in cars, preventing their wide adoption, especially for old car models.

Beyond CPD, there are more works on in-car driver monitoring [68, 72, 80, 82, 83] and/or (adult) passenger detection [1, 2, 40] and even more on general human presence detection in homes especially using radio signals [30, 61, 77, 84, 89]. As the motion and vital signs of adults are of magnitude stronger than those of young children, these approaches cannot be directly applied to solve CPD. The closest to VECARE is BreathJunior [71], which nicely embeds FMCW signals into white noise for infant breathing monitoring, yet relies on a microphone array and has a limited coverage of <1m.

Acoustic Sensing: Acoustic sensing has been an active area in recent years. Various applications have been studied, including gesture recognition [74, 75], imaging [37, 42], localization and tracking [17, 41, 43, 56, 65, 69, 73, 86], vital sign monitoring [36, 53, 70, 71, 82], and healthcare [11, 46, 47], etc. A recent work [35] points out several practical challenges of acoustic sensing, such as audible sound leakage, affecting

³Infrared cameras can detect humans at night, but could still fail in dangerous cases where the car interior is already heated up.

music play and voice call, which are less concerned in our CPD application as the system is expected to only run for a short period after a car is parked. Most of the existing works explore geometrical features such as phase changes, Doppler shifts, TDoA/ToA, etc [9, 53, 74]. Many even rely on a bulky microphone array [69, 71] for phased signal processing. While these works are mostly resilient to multipaths, they do not fully leverage them. In contrast, VECARE investigates a novel statistical acoustic sensing model, which aims to leverage all reflections. Despite extensive studies of statistical WiFi sensing [23, 78, 79, 88–90] and statistical studies on acoustic communication [33, 62], none of the existing work has studied statistical acoustic sensing. We introduce statistical models to acoustic sensing, which we believe will open new directions and inspire follow-up works in the community.

9 Conclusion

We present VECARE, the first CPD system using in-car speakers and microphones. VECARE is an accurate and robust solution to the critical hot car death problem, which can be deployed on massive cars without any hardware changes. To achieve so, we introduce a novel paradigm of statistical acoustic sensing and develop a pipeline of techniques that allows motion detection, breathing estimation, and speed monitoring in a unified framework. Real-world experiments show the remarkable performance of VECARE, rendering it a promising solution in practice. The proposed SAS will inspire more exciting research in the increasingly hot acoustic sensing area.

Acknowledgments

We are grateful to all children participants in the real-world CPD study and their parents. We thank the School of Nursing at HKU for free access to the Laerdal SimNewB simulator. Thanks also go to the anonymous reviewers and to our shepherd, Nirupam Roy. A Appendix

A.1 Speed Estimation

Sampling Rate and Speed: A sufficient sampling rate of CSI is required to estimate speed. We now discuss the relationship. Given a sound frequency f with wavelength $\lambda(f)$, a moving speed v is expected to experience a peak at the delay of $\tau = \frac{x_0 \lambda(f)}{2\pi v}$. Assume we will need at least Q samples to reliably detect a peak, which corresponds to a delay of $\tau_{\min} = Q/F_s$. Then we can derive the minimum sampling rate required to measure a speed of v by $\tau = \frac{x_0 \lambda(f)}{2\pi v} > \tau_{\min} = Q/F_s$, which implies $F_s > \frac{2\pi Q v}{x_0 \lambda(f)}$. In other words, the maximum speed we can support can be calculated as $v < \frac{x_0 \lambda(f) F_s}{2\pi Q}$, which becomes about 0.1 m/s at $f = 20$ kHz (wavelength 1.7 cm), about 0.2 m/s at $f = 10$ kHz, and about 2 m/s at $f = 1$ kHz, assuming $Q = 5$ and a sampling rate of about 50 Hz (considering the sound speed of $c = 343$ m/s). Using lower frequencies immediately allows to support higher speed, which however may suffer more from ambient noises. How to break down the sampling rate limitations and achieve estimation of daily speed (e.g., 0.5 m/s to 2 m/s) using pseudo-ultrasound frequencies remains worthwhile direction.

Speed MRC: For breathing signals, since the periodicity is independent of subcarrier frequency, we can directly perform

MRC across subcarriers. However, a further trick is needed to combine speed signals because, for acoustic signals from 10 kHz to 24 kHz, the difference in the wavelengths cannot be neglected (the wavelength at 10 kHz is approximately twice of that at 24 kHz). Recall $\hat{v} = \frac{x_0 \lambda(f)}{2\pi\tau_s}$. Given the same speed v , the first local peaks of the ACF on different subcarriers will appear at different delays τ_s . Hence, to combine subcarriers for speed signals, we need to first compensate the linear offsets due to different wavelengths. Specifically, we can express the ACF $\tilde{\rho}(f, \tau)$ w.r.t a unit linearly proportional to $\lambda(f)$, i.e., $\mu = \frac{\tau}{\lambda(f)}$, and then average on $\tilde{\rho}(f, \mu)$. The operation is equivalent to scaling the ACF in the time lag dimension, which can be achieved by interpolation in practice.

A.2 Synchronization

Here we show a simple but stringent proof of that synchronization errors do not affect VECARE. Denote the CIR measured under synchronization offsets as $\tilde{h}(t)$:

$$\tilde{h}(t) = \text{circshift}(h(t), \tau_{off}), \quad (7)$$

where $h(t)$ is the true CIR, τ_{off} is the timing offset caused by asynchronization, and $\text{circshift}(\cdot)$ represents circular shift. The time offsets correspond to phase shifts in the frequency domain. Thus we have the asynchronized CSI:

$$\tilde{H}(f) = H(f) \cdot e^{-j2\pi f \tau_{off}}, \quad (8)$$

where $H(f)$ is the true CSI. Thus we get $|\tilde{H}(f)| = |H(f)|$, meaning that VECARE is resilient to synchronization errors.

A.3 ACF Outliers

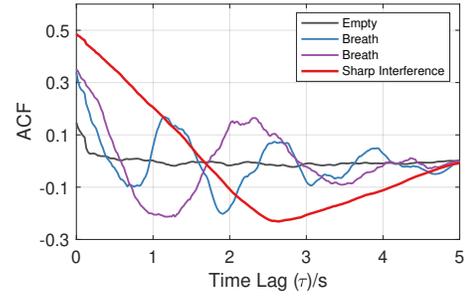

Figure 28: ACF outliers of sharp interference.

Sudden impulse-like noises will cause an abrupt status change in the CSI stream, which will smear the ACF calculation and may lead to false motion detection. We notice that ACF calculated with CSI of an abrupt status change will exhibit a special pattern, which linearly decreases and then linearly increases, as shown in Fig. 28. We also confirmed this by simulation with data stream containing a sudden change in the middle. The ACF pattern is unique and distinguishable from normal ACF in case of motion, breathing, or empty environment. Based on this observation, we design a detector to identify such abnormal ACFs and sift them out for presence detection. The idea is to examine a single valley in the ACF with linear increasing/decreasing trends on the two sides of the valley. The approach turns out to be effective and accurate.

SlimWiFi: Ultra-Low-Power IoT Radio Architecture Enabled by Asymmetric Communication

Abstract

To communicate with existing wireless infrastructures such as Wi-Fi, an Internet of Things (IoT) radio device needs to adopt a compatible PHY layer which entails sophisticated hardware and high power consumption. This paper breaks the tension for the first time through a system called SlimWiFi. A SlimWiFi radio actively transmits on-off keying (OOK) modulated signals. But through a novel *asymmetric communication* scheme, it can be directly decoded by off-the-shelf Wi-Fi devices. With this measure, SlimWiFi radically simplifies the radio architecture, evading power hungry components such as data converters and high-stability carrier generators. In addition, it can cut the transmit power by around 18 dB, while keeping a similar link budget as standard Wi-Fi. We have implemented SlimWiFi through PCB prototype and IC tape-out. Our experiments demonstrate that SlimWiFi can reach around 100 kbps goodput at up to 60 m, while reducing power consumption by around 3 orders of magnitude compared to a standard Wi-Fi transmitter.

1 Introduction

The Internet of Things (IoT) is playing a key role in bridging the physical and digital worlds. IoT will act as the workhorse to fully automate human life, through a new wave of applications in environment/behavior sensing, asset tracking, ambient human-computer interaction, *etc.* As of 2021, the population of active IoT endpoints already reached 12.2 billion, and will surge towards 27 billion in 2025 [27]. Maintaining the connectivity between the IoT fabric and the existing Internet infrastructure entails non-trivial human efforts, and will ultimately be feasible only if the IoT devices can sustain themselves, *e.g.*, through RF energy harvesting. In practice, RF energy harvesting can usually reach at most tens of μW [75] for IoT devices, so any self-sustainable communication paradigm has to adhere to this limit. RFID represents one such paradigm, which is truly battery-free and communicates by merely harvesting and remodulating the RF power from an interrogator (reader). Yet to date, RFID has witnessed limited adoption in consumer applications, due to its limited communication range, relatively high cost of the reader, and limited functionality (mostly restricted to reading preprogrammed information on passive tags).

Ideally, we would prefer to reuse the existing wireless infrastructures (*e.g.*, the pervasive Wi-Fi) as gateways to connect

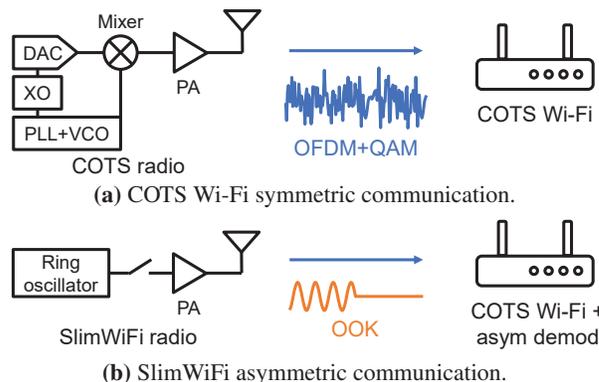

Figure 1: Comparison between COTS Wi-Fi and SlimWiFi.

the ultra-low-power (ULP) IoT radios to the Internet. Unfortunately, mainstream wireless communication standards cannot support battery-free operations due to their high *peak power*. For example, the commercial off-the-shelf (COTS) Wi-Fi, BLE, ZigBee, NB-IoT, and LoRa devices all require tens to hundreds of mW of peak power [34, 60, 61, 70], orders of magnitude higher than that available from RF energy harvesting. Their self-sustained operations are feasible only under an extremely low duty cycle (a few dozen bytes per day) while supported by a bulky power source (*e.g.*, a solar panel).

We argue that the root cause of the high power consumption of such systems lies in the requirement of *symmetric communication*, *i.e.*, the IoT radios must adopt the same high-profile modulation/demodulation hardware as the existing wireless infrastructures. As illustrated in Fig. 1a, to be compatible with existing Wi-Fi access points (APs), an IoT radio needs to support OFDM and QAM, which entails stringent hardware requirements, such as accurate and stable carrier frequency, low phase noise, wideband and high-resolution ADC/DAC, and a high-gain high-linearity (but often low-efficiency) power amplifier, all of which translate into power hungry components. We thus pose an important question: *Is it possible to relax such requirements and make the communication hardware and modulation asymmetric?*

We explore the answers through a novel system design called *SlimWiFi*. SlimWiFi adopts a novel *asymmetric communication* scheme to realize Wi-Fi-compatible ULP radio. Specifically, the SlimWiFi ULP radio builds on a highly simplified architecture as shown in Fig. 1b, capable of only modulating/demodulating on-off keying (OOK) waveforms. But it can directly communicate with existing Wi-Fi APs that

are designed to modulate/demodulate sophisticated OFDM waveforms. Essentially, SlimWiFi shifts the PHY layer complexity to the high-power infrastructure side, and by doing so, it can improve the energy efficiency of the IoT radio by orders of magnitude. Unlike the backscatter-based systems [29, 35, 42, 79] that rely on additional helper devices to generate external carrier signals, SlimWiFi is an active, stand-alone radio transceiver. To materialize the design principles behind SlimWiFi, we need to address two key challenges.

(a) *How to enable direct communication between asymmetric hardware, i.e., the OFDM-based Wi-Fi device and the OOK based SlimWiFi device?* The uplink communication, i.e., demodulating the OOK signal with an unmodified Wi-Fi OFDM device, is very challenging due to the highly incompatible waveforms and demodulation hardware. Note, however, that any demodulation process is essentially sampling and mapping analog waveforms into a binary sequence. The SlimWiFi Wi-Fi receiver thus reverses its OFDM demodulation steps, as well as the Forward-Error-Correction (FEC) decoder, and descrambler, and then reconstruct the incoming OOK symbols merely based on the payload bits reported by the Wi-Fi driver. With this measure, an ordinary Wi-Fi AP can decode the OOK signals from the ULP SlimWiFi transmitter, *without any hardware modifications*. On the other hand, the downlink modulation is straightforward, as recent work [35, 78, 79] has well-explored ways of mapping a sequence of bits into a pseudo-OOK waveform using a WiFi transmitter. To achieve MAC layer compatibility, SlimWiFi delegates the carrier sensing task to the Wi-Fi AP, which uses the CTS-to-self packets to virtually reserve the channel, and then informs the SlimWiFi node to start its transmission.

(b) *How to optimize the SlimWiFi radio hardware to minimize power consumption while maintaining Wi-Fi compatibility?* In commensurate with the complicated modulation, the typical hardware architecture of a COTS Wi-Fi radio necessarily consists of a power amplifier (PA) for a high transmit power, high precision and wideband digital-to-analog converter (DAC) for high-order modulation, and phase-locked loop (PLL) and voltage-controlled oscillator (VCO) for accurate carrier generation. The power consumption of these components is fundamentally governed by physical laws, and almost impossible to fall below several mW [9, 16, 55, 63]. SlimWiFi circumvents the fundamental limitation with a highly simplified radio architecture that leverages asymmetric communication. The SlimWiFi ULP radio eliminates the power hungry DAC/ADC and PLL and affords a more efficient PA owing to the lower power and linearity requirements. As for carrier generation, we adopt a free-running ring oscillator [82], which bears a low frequency stability, but suffices for SlimWiFi as its narrowband OOK signal can be asymmetrically demodulated as long as the carrier falls within the 2.4 GHz ISM band.

To verify the effectiveness of our design, we implement asymmetric communication with a COTS Wi-Fi device and a

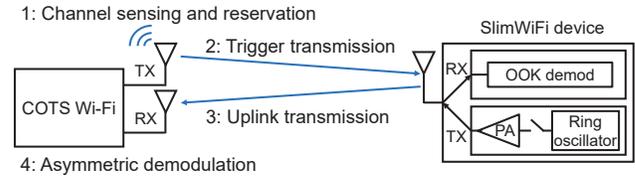

Figure 2: Workflow of a SlimWiFi uplink transmission.

prototype SlimWiFi device. Our experiments demonstrate that the OOK based SlimWiFi signals can be decoded from the payload bits of the Wi-Fi device over a range of 60 m, with a goodput of around 100 kbps. We have also designed and taped out a SlimWiFi IC based on the aforementioned SlimWiFi radio architecture. Our measurement shows that the SlimWiFi only consumes around 90 μ W of power, approximately 3 orders of magnitude lower compared with COTS WiFi radios.

To summarize, we make the following contributions through the SlimWiFi design and implementation.

- We propose SlimWiFi, a novel asymmetric communication paradigm that enables COTS Wi-Fi devices to decode OOK signals from ULP radios. The design enables such ULP radios to reuse the existing Wi-Fi as the IoT infrastructure, which can substantially reduce the deployment cost for attaining ubiquitous connectivity.
- We introduce a new SlimWiFi ULP radio architecture, which leverages the asymmetric communication to enable the first *active* Wi-Fi-compatible transmitter at a peak power of tens of μ W.
- We implement the asymmetric communication system through a PCB prototype and IC tape-out. Our experiments verify the potential of SlimWiFi in supporting self-sustained IoT communication.

2 System Workflow

The SlimWiFi design mainly focuses on the IoT uplink, consisting of the SlimWiFi device and the COTS Wi-Fi radio. The former transmits OOK modulated data, through a highly simplified ULP radio architecture. The latter acts as the demodulator and gateway to connect the SlimWiFi device to the Internet. As illustrated in Fig. 2, a typical uplink transmission attempt involves the following workflow.

(1) The Wi-Fi device first runs standard carrier sensing to acquire the channel and reserves access by transmitting the CTS-to-self frame.

(2) The Wi-Fi device emulates an OOK modulated trigger frame by manipulating the Wi-Fi bit sequence. The SlimWiFi device's ULP OOK receiver decodes the information and synchronizes with the trigger frame.

(3) Following step (2) immediately, the Wi-Fi device initiates the demodulation procedure of its receiver chain, and meanwhile, the SlimWiFi device sends an OOK modulated uplink signal to the Wi-Fi device.

(4) The Wi-Fi device decodes the OOK modulated signal

by applying asymmetric demodulation.

In what follows, we introduce the SlimWiFi asymmetric communication design (Sec. 3) and the SlimWiFi ULP radio hardware (Sec. 4). Our exposition mainly focuses on the novel uplink design (steps 3 and 4). The ULP downlink design (step 2) follows the same asymmetric modulation + simplified hardware principle. It builds on recent cross-technology communication (CTC) and backscatter techniques [20, 35, 45, 67, 78], and will be discussed briefly in Sec. 4.4.

3 Asymmetric Demodulation for SlimWiFi

In this section, we first provide a quick primer on the standard Wi-Fi receiver. Then we introduce the Wi-Fi compatible asymmetric communication in SlimWiFi.

3.1 A Primer on Standard Wi-Fi Receiver

Without loss of generality, we focus on 802.11n, a standard adopted by most modern COTS Wi-Fi devices, running on a 20 MHz channel and single antenna [43]. The upper part of Fig. 3 shows the 802.11n demodulation procedure, which is hard coded into the receiver's IC. The incoming analog signals are first captured by the RF front end and converted into baseband samples. The receiver searches across the samples to identify a standard 802.11 preamble—a predefined OFDM modulated training sequence. If no valid preamble is detected, the samples will be discarded. Otherwise, the receiver will proceed to additional demodulation steps.

The samples are first sliced into *OFDM symbols*, each consisting of 16 samples of cyclic prefix (CP) and 64 samples of data. The CP is redundant samples used to overcome intersymbol interference due to the multi-path effect. The Wi-Fi demodulator needs to remove the CP and apply a 64-point FFT to convert the 64 data samples into frequency-domain, which essentially slices the entire 20 MHz band into 64 *subcarriers*. Only 52 of the subcarriers are extracted as valid data. The remaining are either null subcarriers to mitigate adjacent channel interference or pilots for calibrating the residual offsets of the channel estimation.

Afterwards, a QAM block demaps the complex sample on each subcarrier into one or more bits, depending on the baseband modulation method, *i.e.*, BPSK, QPSK, 16-QAM, and 64-QAM. The resulting bit sequence X contains redundant bits due to forward-error-control (FEC) and needs to be decoded into a sequence Y . The ratio between the length of Y and X is called *coding rate* and can be $1/2$, $2/3$, $3/4$, or $5/6$.

The decoded bits Y need to be further reordered to recover the original transmitted bits. This so-called *descrambling* is performed by an XOR operation with a repeatedly generated 127-bit sequence whose initial state is determined by a *scrambler seed*. The PHY layer processing ends here and the output bits will be reported to the upper layer as a MAC frame. We emphasize that *the entire PHY-layer demodulation is implemented in the Wi-Fi IC and thus cannot be bypassed without hardware modification.*

On the other hand, the MAC layer control, management, and frame processing are usually implemented in software (Soft MAC) or firmware (Full MAC) [31, 47]. The MAC frames will be passed to the Wi-Fi driver and can be post-processed in software.

3.2 Overview and Challenges in Asymmetric Demodulation

The asymmetric demodulation design is grounded on a key observation: *The Wi-Fi OFDM demodulation procedure is deterministic and at least partially reversible.* An OFDM receiver essentially converts the incoming time domain samples into frequency domain through FFT, and then “quantizes” the samples through QAM demapping. Theoretically, any signals within the 20 MHz bandwidth can be *reconstructed from the OFDM receiver's bit sequence output*, by reversing the Wi-Fi demodulation procedure. *The SlimWiFi asymmetric demodulator essentially performs such reconstruction in software at the Wi-Fi receiver to recover the incoming OOK waveforms and subsequently demodulate them*, as illustrated in the bottom part of Fig. 3.

Unfortunately, the standard Wi-Fi receiver blocks, such as CP removal, QAM, and FEC, inevitably induce information loss or ambiguities. As a result, SlimWiFi must address the following key challenges.

