Reconfiguring the Chains. If a Pegasus rack fails, it can be replaced using the standard chain replication protocol [66]. When the failure is noted, the configuration service is notified to remove the failed rack from all chains it participated in, and to add a replacement. This approach leverages the correctness of the underlying chain replication protocol, treating the Pegasus rack as functionally equivalent to a single replica.

If a system reconfiguration changes the identity of the head rack for a key range, subsequent WRITES will get version numbers from a different head switch. If the new head rack was present in the old chain, these version numbers will necessarily be greater than any previously completed writes. If a rack is added to a chain as the head, the `ver_next` in the rack's switch must first be updated to be greater than or equal to the other switches in the chain.

If an individual server fails, a safe solution is to treat its entire rack as faulty and replace it accordingly. While correct, this approach is obviously inefficient. Pegasus has an optimized reconfiguration protocol (omitted due to space constraints) that only moves data that resided on the failed server.

8 Switch Implementation

The coherence directory (§6) plays a central role in Pegasus: it tracks popular objects and their replica sets; it distributes requests for load balancing; it implements the version-based coherence protocol; and it updates the set of replicated objects based on dynamic workload information. In this section, we detail the implementation of the Pegasus coherence directory in the data plane of a programmable switch.

8.1 Switch Dataplane Implementation

Figure 4 shows the schematic of the data plane design for the coherence directory. When a Pegasus packet enters the switch ingress pipeline, a lookup table checks if it refers to a replicated object. The packet then traverses a version number engine and a replica set directory, which implement the version-based coherence protocol (Algorithms 1 and 2). For request packets, one or more servers are selected from the replica set directory, and the packet's destination is updated by an address rewrite table. Finally, all Pegasus packets go through a statistics engine before being routed to the egress pipeline.

We leverage two types of stateful memory primitives available on programmable switching ASICs (such as Barefoot's Tofino [63]) to construct the directory: exact-match lookup tables and register arrays. A lookup table matches fields in the packet header and performs simple actions such as arithmetics, header rewrites, and metadata manipulations. Lookup tables, however, can only be updated from the control plane. Register arrays, on the other hand, are accessed by an *index* and can be read and updated at line rate in the data plane. The rest of the section details the design of each component.

Replicated Keys Lookup Table When adding replicated keys (§6.3), the controller installs its `KEYHASH` in an exact-match lookup table. The table only needs to maintain $O(n \log n)$ entries, where n is the number of servers in the rack. The switch matches each Pegasus header's `KEYHASH` with entries in the table. If there is a match, the index number associated with the entry is stored in the packet metadata to select the corresponding replicated key in later stages.

Version Number Engine We use two register arrays to build the version number engine, as shown in Figure 5. The first register array contains a single element – the next version number. If the packet is a WRITE request, the version number in the register is incremented and the switch writes the version into the packet header. The second register array stores the completed version number for each replicated key, and uses numeric ALUs to compare and update the version number (per Algorithm 2). The comparison result is passed to the next stage.

Replica Set Directory As shown in Figure 6, we build the replica set directory using three register arrays to store: (i) the size of each replica set, (ii) a bitmap indicating which servers are currently in each replica set, and (iii) a list of server IDs in each set. When choosing replicas for Pegasus READ requests,

Figure 5: Design of the switch version number engine. One register array with a single element tracks the next version number. The register is incremented on each WRITE. A second register array stores the latest completed version number for each replicated object. Numeric ALUs compare values in this array with version numbers in the reply headers.

the replica set size is read and fed into the selection logic unit to calculate an index for locating the server ID in the list (the selection logic can pick any servers for WRITE requests). Note that we collapse the server ID list of all replicated keys into a single register array, leveraging the fact that each key can be replicated on at most n servers. Therefore, to locate the i th replica for the k th key, the index is calculated as $k * n + i$ (for brevity, we will use relative indices, i.e. i in the formula, for the remaining discussion).

If the version number engine indicates that the Pegasus reply has a higher version number, the size of the replica set is reset to one, and the replica set bitmap and server ID list are reset to contain only the server ID in the reply packet. If the version number engine indicates that the version numbers are equal, the switch uses the bitmap to check if the server is already in the replica set. If not, it updates the bitmap, increments the replica set size, and appends the server ID to the end of the server list.

To add a new replicated key, the controller sets the replica set size to one, and the bitmap and server ID list to contain only the home server.

Address Rewrite Table The address rewrite table maps server IDs to the corresponding IP addresses and ports, and is kept up to date by the controller as servers are added. When the replica set directory chooses a single server as the destination, the address rewrite table updates the headers accordingly. If the replica set directory selects multiple servers (for a WRITE request), we use the packet replication engine on the switch to forward the packet to the corresponding multicast group.

Statistics Engine To detect the most popular $O(n \log n)$ keys in the workload, we construct a statistics engine to track the access rate of each key. For replicated keys, the switch maintains counters in a register array. This approach is obviously not feasible for the vast number of non-popular keys. The statistics engine instead samples requests for unreplicated keys, forwarding them to the switch CPU. A dedicated pro-

Figure 6: Design of the switch replica set directory. The directory uses three register arrays: one array stores the size of each replica set; another array maintains a bitmap for each set, tracking which servers are currently in the set; the last array stores a list of server IDs in each set.

gram on the switch CPU constructs an access frequency table from sampled packets. The sampling component serves two purposes: it reduces the traffic to the switch CPU and it functions as a high-pass filter to filter out keys with low access frequency. The controller scans both statistics tables to determine when newly popular keys need to be replicated or replication stopped for existing keys, and makes these changes following the protocol in §6.3.

Two separate register arrays track the READ and WRITE count for each replicated key. The controller uses these to compute the read/write ratio, which the selection logic in the replica set directory uses to decide how many replicas to use for each WRITE request.

9 Evaluation

Our Pegasus implementation includes switch data and control planes, a Pegasus controller, and an in-memory key-value store. The switch data plane is implemented in P4 [7] and runs on a Barefoot Tofino programmable switch ASIC [63]. The Pegasus controller is written in Python. It reads and updates the switch data plane through Thrift APIs [62] generated by the P4 SDE. The key-value store client and server are implemented in C++ with Intel DPDK [15] for optimized I/O performance.

Our testbed consists of 28 nodes with dual 2.2 GHz Intel Xeon Silver 4114 processors (20 total cores) and 48 GB RAM running Ubuntu Linux 18.04. These are connected to an Arista 7170-64S (Barefoot Tofino-based) programmable switch using Mellanox ConnectX-4 25 Gbit NICs. 16 nodes act as key-value servers and 12 generate client load.

To evaluate the effectiveness of Pegasus under realistic workloads, we generated load using concurrent open-loop clients, with inter-arrival time following a Poisson distribution. The total key space consists of one million randomly generated keys, and client requests chose keys following either a uniform distribution or a skewed (Zipf) distribution.

We compared Pegasus against two other load balancing solutions: a conventional static consistent hashing scheme for partitioning the key space, and NetCache [29]. The consis-

Figure 7: Maximum throughput achievable subject to a 99% latency SLO of 50 μ s. Pegasus successfully rebalances request load, maintaining similar performance levels for uniform and skewed workloads.

tent hashing scheme assigns 16 virtual nodes to each storage server to improve load balancing. We additionally evaluated a version of Pegasus that supports at-most-once semantics (Pegasus-AMO, as described in §6.4). To allow a comparison with NetCache, we generally limit ourselves to 64-byte keys and 128-byte values, as this is the largest object value size it can support. NetCache reserves space for up to 10,000 128-byte values in the switch data plane, consuming a significant portion of the switch memory. In contrast, Pegasus consumes less than 3.5% of the total switch SRAM. At larger key and value sizes, Pegasus maintains similar performance and memory usage, whereas NetCache cannot run at all.

9.1 Impact of Skew

To test and compare the performance of Pegasus under a skewed workload, we measured the maximum throughput of all four systems subject to a 99%-latency SLO. We somewhat arbitrarily set the SLO to $5\times$ of the median unloaded latency (we have seen similar results with different SLOs). Figure 7 shows system throughput under increasing workload skew with read-only requests. Pegasus maintains the same throughput level even as the workload varies from uniform to high to extreme skew (Zipf $\alpha = 0.9$ –1.2),¹ demonstrating its effectiveness in balancing load under highly skewed access patterns. Since the workload is read-only, Pegasus with at-most-once support (Pegasus-AMO) has the exact same performance. In contrast, throughput of the consistent hashing system drops to as low as 10% under more skewed workloads. At $\alpha = 1.2$, Pegasus achieves a $10\times$ throughput improvement over consistent hashing. NetCache provides similar load balancing benefits. In fact, its throughput *increases* with skew, outperforming Pegasus. This is because requests for the cached keys are processed directly by the switch, not the storage servers, albeit at the cost of significantly higher switch resource overhead.

¹ Although $\alpha = 1.2$ is a very high skew level, some major storage systems reach or exceed this level of skew. For example, more than half of Twitter’s in-memory cache workloads can be modeled as Zipf distributions with $\alpha > 1.2$ [67], as can Alibaba’s key-value store workload during peak usage periods [10].

Figure 8: Throughput vs. write ratio. Pegasus maintains its load balancing advantage across the spectrum of write ratios, whereas NetCache suffers a significant penalty with even 10% writes.

9.2 Read/Write Ratio

Pegasus targets not only read-intensive workloads, but also write-intensive and read-write mixed workloads. Figure 8 shows the maximum throughput subject to a 99%-latency SLO of 50 μ s when running a highly skewed workload (Zipf-1.2), with varying write ratio. The Pegasus coherence protocol allows write requests to be processed by any storage server while providing strong consistency, so Pegasus can load balance both read and write requests. As a result, Pegasus is able to maintain a high throughput level, regardless of the write ratio. Even with at-most-once semantics enforced, Pegasus-AMO performs equally well for all write ratios, by leveraging the randomness in requests’ REQID (§6.4) to distribute write requests to all servers. This is in contrast to NetCache, which can only balance read-intensive workloads; it requires storage servers to handle writes. As a result, NetCache’s throughput drops rapidly as the write ratio increases, approaching the same level as static consistent hashing. Even when only 10% of requests are writes, its throughput drops by more than 80%. Its ability to balance load is eliminated entirely for write-intensive workloads. In contrast, Pegasus maintains its high throughput even for write-intensive workloads, achieving as much as $11.8\times$ the throughput as NetCache. Note that Pegasus’s throughput does drop with higher write ratio. This is due to the increasing write contention and cache invalidation on the storage servers.

9.3 Scalability

To evaluate the scalability of Pegasus, we measured the maximum throughput subject to a 99%-latency SLO under a skewed workload (Zipf 1.2) with increasing number of storage servers, and compared it against the consistent hashing system. As shown in Figure 9, Pegasus scales nearly perfectly as the number of servers increases. On the other hand, throughput of consistent hashing stops scaling after two servers: due to severe load imbalance, the overloaded server quickly becomes the bottleneck of the entire system. Adding more servers thus does not further increase the overall throughput.

We also evaluate the performance of an end-host coherence directory implementation, using Pegasus’s protocol with

Figure 9: Scalability. Pegasus scales nearly linearly up to 16 servers, as no individual server becomes a bottleneck, even with a skewed workload.

Figure 10: Throughput vs. object size. Pegasus provides effective load balancing across a wide range of object sizes. The performance of a traditional design under a uniform workload is shown as a baseline.

a server in place of the switch. Because the directory needs to process twice as many packets as the storage servers for each client request (both requests and replies), this implementation is unable to keep up with even a single server – highlighting the importance of using an accelerated platform like a switching ASIC as the coherence directory.

9.4 Object Sizes

To test if Pegasus can handle different object sizes, we varied the value size from 64 bytes to 1 KB and measured the maximum throughput of Pegasus subject to a 99%-latency SLO under the same skewed workload. We additionally plot the throughput of the consistent hashing system under a uniform workload. Figure 10 shows that Pegasus is equally efficient in load balancing for both small and large objects. Its throughput under a highly skewed workload is virtually equivalent to that of consistent hashing under a zero-skewed workload. Note that the throughput in the figure uses number of operations per second (which should naturally decrease with larger object size), not bits per second.

9.5 Impact of Number of Replicated Keys

Keeping the size of coherence directory small is crucial as switches are highly resource constrained. Our analysis (§4.5) shows that Pegasus only needs to replicate the $O(n \log n)$ most popular keys to balance load under arbitrary access patterns.

Figure 11: Throughput vs. number of replicated keys. For these workloads, only 8–16 replicated keys are needed to achieve most of Pegasus’s load balancing benefit.

What constant factors are hidden here? For adversarial workloads, they are not high (e.g., $8n \log n$) [17]. We show in Figure 11 that they are even lower for our non-adversarial Zipf workload. Specifically, Pegasus only needs to replicate 8–16 keys to achieve its throughput benefit – significantly *less* than $n \log n$. While these numbers would be expected to increase with more servers, they easily remain within the capacity of the switch’s register memory.

9.6 Server Selection Policies

We have implemented two policies for selecting servers for replicated objects: random and weighted round-robin. We evaluated both policies: Figure 12 shows their maximum throughput under different workloads.

Both policies are quite effective at distributing load for uniform and highly skewed workloads when we use a set of dedicated, homogeneous servers with the same load capacity. The random policy begins to fall short, however, when some servers are more capable than others, or background process sap their available capacity. We evaluated this by reducing the processing capacity of half of the servers by 50%. As shown in Figure 12, throughput with the random policy drops 50% as the slower servers become the performance bottleneck, even though the faster servers still have spare processing capacity. By collecting load information from the servers and setting the weights accordingly, the weighted round-robin policy allows both the slower and faster servers to fully utilize their processing capacity.

9.7 Handling Dynamic Workloads

Finally, we evaluated Pegasus under dynamic workloads with changing key popularity, similar to SwitchKV [41] and Net-Cache [29]. Specifically, we selected 100 keys every 10 seconds and changed their popularity rankings in the Zipf distribution. Here we consider two dynamic patterns:

- **Hot-in.** The 100 coldest keys in the popularity ranking are promoted to the top of the list, immediately turning them into the hottest objects. This workload represents extreme fluctuations in object popularities, which we hypothesize is rare in real world workloads.

Figure 12: Comparing Pegasus server selection policies; throughput with a 99% latency SLO of 50 μ s. A random selection policy provides good statistical load balancing when server capacity is uniform; Pegasus’s load-aware policy outperforms it otherwise.