(1) *How to design the OOK signal in order to avoid the impact of information loss while enabling asymmetric demodulation?* The hard-coded OFDM demodulation procedure does eliminate certain incoming samples. For example, CP removal erases part of the signal in the time domain, and data subcarrier extraction removes all information in the non-data subcarriers (*i.e.*, null and pilot subcarriers). If the removed segments contain useful data symbols from the SlimWiFi device, it would be hard to reconstruct them. We thus need to carefully design the SlimWiFi OOK waveform to avoid the impact of information loss (Sec. 3.3).

(2) *How to deal with the reconstruction errors introduced by the COTS receiver?* Besides the information loss from the OFDM block, the QAM and FEC blocks also cause two types of reconstruction errors: *Quantization error*, *i.e.*, the difference between the SlimWiFi signal and the closest point in Wi-Fi's QAM constellation; and *coding error*, *i.e.* the mismatch between the Wi-Fi demodulated bit sequence X and the regenerated bit sequence X' after reversing the FEC, as shown in Fig. 3. SlimWiFi addresses the reconstruction errors by (i) judiciously configuring the receiver parameters and (ii) performing additional channel coding on top of the SlimWiFi signals, as to be described in Sec. 3.4.

(3) *How to integrate SlimWiFi with standard Wi-Fi protocols?* To make SlimWiFi fully compatible with standard Wi-Fi, several PHY/MAC layer primitives are needed, *e.g.*, generating PHY preamble, PHY/MAC headers, and triggering the Wi-Fi receiver to start demodulation. We address these practical challenges in Sec. 3.5.

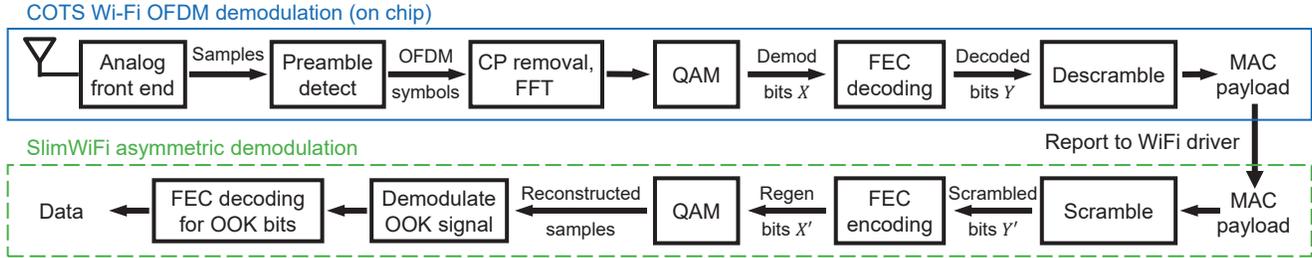

Figure 3: Receiving procedure of a SlimWiFi uplink receiver, *i.e.*, the COTS Wi-Fi device.

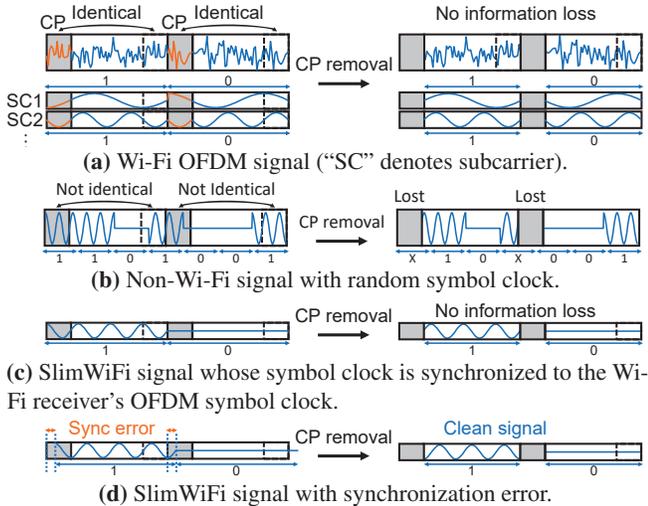

Figure 4: Symbol clock sync to counteract CP removal.

3.3 SlimWiFi Signal Design

3.3.1 Overcoming signal erasures on the COTS Wi-Fi demodulator

In this section, we introduce the transmission waveform of the SlimWiFi device which are designed to circumvent the signal erasures on the COTS Wi-Fi demodulator.

As shown in Fig. 4a, the standard Wi-Fi waveform inside a CP is a replica of the last 0.8 μ s of the OFDM symbol (4 μ s in total) hosting the CP. Therefore, removing the CP does not cause any information loss for the Wi-Fi demodulator. In contrast, for a non-Wi-Fi signal with an arbitrary symbol clock (Fig. 4b), this operation may inadvertently erase 20% of the original signal which makes the demodulation unreliable. To overcome this issue, we choose to synchronize the OOK symbol clock of the SlimWiFi device with the OFDM symbol clock of the Wi-Fi receiver, *i.e.*, 250 kHz for 802.11n. Fig. 4c shows that, with such symbol-level clock synchronization, the SlimWiFi signal acts the same as the signal of one Wi-Fi subcarrier (in Fig. 4a). Therefore, the signal erasure caused by CP removal can be avoided. To realize the symbol level clock synchronization, the SlimWiFi device simply generates a 250 kHz clock and aligns its transmission time to the aforementioned trigger frame (Sec. 2). Such synchronization relies on symbol energy detection and may not be precise. However, as shown in Fig. 4d, the redundant CP part can be utilized

to tolerate the synchronization errors, which we will further verify in Sec. 6.2.

Recall that 12 out of the 64 subcarriers within the 20 MHz Wi-Fi channel are null or pilot subcarriers, eventually discarded by the Wi-Fi demodulator. Therefore, to prevent information loss, the SlimWiFi device should avoid modulating its OOK waveform at the same frequencies as the non-data subcarriers. This in turn imposes more constraints on its signal bandwidth and carrier frequency, which we address below.

3.3.2 Relaxing the hardware requirements on the SlimWiFi radio device

Range, TX power, and bandwidth. The communication range of the SlimWiFi uplink can be estimated based on the classical link budget equation [85]:

$$k_b T_a B + NF + SNR_o = P_{TX} + G_{TX} + G_{RX} - 20 \log_{10}(4\pi d f_c / c)$$

where k_b is the Boltzmann constant, and T_a is the equivalent noise temperature in [K]. B , NF , and SNR_o denote the signal bandwidth, RX noise figure, and SNR threshold for robust decoding, respectively. P_{TX} , G_{TX} , and G_{RX} are TX power, TX, and RX antenna gain, respectively. d is the operating range, f_c is the carrier frequency and c is the light speed.

To achieve a target range d while keeping the SlimWiFi device at ULP, we propose to reduce B , which can in turn lower the total transmit power P_{TX} . This design choice hinges on the observation that we can treat each subcarrier of the OFDM receiver as an individual narrow-band (312.5 kHz) channel. As long as the SlimWiFi signal falls within one of the subcarriers, it can be captured and demodulated by the OFDM receiver. Therefore, even if its P_{TX} is reduced by $10 \log_{10}(20000/312.5) = 18$ dB, the total power of a SlimWiFi symbol can still be equivalent to that of a Wi-Fi subcarrier, and SlimWiFi can still keep the same transmission range as a normal Wi-Fi! The operating range can be further traded off for even lower transmit power. In fact, with the 250 kHz OOK symbol rate the SlimWiFi signal bandwidth is 250 kHz which can already fit within one Wi-Fi subcarrier.

Carrier frequency requirement. Most existing communication standards require an accurate carrier frequency. In particular, a highly stable carrier is crucial for synchronizing OFDM TX and RX, and reducing leakage between subcarriers. However, this usually entails a high-profile carrier generator,

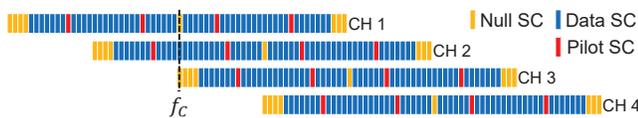

Figure 5: Subcarrier mapping between different channels of Wi-Fi on the 2.4 GHz band. Only 4 channels are illustrated.

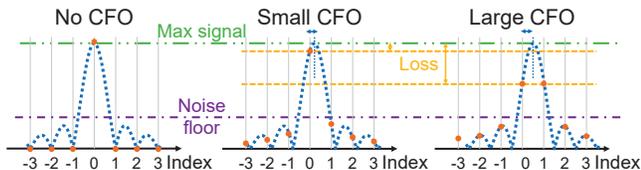

Figure 6: Amplitude of different subcarriers with or without the CFO, when receiving a single tone OOK signal.

consisting of a VCO and PLL which consumes several mW power [54, 66, 71]. The SlimWiFi asymmetric demodulation circumvents this requirement for the first time. As long as the OOK signal’s carrier frequency f_c is located within the 20 MHz Wi-Fi band, it can be captured and recovered by demodulating the Wi-Fi receiver’s subcarrier that covers f_c . However, two issues need to be solved to accommodate the inaccurate carrier frequency.

First, f_c might be in the non-data subcarriers which are discarded by the Wi-Fi receiver. We overcome this problem by making use of the partially overlapped Wi-Fi channel designated in the 2.4 GHz band, where the non-data subcarriers of one channel are the data subcarriers of an adjacent channel, as shown in Fig. 5. With this mechanism, the carrier frequency requirement can be further relaxed from 20 MHz (a single Wi-Fi channel) to 80 MHz (the entire 2.4 GHz ISM band covering 13 Wi-Fi channels). Note that, the Wi-Fi receiver can identify the subcarrier where the SlimWiFi signal is located by simply checking the subcarrier energy level. If the Wi-Fi receiver does not observe any uplink signal after the trigger frame (Sec. 2), then the signal may fall on a non-data subcarrier, and the receiver should switch to an adjacent channel instead.

The second issue is that the OOK carrier frequency f_c may not be aligned exactly with an OFDM subcarrier. Although OOK can be demodulated non-coherently, the carrier frequency offset (CFO) leads to non-orthogonality in the Wi-Fi receiver’s FFT processing, which may in turn affect the asymmetric demodulation. Fig. 6 illustrates a case where a single tone signal (OOK with ON state) spreads to multiple subcarriers due to CFO. Demodulating the OOK signal on a single subcarrier will result in a low SNR. Combining the signal energy across subcarriers does not necessarily help either because it increases the noise bandwidth. Nonetheless, the worst-case SNR loss due to CFO is only 3 dB (signal spreads evenly between two adjacent subcarriers), which will be verified in Sec. 6.2.

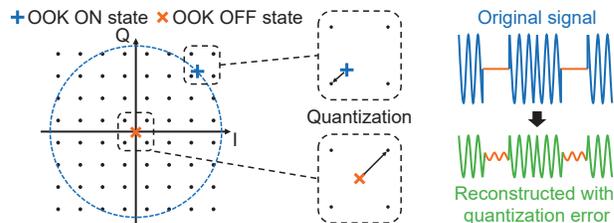

Figure 7: OOK modulated signal with QAM demodulation.

3.4 Resolving Quantization and Coding Errors

3.4.1 QAM and quantization error

The Wi-Fi receiver’s QAM demapping block quantizes the phase and amplitude of the signal on each subcarrier. Fig. 7 illustrates the case when a SlimWiFi OOK signal is demapped on a 64-QAM constellation diagram. For the ON state of OOK, the signal sample will have a non-zero amplitude with an arbitrary phase, hence falling at the outer circle. For the OFF state, the sample will have a near-zero amplitude, falling at the origin point. For other subcarriers where no active signals are located, the demapped sample will be the same as the OFF state.

Essentially, the QAM demapping is performing quantization in the complex domain. Thus the original OOK signal on the active subcarrier can be easily reconstructed through the reverse operation, *i.e.*, QAM mapping which converts bits to a complex number. However, this process will introduce quantization errors, which compromises the SNR of the reconstructed signal. The quantization error depends on the precision of quantization which is determined by QAM modulation order. We thus configure the Wi-Fi receiver to the highest modulation order 64-QAM, leading to the lowest quantization error.

3.4.2 FEC and coding error

When receiving the non-OFDM SlimWiFi signal, the FEC block causes a mismatch between the demodulated bit sequence X and regenerated bit sequence X' shown in Fig. 3. The fundamental reasons are two-fold: (i) The demodulated bit sequence can be treated as an arbitrary bit sequence instead of a valid codeword of FEC; (ii) The standard Wi-Fi FEC decoding is a many-to-one mapping, whereas the reverse operation (*i.e.*, FEC encoding in Fig. 3) is a one-to-one mapping. So there is no guarantee that the reconstructed X' can match the original X by simply reversing the FEC.

Fortunately, we found that the number of mismatched bits is limited and can be mitigated with a careful design. The coding errors induced by the two standard FEC schemes in Wi-Fi, *i.e.*, binary convolutional coding (BCC) and low-density parity check (LDPC), are different. Here we only summarize their properties. The detailed proofs are in Appendix A.

(1) Both BCC and LDPC incur fewer coding errors at a higher coding rate. Therefore, we configure the Wi-Fi receiver to the highest available coding rate (*i.e.*, 5/6) when performing the asymmetric demodulation. With this measure, the fraction

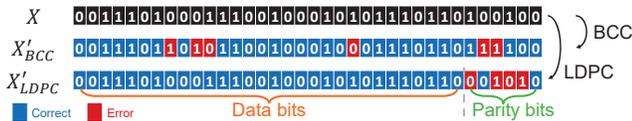

Figure 8: Distribution of coding errors (mismatch between X and X'), for BCC and LDPC, respectively.

of FEC-induced errors can be reduced to around 1/6 and can be further reduced if we apply a separate FEC coding on the SlimWiFi OOK transmitter.

(2) When the Wi-Fi receiver runs the LDPC decoder, the locations of the FEC errors are known a priori on the time-frequency domain. Fig. 8 shows an example of the error distributions when using BCC and LDPC with 5/6 coding rate. X'_{BCC} and X'_{LDPC} are the regenerated bit sequence under BCC and LDPC, respectively. The mismatched bits of the BCC scheme are spread randomly all over the bit sequence X'_{BCC} due to the BCC decoding and interleaving. In contrast, the mismatched bits of the LDPC scheme is always located at the parity bits block (also proven in Appendix A.2).

Based on this observation, we configure the Wi-Fi receiver to LDPC mode in the asymmetric demodulation, which brings two advantages: (i) The error bits are distributed in a periodic way across the reconstructed sequence X' (more details in Sec. 3.6). Therefore, they can be easily corrected by applying a convolutional encoding on the data from SlimWiFi device and using a convolutional decoder on the asymmetric demodulator. (ii) The receiver knows which bits are parity bits (*i.e.*, where the coding errors are clustered). The convolutional decoder can adopt a soft decision decoder which sets those bits with a low log-likelihood ratio, thus improving the decoding performance.

3.5 Practical Challenges

3.5.1 MAC layer configuration

To ensure the MAC payload bits can be used to reconstruct the SlimWiFi signal, we need to resolve two issues: (i) incorrect frame check sequence (FCS), and (ii) limited MAC frame length.

Incorrect FCS. As shown in Fig. 9, the FCS, a 32-bit cyclic redundancy check (CRC) located at the end of the whole frame, is adopted for error protection. Since the received signal is an OOK modulated instead of a valid Wi-Fi signal, it is nearly impossible that the FCS is correct. But we need to capture the data frames through the Wi-Fi driver, even if they fail the FCS check. This is supported by many COTS Wi-Fi devices [2, 21]. A simple software/firmware update can enable the same capability on other Wi-Fi devices.

Data frame length. The length of the payload in a normal Wi-Fi frame is limited by the 2,304 bytes maximum size of the MAC Service Data Unit (MSDU). Recall that SlimWiFi needs to configure the Wi-Fi receiver to the highest data rate (64-QAM, 5/6 code rate, Sec. 3.4). Under this configuration, the maximum number of OFDM symbols is less than 70,

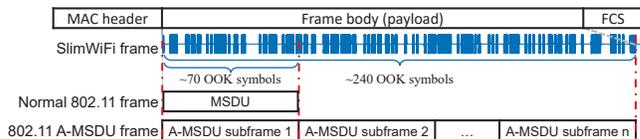

Figure 9: Mapping between the standard Wi-Fi MAC frame and SlimWiFi signal waveform.

corresponding to only 70 OOK symbols as illustrated in Fig. 9. To create a longer frame, we choose to use the aggregate MAC service data unit (A-MSDU) with a quality of service (QoS) data frame, whose maximum size is 7,935 bytes, which extends the frame length to about 240.

3.5.2 Scrambler seed

Since the descrambling is a one-to-one mapping operation on the Wi-Fi receiver, it can be easily reversed by applying a scrambling block with the same scrambler seed. Although the scrambler seed is not reported to the driver, it is set by the PHY header which triggers the receiver's demodulation process (Sec. 3.5.3). Therefore, we can just set a fixed scrambler seed, which can be used to reverse the descrambling block.

3.5.3 Initiating the receiving procedure on Wi-Fi

The final practical challenge lies in generating a valid Wi-Fi preamble and PHY/MAC header. The preamble is needed for triggering the Wi-Fi receiver to start the receiving procedure (packet detection), and is also used for auto gain control, synchronization, and channel estimation. The PHY/MAC header is needed for specifying demodulation parameters such as QAM order, coding rate, scrambling seed, and packet length. Unfortunately, the Wi-Fi preamble and PHY/MAC header are complex OFDM modulated signals, and cannot be directly generated by the SlimWiFi ULP transmitter.

Note that many Wi-Fi devices have separate but co-located transmitter and receiver modules. For example, many Wi-Fi APs [7, 8, 59] usually have multiple transceiver chips (to support concurrent multi-band and multi-antenna operation) which can be configured as co-located TX and RX modules. Therefore, we repurpose the co-located Wi-Fi TX module as an *initiator* to emit a self-initiation frame, comprised of the legitimate preamble and PHY/MAC header but without any payload. Such zero-payload frames are supported by Wi-Fi drivers such as Nexmon [69], or through Wi-Fi frame emulation methods [37]. Upon receiving the initiation frame, the receiver starts its Wi-Fi demodulation workflow followed by the asymmetric demodulation (Fig. 3). Notably, since the transmission of the initiation frame and the reception of OOK data occur consecutively, there is no self-interference between the co-located transmitter and receiver. Therefore, unlike backscatter communication systems, the link budget and receiving sensitivity is not affected by direct Tx leakage or near-far problems [40]. For those Wi-Fi devices with integrated transceivers, a firmware update is needed to enable the receiver to start its demodulation workflow immediately after the transmitter sends out the trigger frame.

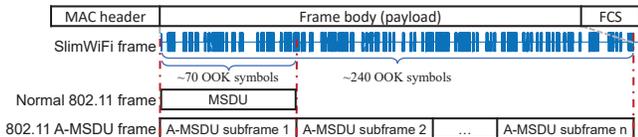

Figure 10: Demodulating the SlimWiFi OOK symbols directly in the frequency domain. The subcarrier with non-zero signal power contains the OOK symbols.

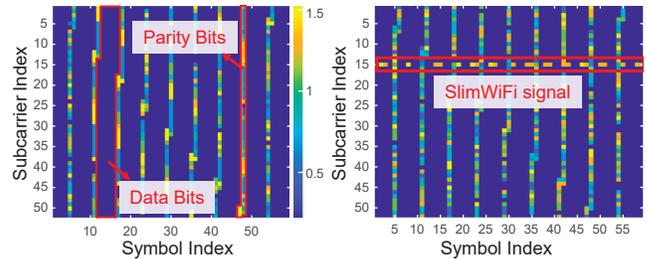

Optimizing receiver gain and sensitivity. A standard Wi-Fi receiver performs automatic gain control (AGC) based on the signal strength of the preamble from the transmitter. For SlimWiFi, since the preamble is from the co-located initiator instead of the actual transmitter, the AGC may be misconfigured. If the initiation frame is too strong, the receiver will set a low gain, leading to insufficient amplification of the incoming SlimWiFi signals. In this situation, the demodulation performance will be bottlenecked by the quantization error (Sec. 3.4.1). Therefore, to achieve the best receiver sensitivity, we would prefer to reduce the power of the initiation frame. This may risk forcing the receiver to tune to a high gain, resulting in the clipping of high amplitude signals. Fortunately, for OOK signals, the clipping effect will not impact demodulation, since clipped signals are recognized as “1” regardless of their amplitude. We will evaluate the effects of the receiver gain in Sec. 6.2.

3.6 Putting Everything Together

Overall, the Wi-Fi receiver follows the processing blocks shown in Fig. 3 to perform the asymmetric demodulation. At a high level, the incoming OOK samples go through the hard-coded normal Wi-Fi demodulation steps which result in a MAC frame. Our asymmetric demodulator reconstructs the complex samples from the MAC frame, by reversing the Wi-Fi demodulation steps, and then decodes the desired bit sequence from the reconstructed samples.