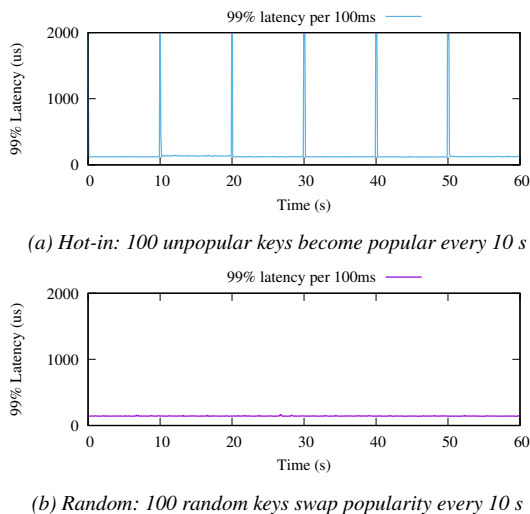

Figure 13: Dynamic workloads. Pegasus reacts quickly to changes in object popularity.

- **Random.** We randomly select 100 keys from the 10,000 hottest keys, and swap their popularities with another set of randomly chosen keys. As the most popular keys are less likely to be changed, this dynamism represents a more moderate change to object popularity.

We evaluate Pegasus for these workloads with a Zipf-1.2 workload and 80% utilization.

Hot-in. Sudden changes to the popularity of *all* hottest keys cause the tail latency to increase. Pegasus, however, is able to immediately detect the popularity changes and updates the in-switch coherence directory. A workload change this drastic is unlikely, but Pegasus nevertheless reacts quickly. Within 100 ms, tail latency observed by clients returns to normal.

Random. Under a *random* dynamic pattern, only a moderate number of the most popular keys are changed. Pegasus thus can continue balancing load for the unaffected keys, and leveraging load-aware scheduling to avoid overloading the servers. No change in 99% end-to-end latency is observed.

Figure 14: Throughput of single-rack vs. multi-rack configuration during a rack failure. After the failure ($t = 0$), the multi-rack configuration continues processing requests but loses some capacity.

9.8 Multi-Rack

To test a multi-rack configuration, we use a larger (but slower) cluster with 72 servers with dual 1.8 GHz Intel Xeon E5-2450 processors. These are organized into two racks, each with 24 storage servers and one Pegasus switch, plus a third rack of client machines. Per-node performance is significantly lower, largely because these servers use 10 Gbit NICs that do not support DPDK.

The two 24-server racks are configured into a 2-replica configuration: each rack acts as the head of the chain for half of the keys and the tail for the other half. Because both replicas need to handle WRITES but only the tail processes READS, adding a second rack not only provides fault tolerance, it doubles read throughput; write throughput remains unchanged.

Figure 14 demonstrates this by comparing a single-rack and two-rack configurations, running a read-only workload with Zipf $\alpha = 1.2$; the two-rack configuration has $1.7\times$ the throughput. At $t = 0$, one rack fails. The two-rack deployment is able to continue processing at half of its speed using the remaining rack. The single-rack deployment, of course, becomes entirely unavailable.

10 Related Work

Load Balancing. Load imbalance in large-scale key-value stores has been addressed by past systems in three ways. Consistent hashing [30] and virtual nodes [12] are widely used, but do not perform well with changing workloads. Solutions based on migration [11, 32, 61] and randomness [49] can be used to balance dynamic workloads, but these techniques introduce additional overheads and have limited ability to handle high skew. EC-Cache [57] balances load using erasure coding to split and replicate values, but works best for large keys in data-intensive clusters. SwitchKV [41] balances load across a flash-based storage layer using switches to route to an in-memory caching layer; it cannot react fast enough to changing load when the storage layer is in memory. NetCache [29] caches values directly in programmable dataplane switches; while this provides excellent throughput and latency, value sizes are limited by switch hardware constraints.

Another class of load balancers are designed to balance

layer 4 traffic, such as HTTP, across a dynamic set of backend servers. These systems may be implemented as clusters of servers, as in Ananta [54], Beamer [52], and Maglev [16]; or using switches, as in SilkRoad [47] or Duet [20]. These systems are designed to balance long-lived flows across servers, whereas Pegasus balances load of individual request packets. Prism [23] provides a way to perform request-level load balancing by migrating TCP and TLS connections, an approach that could be useful for Pegasus as an alternative to its UDP-based protocol.

Several new systems use programmable switches for application-specific load balancing protocols. R2P2 [33] load balances RPCs for stateless services where any request can be handled by any server. Harmonia [69] allows optimized forwarding for read requests in replicated systems by tracking when concurrent writes are in progress.

Directory-Based Coherence. Directory-based coherence protocols have been used in a variety of shared-memory multiprocessors and distributed shared memory systems [4, 19, 22, 31, 34, 36, 37, 40]. These systems can be thought of as key-value stores with fixed-size keys (addresses) and values (cache lines or pages). Directory protocols have been used in general key-value stores as well; IncBricks [44] implements an in-network key-value store using a distributed directory to cache values in network processors attached to datacenter switches. Keys have a designated home node that is involved in writes and coherence operations, limiting load-balancing opportunities for write-intensive workloads. Pegasus stores keys and values only in servers, and its coherence protocol allows any storage server to handle write requests, so Pegasus can load-balance both read- and write-intensive workloads. Both systems can scale beyond a rack and tolerate failures:

IncBricks does so at the individual server level; Pegasus does so at the rack level.

11 Conclusion

With Pegasus, we have demonstrated that programmable switches can improve the load balancing of a storage application. Using our in-network coherence directory protocol, the switch takes over responsibility for placement of the most popular keys. This makes possible new data placement policies that cannot be achieved using traditional methods, such as reassigning the set of replicas on each write or selecting read replicas based on fine-grained load measurements. The end result is that Pegasus increases by $10\times$ the throughput level achievable subject to a latency SLO, compared to a consistent hashing workload. This permits a major reduction in the size of a cluster needed to support a particular workload.

More broadly, we believe that Pegasus provides an example of the class of applications that programmable dataplane switches are well suited for. It takes a classic use case for network devices – load balancing – and extends it to the next level by integrating it with an application-level protocol.

A Artifact Appendix

Abstract

Our artifact includes the following components: 1) P4 source code of the Pegasus switch data plane, 2) Python source code of the Pegasus switch controller, 3) C++ implementation of an in-memory key-value store with Intel DPDK, 4) configuration files and Python/shell scripts for running Pegasus experiments in a cluster, and 5) a TLA+ specification of the Pegasus protocol. The artifact is publicly available at: <https://github.com/NUS-Systems-Lab/pegasus>.

A.1 Artifact check-list

- **Algorithm:** Coherence protocol.
- **Program:** Key-value store, P4 packet processing program.
- **Compilation:** GCC 7.5.0 (Ubuntu 7.5.0-3ubuntu118.04), Barefoot SDE 9.1.1
- **Binary:** Generated from GCC compiler and Barefoot SDE.
- **Run-time environment:** Ubuntu 18.04 LTS (Linux 4.15), Barefoot SDE 9.1.1
- **Hardware:** Dual socket 2.2 GHz Intel Xeon Silver 4114 processors with 20 cores and 48 GB RAM per socket. Mellanox ConnectX-4 25 Gbit NICs. Arista 7170-64S (barefoot Tofino-based) programmable switch.
- **Execution:** Bash and Python scripts.
- **Output:** Throughput. Average, median, 90%, 99% latencies.
- **Experiments:** Experiments as specified in the main paper (§9). Customizable experiment parameters: number of clients and servers, client request rate, read/write ratio, Zipfian coefficient, value size, number of keys, maximum number of replicated objects, and experiment duration.
- **Expected experiment run time:** 10-60 seconds per experiment.
- **Public link:** <https://github.com/NUS-Systems-Lab/pegasus>
- **Code licenses:** MIT license.

A.2 Description

A.2.1 How to access

All source code, configuration files, and scripts are publicly available at: <https://github.com/NUS-Systems-Lab/pegasus>.

A.2.2 Hardware dependencies

The artifact requires a P4 programmable switch (e.g., Barefoot Tofino programmable switch ASIC). The network interface cards on the client and server machines need to support Intel DPDK.

A.2.3 Software dependencies

The artifact has been tested on Ubuntu 18.04 LTS (Linux kernel 4.15). Compiling and running the Pegasus P4 data plane program require the Barefoot SDE (tested with version 9.1.1). Additional software package dependencies:

- libevent
- Intel TBB
- libnuma
- zlib
- DPDK (tested with version 19.11)

- Python Sorted Containers
- Python PyREM

A.2.4 Data sets

Experiments in this artifact expect a text file that contains ASCII keys (one key per line) for the key-value store. We provide a sample keys file, `artifact_eval/keys`, that has one million 64B-keys.

A.3 Installation

First, download or clone the repository. Throughout this document, we will use the following macros:

- `$REPO`: path to the root of the repository
- `$SDE`: path to Barefoot SDE
- `$SDE_INSTALL`: path to Barefoot SDE installation directory

A.3.1 Compiling Client and Server Code

Run `make` in `$REPO`.

A.3.2 Compiling P4 Code

On the target P4 switch:

```
cd $SDE/pkgsrc/p4-build
./configure P4_PATH=$REPO/p4/p4_tofino/pegasus.p4 \
    P4_NAME=pegasus P4_PREFIX=pegasus \
    P4_VERSION=p4-14 P4_FLAGS="--verbose 2" \
    --with-tofino --prefix=$SDE_INSTALL \
    --enable-thrift
make && make install

./configure P4_PATH=$REPO/p4/netcache/one.p4 \
    P4_NAME=netcache P4_PREFIX=netcache \
    P4_VERSION=p4-14 P4_FLAGS="--verbose 2" \
    --with-tofino --prefix=$SDE_INSTALL \
    --enable-thrift
make && make install
```

Note that the location of `p4-build` may depend on the Barefoot SDE version.

A.4 Experiment workflow

A.4.1 P4 Switch

First, start the Pegasus switch daemon on the P4 switch:

```
cd $SDE
./run_switchd.sh -p pegasus
```

Or if running NetCache, run the following:

```
cd $SDE
./run_switchd.sh -p netcache
```

In the switch shell, add and enable all switch ports used by the experiments.

Secondly, modify `$REPO/artifact_eval/pegasus.json` and `$REPO/artifact_eval/netcache.json` with the testbed cluster configuration (refer to `artifact_eval/README.md` for configuration file format).

Thirdly, start the Pegasus switch controller:

```
cd $REPO
./artifact_eval/run_pegasus_controller.sh
```

Or if running NetCache, run the following:

```
cd $REPO
./artifact_eval/run_netcache_controller.sh
```

A.4.2 End-Hosts

First, modify `$REPO/artifact_eval/testbed.config` with the cluster configuration. Refer to `artifact_eval/README.md` for the format of the file.

Secondly, modify the experiment python script `$REPO/artifact_eval/run_experiments.py`. Update `clients` and `servers` with actual host names of the client and server machines.

Lastly, on a machine that has ssh connectivity to all clients and servers, run the following:

```
python2 $REPO/artifact_eval/run_experiments.py
```

A.5 Evaluation and expected result

The experiment python script outputs the following statistics:

- Total throughput

- Average latency
- Median latency
- 90% latency
- 99% latency

Modify `n_client_threads` and `interval` in the experiment script to control the client load. Tune them until getting the maximum throughput with some 99% latency SLO, as reported in the paper.

To evaluate the different workloads and system configurations as specified in §9, vary the following parameters in the experiment script:

- `n_servers`: number of servers used in the experiment
- `node_config`: one of `pegasus`, `netcache`, or `static` (consistent hashing). Note that `pegasus` and `netcache` require running the corresponding P4 switch daemon and controller.
- `alpha`: Zipfian coefficient
- `get_ratio`: percentage of read requests in the workload (0.0 - 1.0)
- `key_type`: key access distribution. Either `unif` (uniform) or `zipf` (Zipfian)
- `value_len`: value size (in bytes)
- `n_keys`: total number of keys

A.6 AE Methodology

Submission, reviewing and badging methodology:

FlightTracker: Consistency across Read-Optimized Online Stores at Facebook

Xiao Shi, Scott Pruett, Kevin Doherty, Jinyu Han,
Dmitri Petrov, Jim Carrig, John Hugg, Nathan Bronson
Facebook, Inc.

Abstract

Social media platforms deliver fresh personalized content by performing a large number of reads from an online data store. This store must be optimized for read efficiency, availability, and scalability. Multi-layer caches and asynchronous replication can satisfy these goals, such as in Facebook’s graph store TAO, but it is challenging for the resulting system to provide a developer-friendly consistency model. TAO originally provided read-your-writes (RYW) consistency via write-through caching, but scaling challenges with this approach have led us to a new implementation.

This paper introduces FlightTracker, a family of APIs and systems which now manage consistency for online access to Facebook’s graph. FlightTracker implicitly provides RYW and can be explicitly used to provide alternative consistency guarantees for special use cases; it enables flexible communication patterns between caches, which we have found important as the number of datacenters increases; it extends the same consistency guarantees to cross-shard indexes and materialized views, allowing us to transparently optimize queries; and it provides a uniform primitive for clients to obtain desired consistency guarantees across a variety of data stores. FlightTracker delivers these advantages while preserving the efficiency, latency, and availability benefits of asynchronous replication for the underlying systems, managing consistency for billions of users and more than 10^{15} queries per day.

1 Introduction

Social media platforms deliver fresh and customized aggregation of content. This feature combination makes it ineffective to aggregate ahead of time; instead each application-level web request at Facebook may issue hundreds or thousands of queries to our graph store TAO [20] to render a single response. This high query amplification means that data store reads must be efficient, low-latency, and highly available. At Facebook, we have addressed this challenge with an asynchronously coupled federation of caches, database replicas, and customized indexes that model social media data and

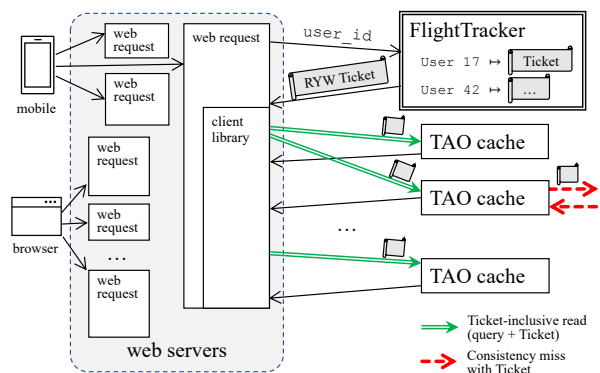

Figure 1: Web request flow with FlightTracker.

metadata as a graph. While this read-optimized ecosystem achieves high performance, it is challenging to provide an intuitive and uniform consistency model to developers.

FlightTracker is our solution for managing RYW consistency for online access to the social graph at Facebook. It preserves the read efficiency, hot spot tolerance, and high availability of eventual consistency while providing RYW consistency. FlightTracker offers a uniform notion of an end user session that spans many stateful services and can be extended to new data stores without architecture changes.