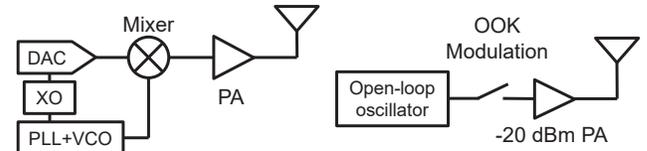

Note that the reverse processing skips the IFFT. Since the OOK signal is narrowband and only occupies one subcarrier, we can directly process the complex samples on that subcarrier, without IFFT-converting them to the time domain, as shown in Fig. 10. The amplitude of the complex sample is used directly to decode the OOK modulated symbol.

To visualize the samples in the time-frequency domain, we collect an example trace with the following configurations: 802.11n with 20 MHz bandwidth, 64-QAM modulation, 5/6 coding rate, LDPC code, and frame length of 2,000 bytes. The waterfall plot in Fig. 11a shows the case without any active transmission. The x and y axis are the symbol index in the time domain, and the subcarrier index in the frequency domain, respectively. The color represents the amplitude of the samples. It can be seen that the samples corresponding to the data bits of the LDPC coded sequence always have a low amplitude (since no coding errors occur there), while the ones corresponding to the parity bits have uncertain results. If we pick the time domain symbols within one subcarrier, the sym-

(a) Traditional active transmitter. (b) SlimWiFi active transmitter.

Figure 12: Transmitter radio hardware architecture.

bols with coding errors (*i.e.* contain parity bits) appear once every 6 symbols. The result corroborates our observations in Sec. 3.4.2.

Fig. 11b shows the case when a SlimWiFi device is transmitting signals, causing a high amplitude to appear at subcarrier 15 of the Wi-Fi demodulator. The other subcarriers remain the same as the idle case. The OOK signals can thus be demodulated using the samples on subcarrier 15.

4 SlimWiFi ULP Radio Hardware Design

In this section, we focus on the SlimWiFi transmitter hardware, which is designed for asymmetric demodulation. We also provide a brief discussion on the ULP OOK receiver which explains how SlimWiFi device interacts with the COTS Wi-Fi device on the downlink.

4.1 High Power Consumption in Traditional IoT Radios

Modern IoT radio designs need to make challenging trade-offs between power consumption and other competing requirements, including range, bit rate, spectrum efficiency, *etc.* Regardless of how they bias the trade-offs, the IoT radio architecture invariantly comprises 3 key components (Fig. 12a): a high power PA to ensure sufficiently high transmit power; a crystal oscillator (XO) reference and carrier generator consisting of a PLL and VCO, to ensure a stable carrier frequency; a high-resolution DAC to support complex modulation schemes. These high-profile hardware components are the main culprit behind the high power consumption [10].

For example, the industry’s most power efficient Wi-Fi radio consumes around 300 mW for TX and 100 mW for RX [34]. BLE consumes 5.1 mW at -20 dBm transmit power and 8.1 mW for RX [61]. ZigBee chip consumes 6.9 mW for transmission and 6 mW receiving [60]. LoRa takes 32.4 mW

Table 1: Power break down of IC implementation

	BLE [63]	SlimWiFi (Simulated)
Power amplifier	2.5 mW	43 μ W
Carrier generation	0.7 mW	30 μ W
Modulation	0.5 mW	\sim 0 μ W
Rest	0.2 mW	N/A
Sum	3.9 mW	73 μ W

and 14.8 mW for TX and RX, respectively [70]. Even the most advanced low power BLE IC [63] which adopts many aggressive optimizations consumes more than 3.9 mW. Table. 1 shows a breakdown of the power consumption of each component. All in all, to achieve extremely low power and open the pathways for battery-free operations, a fundamentally different architecture is needed that evades all the power hungry components.

4.2 SlimWiFi Transmitter Architecture

Owing to the asymmetric communication design (Sec. 3), the SlimWiFi device only needs to generate signals with low transmit power, low-accuracy carrier frequency, and simple OOK waveforms. Therefore, we propose the SlimWiFi active transmitter architecture shown in Fig. 12b. Compared to the traditional active transmitters, the SlimWiFi transmitter: (i) replaces the high-power PA with a low-power PA optimized for constant-amplitude signals at -20 dBm output power; (ii) replaces the closed-loop PLL+VCO with a simple open-loop oscillator; (iii) removes the DAC and uses an RF switch for OOK modulation. With such optimizations, SlimWiFi can bring the power consumption down to 73 μ W in simulation. Table. 1 provides the power breakdown of SlimWiFi in comparison with the aforementioned BLE IC. Now we explain how the extremely low power is achieved.

4.2.1 Transmit power

Existing IoT radio designs aim for long-range, high throughput, and robust communication, which in turn requires a high transmit power. For example, Wi-Fi devices usually transmit at more than 20 dBm (*i.e.*, 100 mW). BLE, ZigBee, or LoRa devices are at around 0 dBm (*i.e.*, 1 mW). The transmit power, and the associated PA hardware, dominates the power consumption of the entire transmitter.

For SlimWiFi, recall it can reduce the transmit power by 18 dB while keeping the same link budget, owing to the narrower bandwidth (250 kHz) (Sec. 3). This comes at the cost of a lower bit-rate, but is a much preferred trade-off for most IoT applications, especially considering the existing Wi-Fi infrastructure can be reused. Since the Wi-Fi preamble is generated by the initiator instead of the SlimWiFi device, the PA only needs to support a narrow bandwidth and can be optimized for high efficiency. Our actual on-chip PA is optimized for -20 dBm, whose power consumption can be as low as 43 μ W with 24 % drain efficiency. This would be equivalent to a Wi-Fi transmitter at $18 - 20 = -2$ dBm, and comparable to the emission power of BLE, LoRa, and ZigBee radios.

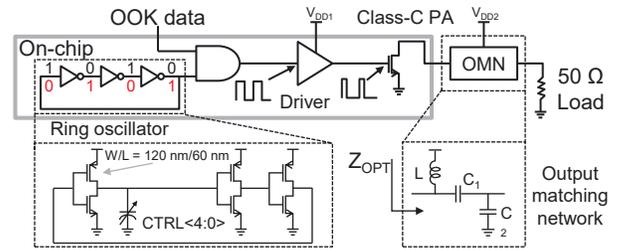

Figure 13: Circuit diagram of the SlimWiFi chip.

However, reducing the transmit power alone cannot bring the peak power to tens of μ W. For example, a BLE IC [61] still consumes 4.5 mW when transmitting at -40 dBm (1 μ W), and [63] still consumes 1.4 mW even without a PA (Table. 1). At an extremely low transmit power, the carrier generator and modulation blocks will become the bottleneck.

4.2.2 Open-loop carrier generation

Traditional closed-loop carrier generators are based on PLL, which can generate a highly accurate carrier frequency but consumes high power due to the requirement of phase detection. For example, typical analog PLLs for IoT consume power in the mW level [54, 71]. All digital PLLs can potentially bring down the power consumption to several hundred μ W [9, 49, 63], but still around one order of magnitude higher than our target power consumption. The asymmetric demodulation design enables SlimWiFi to drastically relax the requirements of frequency stability. Instead of tolerating around 48 kHz (\pm 20 ppm) of carrier frequency offset as in COTS Wi-Fi devices [43], SlimWiFi works as long as its carrier falls within the 80 MHz range of the entire 2.4 GHz Wi-Fi band! Therefore, SlimWiFi can use an open-loop oscillator with low frequency accuracy as the carrier generator. More specifically, we chose an open-loop ring oscillator for the 2.4 GHz carrier generation which consumes only around 30 μ W when implemented on an IC (more details in Sec. 4.3.1).

4.2.3 Low power modulation

To synchronize with the symbol clock of the Wi-Fi receiver (Sec. 3.3.1), the SlimWiFi transmitter uses an RF switch at 250 kHz switching rate to generate the OOK symbols. In fact, our IC implementation realizes OOK by simply powering on and off the PA, without the need of an additional RF switch. Since the open-loop ring oscillator's start-up time (ns level) is much shorter than the symbol period, it can also be power-cycled with the PA, which together can reduce the modulation power consumption to nearly zero.

4.3 IC design

Fig. 13 shows the circuit diagram of our SlimWiFi IC, consisting of an open-loop ring oscillator and a PA optimized for OOK signal at -20 dBm.

4.3.1 Ring oscillator

The ring oscillator consists of an odd number (3-stage in our design) of inverters cascaded into a ring, as illustrated in Fig. 13. The logic input is inverted after passing through the inverters, which causes oscillation between two voltage levels. The open-loop design circumvents the requirement of an external reference clock (*e.g.*, crystal oscillator), thus further reducing the radio cost and form-factor.

The zoom-in plot in Fig. 13 shows the detailed on-chip design of the ring oscillator. It is composed of minimum size transistors ($W/L = 120 \text{ nm}/60 \text{ nm}$) for the minimum area and lowest power consumption. The ring oscillator’s actual carrier frequency output is affected by the process, voltage and temperature (PVT) variations. We introduce a 5-bit binary weighted capacitor bank (CTRL<4 : 0>) loading the first stage of the inverter to tune the propagation delay across different stages of the circuit. This in turn allows us to empirically adjust the oscillation frequency at design time, so it falls within the 2.4 GHz band under typical PVT conditions.

4.3.2 Class-C PA

The carrier is directly modulated by a 250 kHz data sequence and then fed to the inverter-based driver to drive a PA. We choose a Class-C PA for its easy implementation in terms of harmonic terminations and better efficiency at low output power [36]. This comes at the cost of low linearity but is acceptable for SlimWiFi since its OOK waveform is insensitive to clipping distortion (Sec 3.5.3). For a Class-C PA, the relationship between the output power P_{out} , optimal load impedance Z_{OPT} and supply voltage V_{DD} follows [36]:

$$P_{out} = V_{DD}^2 / (2 \cdot Z_{OPT})$$

For the target of -20 dBm output power, the optimal load impedance can be 18 k Ω , which would be impractical to match to the standard 50 Ω . To alleviate this problem, a dual-supply voltage scheme [32] is applied for efficiency enhancement. Specifically, we use a 0.9 V V_{DD1} to supply the VCO and driver stage, and 0.3 V V_{DD2} to supply the final PA stage. Off-chip high-Q components [77] are utilized in the tapped-capacitor output matching network to achieve the impedance transformation.

Table. 2 compares the simulated IC performance with and without the PCB parasitic S-parameter (SP) model (extracted using ADS Momentum). Both simulation results are obtained with chip post-layout parasitic extraction (LPE). The table shows that, when co-simulated with the PCB SP model, the output power and efficiency are degraded, indicating that the PCB parasites can have a detrimental effect on the IC performance. This problem can be solved by integrating the capacitors on-chip to ensure a good match and carefully modeling the inductor on PCB to co-optimize the performance.

Another potential solution is to replace the 50 Ω termination with a non-50 Ω antenna. For example, a patch antenna can have an input impedance of 100-400 Ω at resonance [11],

Table 2: Simulated IC performance

	LPE	LPE +PCB SP
Frequency (MHz)	2451	2438
Pout (dBm)	-19.9	-21.3
Pdrain (μ W)	42.9	43.4
Pvco+driver (μ W)	29.2	29.3
Drain efficiency (%)	23.7	16.9
Global efficiency (%)	14.1	10.1

which can effectively lower the impedance transformation ratio, thus reducing loss in the matching network.

4.4 Downlink ULP Receiver

To enable downlink communication for SlimWiFi, the COTS Wi-Fi transmitter needs to emulate OOK waveforms using OFDM. Such emulation has been well explored in recent cross-technology communication and backscatter systems [20, 35, 45, 67], and can be directly adopted by SlimWiFi. The resulting OOK receiver does not need a carrier generator or PA, and thus consumes even less power than the transmitter.

Considering that the TX power of the COTS Wi-Fi device can be 30 dBm, 50 dB higher than the SlimWiFi device’s transmit power, a similar uplink and downlink range can be achieved even if the downlink OOK receiver’s sensitivity is 50 dB worse than the uplink Wi-Fi receiver. To achieve a 100 m target range, the required receiver sensitivity is 30 dBm + 6 dBi + 2 dBi - 80 dB (FSPL) = -42 dB, which has been achieved in many existing systems. For example, [78] achieves -42.6 dBm sensitivity at 2.8 μ W power; [15] achieves -50 dBm sensitivity at 4.5 μ W. Much better sensitivity (smaller than -70 dBm) can be achieved with wake-up radio designs [3, 17, 30] at tens of μ W power consumption.

Other than the 2.4 GHz carrier, the SlimWiFi device also requires a 250 kHz symbol clock. Such low frequency clock can be generated with a ULP oscillator (*e.g.*, 0.3 μ W [14]) or extracted from the 2.4 GHz carrier through a ULP fraction counting clock as proposed in [84]. The symbol clock can also be calibrated based on the downlink trigger frame which has a 250 kHz OFDM symbol rate.

5 Implementation

5.1 SlimWiFi Device

We have implemented three versions of the SlimWiFi device for different evaluation purposes.

Emulation. To benchmark the performance of the asymmetric demodulation, we need to flexibly control SlimWiFi’s signal transmission, such as carrier frequency, symbol time, transmit power, *etc.* Therefore, we use the WARP software radio [56] to emulate the SlimWiFi signals. To faithfully represent the performance of a real SlimWiFi device, we carefully tune the amplitude of the samples and the RF gain of the WARP board, so that the emulated signal has a calibrated transmission power of -20 dBm, consistent with other versions of implementation.

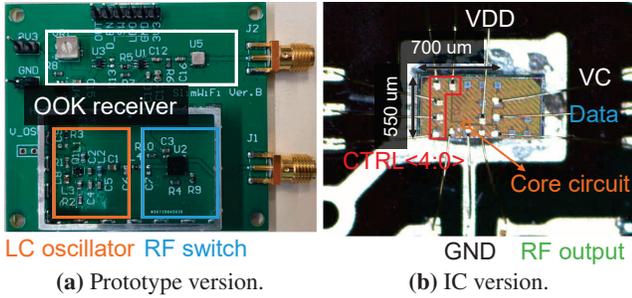

Figure 14: Two versions of the SlimWiFi device implementation.

Discrete circuit prototype. The prototype version thoroughly implements both the SlimWiFi TX and RX on a PCB (Fig. 14a), and is used for end-to-end functional validation of the SlimWiFi design. Following the hardware architecture in Sec. 4.2, the TX device consists of an open-loop LC oscillator BFP720 [33] and an RF switch HMC8038 [5] for OOK modulation. The RLC components of the oscillator are carefully designed to tune the oscillation frequency to the 2.4 GHz ISM band. The OOK RX is implemented by a power detector LT5534 [6] and the sensitivity is tuned to -45 dBm. A Cmod A7 [24] FPGA evaluation board is used to process the trigger frame, synchronize the symbol clock, and generate TX data.

IC fabrication. We also tape out a SlimWiFi transmitter following Sec. 4.3 in TSMC 65 nm RF LP process [74] to evaluate its functionality and power consumption. Die photo of the fabricated chip is shown in Fig. 14b, whose core size is $30 \times 25 \mu\text{m}^2$. The die is directly bonded to a PCB for testing. More advanced process nodes can be utilized to further scale down the chip size and power consumption.

5.2 COTS Wi-Fi Device

We use DWA-192 [21], a Wi-Fi dongle that supports LDPC code and A-MSDU, to communicate with the SlimWiFi device. To calibrate the antenna gain, we replace the original antennas of unknown gain with two 8 dBi antennas [4]. To implement the asymmetric demodulation on this Wi-Fi receiver, we capture the data frames with CommView [73] on the user space of the PC host and implement the signal processing workflow in Matlab. No additional software, firmware, or hardware modification is needed for receiving.

For the initiation procedure discussed in 3.5.3, the DWA-192 firmware does not support the generation of a zero-payload initiation frame. As a workaround, we verified that a COTS Nexus 5 smartphone with Nexmon Wi-Fi driver [57, 69] can be used as the initiator to send the CTS-to-self, trigger frame and initiation frame, thus triggering the demodulation procedure on DWA-192. However, the signal strength of the COTS devices cannot be well calibrated and controlled which hinders us from benchmarking the impact of the power difference between the initiation frame and the SlimWiFi’s signal. Therefore, we use the WARP software radio [56] to send the initiation frame for emulation-based evaluation

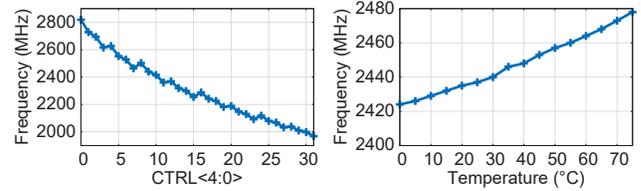

Figure 15: SlimWiFi IC carrier frequency drift corresponding to CTRL<4:0> and temperature.

Table 3: SlimWiFi prototype and chip performance

	Frequency (Drift)	Power Consumption @ TX Power
Emulation	Tunable	N/A @ -20 dBm
Prototype	2460 (± 5) MHz	1 mW @ -20 dBm
Simulated IC	2438 (± 10) MHz	73 μW @ -21 dBm
Fabricated IC	2465 (± 10) MHz	90 μW @ -24 dBm

(Sec. 6.2).

6 System Evaluation

Our evaluation mainly focuses on the SlimWiFi uplink, since the OFDM-to-OOK downlink has been studied in prior research (Sec. 4.4).

6.1 SlimWiFi Device Microbenchmark

We first benchmark the different implementations of the SlimWiFi device. Table. 3 summarizes some important parameters of the SlimWiFi device.

Carrier frequency. We first profile the frequency stability of the SlimWiFi IC with the open-loop ring oscillator. Fig. 15a illustrates the measured carrier frequency when varying the CTRL<4:0> from 0 to 31 with 0.95 V supply voltage at room temperature (25 °C). We see that the ring oscillator design achieves a wide tuning range (around 1 GHz) and fine steps (30 MHz) compared to the 80 MHz frequency tolerance. In addition, as shown in Fig. 15b, the frequency variance is within 54 MHz even when considering a very wide temperature range of 0 to 75 °C. Therefore, it suffices to perform a one-time calibration to tune the oscillator to the center of the the 2.4 GHz band and let it run freely.

We found that the emulated and prototype version of SlimWiFi show consistent behavior compared with the IC version. The prototype board also has an inaccurate carrier frequency, though a relatively lower drift (around 5 MHz). The WARP setup can emulate arbitrary carrier frequencies for evaluation purposes.

Power consumption and transmit power. The discrete prototype version of the SlimWiFi transmitter consumes around 1 mW power when transmitting at -20 dBm. This is already superior to state-of-the-art IoT ICs (Sec. 4). The chip version further cuts the power consumption by an order of magnitude owing to the highly optimized oscillator and PA. Sub-100 μW of power consumption is achieved, for both the simulated and fabricated SlimWiFi chips. The measured

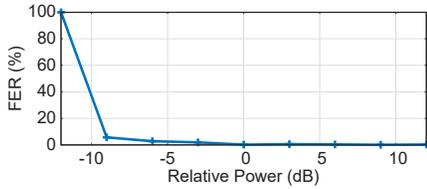

Figure 16: Frame error rate with different relative power between the SlimWiFi signal and the initiation signal.

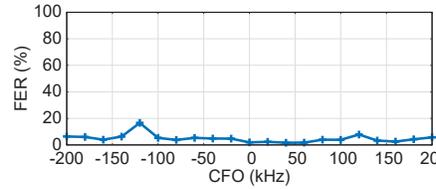

Figure 17: Frame error rate under different carrier frequency offset.

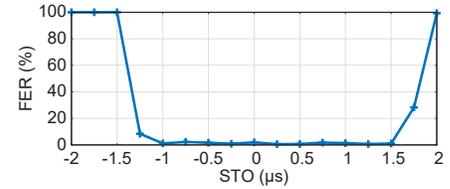

Figure 18: Frame error rate under different symbol time offset.

output power is -24 dBm, which is 3 dB lower than the simulated results. We suspect this is due to the tolerance of the inductor and capacitors used for the high-Q output matching and/or the PCB parasitics (*e.g.* bond wire inductance) not fully captured by the EM simulation. We expect much lower power consumption and a higher PA efficiency is feasible by optimizing the PCB peripherals and by using advanced fabrication processes (lower than 65 nm).

6.2 Microbenchmark for Asymmetric Demodulation

The demodulation performance depends on various parameters, including CFO, symbol time offset (STO), receiver gain, *etc.* Since SlimWiFi uses an open-loop carrier generator that keeps drifting, it is impossible to manually fix these parameters for controlled experiments. We thus calibrated the signal strength and used WARP to decouple and benchmark the impact of each parameter individually.

We conduct link-level experiments in an outdoor parking space, with the following default configurations of the Wi-Fi receiver: 20 MHz 802.11n OFDM, 64-QAM modulation, LDPC coding with 5/6 coding rate and 7935 bytes frame length. Meanwhile, we use WARP to emulate the SlimWiFi device transmitting OOK modulated signals with a frame length of 240 bits and 1/2 BCC coding rate. By default, the link distance is 20 m.

Impact of receiver gain. Recall that the mismatch of signal strength between the initiation signal and the SlimWiFi signal may mislead the Wi-Fi receiver towards a suboptimal gain setting (Sec. 3.5.3). To evaluate its impact, we use the WARP board to transmit the initiation frame along with the emulated signal, so that the strength difference can be intentionally controlled. We consider the relative power of the emulated SlimWiFi signal as 0 dB when the signal strength is the same as that of one subcarrier in the initiation frame. Fig. 16 shows that the receiver performance does not degrade significantly until the relative power is lower than -9 dB, when the receiver gain is too low for robust demodulation. This corroborates our explanation in Sec. 3.5.3. Therefore, instead of adjusting the power of the initiation frame which will lead to complicated management overhead, we can just transmit an initiation frame at a fixed low power. By default, our experiments control the relative power to -6 dB to prevent degrading the demodulation performance.

Impact of carrier frequency offset. Note that the 802.11n subcarrier spacing is 312.5 kHz, and asymmetric demodulation works as long as the SlimWiFi signals overlap with one of the subcarriers. We thus only evaluate the case when the SlimWiFi transmitter’s carrier frequency deviates from a representative Wi-Fi subcarrier 15. To achieve higher SNR, we combine the samples of the two subcarriers that partially overlap with SlimWiFi’s signals, only when the frequency offsets by 140 to 180 kHz (around half of the subcarrier width). Otherwise, the combination may induce more noise (Sec. 3.3.2). With this setting, the worst-case SNR loss is only 3 dB, *i.e.*, when nearly half of the signal power spills into an unusable adjacent subcarrier. To summarize, the asymmetric demodulator can tolerate arbitrary frequency offsets of the SlimWiFi signals in common cases.

Impact of synchronization. To evaluate how the symbol time offset (STO) influences the receiver performance, we manually introduced a delay between the emulated SlimWiFi signal and the initiation frame (both transmitted by the WARP board). The result in Fig. 18 shows that within an STO from -1 μs to 1.5 μs, the receiver performance is not affected in a noticeable manner. Therefore, the system performance should not be affected by the STO since a much better symbol level synchronization can be achieved by the OOK receiver [78, 79]. Notably, the performance is not symmetric around 0 offset (*i.e.*, there is around 0.5 μs more tolerance on positive STO), because of the 0.8 μs redundancy introduced by the CP.

Range and coding rate on SlimWiFi device. Fig. 19a and Fig. 19b show the frame error rate (FER) and goodput with different link distances and BCC coding rate (applied on the data from SlimWiFi device to combat with the coding error discussed in Sec. 3.4.2). The goodput is calculated by only counting the frames with no bit error and including the overhead of channel access, initiation, and trigger frame as discussed in Sec. 2. It can be seen that SlimWiFi maintains a low FER of below 5% even at 60 m of communication range. A goodput of around 100 kbps can be achieved within the range of 60 m. A higher coding rate leads to higher goodput, with some sacrifice on the FER.

Non-line-of-sight (NLoS). We finally evaluate SlimWiFi in an indoor NLoS environment with rich multipath. Fig. 20 shows the deployment setup. We place the Wi-Fi receiver in the living room of a 3B2B apartment, and vary the location of the SlimWiFi transmitter (emulated by WARP). It can be

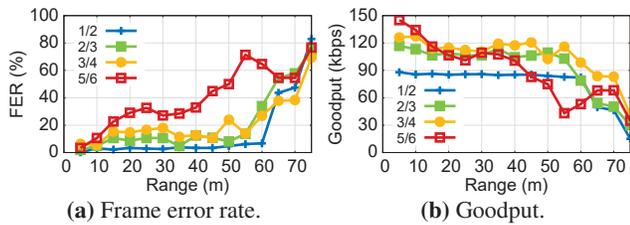

Figure 19: Performance of the asymmetric demodulation receiver *w.r.t.* (a) frame error rate (FER) and (b) goodput at different range and coding rate.

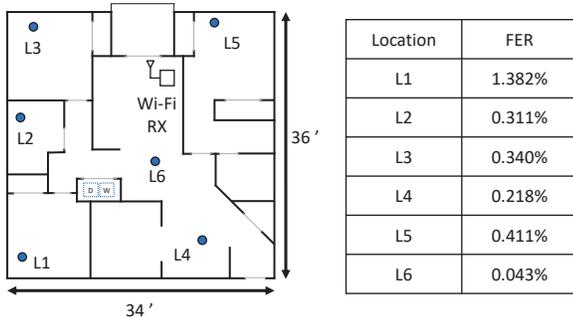

Figure 20: Experimental setup and result for NLoS deployment.

seen that a FER lower than 0.5% is achieved for all the locations except “L1”, despite the multipath and under NLoS. A FER of 1.3% can be achieved at “L1” even though the emulated transmitter is placed at the furthest end of the apartment with 2 concrete walls blocking the LoS. We note that the non-coherent demodulation of SlimWiFi is insensitive to the signals’ phase variations and naturally resilient to the multipath effects. In addition, as discussed in Sec. 4.2.1, although SlimWiFi bears a low transmit power, it still keeps an ample link budget owing to the high sensitivity of asymmetric demodulation, thereby easily achieving whole-home coverage even with NLoS links.

6.3 System Level Evaluation

We now put the workflow in Fig. 2 together and evaluate the SlimWiFi system end-to-end. We use the prototype SlimWiFi device to transmit an OOK signal with a 1/2 coding rate. The initiator’s output power is tuned for the highest receiving gain. The experiments are conducted in an outdoor parking lot. Fig. 21 shows that SlimWiFi can achieve a working range of around 30 m at a FER of 11% and goodput of 78.0 Kbps, and 35 m at a FER of 30% and goodput of 61.5 Kbps. Compared to the result in Fig. 19, the range is reduced by around 1/2. This is reasonable because the impacts of receiver gain, CFO, synchronization error, *etc.* are combined together. For example, unlike the emulated SlimWiFi device, the carrier frequency of the prototype device or IC is not strictly controlled. The resulting carrier frequency offset is unpredictable and will cause up to 3 db of SNR loss (Sec. 6.2) which translates into a range reduction. The result also indicates that the proposed symbol synchronization scheme based on a simple

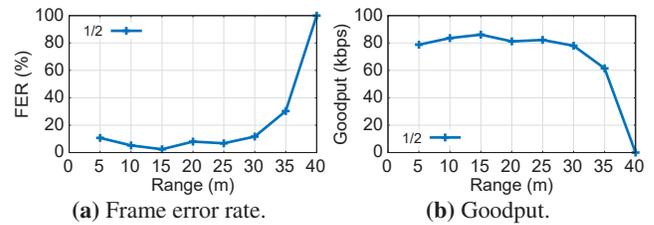

Figure 21: Performance of the SlimWiFi system *w.r.t.* (a) frame error rate (FER) and (b) goodput at different range.

OOK receiver can satisfy the synchronization requirement.

7 Discussion

Other Wi-Fi standards. We use 802.11n Wi-Fi as the Internet gateway for SlimWiFi devices because the 802.11n standard is supported by mainstream Wi-Fi devices. Other OFDM-based Wi-Fi standards can also support asymmetric modulation, albeit with a few limitations: 802.11a/ac only resides in the 5 GHz band which is not ideal for ULP communication due to the larger path loss; 802.11g, the predecessor of 802.11n, does not support A-MSDU and hence can only accommodate 70 OOK symbols in one frame (Sec. 3.5.1); 802.11ax devices are still not widely deployed and the longer symbol period will lead to lower SlimWiFi throughput.

Initiating the Wi-Fi demodulation. The current SlimWiFi implementation requires an initiator as a workaround to trigger the standard Wi-Fi receiver’s demodulation procedure (Sec. 3.5.3). We expect a firmware update to the receiver can enable its self-triggering of the demodulation following the CTS-to-self, as discussed in Sec. 3.5.3. An alternative way to circumvent the initiator is to use the spectral scan function of certain Wi-Fi cards (*e.g.*, the Atheros Wi-Fi [48]), which can continuously report the samples before the QAM block without explicit triggering. We leave the implementation of these approaches for future work.

Ethical consideration. This paper does not involve human subjects and thus does not raise any ethical issues.

8 Related Work

Low-power communication hardware. ULP radio hardware design has been the holy grail of the IoT industry. Many RFIC techniques have been proposed for ULP radios, such as harmonic injection-locked carrier generator [28, 46, 64], crystal-free design [13, 65], power oscillator [58], *etc.* However, these radical radio designs are incompatible with existing IoT network infrastructures. In contrast, SlimWiFi demonstrates for the first time that signals from a ULP OOK radio can be demodulated by a COTS Wi-Fi device. The SlimWiFi ULP radio is extremely simple and can be easily mass-produced and embraced into the existing IoT ecosystem.

We note that most modern network standards have protocol-level power-saving mechanisms [1, 23, 43] based on sleep

Table 4: Comparing SlimWiFi with representative state-of-the-art low-power communication

	Radio architecture	Power	Data rate	Interference	Range	Infrastructure
Wi-Fi [34]	Active	100s mW	High	Low	Long	COTS Wi-Fi
BLE [62]	Active	~ 5 mW	Medium	Low	Medium	COTS BLE
Wi-Fi backscatter [41]	Direct backscatter	1s μ W	Low	Low	Short	COTS Wi-Fi
Braidio [29]	Direct backscatter	10s μ W	Medium	Low	Short	Customized device
PassiveWiFi [42]	FS backscatter	10s μ W	Medium to high	High	Medium	Single tone generator + COTS Wi-Fi
HitchHike [79]	FS backscatter	10s μ W	Medium	High	Medium	COTS Wi-Fi
SlimWiFi	Slim active	10s μ W	Medium	Low	Long	COTS Wi-Fi

scheduling. These mechanisms cannot reduce the peak power consumption—a more essential metric for battery-free communication hardware. Nevertheless, they are complementary to the SlimWiFi design and can be used to further reduce its average power consumption.

Cross technology communication (CTC). The primary motivation behind CTC is to allow different communication standards to exchange messages, so as to reduce interference and enable sharing of data/control information. Recent work has explored both receiver-transparent CTC [18, 20, 39, 44, 45, 50] and transmitter-transparent CTC [26, 37, 38, 51]. However, CTC mainly sticks to the complex modulation adopted by the COTS IoT devices. In contrast, SlimWiFi aims to design the SlimWiFi signal so that it can be effectively decoded by high-profile OFDM demodulators while relaxing the hardware requirement of the transmitter. In addition, existing CTC systems can not be used in ULP settings due to two reasons. First, none of the existing CTC designs can reduce power consumption because they rely on standard transceivers such as Wi-Fi, BLE, ZigBee, and LoRa. Second, they have relatively low communication performance. For example, the recently proposed XFi [51] can only reach 10 m range at 3% FER. For such CTC systems, the majority of the energy is wasted to maintain an unreliable link between heterogeneous hardware, which is not desired in ULP IoT applications. In contrast, SlimWiFi is optimized to achieve a reasonable communication performance targeting IoT applications, with around 3 orders of magnitude lower power than standard transceivers.

Backscatter communication. Recent work has extended classical UHF RFID backscatter communication to realize ambient backscatter, which piggybacks on existing communication links to convey information. For example, Wi-Fi backscatter *et al.* [12, 29, 41, 52, 68] adopt direct backscatter where the tag data is directly modulated to the excitation signal. But due to the self-interference, they usually operate within a very short range and have a very low data rate. PassiveWiFi *et al.* [42, 72, 76, 81, 84] introduces frequency shifting backscattering to deal with the self-interference issues. A single-tone excitation signal is required as an RF carrier source for a low-power backscatter tag, and the tag can reflect and remodulate standard-compatible signals (Wi-Fi, BLE, LTE, ZigBee, *etc.*). HitchHike *et al.* [19, 25, 35, 44, 53, 78–80, 83] apply codeword translation, so that a COTS transmitter, instead of a dedicated single-tone

generator, can be used as an excitation signal source.

Tab. 4 compares SlimWiFi with the representative communication schemes discussed above. Unlike these systems that backscatter signals from existing links, the SlimWiFi device is a *standalone active transmitter* and does not require an external RF carrier signal transmitter. Moreover, as verified in [22], Wi-Fi backscatter systems can cause interference to adjacent Wi-Fi channels, and may inadvertently remodulate and interfere with 5G NR links due to lack of frequency selectivity. Active transmitters like SlimWiFi do not have such out-of-band interference problems. On the other hand, the asymmetric demodulation design in SlimWiFi can also facilitate existing backscatter systems. Owing to the asymmetric demodulation design of SlimWiFi, the backscatter tag can generate a simple modulated signal instead of the sophisticated Wi-Fi compatible signal. Therefore, the tag can evade the need for an accurate and high frequency (tens of MHz) clock source for channel level frequency shifting, which can potentially cut its power consumption by multi-folds.

9 Conclusion

To our knowledge, SlimWiFi represents the first active OOK-modulated radio that can directly communicate with existing Wi-Fi infrastructures. Such asymmetric communication capabilities enable radical simplifications to the radio architecture, opening pathways towards standalone, battery-free Wi-Fi compatible IoT communication. Our SlimWiFi IC achieves a peak power consumption of 90 μ W, but still leaves ample space for optimization, *e.g.*, through more advanced fabrication processes. The asymmetric communication paradigm can be similarly applied to other wireless standards, which we leave for future exploration.

A FEC Errors in Asymmetric Demodulation

In this section, we discuss the behavior of BCC and LDPC when decoding a non-Wi-Fi frame which supports our design in Sec. 3.4.2

A.1 BCC

Viterbi algorithm is widely adopted for BCC decoding. To achieve the maximum likelihood decoding, the algorithm searches among all valid codewords $\{C\}$, to identify the codeword C^l which has the shortest Hamming distance with the input bit sequence. It then outputs the decoded bit sequence Y which can generate the codeword C^l by performing BCC encoding. This means that when we use the decoded bits Y to get the regenerated bits, the regenerated bits $X' = C^l$ will be the exact codeword that has the shortest hamming distance with the original bit sequence X . Since the demodulated bit sequence X has a very low chance to be the same as a valid codeword, the mismatch between X' and X is almost inevitable. However, we found that the number of mismatches between regenerated bit sequence X' and demodulated bit sequence X has an upper limit. Here we provide a quick proof.

For the BCC code with the basic coding rate 1/2, the codewords are generated by bitwise XOR in Eq. 1 where $d[k]$ is the k -th input data bit and $c_1[k]$ and $c_2[k]$ are the corresponding bits in the codeword.

$$\begin{aligned} c_1[k] &= d[k] \oplus d[k-2] \oplus d[k-3] \oplus d[k-5] \oplus d[k-6] \\ c_2[k] &= d[k] \oplus d[k-1] \oplus d[k-2] \oplus d[k-3] \oplus d[k-6] \end{aligned} \quad (1)$$

Consider a data sequence $D = \{d[1], d[2], \dots, d[K]\}$ where K is the length of the input sequence. The corresponding codeword will be $C = \{c_1[1], c_2[1], \dots, c_1[K], c_2[K]\}$. For one valid codeword C^l generated by D^l , the bitwise inverted version (complementary codeword) $\bar{C}^l = C^l \oplus 1$ will also be a valid codeword whose corresponding data bits is $\bar{D}^l = D^l \oplus 1$. When we get the regenerated bit sequence $X' = C^l$, if the mismatch number between X' and X is more than 1/2 of the total bit number, the mismatch number between \bar{C}^l and X will be smaller than 1/2 of the total bit number. Therefore, the hamming distance between X' and X will be higher than \bar{C}^l and X , which is against the shortest hamming distance principle of the decoder. Therefore, the number of mismatches between regenerated bit sequence X' and demodulated bit sequence X should be lower than 1/2 of the total bit number. Fig. 22 gives an example that illustrates the proof.

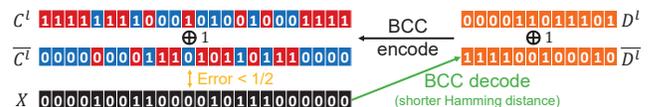

Figure 22: An example of the BCC decoding with complementary codewords at 1/2 coding rate.

For a higher coding rate, the codeword is generated by puncturing the codeword generated by the basic coding rate. Fig. 23 provides an example of how the puncturing is conducted with a 3/4 coding rate while processing the same

sequence in Fig. 22. So the proof still holds, but only for the depunctured sequence. Therefore, to reduce the number of mismatches, we should choose the highest coding rate of 5/6.

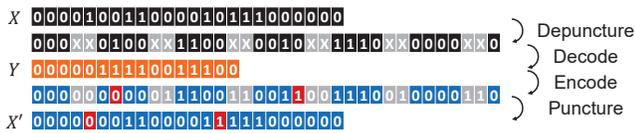

Figure 23: An example of the BCC decoding and regeneration at 3/4 coding rate.

In the previous proof, we only explained the BCC decoding with a hard decision and optimal maximum likelihood decoding. In practice, the error number might vary when considering the soft decision and imperfect maximum-likelihood decoder implementation. But the variation will not diverge the claim.

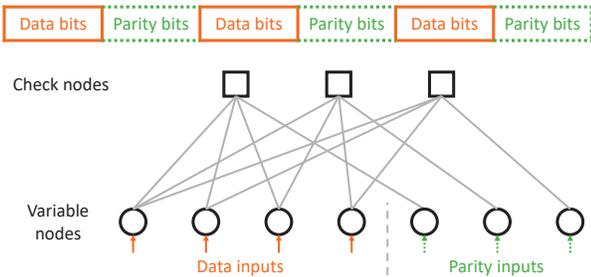

Figure 24: Bit sequence slicing of LDPC coding and an example connection between data bits and parity bits corresponding to one parity-check matrix.

A.2 LDPC

As illustrated in Fig. 24, an LDPC-coded bit sequence is organized into blocks. Each block consists of data bits and parity bits. A predefined parity-check matrix characterizes the connection between variable nodes and check nodes. For LDPC decoding, belief propagation decoders based on the message-passing algorithm are widely adopted. For a soft decision decoder, the inputs of the variable nodes are log-likelihood of the corresponding bits instead of quantized bits. The de-

coder iteratively updates the log-likelihood of the variable nodes and check nodes based on the inputs and the previous status of the nodes by using the sum-product or min-sum algorithm. After iteratively repeating the log-likelihood update, whether the data or parity bits should be flipped will be determined by the final bit log-likelihood of the variable nodes. The bit-flip of the variable nodes happens when the sum of the log-likelihood from the connected check nodes is larger than the input, which in exchange requires that the inputs have a predefined relation corresponding to the parity-check matrix.

Specific to the SlimWiFi asymmetric demodulation, the bit-flip ratio will be extremely low. This is mainly because the inputs are from the OOK signal which does not have the aforementioned relation. Under such conditions, the LDPC decoder is ineffective when decoding, and thus an extremely limited number of the demodulated bits will be falsely “corrected”. A theoretical proof of this conclusion can be found in [51]. Therefore, the data bits part of the regenerated bit sequence will be nearly the same as that of the demodulated bit sequence.

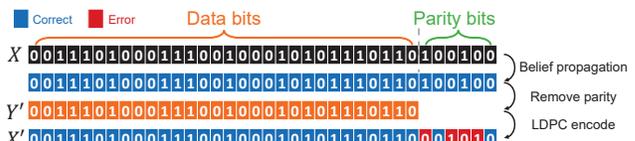

Figure 25: An example of LDPC decoding procedure and the regenerated bit sequence at 5/6 coding rate.

One thing to note is that even though the parity bits part will not be falsely corrected by the decoder, they will be removed after decoding. Since the original data bits do not have a high correlation with the parity bits, the parity bits part of the regenerate bits are not related to that of the demodulated bits. Thus the parity bits part should be treated as unreliable after the regeneration. Then, all bit errors introduced by decoding will be on the parity bits part as illustrated in Fig. 25. Therefore, it is preferable for SlimWiFi to reduce the ratio of parity bits which requires a higher coding rate.

SLNet: A Spectrogram Learning Neural Network for Deep Wireless Sensing

ABSTRACT

Advances in wireless technologies have transformed wireless networks from a pure communication medium to a pervasive sensing platform, enabling many sensorless and contactless applications. After years of effort, wireless sensing approaches centering around conventional signal processing are approaching their limits, and meanwhile, deep learning-based methods become increasingly popular and have seen remarkable progress. In this paper, we explore an unseen opportunity to push the limit of wireless sensing by jointly employing learning-based spectrogram generation and spectrogram learning. To this end, we present SLNET, a new deep wireless sensing architecture with spectrogram analysis and deep learning co-design. SLNET employs neural networks to generate super-resolution spectrogram, which overcomes the limitation of the time-frequency uncertainty. It then utilizes a novel polarized convolutional network that modulates the phase of the spectrograms for learning both local and global features. Experiments with four applications, *i.e.*, gesture recognition, human identification, fall detection, and breathing estimation, show that SLNET achieves the highest accuracy with the smallest model and lowest computation among the state-of-the-art models. We believe the techniques in SLNET can be widely applied to fields beyond WiFi sensing.