FlightTracker consists of a family of APIs and a metadata service. Building on write-set tracking techniques [28, 40, 41, 51] and CRDTs [18, 50], the FlightTracker service accumulates the metadata of a user’s recent writes and exposes the metadata as a data type we call a *Ticket*. Web requests fetch the user’s Ticket once, as soon as the user is identified (see Figure 1). This Ticket is automatically attached on all subsequent queries to the social graph from the web request.

We use a variety of system-specific strategies to ensure that every write identified by the Ticket is reflected in query results. For example, our strategy for caches is to ignore cache entries that may be stale compared to writes in the Ticket; we refer to the resulting cache miss as a *consistency miss*. Systems can propagate Tickets recursively when they need to fetch data from another component while processing a query.

FlightTracker has been in production since 2016. It provides RYW consistency for billions of users and 10^{15} data store queries per day. For the majority of Facebook’s internal applications and developers, FlightTracker is automatic and hidden. Some call sites and higher-layer infrastructure components explicitly manipulate Tickets to strengthen the consistency level. FlightTracker’s loosely coupled design has allowed us to incrementally roll out support to two caching systems, three indexing systems, and two databases. It preserves the efficiency, latency, and availability that these data stores would offer under eventual consistency.

Overall, this paper makes five contributions:

- We summarize challenges Facebook encountered when relying on write-through caching for RYW in TAO, a read-optimized geo-replicated graph store (§ 2).
- We present the Ticket abstraction, which encapsulates the system-specific details of write sets in an extensible manner across service boundaries (§ 4).
- We show how we store and exchange Tickets in the FlightTracker service to provide RYW consistency (§ 3 and § 5) or explicitly satisfy alternative consistency requirements for select use cases (§ 7) while tolerating hot spots (§ 6.5).
- We explain a variety of strategies we used to implement Ticket-inclusive reads in query-serving systems (§ 6), including ones for simple caches and global indexes with complex update pipelines (§ 6.3).
- We evaluate FlightTracker in our production environment, demonstrating that it preserves the useful properties of the underlying read-optimized stores (§ 8), and share some lessons learned (§ 8.5).

2 Motivation

TAO is a read-optimized data store that provides access to the social graph at Facebook [20]. It is implemented using two layers of caches in front of a geo-replicated database. TAO originally relied on write-through caching for consistency. This technique provided RYW on top of eventual consistency, while preserving the read efficiency and hot spot tolerance of the system, since it allowed most queries to be served from a nearby L1 cache server.

As Facebook grew, we found that we needed a better approach to consistency. TAO’s original write-through strategy relied on the use of a fixed communication pattern: users were made sticky to a single L1 cache cluster by the load balancers, inter-cluster communication was limited to traversing a fixed tree, and writes were proxied along the same tree traversal chain that would be followed on a read miss. RYW would be violated if any of the following were true: user requests were routed to another cluster of web servers; the mapping from web server cluster to L1 cache cluster was changed; queries were failed over to a stale replica; cache contents were lost

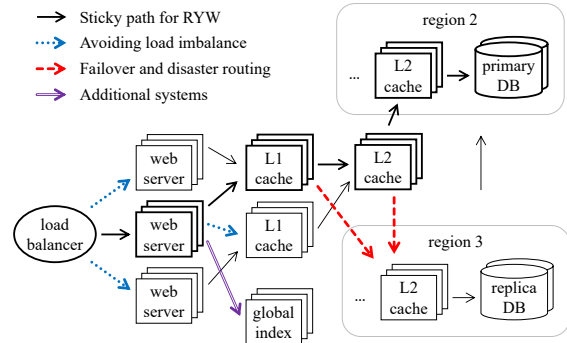

Figure 2: RYW via write-through caching excludes many useful inter-cluster communication patterns.

before asynchronous replication occurred; or any query was served by a data store other than TAO.

2.1 Scaling challenges

As TAO’s footprint grew, we found it increasingly problematic to rely on a fixed communication topology. In fact, each of the conditions required for write-through RYW became harder to satisfy over time. As cross-cluster networking improved, we moved away from pairing and colocating L1 caches with web server clusters, reducing the number of L1 cache replicas per region. This reduced the number of cached copies of data, but it required fractional or dynamic assignment of web server traffic to L1 cache clusters to get reasonable balance. Switching from cluster-sticky to region-sticky user routing improved the load distribution of both the web server clusters and TAO. As the number of geographic regions grew, we started to deploy TAO in some datacenters without a local database replica, routing cache misses to the closest neighboring region. If we were restricted to a tree topology for miss routing and cache invalidation streams, the outage of one database replica would affect multiple regions. Figure 2 shows some of the desirable communication patterns we encountered that break the write-through consistency model. The dotted and dashed arrows show read requests that potentially violate RYW consistency without FlightTracker.

Another recurring issue was queries that needed cross-cluster or global write visibility. TAO marks these queries *critical*, routing them to the L2 cache in the region holding database primaries, near the base of the communication tree [20]. This strategy has latency and availability drawbacks. It is also not tolerant of spiky workloads.

2.2 Cross-system consistency

As we encountered challenges scaling TAO’s write-through approach to consistency, the social graph ecosystem expanded. Application developers moved from directly accessing TAO to using a query language that makes it easy to express multi-hop and attribute-filtering predicates over the graph. This layer of indirection allowed us to build additional systems tailored to a subset of the Facebook query workload.

Some application queries involve many round trips when mapped onto TAO's simple API and transfer a lot of data that the client immediately discards. Global secondary indexes can optimize the communication pattern of these queries, but it is only safe to transparently or retroactively optimize execution using indexes if the index stores have the same semantics as TAO [34]. Our indexing systems are loosely coupled, updated by asynchronous pipelines that reshard, transform, and filter. Loose coupling enables separate development and deployment, but it limits the consistency implementation strategies. Most indexes are sharded differently than TAO, so even if we used a more monolithic design, they could not participate synchronously in the write path without reducing availability and increasing tail latency [17, 54].

Another side effect of moving to the application-level query language for the social graph was that it became easier to use alternate database technologies as the system of record for parts of the social graph, such as for data types that experience high write rates or limited lifetimes. These systems also experience the same consistency challenges as TAO.

Ajoux et al. [10] previously identified four fundamental challenges to providing causal consistency in Facebook's social media platform: integrating across many stateful services, tolerating high query amplification, handling linchpin objects (i.e., hot spots), and providing a net benefit for users. Our experience has been that these challenges also arise when providing RYW consistency and that the most difficult hurdle is producing a design that addresses all of them simultaneously.

2.3 Why read-your-writes?

Consistency models for data stores make guarantees about what writes should be visible to a read. Application developers use these guarantees to reason about the correctness of the entire system. Strong models like linearizability [32] or causal consistency [9] generally provide a simpler experience and mental model for developers, but they constrain the implementation.

Providing consistency guarantees for read-optimized systems boils down to implementing a staleness check to determine whether a cache or replica can serve a read query with its local data. This staleness check must be: (1) local, avoiding network communication in most cases; (2) highly granular, so that few queries result in extra work due to false positives from the checks; and (3) conducive to incremental repair, so that the extra work to find fresh data can be reused for subsequent queries. Importantly, staleness checks are needed for single-replica reads even in systems that use synchronous quorum writes. For example, Raft followers [43] or Paxos acceptors [38] might have no knowledge of a write committed by the leader if they were not part of the commit quorum.

Logical and physical timestamps, such as Hybrid logical clocks [36], Spanner's TrueTime [26], and Occult's compressed vector clocks [41], provide a simple and scalable way to check for staleness—the local data is sufficiently fresh if its

timestamp is higher than the desired read timestamp. Unfortunately, these approaches are neither granular nor conducive to incremental repair. If the local store is 10 seconds behind the desired read timestamp, for example, it cannot service any queries until it has processed all of the missing writes.

For our workload, it is important that we can serve most queries locally, even if the local replicas are a few seconds stale. This led us to reject consistency levels in which all writes (linearizability) or most writes (causal consistency) missing from a stale replica need to be visible. In contrast, RYW allows us to utilize a stale replica by adding fresh versions of only a limited set of writes ("your" writes). We also rejected weaker models like bounded staleness that do not guarantee that a user sees their own writes, which are difficult to use correctly for an interactive application [54].¹

Our experience at Facebook has been that the simple RYW consistency model [51] is a reasonable default for application developers and our end users, with an extension: we want to extend the concept of a session to end users.

User-centric sessions: Our desire to implement user-centric session RYW guarantees means that we experience intra-session concurrency at several levels, as shown in Figure 1: a single web request issues TAO reads and writes in parallel; a single browser or mobile app has many web requests in flight at once; and a user may even be accessing Facebook simultaneously from multiple devices.

The original definition of RYW session guarantees [51] implies that reads and writes within a session are totally ordered and that this intra-session order coincides with the physical order of those operations, as in linearizability. As a result, while the theoretical definition does not require a single-threaded session, implementations limit sessions to a single client, writer, session manager, or server [19, 28, 42, 52].

However, our observation is that application developers do not expect concurrent web requests to communicate with each other. A common mental model is that concurrent requests execute in a random order and possibly interleave with each other, so visibility from one request to the next is only assured if one request finishes before the other starts. An application developer's intuition is that the first moment data is guaranteed to be available is when the write acknowledgement is received by the local program that issued the web request.

This observation led us to the following relaxation of the RYW guarantee, which is what FlightTracker provides:

A read to the social graph will observe all writes done by the same end user in previously completed web requests or in the same web request.

This definition gives us much-needed flexibility for handling intra-session concurrency. Note that as in the original RYW definition, a read may "observe" a write by returning an even newer version of the data.

¹ We think providing both RYW and bounded staleness is an interesting and feasible model, even for our read-optimized environment.

3 FlightTracker

The main idea of FlightTracker is to decompose the problem of RYW consistency into three parts: (1) the Ticket abstraction, a flexible and extensible way of representing write sets across independently developed systems and APIs; (2) the FlightTracker service, generic infrastructure queried once per web request to get a user's recent write metadata; and (3) Ticket-inclusive reads, system-specific mechanisms to ensure that the specified writes are reflected in query results.

Our goal for FlightTracker is to preserve the communication patterns that benefit eventually consistent read-optimized stores. FlightTracker piggybacks on existing messages in these data stores. Most read queries can be served by a single local RPC, maintaining high efficiency and low latency. FlightTracker does not restrict where data stores send read RPCs, which allows them to leverage per-query retry and failover for high availability. FlightTracker supports the aggressive multi-level caching that data stores use to tolerate hot spots. Most of the work to ensure writes become visible to reads is handled by asynchronous pipelines, which retains the desired isolation and loose coupling of the underlying data stores. This piggybacking approach has also made it feasible to incrementally add FlightTracker support to existing mature systems with low overhead.

Figure 3 shows the API extensions a data store needs to implement to integrate with FlightTracker. On a successful write, a data store returns a Ticket identifying the write alongside the result; read queries take a Ticket parameter and guarantee any relevant writes in the Ticket will be reflected in the result.

3.1 An example

Consider a hypothetical social media product using TAO's graph model of versioned nodes and edges, with user nodes, media nodes, edges when a user has enjoyed a particular media instance, and edges when a user trusts another's tastes. Let's say Alice enjoys Mozart's *Requiem*; Bob recently indicated he trusts Alice's taste in art and then expanded his trust in Alice to include music. The resulting subgraph is shown in Figure 5 and Bob's recent writes to TAO would be:

$WriteEdge(\langle 17, TRUSTS, 42 \rangle \mapsto \{ "art" \})$ (1)

$WriteEdge(\langle 42, TRUSTED_BY, 17 \rangle \mapsto \{ "art" \})$ (2)

$WriteEdge(\langle 17, TRUSTS, 42 \rangle \mapsto \{ "art", "music" \})$ (3)

$WriteEdge(\langle 42, TRUSTED_BY, 17 \rangle \mapsto \{ "art", "m..." \})$ (4)

To get RYW consistency, we simply need to ensure that Bob's subsequent data store queries include the effects of these writes. We do this by computing Bob's recent write set once per web request, attaching it to all of his queries, and then making sure the data stores reflect attached writes in the query results.

3.2 Tickets

We store write metadata in a data type we call a Ticket. Metadata to identify a write includes information like the

```
pair<Result, Ticket> write(...); // returns metadata
Result read(..., Ticket); // Ticket-inclusive read
```

Figure 3: API extensions data stores expose to participate in the FlightTracker ecosystem.

```
void appendWrite(SessionId, Ticket); // FT write
Ticket getMergedWrites(SessionId); // FT read
```

Figure 4: The API of the FlightTracker service.

Figure 5: Subgraph for a hypothetical application.

transaction ID and the resulting node or edge version but does not include the data itself. If W_i is metadata that identifies Bob's i -th write above, we might have:

$W_3 = [key \mapsto \langle 17, TRUSTS, 42 \rangle,$

$op \mapsto WriteEdge, v \mapsto 2, txn_id \mapsto 8980]$

$W_4 = [key \mapsto \langle 42, TRUSTED_BY, 17 \rangle, \dots, txn_id \mapsto 8985]$

Bob's Ticket would then be $\{W_1 \dots W_4\}$.

As write sets, Tickets can be joined via set union. Moreover, Tickets are handled and passed around between many independently deployed systems; therefore, they need to be encapsulated, extensible, and forward- and backward-compatible. Inside a Ticket, writes can be enumerated or represented using a low-water mark that implicitly includes all preceding writes. § 4 describes Ticket contents, semantics, and implementation.

3.3 The FlightTracker service

Bob's logical user session spans many web requests, so we need to store metadata for his recent writes elsewhere. To that end, we built the FlightTracker service with an API resembling a hash map of user IDs to recent writes (Figure 4). For example, Bob's entry will be $17 \mapsto \{W_1, W_2, W_3, W_4\}$. The client library calls `appendWrite` immediately after a successful write to the data store before acknowledging success to the application; `getMergedWrites` returns the recent writes for a particular user.

Figure 1 shows an RPC pattern that might occur as Bob browses the music portion of the site. As soon as the web request identifies Bob as the logged-in user, it fetches his RYW Ticket from FlightTracker by calling `getMergedWrites(17)` and puts it into the web request context. When Bob performs a write, the client library joins its metadata into the Ticket in the web request context and also uses `appendWrite` to immediately send the write metadata to FlightTracker. The client library implicitly attaches the Ticket from the web request context to every read query. A single web request performs many such queries, offering ample opportunity to amortize the initial Ticket fetch. Most developers do not explicitly observe or manipulate Tickets.

3.4 Ticket-inclusive reads

It is the responsibility of the data store clients to attach a Ticket that ensures RYW to each query, and it is the responsibility of each query-serving component to ensure that all of the writes in the Ticket are included in a query result.