1 INTRODUCTION

We are entering the era of Artificial Intelligence of Things (AIoT) where trillions of devices are pervasively connected and, more importantly, equipped with advanced sensing intelligence. They can sense the physical space and gain awareness of contexts such as locations, activities, motion, vital signs, etc. With advances in wireless sensing, all these could be achieved using pervasive wireless infrastructure, without dedicated sensors, wearables, or cameras. As promising as it is, existing wireless sensing is approaching its limits using conventional signal processing methods and faces performance bottlenecks in distinguishing task-relevant features

from entangled irrelevant features in signals.

With its remarkable success in numerous fields, deep learning has become increasingly popular, and also seemingly effective, for wireless sensing, promising the next breakthrough for practical wireless sensing systems for AIoT. Most of the prior works perform conventional signal processing (*e.g.*, frequency transformation) in tandem with deep neural networks, such as convolutional neural networks, which are mainly designed for visual data like images and videos. RF data, most commonly Channel State Information (CSI) data, however, fundamentally differs from visual data in multiple unique aspects: 1) *Non-visual*¹: RF data contains physical and geometric connotations in time, space, and frequency domains that are not visually intelligible; 2) *Complex*: RF data is complex-valued with both amplitude and phase information; 3) *High-dimensional*: While visual data are mostly 2D or 3D, RF data comes with multiple dimensions of time, subcarriers, antennas, and/or transceivers. In addition, it is generally more difficult to build a large RF dataset for training than in the computer vision field, both because that RF data collection is cumbersome as it depends on many environmental factors and that RF data cannot be labeled offline since they are not visually intelligible to human eyes. There exists a gap between prior neural networks and the distinct RF data, rendering existing deep wireless sensing systems suboptimal in performance yet over-complicated in model complexity. While there are also other non-visual, complex, and/or high-dimensional data like speech [28, 50], the unique characteristics of RF sensing call for a separate design to push the limit of deep wireless sensing.

We present SLNET, a novel neural network architecture with a *spectrogram analysis-deep learning co-design* for RF data. Rather than performing spectrogram analysis separately from deep learning, SLNET couples them tightly based on an in-depth understanding of their respective limitations in processing RF data. By doing so, SLNET significantly boosts the effectiveness and efficiency of deep wireless sensing. It consists of three major modules:

Learning-Assisted Spectrogram Enhancement: Many

*Zheng Yang is the corresponding author and Yi Zhang is the first student author.

¹RF data can certainly be visualized in many ways. However, we argue that RF data itself is not visually intelligible like images to humans.

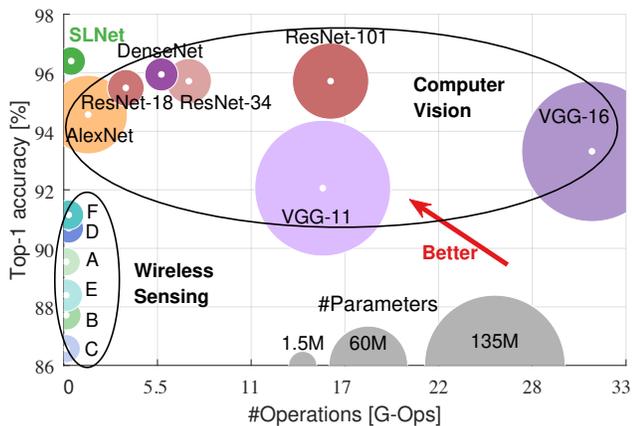

Figure 1: A comparison between SLNET and the state-of-the-art neural networks for WiFi-based gesture recognition task. CV models are accurate but bigger, while existing networks for wireless sensing are relatively small but less accurate. SLNET achieves the highest performance on wireless sensing tasks while reducing computing and memory consumption for practical applications. The radii of the circles represent the number of model parameters. (References: A: [90], B: [22], C: [87], D: [84], E: [30], F: [46])

wireless sensing approaches, either model-driven or data-driven, employ the Fast Fourier Transform (FFT) on a time series of RF data to obtain time-frequency spectrograms of human activities. FFT suffers from errors due to an effect known as leakage, when the block of data is not periodic (the most common case in practice), which results in a smeared spectrum of the original signal and further leads to misleading data representation for learning-based sensing: First, the side lobes “pollute” the spectrograms as they are not from actual human motions but simply the results of spectral leakage. Second, human activities typically contain multiple frequency responses that may be severely affected by the leakage, leading to a “blurred” spectrogram with mixed lobes. Classical approaches reduce leakage by windowing, which cannot eliminate leakage entirely. In effect, they only change the shape of the leakage with different windowing functions to achieve a trade-off between temporal and frequency resolutions. Differently, utilizing learning-based methods promises to push the boundaries beyond classical limitations and, in turn, provide high-fidelity spectrograms for further learning tasks. SLNET introduces a spectrogram enhancement network (§3.1) to learn the best function to minimize or nearly eliminate the leakage, thereby outputting an unparalleled spectrum with high accuracy.

Multi-Resolution Spectrogram Fusion: The frequency resolution of FFT depends on its window size, *i.e.*, the length of the input data block. Using a larger window promises

higher resolution, but only generates a more accurate spectrum when the underlying frequency is quasi-static within the window. In contrast, applying a shorter window improves the responsiveness to fast-changing frequencies, but immediately loses high resolution. Therefore, instead of balancing between conflicting goals of resolution and responsiveness by finding a fixed window length, SLNET employs multiple windows jointly and generates a hologram of multi-resolution spectrograms, which then serves as multi-channel inputs that a neural network can adaptively learn from (§3.2).

Polarized Convolutional Network: The hologram is like an image by format, with each spectrogram serving as a “color” channel. Thus it is straightforward to employ convolutional neural networks (CNN) to extract underlying features from it. Invented for visual data, CNN mainly learns local features irrespective of global locations of objects in an image, allowing images to be shifted. Unfortunately, the locality property makes CNN inappropriate for spectrogram learning, as the global locations, *i.e.*, frequencies, are correlated with the physical properties of a person’s activities, which is not shift-invariant. To preserve global discrimination, we propose a Polarized Convolutional Network (PCN, §3.3). First, we polarize the spectrograms via specially modulated phase information, making them locally unaltered while globally differentiated. Then we design a special convolutional operator to extract features from the polarized and thus complex-valued spectrogram. Compared to CNN, PCN preserves the local features and the global discrimination simultaneously and thus boosts the learning performance. Based on this, we further adopt a compression network for feature deduction and build a task-adaptive network that can be flexibly customized for different sensing tasks.

We implement SLNET on commodity off-the-shelf (COTS) WiFi devices and evaluate its performance for four human-centered sensing applications, *i.e.*, gesture recognition, gait-based person identification, fall detection, and breathing rate estimation. Extensive experiments are conducted in four typical indoor environments including a classroom, a hall, an apartment, and an office. Our results show that SLNET achieves 96.6% accuracy on gesture recognition, 98.9% accuracy on gait identification, 99.8%/97.2% precision/recall for fall detection, and an average error of 2.4 BPM for multi-person breath estimation. Experimental comparisons with over 10 state-of-the-art deep learning models demonstrate that SLNET achieves the highest accuracy with the fewest model parameters and computation operations, as illustrated in Fig. 1, making it more practical and preferable for edge devices (e.g., home routers).

Contributions: SLNET presents a spectrogram analysis-deep learning co-design network distinctively customized for deep wireless sensing on the time series of high-dimensional, complex-valued RF data. We envision that SLNET inspires

tailored deep-learning architectures that are generalizable to multiple tasks and environments of wireless sensing. Further, we believe the techniques introduced in SLNET, including SEN and PCN, are applicable to many fields involving time–frequency signal analysis and spectrogram learning. SLNET is open-sourced here [41].

2 PRIMER

2.1 Preprocessing of RF Data

CSI reflects the channel through which wireless signals propagate. When a person performs an activity, his or her impact on the channel is encoded in CSI, and the activity can thus be inferred from the CSI. Suppose that the person creates L propagation paths between the transmitter and the receiver, the measured CSI is [36]:

$$H(t) = H_s + \sum_{l=1}^L \alpha_l(t) e^{j2\pi \int_{-\infty}^t f_{D_l}(u) du} + n(t), \quad (1)$$

where α_l , f_{D_l} are the complex attenuation and Doppler frequency shift of the signal of the l -th path, H_s is the static part of the channel between the transmitter and the receiver, and n is the additive Gaussian noise.

To recognize the activity of the person, the raw temporal CSI signals are usually transformed into spectrograms via Short-Time Fourier Transform (STFT):

$$S(f, t) = \text{STFT}[H(t)] = \text{FFT}[\varpi] * \sum_{l=1}^L \alpha_l(t) \delta(f - f_{D_l}) + N(f, t), \quad (2)$$

where ϖ represents the windowing function in the time domain, $*$ the convolution operation, and δ the impulse function. N is the frequency response of the Gaussian noise. In Eq. 2, $\sum_{l=1}^L \alpha_l(t) \delta(f - f_{D_l})$ reflects the activity of the person. However, it is distorted by the windowing effect of $\text{FFT}[\varpi]$ and the noise N . As a result, the data fidelity of a spectrogram in representing a person’s activity is impaired. To remove these negative effects in the spectrogram and make the frequency components of interest prominent, a spectrogram enhancement network is developed in SLNET.

Hereafter, we refer to the 2-D output of STFT as *spectrogram* and the 1-D output of FFT as *spectrum*.

2.2 Complex-Valued Neural Network

The neural network acts as one of the most powerful tools in solving various cognitive problems, such as image classification [24], speech enhancement [16], and text translation [31]. A neural network consists of layers of neurons that generate responses according to their inputs. As shown in Fig. 2a, a neuron calculates the sum of the input x weighted with parameters w and the bias and applies a nonlinear activation function σ (e.g., tanh) to generate the output x' ,

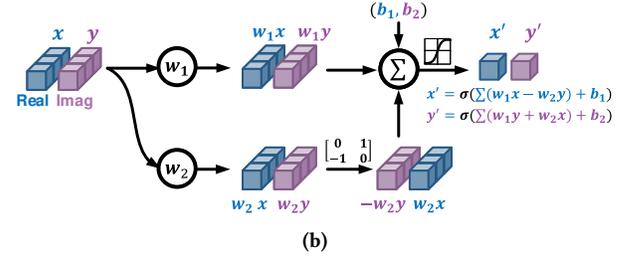

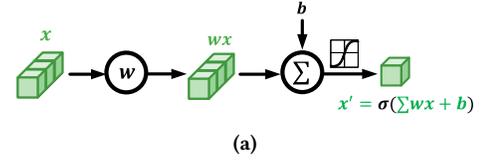

Figure 2: Comparison between (a) real-valued and (b) complex-valued neurons.

i.e., $x' = \sigma(\sum wx + b)$. Recently, neural networks have been used for applications of wireless sensing, such as activity classification [22], gait identification [91], and gesture recognition [90]. However, the phase information of CSI is less exploited or even abandoned in the existing approaches. According to Eq. 1, the CSI phase also encodes important information related to the person’s activity, which, once exploited, can benefit the recognition process. Thus, instead of using a real-valued neural network, SLNET devises a complex-valued neural network, whose neuron processes complex values and fits the complex-valued spectrogram of CSI. As shown in Fig. 2b, a complex-valued neuron consists of two real-valued neurons, which process the real and imaginary parts of the input, respectively. Specifically, suppose the input is $z = x + iy$, the weight is $w = w_1 + iw_2$, and the bias is $b = b_1 + ib_2$, then the output of the complex neuron is $z' = x' + iy'$, where $x' = \sigma(\text{Re}(\sum wz + b))$ and $y' = \sigma(\text{Im}(\sum wz + b))$.

3 SLNET ARCHITECTURE

SLNET is designed as a customized spectrogram learning framework assisted with deep learning for RF data applications. It identifies the limitations of the standard signal processing methods for wireless signals and employs specifically designed deep learning modules to overcome them. Fig. 3 shows the workflow of SLNET, which consists of four parts. First, the *spectrogram enhancement network (SEN)* takes as input a spectrogram transformed from wireless signals via STFT, removes the spectral leakage in the spectrogram, and recovers the underlying actual frequency components. Second, the *Fusion* module combines SEN-enhanced spectrograms with various temporal and frequency resolutions to form a hologram of spectrograms. To coherently combine all spectrograms, SLNET modulates them with linear phases,

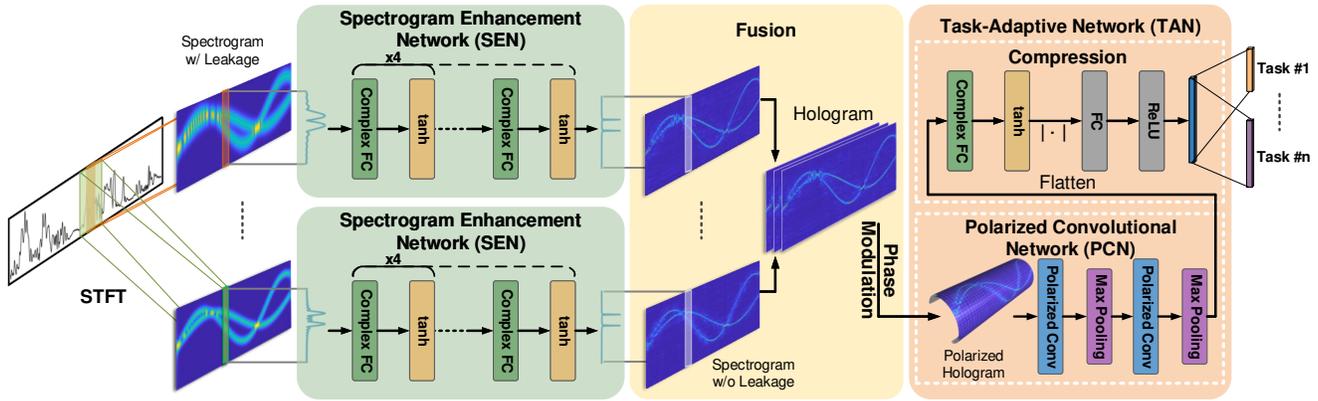

Figure 3: Overview of SLNET. The temporal CSI signal is transformed into spectrograms via a bank of STFT operators with different temporal and frequency resolutions. Each spectrogram is fed into the SEN to remove spectral leakage. Then, a hologram of spectrograms is generated by stacking all enhanced spectrograms and modulating them with linear phases. Next, the hologram is processed with the PCN to generate feature maps, and the compression networks to generate abstract features for specific learning tasks.

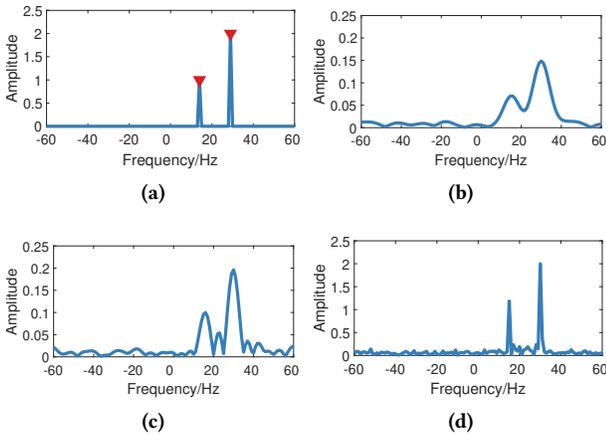

Figure 4: Illustration of spectral leakage. (a) The ideal frequency spectrum with discrete frequency components. (b) The measured frequency spectrum obtained via FFT. (c) The frequency components recovered via least mean square regression. (d) The frequency components recovered from SLNET’s SEN.

and the result is termed a polarized hologram. Third, the *polarized convolutional network (PCN)* module processes the hologram to obtain feature maps with general representativity. Finally, we adopt a *compression network* for feature deduction and build a *task-adaptive network (TAN)*, which can be flexibly adapted for different sensing tasks.

3.1 Spectrogram Enhancement Network

Standard signal processing transforms temporal CSI signals to a time-frequency spectrogram via STFT. A certain STFT operator truncates the time series of signals using a slid-

ing window with a fixed length. However, the truncation results in the windowing effect, which convolves the ideal frequency spectrum with a sinc function and creates spectral leakage in the frequency domain. Some classical windowing functions (like Hamming or Gaussian window [13]) can be multiplied with the truncated signal to mitigate the spectral leakage, but none of them completely removes the leakage. Fig. 4a illustrates an ideal frequency spectrum with two frequency components at 15 and 30 Hz. As shown in Fig. 4b, the estimated frequency spectrum obtained via STFT and Gaussian window has significant spectral leakage and additive Gaussian noise. Formally, suppose the ideal and estimated frequency spectrums are s and \hat{s} respectively. We have:

$$\hat{s} = As + n, \tag{3}$$

where n represents the additive Gaussian noise vector and A is the convolution matrix of the windowing function in the frequency domain. Based on Eq. 2, the i -th column of A is:

$$A_{(:,i)} = \text{FFT}(\varpi) * \delta(i). \tag{4}$$

The spectral leakage significantly distorts the frequency spectrum, producing unwanted side lobes and inaccurate frequencies and amplitudes. For example, when two frequency components are close to each other, their spectral leakage interacts, and the weaker component becomes less prominent, as shown in Fig. 4b. Such spectral leakage is caused by the truncation of the STFT operation and is not relevant to the sensing targets, and is essential to be removed before applying the frequency spectrum to sensing tasks.

Given the relation between the ideal and estimated spectrum as in Eq. 3, it is straightforward to recover the ideal spectrum via the least mean square (LMS) regression:

$$s = \text{argmin}_s \|\hat{s} - As\|_2. \tag{5}$$

However, the LMS regression tends to output suboptimal

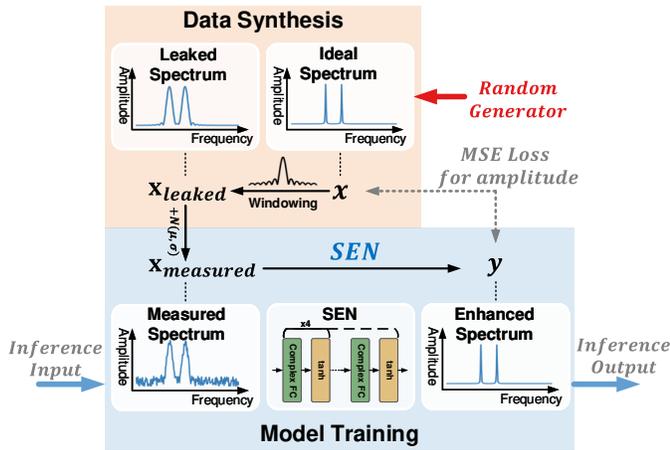

Figure 5: Data synthesis and training process of SEN.

solutions with inaccurate side peaks, as shown in Fig. 4c, due to the existence of Gaussian noises. In contrast, the ideal frequency spectrum of CSI signals tends to be sparse, due to the sparsity of moving objects exposed in the wireless channel [90]. By adding the l_0 -norm regularization, the recovered spectrum is closer to the ideal spectrum. However, the l_0 -norm regularization makes the computational complexity of the problem exponential to the dimension of the frequency spectrum s [6], which is thus intractable. Besides, the sparse Fourier transform that aims to solve this issue also suffers from high complexity [14].

To efficiently recover the ideal spectrum, we resort to the neural network. Compared with the optimization methods, the learning-based method offloads the computation efforts to the training phase and enables efficient linear computation in the testing phase. In addition, the neural network can regress arbitrary functions and is resistant to noises thanks to its continuity in the hidden space. To achieve it, we develop the dedicated network SEN. As shown in Fig. 5, the SEN takes as input the measured complex-valued frequency spectrum and outputs the recovered spectrum. The SEN consists of four complex-valued fully connected layers with the hyperbolic tangent activation function.

To train the SEN, the training dataset has to embrace the complexity of the frequency spectrum, which is extremely high due to the wide amplitude and phase range of wireless signals and random channel noises. For example, the frequency of interest for human-centered sensing is within $[-60, 60]$ Hz and usually, at most five frequency components can be observed for major reflections from the human body [55]. That is, after normalizing the signal amplitude, a spectrogram can consist of 1 to 5 frequency components, whose amplitudes, phases, and frequencies are in $[0, 1]$, $[0, 2\pi]$, $[-60, 60]$ Hz, respectively. As collecting data with labeled ground truth from real scenarios is challenging,

we instead synthesize the training data, which turns out to be sufficiently effective. As shown in the upper part of Fig. 5, we randomly generate ideal spectrums with 1 to 5 frequency components, whose amplitudes, phases, and frequencies are uniformly drawn from their ranges of interest.

Then, the ideal spectrum is converted to the leaked spectrum following the process in Eq. 3 to simulate the windowing effect and random complex noises. The amplitude of the noise follows a Gaussian distribution, and its phase follows a uniform distribution in $[0, 2\pi]$. The SEN takes the leaked spectrum as input and outputs the enhanced spectrum close to the ideal one. Thus, we minimize the L_2 loss $L_{\text{SEN}} = \|\text{SEN}(\hat{s}) - s\|_2$ during training. During inference, the spectrums measured from real-world scenarios are normalized to $[0, 1]$ and fed into the SEN to obtain the enhanced spectrum for further processing. Fig. 6 shows an example of the spectrogram when a person performs a gesture. As is shown, the frequency components caused by the pushing and pulling gesture are clearly recovered by the SEN.

3.2 Multi-Resolution Spectrogram Fusion

The SEN refines the frequency spectrum of the CSI signals by recovering its underlying frequency components. Thus, it assumes that the frequency components remain quasi-static during the sliding window where the frequency spectrum is generated. However, the Doppler frequency shifts induced by human activities keep changing, which may violate this assumption. For example, in the fall detection scenario, the speed of the human body changes between 0 m/s and 5 m/s, creating significant variations in signal frequencies. To illustrate its impact on SEN, we use an example of two components with changing frequencies, as shown in Fig. 7a. The measured spectrogram with a sliding window of 251 ms is shown in Fig. 7b and the refined spectrogram from SEN in Fig. 7c. While SEN correctly distinguishes the two components in the first half of the spectrogram, it fails to recover them clearly in the second half, due to the rapidly changing frequencies of the components.

One straightforward solution is to use a shorter sliding window, during which the rapidly changing frequencies can be approximately viewed as quasi-static. However, using a shorter sliding window reduces the frequency resolution, which limits the ability of the SEN to remove the spectral leakage of the two close frequency components. Fig. 7d shows the output of the SEN using a sliding window of 125 ms. With a shorter sliding window, the SEN recovers the second half of the spectrogram with fast-changing frequencies. However, it does not separate well the close frequency components in the first half of the spectrogram, due to the coarse frequency resolution of the short sliding window.

To overcome the limitation of the temporal and frequency

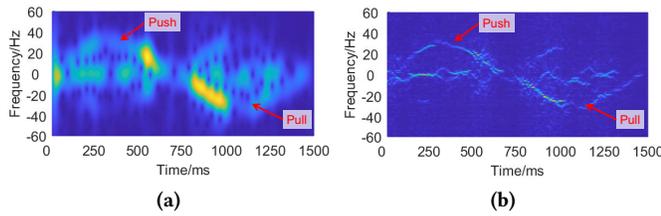

Figure 6: Illustration of the spectrogram of a pushing and pulling gesture. (a) The measured spectrogram and (b) the enhanced spectrogram from SEN.

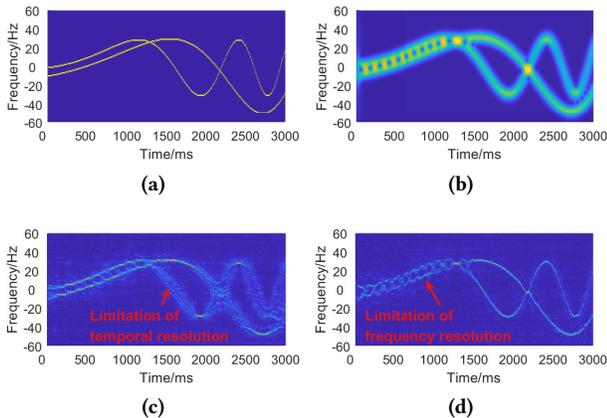

Figure 7: Illustrations of SEN-enhanced spectrograms. (a) The ideal spectrogram with two frequency components. (b) The measured spectrogram from STFT with a sliding window size of 251 ms. (c) The enhanced spectrogram with a window size of 251ms. (d) The enhanced spectrogram with a window size of 125 ms.

resolutions of the spectrogram, instead of using a fixed sliding window, SLNET employs a bank of sliding windows with different lengths (similar to [73]). For each sliding window, the corresponding spectrogram is processed via the SEN that is pre-trained with the synthesis spectrograms with the same window length. All SEN-enhanced spectrograms are then concatenated as multiple channels to form a hologram of spectrograms. As each spectrogram encodes useful information for a certain range of temporal and frequency resolutions, we further resort to the neural network to adaptively combine all the spectrograms.

3.3 Task-Adaptive Network

SLNET employs the Task-Adaptive Network to further adapt the hologram of enhanced spectrograms to various sensing tasks, such as gesture recognition, gait identification, and fall detection. As shown in Fig. 3, the TAN consists of two modules, the PCN module that captures high-level feature maps of the hologram and the compression module that

reduces feature dimension for specific tasks.

Polarized Convolutional Network. A hologram can be treated as an image where each spectrogram spanning in 2-D time and frequency dimension is as one of its “color” channels, and, by doing so, a CNN [15, 24] can be applied to extract the underlying features of the hologram. However, the solution is not optimal, as explained below.

Each neuron in CNN only takes a local field of the input to generate the output. All the neurons in each layer share the same weights to ensure that the local features are preserved irrespective of their global locations. As a result, CNN is particularly tailored for visual data since it focuses on local dependencies and is invariant to global shifts of objects in images. This shift-invariant property makes CNN inappropriate for spectrogram processing, as the global locations, i.e., frequencies, of the frequency components are correlated with the physical properties of the person’s activities. In another word, a shift along the frequency dimension means a change in the moving status of the person, which is highly possible due to a different activity. Besides, the local patterns of the spectrogram capture the instant motion status of the target, which is still needed for sensing tasks. Hence, it is necessary to develop a new model that simultaneously preserves local dependency and global discrimination.

We propose to modulate the spectrograms with phase information, which is discarded in existing wireless sensing models, to explicitly encode global locations in the spectrogram while retaining its local correlations. Specifically, it is expected that the adjacent frequency components have similar phases while the distant ones have discriminative phases. Thus, we modulate the spectrogram with phases that vary linearly along the frequency dimension, i.e., the modulated phase of the i -th frequency bin is:

$$\phi_i = i \frac{\phi_h - \phi_l}{M} + \phi_l, \quad (6)$$

where ϕ_h and ϕ_l are the phases modulated to the lowest and highest frequency bins, and M is the number of total frequency bins. As a result, global discrimination is introduced along the frequency dimension while the shift-invariant property is preserved along the time dimension. Note that we apply the proposed polarized phase modulation, rather than incorporating the original phase information because the raw phase contains significant errors due to carrier frequency offsets and timing offsets, *etc.* [37, 57].

The frequency components modulated with phases can be viewed as polarized in a 2-D complex plane. To process the polarized spectrograms, we propose the PCN network. PCN consists of two pairs of convolutional layers and max-pooling layers, which are responsible for higher-level feature extraction and dimension reduction, respectively. As shown in Fig. 8a, the polarized hologram is applied with a convolutional layer to extract local features followed by

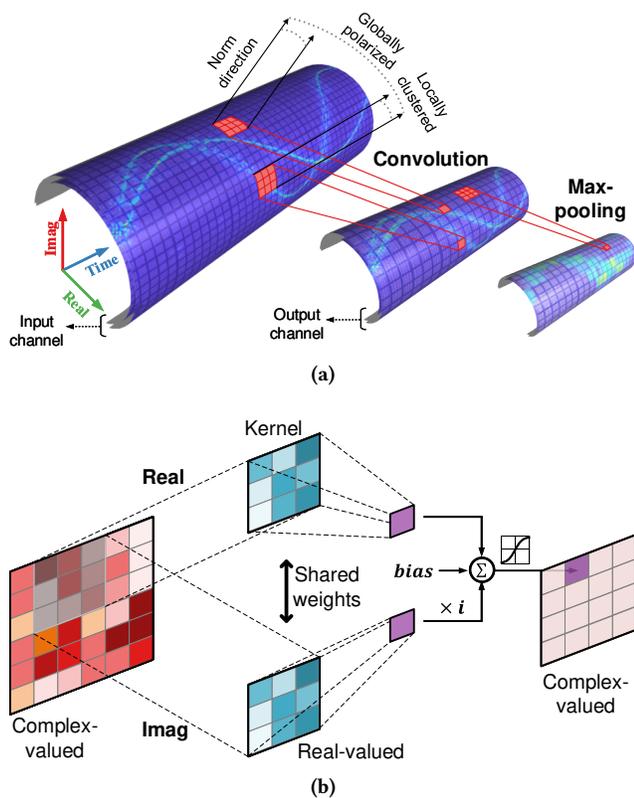

Figure 8: The (a) structure and (b) convolutional operations of the Polarized Convolutional Network.

a max-pooling layer to reduce the feature dimension. The elements within each kernel are locally clustered, while the elements within different kernels are globally polarized to have better global discrimination benefiting from the linear phase introduced. In practice, several convolutional layers can be cascaded to obtain higher-level features of the input spectrograms. The input channel represents the number of fused spectrograms in the hologram or the number of output channels in the previous convolutional layer. For each convolutional layer, Fig. 8b illustrates the convolutional operations in complex domain. The real-valued kernels are convolved with the real and imaginary parts of the spectrograms separately and combined with a bias to get the final complex-valued output. The max-pooling layer downsamples the features with the maximum amplitude and outputs the complex-valued features.

Feature map compression. SLNET further adopts a compression network to reduce the high dimensions of the feature maps generated by the PCN and obtains a condensed representation of features for specific tasks. The compression network consists of a complex-valued fully connected (FC) layer with the *tanh* activation function and a real-valued FC layer with the *ReLU* activation function. To connect two

FC layers, SLNET calculates the absolute value of the output from the complex-valued FC layer and inputs it to the real-valued FC layer. The output features can be further fed into additional FC layers customized for different tasks. For example, an FC layer with N output units followed by a softmax activation function can be used for a gesture classification task with N gestures, while an FC layer with 1 output unit followed by a sigmoid layer can be used to predict the likelihood of human fall for the fall detection task.

We employ the pre-trained SENs to obtain the enhanced spectrograms and feed them into the TAN for training. The L_2 loss between the output of the TAN and the ground-truth label is minimized, and the RMSprop optimizer is used. During inference, SLNET takes as input the measured CSI spectrograms and outputs the prediction result.

4 IMPLEMENTATION & EXPERIMENTS

4.1 Implementation

Hardware. SLNET collects CSI measurements from commodity Intel 5300 WiFi Network Interface Cards (NICs) equipped on off-the-shelf mini-computers. The three antennas of the NIC are separated apart by half of the signal wavelength, i.e., 2.85 cm. The operating system of the mini-computer is Ubuntu 10.04 with Linux CSI Tool [12] installed to log CSI readings. The NIC is set to operate on channel 165 with a center frequency of 5.825 GHz. We set all the receivers to work on monitoring mode and inject the transmitter to broadcast at a rate of 1,000 packets per second. All the devices are connected to a router and remotely controlled. We employ a workstation equipped with an NVIDIA GeForce 2080Ti GPU to host the DNN model.

Software. We implement SLNET mainly for benchmark analysis. The data² is collected with a Linux shell script, and CSI measurements are preprocessed [36] with Matlab. The dataset [70] and code [69] is available to public. Instructions to use this dataset can be found in our released tutorial [68]. The PyTorch [34] library is adopted to implement the custom complex-valued neurons. Raw CSI is preprocessed in a similar way as in [90]. The SEN module is trained offline with randomly generated spectrums. A total of 5,000 epochs is used to train the SEN models, each of which contains 100 batches \times 128 instances of generated spectrums. We pre-train an SEN for each resolution of the spectrogram. Three resolutions are used with window sizes of 125 ms, 251 ms, and 501 ms, respectively. The TAN is trained by the data measured from real deployment scenarios and enhanced by the pre-trained SEN. All the models are trained with Adam optimizer at a learning rate of 0.001. Batch normalization and dropout techniques are applied during training. In practice, the model can be trained offline, except for the use case of

²All experiments that involve humans satisfy our IRB requirements.

gait recognition where a user needs to register himself first.

4.2 Experiments

We evaluate SLNET in four WiFi sensing applications, including gesture recognition, gait identification, fall detection, and breath estimation. We mainly focus on WiFi CSI sensing in this paper and leave it for the future to explore SLNET’s potential for other modalities like acoustic sensing.

Gesture recognition. Device-free gesture recognition [2, 90] is one of the core enablers for human-computer interaction. To evaluate the performance of SLNET for gesture recognition, we conduct experiments in a classroom (sketched in Fig. 9a). One WiFi transmitter and six receivers are placed at a height of 110 cm to capture the motion of human arms. The users are asked to stand at the five marked positions and face the second, third, or fourth quadrant. Eight users (6 males and 2 females) participate in this experiment, with heights varying from 155 cm to 185 cm and ages from 22 to 28. They perform 16 gestures, including 6 sign gestures (push and pull, sweep, clap, slide, draw a circle, and draw zigzag), and 10 input gestures (draw digits 0 to 9). We collect a total of 6,000 data samples (8 people \times 6 gestures \times 125 instances) for the sign gestures and 5,000 samples (2 people \times 10 gestures \times 250 instances) for the input gestures. The sign gestures are used in §5.1, and the input gestures are used in the other evaluations. We use the ratio between the number of correctly recognized gestures and the number of all samples as metrics.

Gait identification. Gait has been exploited [18, 64] for human identification. To evaluate the performance of SLNET for gait identification, we conduct experiments in a hall (sketched in Fig. 9b). The devices are placed similarly to that in the gesture experiment. The users are asked to walk freely across the center of the area with eight directions separating 45 degrees apart. Eleven users (7 males and 4 females) participate in this experiment, and their heights vary from 155 cm to 183 cm, and their ages vary from 20 to 26. We collect a total of 3,600 data samples, among which 2,800 samples (7 people \times 8 directions \times 50 instances) are from 7 users, and 800 samples (4 people \times 8 directions \times 25 instances) are

Motion	Types	Sub variations
Fall	sit-then-fall, lose-balance, kneel-then-fall, trip walk-then-fall, slip	forward, backward, lateral, on-position
Normal	walk, sit-down/stand-up, run, bend-and-pickup, squat, dance, open/close door, open/close fanner	

Table 1: Fall and normal activities in SLNET

from the other 4 users. We use the ratio between the number of correctly identified gait samples and the number of all samples as metrics.

Fall detection. Fall is a major cause of impairment among senior citizens, and some works [33, 52] have tried to detect falls with wireless signals. To evaluate the performance of SLNET for fall detection, we conduct experiments in an apartment (sketched in Fig. 9c). A pair of WiFi devices are placed at the height of 135 cm and 40 cm, respectively, in the living room and the balcony at a distance of 4.5 m. We recruit a voluntary family with 5 members (two males and three females with heights varying from 160 cm to 181 cm and ages varying from 20 to 50). The observed fall and normal activities are described in Tab. 1. When collecting fall data, we require the users to wear protective gear, and the floor is covered with foam. Additionally, we augment the dataset by leveraging a manikin [25] to fall. In total, we collect 2,000 normal instances and 556 fall instances, among which 300 falls are from the manikin, and 256 are from the five users. We use precision and recall as metrics [45].

Breath estimation. Breath rate [67, 78, 83] is an important vital sign that can indicate the condition of physical health. To evaluate the performance of SLNET for breath estimation, we conduct experiments in an office (sketched in Fig. 9d). A pair of WiFi devices are placed at a height of 1 meter to capture the signal reflection from seated participants in the discussion zone. We recruit three participants with heights varying from 172 cm to 185 cm and ages varying from 22 to 26. For each experiment, two of the participants sit in the chairs and breathe naturally. We collect a total of 19 groups of data with a duration of approximately 44 minutes. We use the Breath Per Minute (BPM) error between the estimated

respiration rate and the ground truth as metrics.

We first conduct experiments on all tasks to demonstrate the generality for multiple tasks. Then we carry out ablation and parameter study with gesture recognition as the example task due to the space limit. Unless otherwise stated, the results below are obtained on a 10-fold validation basis where we randomly split the datasets into training and testing parts.

5 EVALUATION

5.1 Comparison Study

5.1.1 Comparison between learning models. To validate the effectiveness of the whole SLNET for wireless sensing, we compare it with 12 typical neural models used in different modalities, including WiFi sensing, FMCW-radar sensing, acoustic sensing, computer vision, and other tasks that leverage Complex-Valued Neural Networks (CVNNs). It is worth noting that the implementations of these networks differ slightly from those in the cited works. As the networks presented in those citations are designed for tasks beyond WiFi sensing, we borrow the backbone architectures and customize them for our own tasks and datasets. The comparison is performed with multiple metrics in terms of model complexity and recognition performance. For model complexity, we evaluate the number of parameters of the models, which is perceived as an effective estimate of the memory requirements and training overhead. For recognition performance, the metrics are discussed in §4.2.

WiFi (4 baseline models): We compare a hybrid CNN-RNN model similar to [23, 90] with three convolutional layers, a GRU layer, and four FC layers; an adversarial model [8, 22] with three convolutional layers as the feature extractor, two FC layers as the activity recognizer, and two FC layers as domain discriminator; an encoder-decoder model with ten FC layers as in [39, 79]; and the time-frequency feature learning model introduced in STFNet [73].

FMCW (2 baseline models): Similar to [87], we design an adversarial model with three convolutional layers and a GRU layer as the feature extractor, two FC layers as the activity recognizer, and two FC layers as the domain discriminator. We further compare a CNN model with three convolutional layers and four FC layers as in [84, 86]. The model is applied to the real and imaginary parts of complex-valued features separately.

Acoustic (1 baseline model): We compare an RNN model with a GRU layer and six FC layers as in [30].

Vision (3 baseline models): We compare three baseline models including VGG-11 [40], resnet-18 [15], and densenet [20]. The input and output layers are reshaped to accommodate our tasks.

CVNN (2 baseline models): We compare two CVNN networks that are not originally designed for wireless sensing

Modality	Ref.	Gesture	Gait	Fall ¹	Para ²
WiFi	[23, 90]	90.6%	95.1%	92.8%, 96.3%	1.07M
	[8, 22]	89.0%	96.6%	96.4%, 84.3%	2.72M
	[39, 79]	84.3%	83.3%	96.8%, 93.8%	5.77M
	[73] ³	78.9%	70.9%	95.5%, 96.8%	0.06M
FMCW	[87]	88.0%	95.4%	96.0%, 96.0%	1.06M
	[84, 86]	91.6%	96.4%	99.7%, 95.7%	2.76M
Acoustic	[30]	89.6%	95.4%	90.6%, 98.3%	6.08M
Vision	[40]	88.3%	90.1%	95.3%, 95.3%	128.8M
	[15]	91.9%	96.6%	97.0%, 95.6%	11.18M
	[20]	91.0%	97.7%	99.8%, 96.3%	6.96M

Table 2: Comparison against 12 baseline models. ¹ The two metrics are precision and recall. ² Number of parameters in Million. ³ Trained with 10,000 epochs to converge.

tasks. Similar to [17, 32], we implement an encoder-decoder model with five complex-valued FC layers and three real-valued FC layers. Similar to [46], we evaluate a CNN model with two complex-valued convolutional layers, two complex-valued FC layers, and two real-valued FC layers.

The input of the baseline model [73] is CSI amplitude with a size of $(T, 30, C)$, where T represents the time snapshots of data samples, 30 represents the number of subcarriers, and C represents the number of WiFi antennas. The input of the other baseline models is raw DFS with a size of $(121, T, C)$, where 121 represents the frequency bins within $[-60, 60]$ Hz. For the signals collected by multiple antennas, we perform PCA analysis on the subcarriers of all three antennas and use the principle components for spectrogram1 analysis.

Tab. 2 presents the performance of the baseline models and SLNET. Three key observations can be derived from the results. First, the models used in computer vision tasks achieve better performance than most of the other baseline models. This is because the vision models are heavily parameterized, which endows them with strong representation capabilities. However, for wireless sensing tasks, a less parameterized neural network is preferable due to the cumbersome data collection and the lack of the wide availability of public datasets. SLNET is designed for this purpose. Second, the models that work in complex domain [17, 32, 46, 84, 86] achieve better performance than those real-valued models. This verifies our assumption that the phase of wireless signals embodies valuable information. SLNET strives to exploit this information with its custom neurons. Third, the advantage of SLNET over baseline models is more significant for the gesture and gait tasks than the fall detection task. This is because fall detection is a binary classification problem that is simpler than the other tasks. SLNET is advantageous in complicated

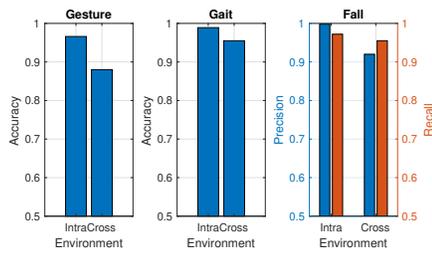

Figure 10: Performance across environments.