Our applications do not expect to have exclusive access to the social graph or to read from snapshots; reads are always allowed to return data that is fresher than expected. In Ticket-inclusive reads, a Ticket specifies a lower bound on writes that should be visible. A Ticket that encodes a superset of another can always be safely substituted at read time, as anything made visible by the superset Ticket might have been visible anyway as part of normal asynchronous replication.

Cache queries: After getting his RYW Ticket, Bob's web request performs two queries to TAO's cache. The simplicity of the TAO API makes it straightforward for the cache to validate the freshness of its cache content—a TAO replica compares the versions of the data in question against the versions specified in the Ticket. For example, if the request is reading a list of all of the users that Bob trusts ($GetEdges((17, TRUSTS, *))$), then W_3 implies the edge to Alice must be present with version ≥ 2 .

In Figure 1, the first TAO query was a cache hit unaffected by the Ticket. This is the common case. The second TAO query shows a *consistency miss*, where the local cache contents are stale. In this case, the cache goes upstream and merges the fresh edge into the local list before responding. Note that the upstream query has the same Ticket attached, which recursively ensures visibility of Bob's recent writes.

Index queries: If Bob is browsing the song with ID 55, we would like to display Bob's trusted users who also enjoy it. This involves finding all x where $\langle 17, TRUSTS["music"], x \rangle \wedge \langle 55, ENJOYED_BY, x \rangle$. This two-hop query is not well suited to TAO, because both the `TRUSTS` and `ENJOYED_BY` edge lists may be too large to fully cache. We can optimize this type of query by materializing a global secondary index. Specifically, we might use a list-intersection index with edge lists for `TRUSTS` edges that include "music" and `ENJOYED_BY` edges from "music" MEDIA nodes.

An index leaf (read server) does not have enough information to accurately identify missing writes, because writes that are filtered by the update pipeline will never arrive. For example, W_1 can be filtered upstream because it is not a `TRUSTS` edge that includes "music" and thus does not change any materialized lists. Without extra information, an index leaf will consider W_1 missing forever. Any such index leaf cannot satisfy a Ticket-inclusive read with Bob's Ticket with W_1 in it. We solve this problem by tracking the delivery information of recent writes, including the recent routing and filtering choices of the update pipeline as well as the delivery status to the index leaves. This FlightTracker-ReverseIndex (FT-RI) component builds an index of recent writes to the actions taken by the index update pipeline (§ 6.3). Queryable using

the metadata present in Tickets, the delivery information is used by the index client library to determine whether an index read result is fresh enough. If stale, the client library uses strategies such as read repair or retry to obtain a fresh result.

§ 6 describes our full range of strategies to ensure results of Ticket-inclusive reads reflect all writes in a Ticket.

4 Ticket details

A Ticket is a set of write metadata. We use Tickets to identify writes to the social graph regardless of where the writes are committed. Tickets allow generic infrastructure to track and identify writes across many independently deployed systems, while letting databases convey system-specific details. For clarity, we refer to the systems that persist the normalized data and generate the write metadata as “databases,” as opposed to other data stores such as caches and indexes which mostly serve reads and proxy writes.

A Ticket is implemented as a union of custom per-database representations. On a write, a single-database Ticket is minted with only metadata for the newly committed write (Figure 3). It can then be joined with other Tickets or otherwise used by FlightTracker and custom applications, producing Tickets that may contain writes from multiple databases.

The encapsulation of Tickets and the semantics of Ticket-inclusive reads together give us great flexibility in the Ticket implementation. Since Ticket-inclusive reads interpret Tickets as lower bounds, read results containing additional writes or fresher writes than exactly encoded in the Ticket are unsurprising to the applications. Furthermore, thanks to encapsulation, applications cannot examine the exact content or representation of a Ticket, which means we can always safely include additional writes inside a Ticket. We leverage this flexibility in Ticket compaction (§ 4.2) and Ticket replication in the FlightTracker service (§ 5).

4.1 Identifying a set of writes

The naive strategy of identifying writes by globally unique IDs is easy to implement but difficult to use—read-serving data stores must keep track of all write IDs to determine whether the local replica is sufficiently up-to-date. Assigning a total write order allows systems to identify writes by their ordinal positions. However, ordering implies synchronization via communication or via timed-wait [26]. To preserve the efficiency benefits of asynchronous replication, databases often opt for limited-scope ordering. In our experiences, there are three natural scopes:

- Per-key: Any strictly monotonically increasing value can be combined with a key to identify a particular change to that row or object. This version need not be contiguous—a monotonically increasing timestamp would also suffice.
- Per-shard: Many databases totally order all writes to a particular shard, but give no order guarantees between shards.

- Global: Some systems [26, 53] offer total order of all writes globally. HLCs or known-accuracy clocks can also order writes across shards and database types.

All of the databases supported by FlightTracker have the following properties which allow us to further simplify our assumptions. Our databases expose a versioned key-object model. They are sharded and maintain a total order for all writes within a shard; furthermore, writes in a single shard are replicated in the same order. The commit-time information (such as commit timestamps or transaction IDs) can thus specify a contiguous prefix of that shard and serve as a low-water mark to determine the replication state of a data store.

Most fields in a Ticket can be and are empty. When new Tickets are minted, they can include any information known at commit time, such as per-key versions, commit timestamps, or transaction IDs. While not necessary, including more metadata allows flexibility in interpreting and using the Ticket. Figure 6 shows an example Ticket structure with two databases.

For a data store or client to determine whether a read result is sufficiently up-to-date, this metadata needs to be accessible on reads, which means that it should be stored alongside the data. While this overhead appears non-trivial (e.g., up to 8-bytes per key), our databases already persist these versioning primitives, so the additional cost is negligible.

Although we describe the Ticket abstraction in the context of databases at Facebook, it is applicable and extensible to other databases. Many natively support and store per-key versioning primitives, such as the `rowversion` of Azure SQL Database [13]. Per-shard or global-scope ordering also often underlies modern databases, where writes can be identified by sequence numbers or timestamps stored alongside the client data (e.g., `zxid` for ZooKeeper [33], `hlc` in CockroachDB [2], `offset` in Kafka [35], `LSN` in LogDevice [4]).

4.2 Ticket joining and compaction

Two important operations on Tickets are joining and compaction: joining combines Tickets and compaction reduces their space footprint. Both are local operations with no need for RPCs or information outside the input Tickets.

The *join* operation, which is essentially set union, produces a Ticket that is a superset of all the inputs. It is the primary API for Tickets. For example, data store clients can join Tickets to combine metadata from multiple shards or multiple databases; the FlightTracker service joins Tickets to accumulate per-user recent writes (§ 5); select applications join Tickets to express additional constraints for their reads (§ 7).

Compaction helps Tickets overcome the scaling limit of write set tracking techniques. The idea is straightforward. Tickets represent writes that should be visible, i.e., a kind of lower bound; we can raise the lower bound in exchange for a more compact representation. Intuitively, doing Ticket-inclusive reads with the resulting Ticket makes their constraints equally or more stringent.

Formally, Tickets are CRDTs [50] and the compaction

```
struct RepForDatabaseA {
    map<WriteKey, tuple<Version, TxnId, Timestamp>> perKeyMap;
    map<ShardId, pair<TxnId, Timestamp>> perShardMap;
};

struct RepForDatabaseB {
    map<WriteKey, tuple<Version, Hlc>> perKeyMap;
    map<ShardId, Hlc> perShardMap;
};

struct Ticket {
    RepForDatabaseA repA;
    RepForDatabaseB repB;
    Timestamp globalTs;
};
```

Figure 6: Tickets represent the union of the writes identified by each field.

techniques we use are CRDT *inflation* operations [18]: the per-scope ordering and subset-superset relation define the \leq partial order. Ticket inflation produces a Ticket that is \geq the input Ticket according to this order. The resulting Ticket may need fewer bytes to represent. Not all inflation reduces Ticket size but the three types of inflation we use below do:

Per-scope compaction: Keeping the highest version for each key and the highest transaction ID for each shard lets us discard metadata with older versions or transaction IDs. This compaction is performed during every join.

Cross-scope compaction: Some databases have static shard assignments and include both per-key versions and per-shard transaction IDs in the Tickets (such as DatabaseA in Figure 6). Replacing per-key metadata with a per-shard transaction ID can greatly reduce the Ticket size, especially for shards with many individual writes. Suppose the edges from the example in § 3.1 among many other writes are all on shard *X*. We can then compact a Ticket $T_1 = \{W_3, W_4, \dots, W_{100}\}$ to $T_2 = \{\text{shard}_X : \text{txn_id} \mapsto 8985\}$.

Cross-scope compaction offers us a tradeoff between the Ticket size and the cost of serving the Ticket-inclusive read. Since a compacted Ticket semantically encodes more writes, the read is less likely to be served locally. E.g., T_2 requires all writes on shard *X* with $\text{txn_id} \leq 8985$ to be replicated. Thus, this type of compaction is performed heuristically and sparingly in the FlightTracker service.

Global compaction: We can inflate a Ticket into a global-scope timestamp to represent all writes that have earlier timestamps. Global compaction only happens in the FlightTracker service for writes older than 60 seconds, since we assume the replication lag of our data stores plus clock skews are much smaller. Given the long threshold, global compaction does not have to be exact—older writes do not need to be removed from a Ticket immediately since they purely reduce Ticket size. Thus, the timestamps used for compaction could either be the logical commit timestamp generated by the database or the physical timestamp generated by the data store after the write completes. Global compaction lets FlightTracker store only 60s of data, which greatly reduces its working set.

Additionally, we define a Ticket-inclusive read with an

empty Ticket as implicitly encoding the constraint of returning data no more than 60 seconds stale relative to the current physical timestamp of the replica serving the read. This way, in most cases, we avoid the need to pass around Tickets containing only a single old global timestamp.

4.3 Physical representation

As a cross-system primitive, Ticket presents a number of interesting software-engineering challenges. Ticket-handling code runs inside systems with widely varying deployment frequencies, so Ticket must be both forward- and backward-compatible. Ticket **encapsulates** implementation-specific details from multiple systems, but because clients can join Tickets, it cannot leave encoding and decoding up to the data stores. Ticket must be **extensible** and **loosely coupled**, allowing metadata for new systems to be added without affecting existing systems. Ticket must also be **efficient** enough to use on each query in our read-heavy environment.

We address some of the above challenges by using Thrift [8], a serialization format originally designed for efficient and portable RPC. We define the Ticket data structure using the Thrift interface definition language (IDL).

Compatibility: Thrift handles the majority of forward- and backward-compatibility issues, as unknown fields from future versions are silently skipped. Care must still be taken as we introduce new metadata fields to existing systems in the Ticket. For example, if two writes with the same key and timestamp are differentiated by a transaction ID, older code unaware of transaction IDs may be surprised to see a duplicated write.

Serialization: We currently support two serialization formats, identified by the prefix. The default is an LZ4-compression [25] of the Thrift Compact encoding. This is used across all RPC boundaries, making it easy to tunnel Tickets through other systems. The second is the Thrift JSON encoding for readability in debugging and logging.

Encapsulation: A Ticket's internal struct is accessible to systems that mint new Tickets or perform Ticket-inclusive reads. Clients that need not inspect Tickets can treat them as opaque tokens. We provide language bindings and utility functions for code that needs to examine the Ticket internals.

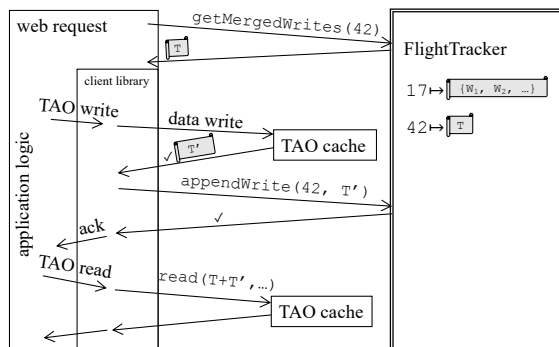

Figure 7: Web request flow with the FlightTracker service.

We chose the name *Ticket* to minimize assumptions developers would make about its semantics. Infrastructure engineers often conflate a visibility guarantee on a specific write (Transaction 8980) with a guarantee on a contiguous prefix (Transactions 1...8980); a new name reduces this tendency.

Extensibility and loose coupling: As shown in Figure 6, each database can customize its own representation. Extending the Ticket structure to support an additional database boils down to adding a field in the main struct and updating the join function. Loose coupling between databases is provided by using different fields for each.

5 FlightTracker service implementation

The API of the stateful FlightTracker service (Figure 4) is extremely simple, consisting of just two operations. As shown in Figure 7, a web request calls `getMergedWrites(user)` at the beginning to get the user session's RYW Ticket; the client library call `appendWrite(user, ticket)` after a database write with the newly minted Ticket and only acknowledge the write to the application if *both* the data store write and `appendWrite` succeed. To reduce ambiguity, we use “data writes” to refer to data store operations and use “metadata writes” to refer to FlightTracker operations.

FlightTracker has the following requirements:

- **High throughput:** FlightTracker is subject to the full write throughput of all the underlying data stores, since every data write results in a metadata write to FlightTracker. Its effective replication factor is lower than a globally replicated store like TAO, because most writes are only stored in the writing user's region. Its read throughput is proportional to the number of web requests.
- **Low latency:** Data writes are not acknowledged until their metadata is recorded in FlightTracker, so FlightTracker adds to application-visible write latency.
- **High availability:** Unavailability of FlightTracker implies loss of availability or loss of RYW consistency for clients. The decoupled nature of FlightTracker allows us to let some use cases fail open (available but inconsistent) while others fail closed (unavailable).
- **Durability:** A Ticket passed to `appendWrite` should be included in `getMergedWrites` even when there are machine failures. FlightTracker uses a single-round quorum protocol that does not provide atomicity because it is okay for a failed or in-progress `appendWrite` call to be visible.

The working set of FlightTracker is relatively small, as FlightTracker compacts Tickets as it merges them (§ 4.2). Put more practically, if queries are only routed to replicas that are at most 60s stale, then write metadata older than 60s are safe to compact away. Our data stores track the staleness of their own replication streams and a vast majority (>99.99%) of the servers are no more than 60s stale.

5.1 Replication

We implement FlightTracker as a quorum-based store. We statically determine the number of replicas N ; the FlightTracker client broadcasts an `appendWrite` to all replicas and considers it successful when W replicas acknowledge the write; a `getMergedWrites` query contacts R replicas and joins the retrieved Tickets.

This plain *single-round* quorum protocol with $R + W > N$ is sufficient to provide the desired correctness guarantee for FlightTracker. A previously appended Ticket will be returned by at least one replica in R , since $R + W > N$ guarantees overlap between the read and write quorums. Merging the read results via `join()` from all R replicas ensures durability: the Ticket will be included in the final read result.