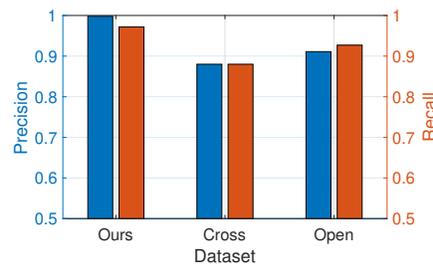

Figure 11: Performance on open dataset [33].

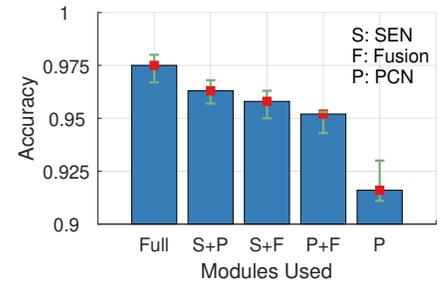

Figure 12: Ablation study on the modules of SLNET.

human sensing scenarios. The most relevant work to SLNET is STFNet [73], which designs customized neural operations to process sensor and RF data. However, while the performance on fall detection is comparable with the other models, it is not desirable for gesture and gait identification tasks. This is because STFNet is built upon the traditional STFT that suffers from spectral leakage. This leakage, when appearing in the spectrogram with clustered frequency components (typical for gesture and gait motion), will distort and even mislead the learning process when searching for the underlying signal structures. The lightly parameterized model in STFNet makes this problem even more challenging. On the contrary, SLNET alleviates this leakage with SEN before learning the hidden features with task-specific networks, ensuring high-fidelity motion representations.

5.1.2 Performance for unseen environments. Wireless sensing systems are prone to environmental changes when deployed in various environments. In this experiment, we evaluate the performance of SLNET when it is applied in *unseen* environments/users after training. Specifically, for the gesture recognition task, we set up another system in an office, which has different layouts and sizes with the classroom illustrated in Fig. 9a. Four volunteers participate in the experiments, and we collect a total of 3,000 gesture samples. For the gait identification task, we collect 600 instances of walking samples from three volunteers in a discussion room, which has a smaller size and more furniture compared with the hall illustrated in Fig. 9b. For the fall detection task, we collect 500 walking samples and 200 falling samples in an office room with different layouts and sizes from the apartment in Fig. 9c. For each task, we train SLNET from scratch with the data collected from one site and test it with the data collected from another.

Fig. 10 demonstrates the performance. As is shown, when deployed in unseen environments without any model adaptation, the performance of SLNET slightly decreases but is still encouraging. SLNET is based on the spectrograms of wireless signals, making it more robust to the surrounding static ob-

jects. However, this also makes it prone to changes in relative locations and orientations between users and devices. This is because the frequency components in RF spectrograms are induced by the Doppler shifts, which depend on the moving direction and locations. SLNET is not particularly designed to resolve this problem, yet we believe it can be further addressed by domain adaptation mechanisms [10, 22, 90].

5.1.3 Performance on open datasets. We further evaluate SLNET on a publicly available open datasets. We mainly study fall detection using the dataset released in [33], since it is nearly impossible to find open datasets that have the same types of gestures for gesture recognition or have the same users for gait recognition. This dataset has a total of 181 clearly annotated fall samples and 297 samples of normal activities collected from five rooms of a typical apartment. We compare three settings: 1) We only use our own dataset and split it into non-overlapped train and test parts; 2) We train the model with our dataset and test it with the open dataset; 3) We only use the open dataset and split it into separate train and test parts. The results in Fig. 11 show that SLNET achieves close to 90% precision and recall when trained on our dataset and tested on the open dataset. Despite being degraded, we believe the performance is still encouraging, as the testing data are from completely different and unseen settings with different users, environments, devices, types of falls, etc. Compared with the performance in [33], the precision of our system increases by around 5%, demonstrating the effectiveness of the proposed spectrograms learning pipeline. Considering the promising performance of SLNET in both intra-domain and cross-domain scenarios, We believe SLNET points a valuable direction to applying wireless sensing systems for real-world applications.

5.2 Ablation Study

SLNET consists of three key modules, i.e., SEN, Fusion, and PCN. To validate their effectiveness, we perform an ablation study for these modules. To do so, we remove it from SLNET while adapting the two modules to the input and output

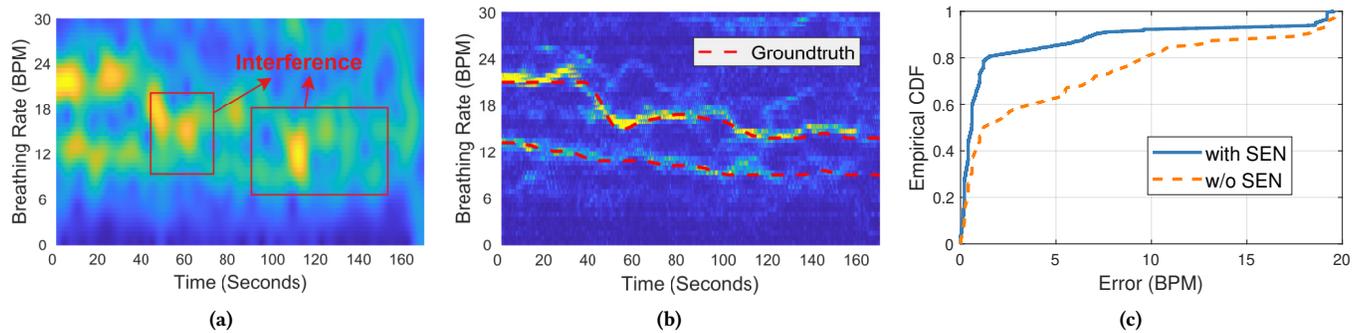

Figure 13: Accuracy for breath estimation. (a) The raw spectrogram from traditional FFT. Spectral leakage causes severe interference for the close frequency components, making it hard to differentiate the breath rates of different people. (b) The enhanced spectrogram with SEN. Frequency components can be clearly discriminated. (c) The accuracy of breath rate estimation with raw and enhanced spectrograms.

format. Specifically, for the SEN module, the originally leaked spectrograms are used as the input of the Fusion and PCN modules. For the Fusion module, only the spectrograms with a window size of 251 ms are enhanced by the SEN and used as the input of the PCN. For the PCN module, the output of the Fusion module is fed to two conventional CNN layers and one max-pooling layer, followed by one FC layer as the output layer. In addition, we further remove both the SEN and the Fusion modules to evaluate their joint performance.

As shown in Fig. 12, the accuracy decreases from 97.5% to 96.2%, 95.6% and 95% when the Fusion, PCN and SEN are removed respectively. The accuracy further decreases to 91.2% when only the PCN is used. The result of the ablation study demonstrates the effectiveness of the three modules of SLNET. It is also worth noting that the benefit brought by the SEN module is more significant than others, meaning that the spectral leakage problem cannot be neglected in wireless sensing tasks, and SLNET successfully resolve the problem.

Multi-Person Breathing Rate Estimation Performance. Even though SLNET is designed for motion recognition tasks that attempt to leverage deep learning schemes, its components are valuable beyond that scope. For example, the SEN module can be used to mitigate the spectral leakage induced by the Fourier transform, which could potentially boost the performance of sensing systems that involve spectral analysis. To validate the effectiveness of SEN, we design a human breath estimation experiment in this part.

Breath estimation plays an important role in healthcare, and some recent works [51, 78] exploit the feasibility of using WiFi signals to estimate the respiration rate. A typical way to do this job is to convert the time domain CSI measurements into a frequency domain spectrogram and characterize respiration rates with the prominent frequency components. However, when multiple people breathe concurrently, the spectral leakage problem will severely blur the spectrogram

components and make it difficult to discriminate the respiration of different people. With the SEN module, we envision that the leakage will be mitigated or even eliminated, contributing to improved respiration rate estimation accuracy.

In this experiment, two participants sit in chairs and breathe naturally. One of them has just finished some exercise. To obtain ground truth, each of the participants has a smartphone tied to his chest to measure the acceleration of the body induced by breath movements. We apply STFT with a window width of 6,000 (60 seconds) on the acceleration measurements and detect peaks in the spectrogram to represent the respiration rate of each participant. We downsample CSI to 10 Hz and apply STFT with a window width of 251 (25.1 seconds) to get the spectrograms of CSI measurements. We then apply SEN to the spectrograms and pinpoint the two most prominent peaks therein to characterize the respiration rates of the two participants.

Fig. 13a and Fig. 13b demonstrate the raw and enhanced spectrograms of WiFi. As can be seen, the raw spectrogram is severely distorted by the leakage effect, and the frequency components corresponding to the two participants are blurred. By applying SEN, two distinct frequency components can be observed and approximate ground truth very well. Fig. 13c presents the empirical CDF of the respiration rate estimation error. With SEN applied, the average error is 2.4 BPM and the 80%-tile error is 1.4 BPM. Without SEN, the performance deteriorates to 5.0 BPM for average error and 9.5 BPM for 80%-tile error. This experiment demonstrates SEN’s strong capability of removing spectral leakage. This merit makes it especially suitable for human-centered sensing tasks, where the human-induced frequency components are tightly clustered and demand to be discriminated.

5.3 Parameter Study

5.3.1 Impact of training epochs of the SEN. In practice,

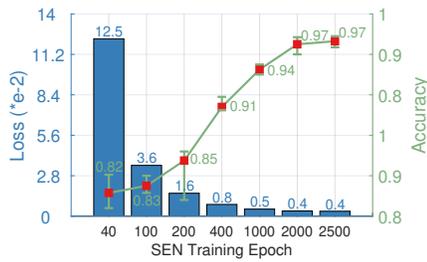

Figure 14: Impact of SEN training epochs.

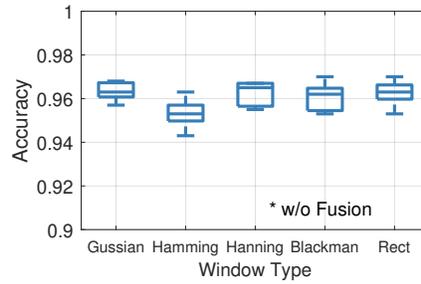

Figure 15: Impact of window type.

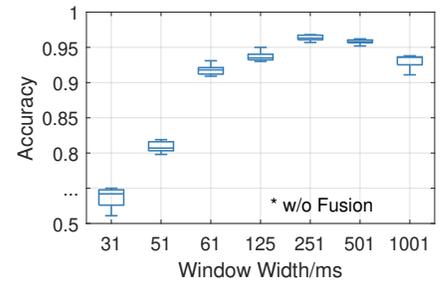

Figure 16: Impact of window width.

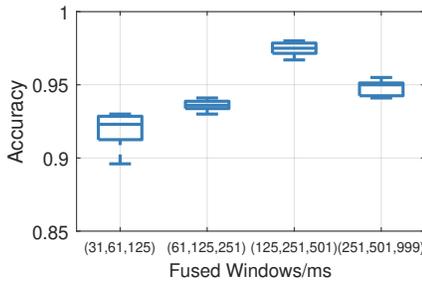

Figure 17: Impact of fused window width.

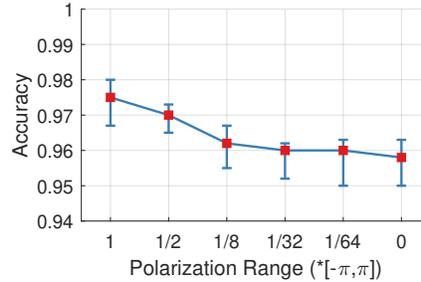

Figure 18: Impact of phase modulation range.

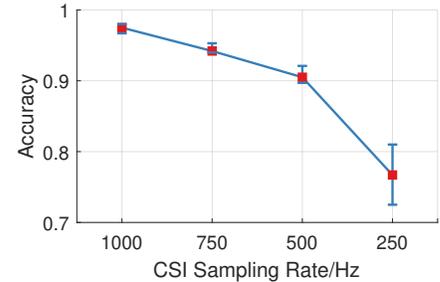

Figure 19: Impact of CSI sampling rate.

we randomly generate data samples during each training epoch. With more training epochs, the SEN should capture the underlying structure of spectrograms better and improve the system recognition accuracy. To reveal the relationship between training epochs and performance, we train the SEN with different numbers of training epochs from 40 to 2500 and integrate them into SLNET. For each SEN, the TAN module is retrained from scratch. We record the validation loss of the SEN and the recognition accuracy of the overall SLNET. As shown in Fig. 14, the validation loss for SEN training tumbles and the overall accuracy proliferates when the epochs increase from 40 to 2,000. The performance becomes stable when the SEN is trained with more epochs.

5.3.2 Impact of window type. Some window functions [13] have been proposed to suppress spectral leakages, such as Hamming, Hanning, and Blackman windows. In this experiment, we evaluate the system performance with regard to these windows. For each window function, we train an independent SEN module with spectrograms calculated with it. The TAN module is then trained from scratch with different SEN modules. We record the overall recognition accuracy concerning different window functions. As shown in Fig. 15, different window functions have little impact on the performance of SLNET, demonstrating the effectiveness of SEN for the removal of spectral leakage.

5.3.3 Impact of window width. In this experiment, we

evaluate the impact of the window width on the system performance. Specifically, we train an SEN module for each window width. The Fusion module of SLNET is removed to evaluate each window width. The TAN modules are retrained accordingly, and the overall recognition accuracy is recorded. As shown in Fig. 16, when window width increases from 31 ms to 251 ms, the overall accuracy proliferates from 74% to 96%, but tumbles to 92.5% when window width further increases to 1001 ms. It is because a very small window leads to a coarse-grained frequency resolution, while a very large window cannot capture the rapid change of frequency components in the time domain. The result reveals that a width of 251 ms is the best for the gesture recognition task. However, it is noted that a single-resolution spectrogram for wireless sensing tasks is not the optimal solution, as verified by the ablation study.

5.3.4 Impact of combinations of different window widths. In this experiment, we evaluate the impact of different combinations of window widths. For each combination, we use the corresponding SEN modules to enhance the spectrograms and combine them as holograms. The TAN module is retrained for each combination. The overall recognition accuracy with different combinations is reported. As shown in Fig. 17, the best combination of window widths is (125, 251, 501) ms and the worst is (31, 61, 125) ms. The combination of three windows outperforms either one of these windows independently. The performance could be

further improved with more window widths fused at the cost of increased computational complexity, which is limited in edge devices in practice. For SLNET, the combination of (125, 251, 501) ms is adopted to achieve a trade-off between performance and complexity.

5.3.5 Impact of polarization range of PCN. The PCN module of SLNET is designed to extract both local and global features simultaneously from the holograms. In this experiment, we evaluate the impact of the range of the linear phase modulated to spectrograms in SEN. Specifically, the phases are set to be within $k * [-\pi, \pi]$, where k changes from 0 to 1. For each phase range, we retrain the TAN model from scratch. The overall recognition accuracy concerning different phase ranges is reported. As shown in Fig. 18, the accuracy decreases from 97.5% to 96.0% when the polarization range decreases from $[-\pi, \pi]$ to $[0, 0]$, which reveals that the PCN with phase modulation is effective in spectrogram-based sensing tasks.

5.3.6 Impact of CSI sampling rate. The impact of the CSI sampling rate is evaluated in this part. Specifically, we down-sample the original CSI streams (1,000 Hz) before spectral analysis and input the corresponding spectrograms in SLNET. Both SEN and TAN are retrained for each downsampling rate. As shown in Fig. 19, when the CSI sampling rate decreases from 1,000 Hz to 500 Hz, the accuracy gradually decrease from 97.5% to 90% and further tumbles to 76% with a sampling rate of 250 Hz. It is because, with a lower sampling rate, the CSI signals have a poorer temporal resolution and cannot capture the rapidly changing frequency components. In addition, the signal-to-noise ratio decreases with the reduced number of samples for spectral analysis. These factors together deteriorate the recognition performance of SLNET.

6 RELATED WORK

Model-based wireless sensing. Model-based wireless sensing works [2, 4, 38, 49, 52, 60, 62, 74] try to establish quantitative relations between wireless signals and human activities via non-learning based approaches. Many applications have been explored and enabled, including gestures [2, 35, 44, 47, 75], walking [56, 57, 64, 76], falls [19, 21, 33, 45], and respiration [1, 27, 58, 61, 78], and tracking [3, 37, 63, 66], etc. These approaches have the benefit of being interpretable and usually efficient. For example, WiGest [2] empirically builds a link between received signal strength (RSSI) and hand-moving patterns. SMARS [78] exploits breathing estimation by periodicity finding. However, these approaches are constrained by the coarse-grained signal and motion models and are approaching performance limits in real environments. More works are seeking learning-based schemes for better performance, and SLNET is one among them.

Learning-based wireless sensing. Early works mainly rely on signal processing and employ traditional machine learning [48, 56, 57, 59, 64, 76, 77]. With the impressive achievements in computer vision using deep neural networks, more effort [9, 10, 22, 45, 54, 71, 72, 79, 80, 82, 85, 86, 88, 90] has been put into applying deep learning models in wireless sensing tasks. Among them, Widar3.0 [81, 90] leverages CNN and RNN networks to learn from its novel motion feature BVP. RFPose [84], RFPose3D [86], and RFAvatar [85] use CNN models to capture human skeleton and mesh of body. Many works [10, 22, 49, 79, 90] employ sophisticated network architectures like adversarial learning, transfer learning, and meta-learning to solve the environment-dependency problem of wireless sensing, while others aim to reduce cumbersome data collection for training [7, 11, 42, 53, 65]. Some works e.g., [84–86] on FMCW sensing, have further considered customized models for the unique properties of RF data. Existing works either learn from the time series of raw CSI, with both amplitude and phase, or convert them into the frequency-domain representation or other feature space. Despite some time-domain approaches for speech separation [29, 43], recent works like STFNETs [73], which extends DeepSense [72], and UniTS [26] both pursue and demonstrate superior performance of temporal-spatial learning with STFT operators. Noticing phase encodes essential spatial information, complex-valued neural networks [5] have been explored in the DL community [17, 32, 46] and exploited especially for radar sensing [89], acoustic sensing and speech processing [28, 50].

7 CONCLUSION

This paper presents SLNET, a spectrogram analysis-deep learning co-design for deep wireless sensing. We demonstrate SLNET’s remarkable performance in gesture recognition, gait recognition, fall detection, and breath estimation, showing the highest accuracy and lowest computation compared to the state-of-the-art models. We believe SLNET is a unique deep-learning framework for WiFi sensing. At the same time, the techniques can be used, jointly or separately, to augment the spectrogram quality and enhance learning performance for many applications in signal estimation, frequency analysis, sensing with acoustic/millimeter-wave signals, etc.

Abstract

High-speed ASIC switches hold great promise for offloading complex packet processing pipelines directly in the high-speed data-plane. Yet, a large variety of today’s packet processing pipelines, including stateful network functions and packet schedulers, require *storing* some (or all the) packets for short amount of times in a programmatic manner. Such a programmable buffer feature is missing on today’s high-speed ASIC switches.

In this work, we present RIBOSOME, a system that extends programmable switches with external memory (to store packets) and external general-purpose packet processing devices such as CPUs or FPGAs (to perform stateful operations). As today’s packet processing devices are bottlenecked by their network interface speeds, RIBOSOME carefully transmits only the relevant bits to these devices. RIBOSOME leverages spare bandwidth from any directly connected servers to store the incoming payloads through RDMA. Our evaluation shows that RIBOSOME can process 300G of traffic through a stateful packet processing pipeline (*e.g.*, firewall, load balancer, packet scheduler) by running the pipeline logic on a *single* server equipped with one 100G interface.

1 Introduction

Network Function Virtualization is an essential architectural paradigm of today’s networks [32]. Operators create and manage complex packet processing pipelines by combining together Network Functions (NFs), which are then deployed on the infrastructure. Network functions that require simple computations are generally deployed onto *cost-effective* ASIC-based switches, whereas more complex packet processing computations must be deployed on *expensive* general-purpose CPUs or FPGAs due to the inherent difficulty and cost of designing complex ASIC circuits [4]. Unfortunately, the networking stack of general-purpose servers and FPGAs is significantly slower in processing packets than dedicated ASIC hardware counterparts, ultimately increasing the energy footprint and cost of operating a large network.

Deploying network functions that have to manage large amounts of frequently changing *stateful per-flow* information in a cost-effective manner (*i.e.*, entirely on an ASIC switch) has been an elusive goal.