FlightTracker does not need to guarantee atomicity. Recall that given Ticket encapsulation and how Tickets are used as lower bounds, we can safely include additional write metadata in Tickets without violating the overall RYW consistency (§ 4). If a metadata write fails to reach W FlightTracker replicas or is still in progress, FlightTracker *can* safely include it in the result of `getMergedWrites`. Moreover, if a data write succeeds but its metadata write to FlightTracker fails, we consider this write an “unacknowledged success,” i.e., the data store client errors out the data write to the application. Application developers do not expect to see failed data writes but know how to handle them if they do show up. Since many of Facebook’s applications are built on eventually consistent stores, applications are used to reading fresher writes (e.g., from other applications). Thus, unacknowledged successes are acceptable as long as they are infrequent.

For example, suppose we have a FlightTracker deployment with $N = W = 3$ and $R = 1$; data writes for W_5 and W_6 completed, but the metadata write for W_5 failed and the metadata write for W_6 is in progress. The state of the three FlightTracker replicas is $\{W_5, W_6\}, \{W_6\}, \{\}$. A first metadata read could return a Ticket of $\{W_5, W_6\}$ and a subsequent metadata read could return $\{\}$. This is permitted: W_6 has not completed so RYW does not apply yet; W_5 , while written in the database, has returned an error to the application, thus the application should have no expectation of visibility either way.

FlightTracker’s default setup is a region-local quorum, as Facebook pins logged-in users to a region. We leverage the regional placement to ensure low latency for FlightTracker accesses. Since FlightTracker has a small working set, we choose to store everything in memory and adjust N for redundancy. Empirically, we’ve found $N = 3$ offers a good trade-off between low latency and sufficient redundancy (§ 8).

We statically map user IDs onto logical shards, which are dynamically placed within each FlightTracker replica. Shard placement is aware of load-balancing and covers failure detection. Some use cases use non-user session IDs and cross-region quorums (§ 7.3).

5.2 Failure tolerance

Machine failure is the most common failure that must be handled. Our strategy for this also handles network issues and gaps in coverage during shard movements. We leverage the global compaction bound to restore resiliency after a FlightTracker machine gets a new shard assignment or dynamic shard movement. FlightTracker “warms up” in the first 60 seconds after a shard comes online by accepting all writes but not serving reads. Rejected reads are retried on warm replicas.

5.3 Fail closed vs. fail open

One of the challenges identified by Ajoux et al. [10] was ensuring consistency mechanisms provide a net user benefit. Some applications would prefer to continue a web request even if `getMergedWrites` fails, for example. Given that we have the option to cleanly fail open on a per-query basis, it is difficult to argue for a uniform fail-closed policy. If FlightTracker is completely reliable, there will be vanishingly few inconsistencies even with a fail-open policy, so there is no benefit to fail-closed; on the other hand, if FlightTracker is not completely reliable, then use cases that prefer availability will be harmed by fail-closed. A future option would be to rate-limit fail-closed for those use cases and escalate all fail-open potential RYW violations to an engineer.

Since an error is reported to the application when a data write succeeds but the corresponding `appendWrite` fails, FlightTracker write availability caps the data store availability. FlightTracker is in-memory and region-local, so it has much higher write availability (§ 8) than our underlying persistent data stores; it has a minimal impact on application-visible write availability. Although less important now, the option to fail open was crucial to reducing risk during early rollout.

6 Ticket-inclusive reads

Once FlightTracker has attached a Ticket to a query, it is the responsibility of the data store to ensure that every write identified by the Ticket is reflected in the query result.

The general pattern for implementing Ticket-inclusive reads is that the data store (client or server) filters the writes in the Ticket for relevancy, then checks against its local state to see if they have already been applied. Frequently, the writes in a Ticket are irrelevant to the read (e.g., a write to a `MEDIA` node is irrelevant to reading Alice’s `TRUSTED` users) or have been replicated and included locally, in which case the Ticket does not change the result and the read can be served locally.

In the uncommon case that some writes are possibly relevant but missing, i.e., the local data is *possibly* stale, the data store uses a more expensive non-local action to fix the query result. The specific strategies for each of those steps depend on query semantics, the way in which writes are encoded in the Ticket, and what information is locally available.

6.1 Filtering by relevance

Filtering works best for the most granular write representations such as per-key versions. In contrast, timestamps define a write set that includes a contiguous prefix of the history of all data systems at Facebook, which can never be filtered.

For database-specific encodings, a coarse level of filtering happens when the data store ignores writes from other databases in the Ticket. It is also fast and easy to filter by static information in the Ticket or in data store configs, such as TAO object types (e.g., `USER` or `ENJOYS`) or database tables. For Ticket representations that contain keys, we can further filter writes based on query parameters such as the desired node ID. This is highly effective for point queries and simple range queries like TAO's and works for some indexes.

Type and query parameter filtering can be done on the client, which avoids the need to even include a Ticket on most queries. We refer to this operation as *cropping* and have integrated it in the client libraries of all data stores we support.

6.2 Checking inclusion

The systems that incorporate FlightTracker provide eventual consistency on their own, mostly using asynchronous replication. The large majority of writes are delivered with low latency, so most writes are included at the check time.

For database replicas and caches sharded by key, we replicate in write order (i.e., in per-shard *txn_id* order). The replication stream pointer is a compact way of identifying the set of writes included in the local store. If the latest replicated record was 8983, for example, then the write W_3 with $txn_id \mapsto 8980$ is included but W_4 with $txn_id \mapsto 8985$ is not.

Cache misses can fetch values from ahead of the replication pointer, so a single low-water mark is not sufficient for high-granularity inclusion checks. TAO maintains a *key* \rightarrow *txn_id_{safe}* mapping that identifies when a particular cache entry is known to include writes newer than the local low-water mark. *txn_id_{safe}* records the replication position of the upstream source when it serviced the cache miss, not necessarily the transaction at which the key was updated. For example, if a cache with low-water mark 8983 took a cache miss and fetched the edge in W_4 from a database replicated up to 9000, it will have a cache entry with $txn_id_safe \mapsto 9000$ for the edge; the cache is now able to serve point reads to the edge locally if the Ticket has W_4 or even $\{shard_x : txn_id \mapsto 9000\}$. This exception map is essential to ensuring that Ticket-inclusive queries can still be cache hits.

6.3 Relevance and inclusion for global indexes

Both relevance and inclusion checking are much more challenging for global indexes. An index that lets us find media nodes by their name, for example, will be partitioned using a mutable data attribute rather than by the node's key.

While in this case it would be feasible to include the indexed attribute in the Ticket, we avoid this approach. It bloats the Ticket without solving the problem for all indexes, be-

Figure 8: Stages of the asynchronous index update pipeline inform FT-RI as they process writes.

Figure 9: Web request flow with FT-ReverseIndex.

cause the indexed attributes might be from adjacent nodes or edges in the graph. It requires writers to be aware of all index schemas and cannot scale to handle fan-in cases, where a single write affects a large number of index rows. In the example in § 3.4 where we want to answer queries such as “return a list of trusted users who also enjoy a particular song,” the graph indexing system materializes an ordered list of $\langle user.id, media.id, list(trusted_user.id) \rangle$ tuples. Checking whether a write like W_3 (which expands the `TRUSTS` edge to include “music” between Bob and Alice) is relevant or locally applied to an index server requires the list of `MEDIA` nodes that Alice `ENJOYS`. This list could easily bloat the Ticket should we take this approach.

Another option we rejected was to ignore relevance checking for indexes and focus only on inclusion. This would require plumbing information about the replication water marks of all shards through the index update pipeline, perhaps using a compressed vector clock scheme like Occult [41] to avoid the need to deterministically merge across millions of replication streams. To distinguish lack of new updates from staleness in replication, each stream needs heartbeats, which results in a lot of overhead for cold shards and small indexes.

Our solution is to build an inverted index from writes to the actions taken by the index update pipeline. We store this in a stateful component named *FlightTracker-ReverseIndex* (FT-RI). We describe the interactions between the index update pipeline and FT-RI shown in Figure 8 with the example of W_3 and the intersection index. Based on W_3 's type and index schemas, FT-RI determines the indexes W_3 could affect and initially assumes it could affect every row in those indexes. As W_3 goes through the update pipeline, each stage of the pipeline informs FT-RI when it is about to filter out W_3 for some or

all indexes. We also require the update pipeline to propagate W_3 's metadata all the way to the index leaf servers unless W_3 is filtered out entirely. The update pipeline determines that W_3 matters only for index rows of the form $\langle 17, \text{media.id}, 42 \rangle$ in the intersection index and informs FT-RI. When a leaf applies the index row updates generated due to W_3 , it informs FT-RI of its server identifier and the part of the index state was updated. This way, FT-RI narrows down the scope of the indexes and read queries W_3 might affect.

As shown in Figure 9, to perform both relevance filtering and inclusion checking for a Ticket-inclusive index read, the client library first sends the query and the Ticket to FT-RI. FT-RI then returns the subset of writes that might be relevant (since they have not been reported as filtered) and not yet included (since they are still missing from the index leaves).

The client consults FT-RI before the query is sent to the index, so the set of missing writes may include false positives. False negatives would lead to RYW violations, so they must be avoided. To minimize the false positive rate without introducing any false negatives, FT-RI returns a map from writes to the physical servers where it may be missing. The client checks this information against the query execution plan, in case the stale server was not actually consulted. It can also be used to make intelligent replica choices and to retry only the stale portion of a query.

FT-RI accumulates a set of irrefutable facts about writes, so its internal state is a CRDT. It exploits the same single-round quorum protocol as FlightTracker (§ 5) for replication. FT-RI also shares much of the same infrastructure and is deployed as a RAM-only regional service.

6.4 Strategies to handle local staleness

This section describes ways to get the correct result when a potentially relevant write might be missing from the local data store. Our approaches fall into two categories: when the Ticket enumerates individual writes, the data store can request the data from upstream and cache the result for the next reader; if the Ticket contains a contiguous prefix, such as after compaction, we generally only reevaluate the query (on a different replica or at a later time), as it is expensive or impossible to request the contiguous prefix. In production, we use every strategy below but index repair.

Delay and retry: When we realize a data store is stale, a simple option is to just try again later. This strategy is not sufficient on its own, but it can be used as a first try to reduce the frequency of a more costly strategy.

Replica selection: Data stores are replicated for read availability. When one replica is stale, we can contact another replica that is up-to-date, especially if it is nearby. This strategy can lead to correlated failures such as thundering herd, so we only use it for low-volume workloads or behind a cache.

Consistency miss: When a Ticket identifies individual writes by key, caches that keep per-key versions (§ 4.1) can easily determine which data items are stale. They can use their

normal miss-handling logic to pull data about the missing writes from their upstream source, passing on the Ticket to recursively ensure visibility.

Even client-side hot object caches can similarly take consistency misses, which otherwise rely on TTLs to get fresh data. This is integral to our tolerance of read hot spots (§ 6.5).

Index bypass (re-materialization): Indexing systems have the option to fall back to the source of normalized data to answer a read query, though this is an expensive option. Quite a few of our indexes are materialized on-demand, so this fallback functionality is already regularly exercised.

Read repair: Read repair looks for possible matches to components of an index predicate among the writes in a Ticket, uses point queries to a non-index store like TAO to evaluate the full predicate, and then fixes the index result accordingly. Read repair can reduce complexity and latency. Consider the example in § 3.4 where we want to find Bob's trusted users who also enjoy Song 55. If W_3 on edge $\langle 17, \text{TRUSTS}, 42 \rangle$ is in the Ticket and the read repair library sees that node 42 (Alice) ENJOYS Song 55 from TAO, it adds node 42 into the result set.

Index read repair does not completely avoid extra communication on following queries, like consistency misses in a cache, but it avoids the need for future cross-region calls.

FT-RI filters out writes we do not need to repair. As shown in Figure 9, the client library queries FT-RI to find which of Bob's relevant writes have not yet been applied before querying the index and read repair. We initially tested read repair without FT-RI, treating every write a user had made in the last 60 seconds as undetermined. FT-RI for list intersection indexes has only a modest effect on the average number of edges to be checked for read repair, but it provides a dramatic reduction for the worst cases.

Read repair has its limitations. Firstly, certain indexes with aggregation cannot be read repaired. For example, if an index query only returns the size of the intersection, the read repair library would not know which writes have been applied in the result. Fortunately, the vast majority of our online index usage returns set results that can be repaired. Secondly, client-side read repair for complex indexes, such as ones that require traversing 3+ hops in the graph or those with large fan-outs, could duplicate the transform and processing logic of the update pipeline and index leaves, resulting in extra complexity. The above challenges are akin to those encountered in deferred incremental view maintenance in the database community [23, 24, 47, 58].

Index repair: Repairing the index by synchronously invoking the index update logic is more complex, but avoids many of the limitations of client-side read repair. We have not yet explored this option.

6.5 Handling hot spots

Handling linchpin objects is one of the major challenges of a social networking workload [10]. Read hot spots are a much

bigger concern than write hot spots in our read-heavy workload. Caches like TAO handle read hot spots by storing more local copies of the data, including on the client-side. Ticket-inclusive reads for cache queries are cache-able, preserving this hot spot tolerance. We cannot always cache post-repair index results, but the data fetched to perform repair is always locally cacheable.

Aside from hot objects for the overall system, FlightTracker has its own hot spots: since FlightTracker is sharded by `session_id`, it has different hot spot patterns from the underlying data stores. These hot spots are more likely due to user-triggered actions such as batch processing or from custom sessions (§ 7.3). To alleviate write hot spots, FlightTracker’s client library batches metadata writes without concerns for sacrificing write availability, since all FlightTracker writes are conflict-free. On the FlightTracker server side, we proactively detect sessions that are frequently accessed. For a hot session that spawns many web requests and thus results in many metadata reads, we coalesce these metadata reads into short time buckets, and respond to all reads in a bucket with the same response. These strategies have eliminated hot spots as a significant error source for FlightTracker (§ 8).

7 Beyond RYW: Explicit write visibility

Certain applications need visibility guarantees beyond a single end user or across regions, where our default user-centric RYW consistency falls short. To obtain desired visibility guarantees, we enable them to explicitly manipulate Tickets or customize FlightTracker session IDs. These applications are responsible for explicitly identifying the writes and preventing the Tickets from growing too large.

7.1 Embedding Tickets in notifications

Facebook’s notification infrastructure for GraphQL Subscriptions [48] fans out to all subscribers when a publisher event occurs. To render personalized notifications for each subscriber, GraphQL queries TAO in the subscriber regions. This pub-sub system races with TAO replication. To ensure that the query sees all of the writes associated with the event, we include and pass along the original publisher’s Ticket. When rendering the notification, GraphQL transiently joins it with the subscriber’s Ticket to query TAO. This is all hidden in the product infrastructure layer from product developers.

Subscriptions with a high subscribers fanout could result in a storm of consistency misses. Though TAO would only go cross-region once for this data, many requests would be stalled waiting for the result. Thus, we prefetch data in the Ticket into the local region’s TAO before notification fanout.

7.2 Data-derived additional sessions

When a user performs a write that includes another person’s User ID, such as when Bob created a `TRUSTS` edge to Alice, the write is naturally associated with the other user’s Flight-

Tracker session. For some edge types, we act on this by having the client library perform extra `appendWrites` calls, pushing the write to both the normal RYW session and the session identified by the destination node. These additional writes are sent to every region. We do not push the entire writing user’s Ticket into the data-derived additional sessions; only the user-terminated edge write gets strengthened visibility guarantees. As users are highly connected [7], this conservative choice avoids the potential for super-linear growth of write sets.

7.3 Explicit global sessions

Some applications need visibility guarantees beyond a single end user or across region. We allow them to customize their session IDs and configure quorum and compaction in FlightTracker on a per-use-case basis.

Facebook’s async job scheduling framework, similar to Celery or Resque [1, 5], enables web requests to schedule followup jobs such as sending email invites or long running migrations. These jobs may run in any region, but all of the writes from the original user session must be visible. To provide this guarantee, we use `job_id` as the session ID, which is the same for all tasks that are part of a job. Given the relative read-write ratio, we require a write to be replicated to most replicas in all regions and a read to be read from a few (usually region-local) replicas. We provide a utility function for the job framework to collect the writes the web request has done and send to FlightTracker under the appropriate job ID. When a job starts, it fetches a Ticket from FlightTracker using its job ID and uses Ticket-inclusive reads thereafter.

We also use global sessions for some TAO objects as an alternative to TAO’s critical reads. Critical reads ensure write visibility by proxying reads to the region of the object’s database primary, at the expense of increased latency, reduced efficiency, and reduced availability. If we record all writes to this object in a global session using its ID, we can replace the critical read: querying region-local FlightTracker to get a Ticket for this session and querying that object with a Ticket-inclusive read will return the latest successful (or newer) write. This approach shifts the cross-region latency to write time and increases read availability.

8 Evaluation

FlightTracker allows Facebook to get the read efficiency, hot spot tolerance, and high availability of eventual consistency while providing RYW consistency with a rich notion of user sessions that spans many stateful services.

8.1 Environment

Facebook serves millions of user requests per second. These user requests amplify to more than ten billion read queries per second to our online graph data stores, which also process tens of millions of writes per second.

Each of our stateful data stores, such as TAO and its indexes,

Figure 10: The size distribution of FlightTracker read responses in our production environment for different global compaction thresholds.

are deployed across over ten datacenter regions. Cache and indexing systems maintain asynchronously updated replicas in every region, while database replicas are present only in some regions. More than 99% of cache and index queries are served without any cross-region communication.

8.2 FlightTracker operational characteristics

FlightTracker has been in production for over four years. It manages RYW consistency for two database technologies, two cache types (including TAO), and three indexing systems. FlightTracker serves more than 100 million Ticket reads and 20 million Ticket writes per second.

We measured FlightTracker’s availability as observed by the client over 30 days. Measuring errors from the client side offers an end-to-end picture, because it includes unavailability due to misconfiguration, networking issues, and collateral damage from other problems. FlightTracker’s overall read error rate was 1.1×10^{-7} . When examining the availability data for 15-minute buckets, all but 8 buckets over the month of data indicated at least 99.9999% of read availability. FlightTracker’s write availability was an order of magnitude higher than the write availability of the underlying databases.

8.3 FlightTracker overheads

Request and response sizes: The bane of explicit write-tracking techniques is handling large write sets. The Tickets fetched from FlightTracker contain all recent writes for a user that are not globally compacted (§ 4.2), so they tend to be the largest explicit write sets passed around in our systems. Figure 10 shows the size distribution of metadata read responses in production for different global compaction thresholds, measured in the number of writes in the returned Ticket. In production, we use 60s as the default, but as shown, extending it to 2 minutes does not significantly bend the curve.

Ticket serialization includes compression using LZ4 [25]. Figure 11 shows that this provides a useful benefit for Tickets with more individual writes, improving encoding efficiency by up to a factor of three. Table 1 shows that cropping in the client is effective; Ticket sizes attached to read queries are

Operation	Avg	P50	P99
FlightTracker metadata read response	250	0	2805
FlightTracker metadata write request	156	129	447
Ticket-inclusive read from cache	110	0	450
Ticket-inclusive read from indexes	225	152	607

Table 1: Serialized sizes of Tickets attached on various requests and responses, in bytes.

Operation	Avg	P50	P99
FlightTracker read	288 μ s	226 μ s	1.4 ms
FlightTracker write	376 μ s	326 μ s	1.5 ms
FT-ReverseIndex read	304 μ s	236 μ s	1.5 ms
FT-ReverseIndex update	428 μ s	311 μ s	1.2 ms

Table 2: Client-measured latency of FlightTracker and FT-RI.

Service	CPU	RAM
Application (web) servers	0.7%	0.06%
TAO L1 and L2 cache	0.8%	0.01%
Indexes and materialized views	0.98%	2.6%

Table 3: Relative CPU and memory costs of all code paths related to Ticket, FlightTracker, or FT-ReverseIndex.

much smaller than the full write set pulled from FlightTracker.

Latency: FlightTracker and FT-RI have low latency for both reads and writes, as shown in Table 2. Both of these services are RAM-only and process all of their reads and writes from the local datacenter region. Queries for custom use cases (§ 7.3) are excluded in the table.

Footprint: The footprint of FlightTracker includes extra work and data in client libraries, extra work and space inside the data stores to enable Ticket-inclusive reads, and servers devoted exclusively to running the FlightTracker and FT-RI services. Table 3 shows that FlightTracker-related code paths consume only a small amount of the CPU and memory in clients and Ticket-enabled query-serving systems. The FlightTracker and FT-RI services use less than 2% as many servers as TAO and its indexes.

Extensibility: The Ticket abstraction is designed to be extended to handle new databases and new ways of encoding write metadata for the benefit of new projections. Since it was deployed to production, we have changed the Ticket Thrift schema 22 times, and we have made changes to the core Ticket join logic 50 times. Extending the Ticket abstraction to cover a new database does not increase the serialized size, but it does increase the heap footprint of the deserialized C++ objects. FlightTracker’s RAM consumption increased by 5% when we added support for a second type of database.

8.4 FlightTracker effectiveness

RYW for caches: FlightTracker enabled our caches to no longer rely on fixed communication topology to provide RYW consistency. It provided an opportunity to apply additional techniques to improve efficiency and reliability for our caches.

Figure 11: LZ4 improves serialized encoding efficiency by up to a factor of three for Tickets with more individual writes.

Today, 0.2% of the TAO reads have a non-empty Ticket attached, and 3% of those reads are for updates that have not yet been replicated via the per-shard replication stream. We allocate around 40MB per TAO instance for caching the result of Ticket-inclusive reads, resulting in a hit rate between 30% and 80% depending on the type of query. This hit rate is not evenly distributed: frequently read hot objects account for the bulk of hits. Fewer than 3% of TAO reads that end up going across regions are due to consistency misses.

Ticket-inclusive reads reduce cross-region traffic when they replace primary-DB-only queries for use cases that need stronger consistency guarantees. In one extreme use case where the cache only tracked per-shard replication progress, Ticket-inclusive reads reduced the percentage of queries going upstream from 20-40% to near 0%.

RYW for indexes: FlightTracker identifies that between 0.01% to 0.4% of indexing reads can benefit from read repair or other staleness handling strategies.

Explicit use cases: In the event delivery use case (§ 7.1), 3% of the subscribers’ reads are for publishers’ recent writes. 0.5% of these reads would have returned stale data without the publisher’s Ticket. Six use cases benefit from global sessions (§ 7.3), totaling 46k writes and 700k reads per second. They often set large write quorums to optimize for read availability and latency.

8.5 Experience and lessons learned

An early lesson was that identifying the appropriate user for a web request was much more difficult than we originally expected. Request endpoints may be invoked before login or after logout; internal applications may track user contexts using bespoke mechanisms; and applications may involve multiple identities, such as when a user manages a business account. Getting high query coverage involved a lot of manual work to discover alternate user contexts and identify endpoints that are not expected to be associated with a user.

Global sessions tend to be used for metadata stored in TAO, such as for product flows modeled as state machines. The addition of global sessions to a code base is often done fairly late in the product development cycle, to fix issues neglected in the initial design. Our ability to strengthen write visibility

for such call sites, without data migrations or schema changes, is an important part of making RYW a reasonable default.

The applications that cause the most challenge operationally need RYW consistency the least. These tend to be internal applications that perform batch processing or involve massive fan-out. They often cause write hot spots in the data stores but rarely read what they wrote afterwards.

Closing consistency loopholes with FlightTracker revealed the underlying systems were not actually eventually consistent. We have found low-probability bugs that cause permanent inconsistencies in TAO, graph indexes, and even database replication. These bugs were previously difficult to notice, as they were outnumbered by transient inconsistencies. Ticket-inclusive reads should never return old data, so now that we have FlightTracker even a single occurrence of a stale result is actionable. Bugs leading to permanent inconsistencies included protocol flaws, incorrect handling of error conditions, and relying on data invariants that were not honored by all historical data.

9 Limitations and future work

Our approach still relies on region-sticky user routing. We could avoid this limitation by always using global quorums like in § 7.3, but this would increase latency. We plan to eventually make user RYW sessions global by maintaining a map from user to region in FlightTracker, rehome sessions when the mapping changes.

The relative efficiency of our solution depends on amortizing the cost of the metadata reads across many TAO queries, and depends on the set of writes being relatively small. Environments with fewer reads have a different set of tradeoffs. This limitation is less applicable to index queries, because those tend to do more work per operation.

FlightTracker does not provide consistency for “unacknowledged successes.” As described previously in § 5.3, unacknowledged successes happen when a data write has a client error like a timeout or if the metadata write fails. We have not seen this to be a problem in practice, probably because the issue exists even without FlightTracker.

Some queries are difficult to repair: TAO top-N queries for large edge lists result in unnecessary consistency misses; index queries to a materialized aggregation (such as counts) can be detected as stale by FT-RI, but the stale result cannot be fixed with read repair; and list intersection queries that involve more than two lists are also difficult to repair.

The FlightTracker service compacts Tickets into a timestamp bound, so that we will take a consistency miss if replication exceeds the global compaction bound of 60s (§ 4.2). The global compaction bound is not fully rolled out as of publication time, so tail latency events in the replication pipeline can result in RYW violations. This has not been a big issue in practice because it requires that the first read of a write occurs after the global compaction interval but before replication.

Although some of our motivations are specific to Facebook’s workload, our desire to provide user-centric sessions is widely shared [42,55], as is our desire to extend consistency guarantees to global indexes [3,12,30,34]. Cache invalidation is also a perennial challenge for systems at all scales.

Our FlightTracker approach is generalizable: designed for heterogeneous data stores, Tickets can easily be extended to other data stores without much overhead (§ 4.1); the API extensions data stores need to implement (Figure 3) do not require core replication protocol changes and have relatively small overhead (§ 8.3); the client library where a lot of the FlightTracker logic lives can be implemented and rolled out gradually. Our approach is especially beneficial when trying to retrofit indexing systems, because it allows us to separate the reverse metadata index into its own component.

10 Related Work

Stronger consistency atop eventually consistent stores: Many eventually consistent systems offer options to opt for stronger consistency levels. Systems such as Cassandra [37], Riak [6], and RedBlue [39] provide strong consistency either by routing read requests to the leader or by adjusting their commit protocols. To provide bounded staleness, Azure CosmosDB [21] could backpressure writes. In contrast, FlightTracker serves most reads from a single local replica.

Index consistency: Most of these systems, including Amazon’s DynamoDB [11,12] and Google AppEngine Datastore [31], do not extend the stronger consistency levels to global secondary indexes. Twitter’s Manhattan [49] extends RYW to global secondary indexes by including them in a cross-shard transactional write, doubling latency [34,55]. Couchbase [3] supports RYW for reads to its global indexes using a timestamp in the client session. It accomplishes this by deterministically merging updates to all shards, limiting scalability in the number of shards.

Bailis et al. [15] proved that index consistency can be implemented with better availability characteristics than approaches that include indexes in general-purpose transactions.

Implementing RYW sessions: Session RYW [51] is intuitive and implementable with low overhead [14,27]. Bayou [28] and Pileus [52] provide session guarantees that span multiple servers by managing the session state in their client libraries. Bermbach et al. [19] similarly observed that client-centric consistency should focus on end users; their approach nonetheless assumes that a session is sticky to a single application server. PathStore [42] address the same challenge where clients interact with multiple data store replicas by using a session migration protocol on *every* replica switch. In contrast, FlightTracker manages session state in an intermediate layer between the client and the data servers.

Write-set tracking for stronger consistency: Systems like COPS [40] and SwiftCloud [56] track dependent write sets to provide causal consistency. They also provide

client contexts that are similar to FlightTracker sessions. BoltOn [16] layers causal consistency guarantees via a shim over eventually consistent stores. Its design shares similar principles as FlightTracker, aiming to retain the desirable properties of eventually consistent stores. For these systems, the dependency sets need to be stored in the database and cached on the client-side.

TxCache [46] provides transactional (but possibly stale) consistency for application-level caching and uses the terms *staleness miss* and *consistency miss* (both of which are included in our use of the term consistency miss). Its design focuses on single datacenter and treats materialized views as cacheable results from user-specified functions, which is insufficient for our applications.

To reduce the metadata size, systems like Occult [41] and Wukong+S [57] use structural or temporal properties to compress write sets and vector timestamps. FlightTracker uses CRDT inflation to compact Tickets and trims irrelevant writes to reduce network overhead, but mainly avoids metadata size explosion by providing a weaker consistency level.

Tradeoff between cache hit rate and consistency: Zanzibar [44] is built on top of Google’s linearizable Spanner [26], but chooses to expose a weaker consistency model to clients to improve its read efficiency and latency. Its zookies play a similar role to FlightTracker Tickets, encapsulating consistency information, but they are used only by Zanzibar itself.

CRDT quorum protocols: The single-round FlightTracker protocol is at its core CRDT [50] using quorum replication [29]. Gryff [22] and CURP [45] similarly leverage commutativity of writes. Because FlightTracker does not need atomicity, a single round suffices.

11 Conclusion

This paper introduces FlightTracker, our approach for providing RYW consistency for Facebook’s social graph. FlightTracker operates in a read-optimized ecosystem of asynchronously replicated caches, database replicas, and indexes. It preserves the read efficiency, hot spot tolerance, and loose coupling benefits of eventual consistency, and it has allowed us to circumvent the scaling challenges we encountered when using write-through caching for consistency.