To understand the requirements posed by multi-terabit per second stateful packet processing, we analyze a set of real-world CAIDA traces in the 2013–2019 period [6]. Through a linear regression, we observe that *i*) the number of active flow connections traversing a switch is 120 K for every gigabit of forwarded traffic and *ii*) there are 4 K new flow connections for every gigabit of forwarded traffic. This translates to 385 M active flows and 12.8 M new flow-table insertions per second on a 3.2 Tbps forwarding pipe. With a 17 B flow-state entry (*i.e.*, a 5-tuple + action), as in a Layer-4 load balancer, the memory requirement becomes 6.5 GB, which go beyond the stateful memory that is available on today’s ASIC chips.

In this work, we aim at designing a stateful per-flow packet processor system that satisfies the following requirements:

- **Expressiveness**, by supporting a variety of complex stateful logic (*e.g.*, load balancers, packet schedulers).
- **High Throughput**, by achieving superior performance compared to existing expressive designs.
- **Dynamicity**, by supporting very frequent modifications to its stateful data structures.
- **Cost Effectiveness**, by reducing the costs and power consumption for operating this system.

Building a system that supports the above requirements is highly challenging. The expressiveness requirement requires a system to rely (at least to some degree) on general-purpose CPUs or FPGAs. We distinguish between two types of systems that require external resources:

- Systems that use **dedicated** external devices to realize complex NFs. An example within the first category is Tiara [46], a clever load balancer system that reroutes packets from a switch to 16 ports that are connected to FPGAs performing per-packet load balancer calculations. While such solutions are expressive, they are not cost-effective. Half of the devices connected to a 32-port programmable switch are used exclusively to perform stateful packet processing operations.

This reasoning motivates the next type of approaches.

- Systems that rely on **shared** external devices whose resources are primarily used for running customers' applications. Such systems embrace emerging disaggregation paradigms in which applications runs on resources that are combined together on demand. As an example, TEA [21] is the first system to efficiently enlarge the memory of the switch by cleverly crafting RDMA messages to access remote memory on shared CPU-based servers. TEA exploits the well-known large amount of spare of bandwidth and memory resources in datacenters [23]. This design allows operators to make better utilization of the resources available on an external general-purpose server: customers' applications run on general-purpose servers and any spare bandwidth and memory resources are used by the switch to store all the per-flow connection states that are required to process terabits of traffic. Unfortunately, as we show in our motivation section, TEA cannot support expressive network functions, as only the state is stored on external servers while the forwarding rules are applied on the ASIC switch, which does not support advanced logic.

In this work, we present RIBOSOME, a system that is expressive, flexible, cost effective, and achieves high-throughput packets processing. RIBOSOME relies on two fundamental observations. First, in a large fraction of stateful per-flow network functions the bottleneck is the bandwidth between the switch and the packet processor. For example, a load balancer saturates a 100Gbps interface with just 3 CPU cores on a real-world trace [12]. Second, many network functions do not need to analyze the entire packet but only the relatively small portion of a packet containing its headers.¹ To put things into perspective, a load balancer that operates on a 5-tuple (13 bytes) field, would only require receiving 13 B per packet instead of potentially 1.5 KB full size packets.

RIBOSOME relies on dedicated external packet processors to process packet headers while storing packet payloads on shared general-purpose servers without any CPU intervention (*i.e.*, using RDMA technology). More specifically, we leverage the advanced capabilities of emerging high-speed programmable switches to receive packets, split them into headers and payloads, and reconstruct them after the NF processor has updated their headers or re-schedule their transmission. By only processing packet headers, we overcome the bandwidth bottleneck at the dedicated devices, which allows us to process significantly higher numbers of packets on the same dedicated machine. As all data structures are handled by CPUs, we support high numbers of modifications to these data structures.

We motivate this design approach with the following observation: storing & fetching payloads are two operations that only require simple support for writing & reading on

¹We do not claim novelty for this observation but rather for the novel trade-off achieved by the design of our packet processing architecture and our fine-grained evaluation.

a memory. These memory operations are general, making it attractive to offload the storage & fetching of payloads on shared memory resources (*e.g.*, RDMA). Using shared resources to store payloads allow operators to make more efficient utilization of the memory resources existing in a network (such as a datacenter). We then rely on dedicated resources for processing packet headers. In this case, the rationale is that the performance achievable by a stateful network functions highly depends on temporal and spatial factors (*e.g.*, high cache-locality), and is therefore less suitable to be executed on shared resources. Finally, RIBOSOME brings benefits when an NF only needs to inspect a small part of a packet, *e.g.*, a load balancer. RIBOSOME does not bring benefits when the NF requires access to the entire packet (*e.g.*, a deep packet inspection function).

We implement RIBOSOME on an ASIC programmable switch, with FastClick [1] as the NF packet processor, and RDMA to store payloads on other servers. We evaluate RIBOSOME using an empirically-derived multi-100G traffic trace. Our micro-benchmarks show that a general-purpose server processes 70 Mpps on a single server, which would correspond to 560 Gbps of traffic with 1KB average packet size. Based on this estimate, we observe that one would need only three 100G ports on the programmable switch to process 1.6 Tbps of traffic (whereas systems like Tiara would need 16 ports).

We also evaluate the entire system using 4 RDMA servers and a single 100-Gbps dedicated server to process 300 Gbps of traffic. Our results show that the bandwidth requirements at the dedicated server are merely 20 Gbps.

To summarize, our contributions are:

- We propose a new disaggregation-based architecture to circumvent the inherent constraints of high-speed ASIC switches both in terms of logic and memory. We design a system to perform stateful packet processing that carefully splits operations between dedicated and shared resources, where headers are processed by dedicated servers while payloads are stored on shared resources.
- We present the first programmable buffer abstraction that is suitable for Tbps NF packet processing.
- We make the observation that today's deployment of NFs onto general-purpose CPUs is severely bottlenecked by the server bandwidth, thus motivating the splitting of the packets into headers and payloads.
- We demonstrate a single server processes up to 70 M small-size packets per second and the bottleneck moves onto the PCIe. With 3 servers, one could process 210 M packets per second, which is equivalent to roughly 1.6 Tbps of 1KB-size packets. We discuss future optimizations to overcome this limit with future-available hardware.
- We demonstrate in a small testbed that RIBOSOME processes 300 Gbps using a single dedicated NF processor, whose bandwidth requirement is just 20 Gbps.
- We demonstrate a $2.2\times$ speedup over the state of the art for

running complex packet schedulers [11], on similar server hardware. By doing so, we show that we have fundamentally pushed the performance barrier achievable with a combination of a programmable switch and commodity servers.

- We release all our P4 and FastClick code for running RIBOSOME including a high-speed implementation of RDMA on the Tofino programmable switch [40].

2 Motivation

We start this section by quantifying the memory and flow-table update requirements of general ASIC switches. Based on an analysis of real-world traffic traces, we posit that today’s (but also next-generation) ASIC switches do not have enough memory to support stateful per-flow NFs. We then quantify and discuss the limitations of the state-of-the-art systems using dedicated resources (*i.e.*, PayloadPark [13] and Tiara) as well as shared resources (*i.e.*, TEA [21]).

ASIC switches have constrained memory. Several existing approaches, such as SilkRoad [31], Cheetah [3] and SwiSh [47], propose to store the entire state required to operate a specific NF entirely on the memory available on the chip of an ASIC switch. However, the amount of memory available to store per-flow state on existing high-speed ASIC chips is a renowned constrained resource that may not be sufficient for NF applications that handle very large amounts of flows. We run some back-of-the-envelope calculations to upper bound the amount of state that could potentially be stored on an ASIC using SRAM technology. Assuming one could use the entire chip area for SRAM memory (*i.e.*, no I/O, no buffers), an 826 mm² chip using 7nm technology would only store at most 5GB of flow state in SRAM [7]. We show in this section that this amount of memory would suffice to only store ~10% of the state required on a multi-terabit per second switch. In practice, the amount of memory is below this estimate as typically I/O and buffers occupy roughly 50% of the chip area and some memory is used to implement the packet processing logic. For example, a 16-nanometer high-speed ASIC switch contains 1.5-15.4MB per terabit of forwardable traffic (*i.e.*, 10-100MB of SRAM on a 6.5 Tbps ASIC chip) [14, 29, 31].

To understand the implications of potential future trends on the feasibility of storing per-flow state on ASIC chips, we analyze CAIDA traces in the 2013 – 2019 period for the NYC and CHI monitored links, for which there are publicly available statistics [6].² The throughput for these traces ranges from 2 Gbps to 6.5 Gbps. Each trace contains the number of IPv4 and IPv6 forwarded packets, their mean packet size, the trace duration and the flows per second. The flow per second field represents the number of distinct flows in the trace divided by the duration of the trace.³ We define a flow to

²We select this type of traces as we do not have access to datacenter traces at per-packet granularity (*i.e.*, no sampling).

³We verified it by taking the Caida-nyc 2018-03-15 trace, counting the

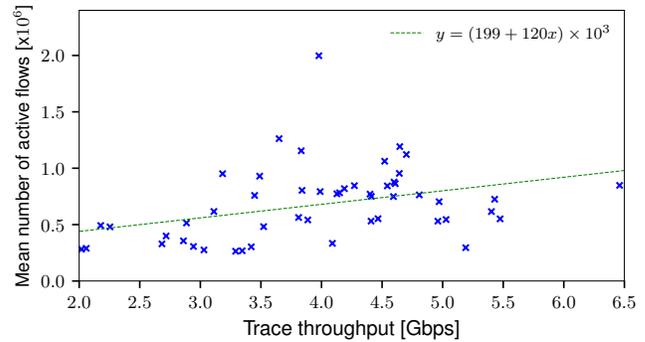

Figure 1: Number of active flows in historical CAIDA traces from 2013 – 2019 from Chicago and NYC.

be *active* if that flow has sent a packet in the last 30 seconds.⁴ If a flow is active, it means the stateful processor must keep state for that flow. In the following analysis, we assume that one needs to deploy a basic load balancer that stores 17 B for each single flow (*e.g.*, 13 B for the 5-tuple and 4 B to store the private IP destination address). We define the *mean number of active flows* in a trace as the number of active flows divided by the duration in seconds of the trace multiplied by 30 (*i.e.*, the threshold to determine if a flow is active). In Fig. 1, we report the mean number of active flows (*y*-axis in millions, blue crosses) with respect to the trace throughput (*x*-axis) for each single trace in the studied period. We first observe that 3 out of 53 traces already require more memory resources than those available on a real-world pipe of a high-speed ASIC, *i.e.*, the traces require above 20 MB of memory as they contain more than 1.1 M active flows.⁵ This means that storing state for a real-world trace recorded at roughly 10 Gbps would require roughly 20% of the existing memory on a 16-nm ASIC switch chip (which is in the 10-100 MB range).

We also plot a linear regression (green dashed line) that we use to estimate the memory requirements for a switch transporting terabits of traffic (such as recent 25.6 Tbps switches [5, 18]).⁶ The steepness of the regression line is 120 K active flows per Gbps of traffic. We estimate the mean number of active flows on a 25.6 Tbps switch to be 3 072 M, which would require 52 GB of memory to store the corresponding state for a load balancer (*i.e.*, 17B per flow). This memory requirement is 300× higher than what is available on 7nm high-speed ASIC switches today [18] and roughly 10x the maximum amount of SRAM memory realizable on a

number of flows, and dividing by the trace duration, obtaining the same number.

⁴We use a 30-second threshold based on real-world timeouts used in the Facebook Katran load balancer [9].

⁵This is a lower bound since we take the mean of the active flows but peaks with higher number of active flows are likely to arise in the traces.

⁶The assumption may not be perfectly accurate but we do not have access to a datacenter trace at terabits per second speed and *per-packet* granularity (*i.e.*, no sampling).

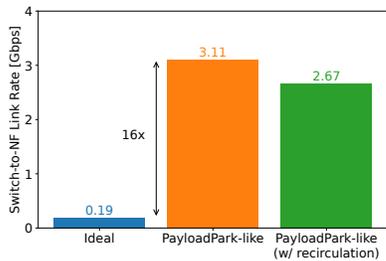

Figure 2: Ideal vs PayloadPark-like on CAIDA trace.

825mm² ASIC chip. Finally, we also note the memory on the pipe should be used for implementing other functionalities.

ASIC switches cannot support frequent per-flow state insertions from the control plane. Today’s ASIC chips support a specific amount of modifications to their flow-tables through the control plane [3,31]. For example, a 16-nm 3.2 Tbps ASIC switch supports ~100K flow-table entry modifications per second only [46]. To the best of our knowledge, this is the highest (publicly available) table update frequency achieved by a 16-nm ASIC switch through the control plane and we are not aware of public measurement studies showing such high-frequency insertions entirely in the faster data-plane of a multi-Tbps ASIC switch. Based on our analysis of the aforementioned CAIDA packet trace, we observe that the number of rule modifications is lower bounded by the amount of flows per second. Based on a similar regression, we obtain that the number of flow insertions per second grows by 4 K per Gbps of traffic. When we use this linear regression to estimate the amount of flow insertions on a 3.2Tbps ASIC switch, we obtain 12.8 M per-flow insertions per second, which is roughly 100× higher than the aforementioned 100 K flow-table modifications using an ASIC switch.

Now that we have quantified the amount of memory resources required to store the per-flow state of an NF, we discuss advantages and limitations of the three main state-of-the-art approaches to implement NF processors on top of programmable network hardware. We focus on the work that closely relates to our system and we defer the reader to Sect. 8 for a broad discussion of the existing related work.

NIC-based approaches that split packets are bottlenecked by the NIC speed. The *nicmem* system [35] is an NF accelerator that resides completely on a general-purpose server and does not involve any programmable switch. A packet arriving at the Network Interface Card (NIC) of a *nicmem*-equipped server is split into a header that is sent to the CPU cores and a payload that is stored on the small NIC memory. This approach comes with several benefits: higher hit cache ratio as payloads do not pollute CPU caches and 80% higher packet processing throughput. The inherent limitation of this work is that the throughput of the NF server is limited by the NIC speed (e.g., a 100 G NIC can only process 10 M packets with size 1.25 KB). To process 800 Gbps of traffic, *nicmem* must connect to 8×100G ports on the switch. In this paper, we

argue that an NF server should only receive the relevant bits (e.g., the packet headers). This approach reduces bandwidth overheads toward external NF servers, reducing the number of ports on the switch that must be connected to dedicated resources. The remaining ports can be used for connecting the switch to other shared resources (where the payloads could be buffered) or devices. Moreover, traditional server- or NIC-based approaches (including *nicmem*) force the storage of the payload to be performed on the same machine that processes the header. Conversely, RIBOSOME decouples these two operations and it leverages spare memory resources in the network for performing the simpler payload storage.

Storing payloads at the switch does not mitigate bandwidth overheads. The *PayloadPark* [13] system also splits headers from payload but performs this operation directly on a programmable switch instead of the general-purpose server. The benefits of splitting a packet at the programmable switch instead of doing that at the server (as in *nicmem*) is that one can forward just the headers to the servers and store the payloads on the programmable switch. To implement a load balancer, a server could receive just 13 B from each packet (i.e., the 5-tuple), thus potentially processing almost one billion packet headers per second through a 100 G interface. Unfortunately, *PayloadPark* suffers from an inherent constraint of high-speed ASIC devices. First, it is not possible to store the entire payload of a packet into the switch memory in a programmable manner.⁷ Consequently, *PayloadPark* only stores the first 160 (352) bytes of payload for each packet without (with) recirculating it, thus letting most of the payloads still going to the external server.

To quantify the reduced performance gains, we have analyzed again the aforementioned CAIDA trace for three scenarios: *i*) when only a 54-byte header is sent to an external NF server, which we call *Ideal*, *ii*) when only 160 bytes of payloads are removed from the packet sent to the external NF server, which we call *PayloadPark-like*, and *iii*) a *PayloadPark-like* system that recirculates packets to store 352 bytes. Fig. 2 shows the link rate in Gbps between the switch and the external NF server (y-axis) for the three aforementioned systems. The ideal system requires 16× and 14× less bandwidth than the *PayloadPark-like* system with and without packet recirculation. We note that producing ASICs that would store larger parts of the packet in a programmatic manner would become significantly more complex and expensive [4] and are therefore neither available today nor in the near future.

Desiderata: large external memories shared with other applications. The goal of our work is to overcome the inherent limitations of ASIC switches and find an alternative design that keeps bandwidth requirements as close as possible to the ideal bar in Fig. 2. Since the memory on a switch cannot be used to store payloads in a programmatic manner, we fo-

⁷The payload is temporarily stored by the switch while the headers are being processed.

cus our attention to leveraging external *unused* resources that are shared with customers' applications. As storing payloads only requires storing information into memory (without any complex logic), we focus our attention onto RDMA technology to store and retrieve payloads between a programmable switch and a set of external servers that are deployed to run customers' applications. Leveraging RDMA from a Tofino switch is not a new idea per-se as it has been already explored in TEA [21], a network function accelerator, and Dart [24], a monitoring system. We now discuss existing limitations of TEA, which will motivate our design. We note that some limitations of TEA are due to its design while some others are related to the functionalities that are today available on ASIC switches.

TEA cannot run complex NF logic such as packet schedulers. TEA [21] is the first framework to implement NFs using a programmable switch and leveraging additional RDMA-accessible memory to store per-flow state. In TEA, a packet is forwarded from the switch to the RDMA server that stores the rule used to process the packet. Both the packet and the rule are forwarded back to the switch, where the rule is applied to the packet. Unfortunately, this design does not support more complex per-flow network functions (*e.g.*, advanced load balancers, batch-based NF processing, etc.) since the only logic that can be performed in TEA is the one that is supported by the switch. For example, TEA cannot support advanced per-flow packet scheduler such as Reframer [11], where packets arriving at an NF are buffered for a few tens of microseconds and are then reordered to increase their per-flow spatial locality (*i.e.*, placing packets belonging to the same flow close to each other). The reason why TEA cannot support such NFs is that TEA can only "buffer" a single packet while reading its rule but it cannot buffer arbitrary sets of packets in a programmatic manner. We are not aware of any existing ASIC switch supporting such programmable buffers for packets.

TEA cannot handle per-flow rule insertions at high speed. When a new packet of a flow arrives at the switch, TEA states that "since it takes some time to complete an insertion operation, new entries are first inserted in to an SRAM stash". However, the insertions into the Stash are performed through the control-plane, which is renown to take up to 1ms to perform insertions [31].⁸ In any case, the limit of flow-table insertions per second derived in Tiara [46] also applies to any table modification on TEA, which severely undermines the ability of TEA to perform a large number of flow-table insertions per second.

In the remaining sections, we address the following question:

"Can we design an NF packet processor that retains the high-throughput of an ASIC switch while supporting dynamic per-flow stateful network functions in a cost-effective manner?"

⁸We do not have access to the original P4 code of TEA.

3 System Design

We now present an overview of RIBOSOME, a NF accelerator for stateful per-flow packet processing that relies on a novel design to overcome the limitations of existing architectures based on programmable switches and external devices.

Design space. We first divide the design space into *i)* systems built entirely *within a switch* and *ii)* systems using *external devices*. In the first category, realizing stateful packet processing entirely using ASIC-based switches is out of reach because of both memory limitations and limited modifications per second to the stateful data structures. In the second category (*i.e.*, systems with external devices), we further divide into two categories: *a)* systems that only use external *dedicated resources* and *b)* systems that also rely on external *shared resources*. In the following, we discuss these two types of systems and we refer the reader to Table 1 for a summary of the architectural and communication overhead differences

The table covers three types of operations (*i.e.*, the processing of the header, the storage of the packet, and the splitting and merging of the packet with the header (if any)) as well as the communication overheads in terms of bits and number of packets transmitted to the NF and the shared servers for each incoming packet at the switch.

Delegating all stateful packet processing functionalities to *dedicated* external FPGAs or CPUs (*e.g.*, Tiara [46], nicmem [35]) results in a high utilization of the switch ports to interconnect the external dedicated devices (*i.e.*, to process 800 Gbps of traffic, 8x100G ports on a switch must be connected to dedicated devices). PayloadPark [13] reduces bandwidth requirements toward externally dedicated devices. However, it only saves 1280 bits of bandwidth per transmitted packet, which only slightly reduces the number of ports on the switch that are connected to dedicated devices when the average packet size of a trace is in the 1 KB range.

Leveraging *shared* resources mitigates these overheads as ports on a switch can be connected to devices running other types of computations. Some recent work (*e.g.*, TEA [21]) delegates the storage of payloads on shared memory while relying on the switch to run the stateful packet processing logic. However, the logic implementable on an ASIC switch is limited (*e.g.*, no batch-based stateful processing as in packet schedulers or rate limiters). Moreover, it is difficult to use CPU-bypass technologies like RDMA to insert per-flow state inside the external server memory because RDMA only supports basic primitives (*e.g.*, Read, Write) and cannot be easily used to perform insertions at high-frequency [37]. Striking the correct balance in the usage of dedicated and shared resources and the architectural choices is the main goal of this section.