KVell+: Snapshot Isolation without Snapshots

Abstract

Snapshot Isolation (SI) enables online analytical processing (OLAP) queries to observe a snapshot of the data at the time the query is issued, despite concurrent updates by online transactional processing (OLTP) transactions. The conventional implementation of SI creates a new version of a data item when it is updated, rather than overwriting the old version. Versions are garbage collected when they can no longer be read by any OLAP query. Frequent updates during long-running OLAP queries therefore create significant space amplification, and garbage collection can give rise to latency spikes for OLTP transactions. These problems are exacerbated on modern low-latency drives that can persist millions of updates per second.

We observe that analytic queries often consist in large part of commutative processing of data items resulting from range scans in which each item in the range is read exactly once. We introduce Online Commutative Processing (OLCP), a new model for processing analytical queries, that takes advantage of this observation. Under OLCP, analytical queries observe the same snapshot of the data as they would under conventional SI, but space amplification and garbage collection costs are largely and oftentimes nearly entirely avoided. When an item in such a range is updated, the old version of the item is propagated to the OLCP queries that might need it instead of being kept in the store.

We demonstrate OLCP's expressiveness by showing how to formulate, among others, the TPC-H benchmark queries in OLCP. We implement OLCP in KVell+, an extension of KVell, a key-value store for NVMe SSDs. Using YCSB-T, TPC-CH and production workloads from Nutanix, we run a wide range of analytics queries concurrently with write-intensive transactions. We show that OLCP incurs little or no space amplification or garbage collection overhead. As a surprising by-product we also show that OLCP speeds up analytical queries compared to SI.

1 Introduction

The desire to run frequent analytics on fresh data has led to the recent development of databases that allow concurrent processing of online transaction processing (OLTP) and online analytical processing (OLAP) [34]. To isolate OLAP queries from OLTP updates, databases typically rely on Snapshot Isolation (SI) [51, 66, 69]. SI provides OLAP queries with a snapshot of the database at the time the query is issued, independent of later updates made by OLTP transactions. Conventionally, SI is implemented by multi-versioning [6]: an update generates a new version of a data item, and previous versions are kept for as long as they belong to an active OLAP query's snapshot. Versions that no longer belong to such a snapshot are garbage collected. Long queries may thus cause the store to grow—a phenomenon known as *space amplification*, and garbage collection may provoke latency spikes.

Minimizing disk usage is important in production systems. Facebook found that "storage space is the bottleneck" [23], and Alibaba Group runs garbage collection with "the highest priority to prevent waste of storage space" [32]. Space amplification is particularly problematic when the dataset is stored on modern storage devices. NVMe SSDs can persist millions of items per second. Furthermore, because random and sequential access bandwidth are nearly identical, scanning data is no longer faster than performing random access updates. An analytical query running concurrently with write-intensive transactions may therefore cause the size of the store to increase manyfold.

Space amplification is a well-known problem for in-memory SI data stores. Various solutions have been developed, but they perform poorly on disk-based systems. Executing transactions sequentially avoids the need for locking and versioning [28], but is impractical when I/O latencies have to be overlapped with CPU use. Creating snapshots using operating system fork and copy-on-write techniques [39] incurs very high file system overheads when applied to disk-based systems. Closest to our work, Steam [8] trims versions that do not belong to any *active* snapshot, providing efficiencies

for some workloads. We propose a more radical re-design, suitable also for disk storage, that seeks to altogether avoid keeping old versions in the store.

Our approach is based on the following two observations. First, most OLAP queries scan data, but are oblivious to the order in which they read items, because the operations performed on items are commutative. Second, OLAP queries read scanned items at most once. For instance, queries that compute sales statistics (e.g., the most popular item in a region) can perform their operation by scanning items once in any order. Based on these observations, we define a new class of processing: OnLine Commutative Processing (OLCP). OLCP queries declare so called *scan ranges*. When an item in a scan range is updated by a concurrent transaction, its old value is processed by OLCP queries and then discarded, instead of being kept in the store.

Scan ranges have numerous advantages. First, because no versions are kept for items in scan ranges, space amplification is limited, and GC overhead is reduced. Second, because OLCP queries process items in scan ranges as they are modified, they read more data from memory and less from disk, and thus have higher throughput than their OLAP counterparts. The trade-off is that an OLCP query can read items belonging to its scan ranges only once. In addition, scanned items are not guaranteed to be read in order.

In addition, OLCP queries can declare *point ranges*, ranges of items on which they want to perform point queries. Items in point ranges are versioned, as in the conventional SI implementation. The combination of scan ranges and point ranges allows OLAP queries to be expressed efficiently in OLCP. Moreover, a very large subset can be expressed in a manner so that they derive great benefit from OLCP, including reduced space amplification, no GC-induced latency spikes, and higher throughput.

We implement OLCP queries in Kvell+, an extension of Kvell [45]. In Kvell+, scan and point ranges are declared through an interface inspired by the MapReduce paradigm [19]. OLCP queries declare a `map` function that is called *exactly once* on all items that belong to scan ranges. The items that `map` reads correspond to the items that the query would have read under conventional SI (i.e., belonging to the snapshot at the start of the query). The `map` function can also perform point queries on items in point ranges. In the absence of updates by OLTP transactions, `map` is called on items in scan ranges in lexicographic order, but when an item is updated, we *propagate* its old value to OLCP queries. The old value is processed by the OLCP queries (potentially breaking the lexicographic order of the scans) and then deleted from the store. Space freed by the deletion can be reused to store new items.

OLCP can easily be integrated in existing applications, either manually, using an SQL-to-MapReduce tool [44, 71], or automatically at the SQL query-plan level. OLAP and OLCP queries can run simultaneously on the same data. A developer

may therefore choose to port existing OLAP queries that create substantial space amplification to OLCP, while leaving less problematic OLAP queries to run under SI.

We make the following contributions:

- The OLCP query model.
- A detailed explanation and examples showing how to port OLAP queries (e.g., MapReduce analytics, TPC-H queries) to OLCP.
- The implementation of OLCP in Kvell+.
- A comparison of OLCP to SI and Steam [8] in terms of space amplification, tail latency and throughput.

Roadmap. Section 2 presents the key OLCP principles. Section 3 explains in detail how data analytics workloads can greatly benefit from OLCP. Section 4 discusses the implementation. Section 5 shows our experimental evaluation results. Section 6 presents the related work, and Section 7 concludes.

2 OLCP Overview

In this section, we explain OLCP’s design principles, advantages, and limitations. We explain how to perform scans concurrently with propagation events.

2.1 OLCP in a nutshell

The main goal of OLCP is to reduce the time that old item versions spend in the store. OLCP allows the store to *reduce the lifespan of old versions down to the duration of OLTP commits*. In a conventional SI implementation, OLAP queries force the store to keep old versions for the entire duration of the queries. In contrast, OLCP queries process old versions as they are generated. Once the old version of an item has been processed, it is deleted from the store and its space can be reused to store new items.

OLCP advantages: OLCP provides the same guarantees as SI, with virtually no space amplification. Furthermore, because OLCP queries process items as they are being updated, OLCP queries avoid reads to disk, improving the throughput of analytical queries.

OLCP requirements: To completely avoid space amplification under OLCP, queries need to support scanning out-of-order and to access each item in the scan ranges only once. These requirements can be relaxed at the expense of increased space amplification, but OLCP’s space amplification is always lower than that of conventional SI implementations. OLCP queries are widely applicable and constitute an efficient replacement of OLAP queries, as we demonstrate in Section 3.

2.2 OLCP interface

MapReduce interface: The interface of OLCP is inspired by the event-driven MapReduce paradigm [19]. An OLCP query is created and executed by a single function call:

```
t = olcp_query(map, payload, [scan_range1,
                             scan_range2, ...], [point_range1, ...])
```

The `olcp_query` call takes the following parameters:

- **A map function callback.** OLCP guarantees that the map callback is called exactly once on all items within the scan ranges. The exactly-once guarantee is essential to limit overheads. Without it, OLCP would have to maintain a list of items they have already seen, which could have prohibitive CPU and memory overhead for large scans. The item versions provided to the map callback correspond to those that the query would have scanned under SI (i.e., those belonging to the snapshot at the time the query is launched).
- **Payload for the map callback.** An arbitrary pointer to application specific data. Usually used to retrieve or store intermediary computation results.
- **Scan ranges.** This range can be the entire store. If ranges overlap, the map function is called only once per item belonging to the ranges. Items belonging to the ranges are not versioned and induce no space amplification. In return, items belonging to the ranges are not guaranteed to be scanned in order (old versions might be scanned before their turn to avoid keeping them in snapshots).
- **Point ranges.** OLCP queries may also declare ranges of items that they might access using point queries. Items within those ranges are versioned until the query is committed and may induce space amplification. Items in the point ranges can be accessed multiple times, and scans on these ranges are guaranteed to happen in lexicographic order. Many analytical processing queries can be expressed without using point queries, as we show in Section 3.

Items outside of the scan and point ranges are neither versioned nor propagated. The `olcp_query` function blocks until the scans are complete. After calling `olcp_query`, a developer might choose to do further processing on the payload. In the remainder of this paper, we do this processing in a `reduce` function.

2.3 Scans, propagation and space reclamation

Algorithm 1 presents pseudo code for scanning, updating and propagating updates in a store that supports OLCP queries. For simplicity, we present a sequential implementation that does not support point ranges. A full implementation would have to handle possible races between scans and propagations and delay the deletion of items belonging to point ranges. We

also assume the use of timestamps to define snapshots, as is common in SI implementations.

Algorithm 1 Pseudo-code of a sequential implementation of updates, propagations, and scans.

```
1  /*OLCP commit: create a new version and add the
2  old version in GC queue */
3  timestamp t_commit = now();
4  active_commit_timestamps.add(t_commit);
5  foreach(item i in updated_items) {
6      kv.write(i, t_commit);
7      gc.add(get_oldest(i), t_commit);
8  }
9  active_commit_timestamps.delete(t_commit);

11 /* GC */
12 timestamp t_min=min(active_commit_timestamps);
13 foreach(item i in gc) {
14     // Only delete items from
15     // fully committed transactions
16     if(i.t_commit >= t_min)
17         break;
18     foreach(olcp o in running_olcp) {
19         if(o.in_snapshot(i)
20             && i.key > o.last_scanned)
21             o.propagation_queue.add(i);
22     }
23     delete(i); // remove from the store
24 }

26 /* OLCP query thread */
27 item last_scanned = get_first(scan_range);
28 do {
29     if(last_scanned != EOF) {
30         map(last_scanned, payload);
31         get_next(&last_scanned);
32     }
33
34     while(item i = propagation_queue.pop())
35         if(i.key > last_scanned)
36             map(i, payload);
37 } while(last_scanned != EOF);
```

Scans: OLCP queries request items from the store in lexicographic order using the `get_next` function (line 31 of Algorithm 1). When there are no concurrent OLTP transactions, the scan happens as it would in a conventional SI implementation: items are read in lexicographic order, and the map function is called on each of them. In OLCP, however, this order can be "interrupted" by propagations resulting from updates by OLTP transactions to items in the scan ranges. When receiving a propagated item, the OLCP query checks that it has not yet scanned the item and, if so, calls map on it (lines 35-36). Afterwards, the OLCP query resumes the scan from the last scanned item using the `get_next` function.

Propagation and space reclamation: The key to avoiding space amplification with OLCP queries is to delete old data as soon as possible. However, an old version of an item cannot be deleted as soon as a new version is created. When an OLTP transaction updates multiple items, old items can be deleted

only after *all* new items are persisted (to allow recovery in case of a mid-commit crash). Hence, the deletions must happen *after* a transaction has committed. Consequently, the store must maintain multiple versions of committed items for the duration of an OLTP commit.

Committing an OLTP transaction then consists of updating the modified items in the store and enqueueing the oldest version of those items on the GC queue (lines 6-7 of Algorithm 1). After the commit is completed, the GC propagates and deletes items. An item is propagated to an OLCP query only if it belongs to the query's snapshot and if it has not yet been scanned. We rely on the lexicographic order of the scan to efficiently ensure this latter property (line 20). In our pseudo code, we choose to enqueue propagated elements in a per-OLCP query queue (line 21), but an implementation might choose a different communication mechanism between the store and running OLCP queries.

Space reclamation efficiency: In practice, the number of versioned items in OLCP is small. When an OLCP query does not use point ranges, a rough estimate of the number of versioned items in OLCP is the number of updates per transaction times the number of concurrent commits. In a conventional implementation of SI, this number is much higher, since the system needs to keep old versions of all items updated during the lifetime of OLAP queries.

Old versions are also only kept for a much shorter time in OLCP. Figure 1 summarizes the lifespan of objects, executing an OLTP transaction concurrently with an (a) OLAP or (b) OLCP query. With OLAP queries, the store has to keep all versions of items for the duration of long queries (minutes), while OLCP allows the store to remove old versions after at most a few commits (microseconds).

OLCP queries can run alongside OLAP queries. In that case the deletion and propagation of items is postponed to ensure the correct execution of OLAP queries: items are deleted and propagated when they no longer belong to an OLAP snapshot. OLAP queries may thus reduce the effectiveness of using OLCP.

Figure 1: Lifespan of items under OLAP (a) and OLCP (b). OLAP forces an old item version to be kept for the entire duration of the OLAP query, while OLCP needs to keep it only for the duration of the commit of the OLTP transaction that produces the new version.

2.4 Informal correctness argument

Correctness requires that, despite concurrent OLTP transactions, OLCP queries read the same items from their scan ranges as they would have read under a conventional implementation of SI, and that these items are processed *exactly once*. The correctness relies on the following observations.

An item is propagated at most once, and the propagated item belongs to the query's snapshot. If an item is not updated, then no propagation occurs. If an item is updated once, its old version is propagated only if it belongs to the snapshot (line 19 in Algorithm 1). If an item is updated multiple times, all old versions are put in the GC queue, but only one of them belongs to the snapshot and is propagated.

An item is processed exactly once. If an item is not propagated, it is read as part of the scan. The scan does not "skip" items: after scanning an item, a query always requests the next item from the store regardless of concurrent propagations. Thus, a query always scans its entire *scan_ranges*. Only items that have not yet been scanned are propagated (lines 20 and 35 in Algorithm 1).

From the previous observations, we conclude that an OLCP query processes all the items belonging to its scan ranges exactly once, and that the processed items belong to its snapshot. As a result, a developer need not consider the distinction between scanned and propagated items.

2.5 Example

Figure 2 illustrates with an example some of the complex interleavings between OLTP and OLCP. An OLCP query T scans a range of 5 items. T has snapshot timestamp 0. The initial versions of all five items have timestamp 0, and therefore belong to T's snapshot. Despite various updates by OLTP transactions, T correctly calls `map` exactly once on all five initial item versions.

Of particular interest in this execution is item d that is updated twice, at t_2 and t_4 , but only d_0 is propagated. Despite being interrupted by the propagation of d_0 , T correctly

resumes its scan from b_0 at time t_3 . Finally, at t_5 , a is not propagated because the query already scanned b , and at t_6 , c is not propagated because it has just been scanned.

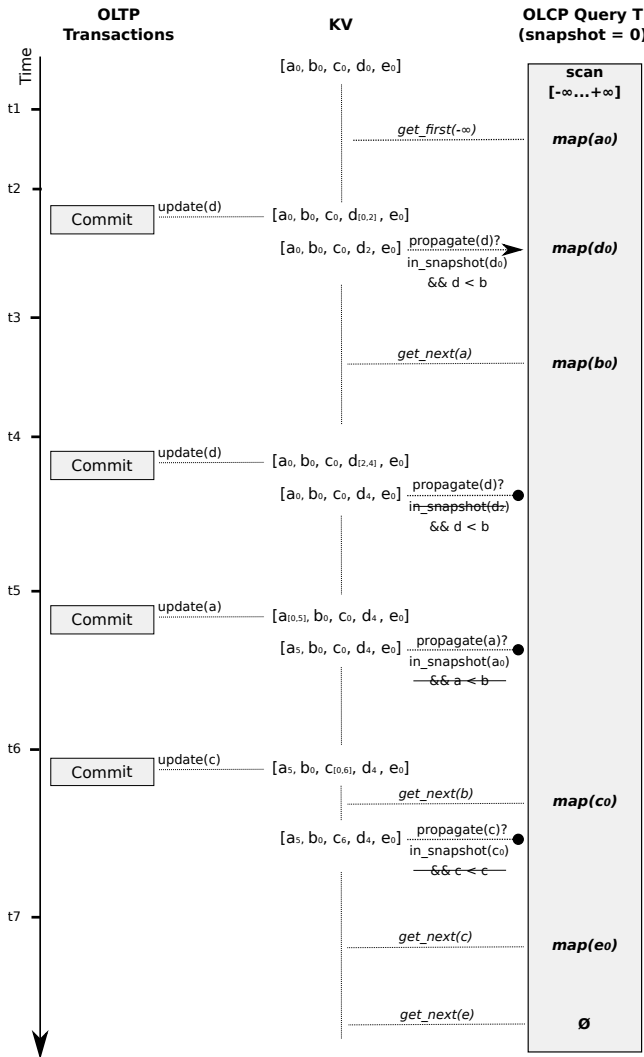

Figure 2: Possible interleavings between a scan and various propagations. Arrows indicate that an item is propagated to the OLCP query, rounded segments indicate that an item is not. At the end, the `map` function has been called exactly once on all items initially contained in the scan range.

3 Using OLCP in practice

Below, we explain how OLCP can be widely used in practice to eliminate space amplification. Analytical processing is typically done in the following three ways:

1. Multidimensional OLAP (MOLAP) analytics,
2. Relational OLAP (ROLAP) analytics, and
3. MapReduce-style analytics.

3.1 MOLAP analytics

MOLAP databases provide a traditional platform for data analytics which is widely used in Business Intelligence applications (e.g., IBM Cognos [14], Oracle Essbase [56], and iccube [35]). The data is first extracted from a relational database, transformed into a specialized multidimensional cube format, and then transferred into the MOLAP database. OLCP can be used during the extraction phase to get a snapshot of the database with little space overhead. Using a conventional implementation of SI, updates performed during the extraction create space amplification, and the relational database may stall once the extraction is complete because of GC. To avoid these issues, database administrators usually run the extraction during the night when the load is low. OLCP allows extractions to occur at any time without space overhead or database stalls.

3.2 ROLAP analytics

ROLAP tools query the main relational database directly through a language like SQL. In this paper we use SQL syntax for simplicity, but other languages with similar constructs can be used as well. Analytical queries consist of a combination of three types of building blocks.

1. Decomposable aggregate functions (e.g., SUM, COUNT).
2. Aggregate functions (e.g., GROUP BY, CUBE, ROLLUP).
3. Joins.

We show that for these three types of operations OLCP reduces space amplification. *Most ROLAP operations have no space overhead under OLCP.*

Decomposable aggregate functions: Decomposable aggregate functions are the least complex of the three query building blocks. They consist of commutative operations that only require one pass over the data (e.g., SUM, MIN, MAX, AVG).

Nutanix uses decomposable aggregate functions to compute simple statistics on a store that keeps track of disk blocks allocated to virtual machines in a datacenter. For instance, Algorithm 2 counts the number of disk blocks that have not been accessed for the last two hours. The query is used to estimate the percentage of allocated storage that is infrequently accessed. Algorithm 3 presents the equivalent using OLCP. For simplicity, we present a sequential version of the algorithm. In practice the `map` function can be called concurrently by multiple threads, and we use per thread payloads that are merged at the end of the scan.

The query is executed with low priority in order to avoid interfering with other workloads. This query used to be executed under read committed to avoid the space amplification overhead of SI (under read-committed, old data is removed from the store and the scan reads the most recent version of committed items). Unfortunately, under read committed,

this query overestimates the number of accessed blocks because, when a block is accessed after the start of the query, it is impossible to know if the block was idle in the past two hours prior to the query, since this information is lost after the update. Executing the query with OLCP, and thus with SI guarantees, produces a precise estimate of disk usage.

Algorithm 2 RocksDB pseudocode for counting the number of disk blocks in a datacenter that have not been used in the last two hours.

```

1 size_t count = 0, target_time = now() - 2;
2 Iterator *it = ...;
3 for(it->SeekToFirst(); it->Valid(); it->Next()){
4     block_t *t = it->value;
5     if(t->last_access < target_time)
6         count++;
7 }
```

Algorithm 3 OLCP pseudocode for counting the number of disk blocks in a datacenter that have not been used in the last two hours.

```

1 map(item *i, payload *p) {
2     if(i->last_access < p->target_time)
3         p->count++;
4 }
5 payload p={.target_time = now()-2, .count=0};
6 t = olcp_query(map, &p, [...], NULL);
7 commit(t);
```

Aggregate functions: Like decomposable aggregate functions, these queries do not require items to be accessed in order, and the data is accessed only once. The difference is that these queries group items into categories and compute statistics for each group (e.g., using the GROUP BY clause and its extensions like CUBE and ROLLUP).

We illustrate how OLCP reduces space overhead with the first query from the TPC-H suite [74] (Algorithm 4). Algorithm 5 presents its equivalent using OLCP (for simplicity we use the name of the tables to represent the ranges of keys). The query provides a summary pricing report for all items shipped before a given date, aggregated by a flag and a status. This query is more complex than the previous example because it requires grouping analyzed items in buckets and returning them in order. Since the number of flags and statuses is small, the number of buckets is small, and the summaries can be computed in memory. If the number of summaries to be computed was large, the map function could use point queries to load and store temporary summary results from disk. After the scan completes, the summaries are sorted in a reduce function.

Joins: ROLAP joins are typically *hash joins* or *nested loop joins* [30]. An analysis of the query plans of Microsoft SQL [12] for the TPC-H queries shows that approximately 70% of the joins are hash joins, and the remaining 30% are nested loop joins.

Algorithm 4 First query of TPC-H.

```

1 select l_returnflag,
2        l_linestatus,
3        sum(l_quantity) as sum_qty, [...]
4 from lineitem
5 where l_shipdate <= '1998-09-04'
6 group by l_returnflag, l_linestatus
7 order by l_returnflag, l_linestatus;
```

Algorithm 5 First query of TPC-H using OLCP.

```

1 map(item *i, payload *p) {
2     if(i->l_shipdate < "1998-09-04")
3         return;
4     string k=i->l_returnflag+"|"+i->l_linestatus;
5     p->sum_qty[k] += i->l_quantity;
6 }
7
8 reduce(payload *p) {
9     sort(p->sum_qty); // sort p by key
10    return p->sum_qty;
11 }
12
13 payload p = { ... };
14 t = olcp_query(map, &p, [lineitems], NULL);
15 commit(t);
16 reduce(&p);
```

Hash joins are usually performed in two steps. First, the join scans the first table, and builds a hash table (build phase). Then, the join scans the second table and probes the hash table for matches (probing phase). Building the hash table only uses one-time commutative reads. By putting the first table in the scan ranges, OLCP avoids any space amplification during the build phase. The probing phase then occurs in the *reduce* function, with the second table in the point ranges. In general, hash joins can easily be ported to OLCP by placing the more frequently updated table in the scan ranges and the less frequently accessed table in the point ranges.

Algorithm 6 presents the fourth query of TPC-H. The query counts the number of orders ordered in a given quarter of a given year in which at least one lineitem (item of an order) is received by the customer later than its committed date. In Microsoft SQL, the build phase is performed on the "orders" table and the probing phase on the "lineitem" table. Algorithm 7 presents a port of this query plan to OLCP. The "orders" table is placed in the scan ranges, and the "lineitem" table in the point ranges. The hash table is built in the map function, and the scan of lineitem and the probing is done in the reduce function. While the query is running, updates on the "orders" table, or any table that is not accessed by the query, do not induce any space amplification. Items in the "lineitem" table are versioned. If "lineitem" were known to be frequently updated, the query plan could easily be modified to build the hash table using "lineitems" and scanning the "orders" table next.

Algorithm 6 Query 4 of TPC-H in SQL.

```
1 select o_orderpriority, count(*) as order_cnt
2 from orders
3 where
4   o_orderdate >= date '1995-01-01'
5   and o_orderdate < date '1995-04-01'
6   and exists (
7     select *
8     from lineitem
9     where l_orderkey = o_orderkey
10          and l_commitdate < l_receiptdate
11   )
12 group by o_orderpriority
13 order by o_orderpriority;
```

Algorithm 7 Pseudo code of Query 4 of TPC-H using OLCP.

```
1 map(item *i, payload *p) {
2   if(i->o_orderdate >= '1995-01-01'
3     && i->o_orderdate < '1995-04-01')
4     p->hash[i->o_orderkey] = ...;
5 }
6 reduce(payload *p) {
7   // Scan versioned lineitems
8   hash_t res = {};
9   foreach(lineitem_t l in lineitems) {
10    if(p->hash[l->l_orderkey]
11      && l->l_commitdate < l->l_receiptdate)
12      res[l->o_orderdate].order_cnt++;
13   }
14   return sort(res);
15 }
16 payload p = { ... };
17 t=olcp_query(map, &p, [order], [lineitem]);
18 reduce(&p);
19 commit(t);
```

Nested loop joins iterate over two tables in order. Because of the order constraint, nested loops do not naturally fit the OLCP model. However, it is often possible to adapt nested loops to OLCP with minor changes to the query plan. Query 17 of the TPC-H benchmark (Algorithm 8) is an example of a complex join query that is executed using nested loops in the Microsoft SQL query plans for TPC-H. This query gets items of a given brand that sold five times less than the same item from other brands. It then computes the total revenue loss that would have occurred if these items had not been sold. The query is divided in two sections: *tinner* computes the average number of sales per "partkey" item, regardless of the brand, and *touter* gets the sales information for a given brand.

The number of "partkey" items is small (10K) compared to the number of order items (90M), and orders are aggregated by "partkey". Algorithm 9 presents pseudo code of a possible implementation. Lineitem (list of ordered items) is scanned, and the map function simultaneously computes information for the *tinner* and *touter* queries. The map function performs one point query to the "partkey" table to get the brand of the scanned item. A reduce function then aggregates per-partkey

information and outputs the total price of the items that match the criteria. The memory required to execute this query is low (hashtable with 10K entries). The "partkey" table is the only table that is accessed using a point query. Since "partkey" is read-mostly, this query has negligible space amplification when executed with OLCP.

Algorithm 8 Query 17 of TPC-H.

```
1 select sum(l_extprice) / 7.0 as avg_yearly
2 from
3   (
4     select l_partkey, l_quantity, l_extprice
5     from lineitem, part
6     where p_partkey = l_partkey
7           and p_brand='Brand#34'
8           and p_container='MED_PACK'
9   ) touter,
10  (
11    select l_partkey as lp,
12           0.2*avg(l_quantity) as lq
13    from lineitem
14    group by l_partkey
15  ) tinner
16 where touter.l_partkey = tinner.lp
17 and touter.l_quantity < tinner.lq;
```

Algorithm 9 Pseudo code of Query 17 using OLCP.

```
1 map(item *i, payload *p) {
2   string k = i->l_partkey;
3
4   // Tinner
5   p->tinner[k].l_quantity_sum += i->l_quantity;
6   p->tinner[k].l_quantity_count++;
7
8   // Touter
9   part_t *part = kv_get("part"+k); // Seek
10  if(part->p_brand == "Brand#34"
11    && part->p_container == "MED_PACK") {
12    p->touter[k] += {
13      l_quantity = i->l_quantity,
14      l_extprice = i->l_extprice
15    };
16  }
17 }
18 reduce(payload *p) {
19   double l_extprice_sum = 0;
20   foreach(string k in p->touter) {
21     double lq = 0.2*p->tinner[k].l_quantity_sum/
22       p->tinner[k].l_quantity_count;
23     foreach(int i in p->touter[k]) {
24       if(p->touter[k][i].l_quantity < lq)
25         l_extprice_sum+=p->touter[k].l_extprice;
26     }
27   }
28   return l_extprice_sum / 7.0;
29 }
30 payload p = { ... };
31 t=olcp_query(map, &p, [lineitems], [parts]);
32 commit(t);
33 reduce(&p);
```

3.3 MapReduce analytics

MapReduce provides a highly parallelizable and scalable framework. This approach is popular for computing simple analytics on vast amounts of data, employed for instance to obtain cluster management statistics [9], to compute popular search-word and query trends [20], and to analyze time-series workloads in IoT, recommender systems and finance [1]. Essentially, the mappers are doing a background scan on the store (e.g., Cassandra, RocksDB), and push the items of interest into a MapReduce system (e.g., Hadoop, CouchDB, Phoenix [52]). These scans take on the order of a few hours and happen concurrently with the foreground workloads, which can be write-heavy [3]. Using the conventional implementation of SI causes prohibitive space amplification because incoming updates need to be tracked over a long time span. To avoid the space explosion, these statistics are usually collected in read-committed mode and thus have lower accuracy. In contrast, OLCP supports consistent one-pass scans, with no space overhead.

4 Implementation

In this section, we describe our implementation of SI and OLCP. The source code of our implementation is available at <https://github.com/BLepers/KVell>. Our implementation adds approximately 4,000 lines of code on top of KVell.

4.1 KVell

As noted in previous work [45], when running on modern fast drives, existing KVs that support SI, such as WiredTiger and RocksDB, run into a CPU bottleneck and are unable to write data at disk speed. As a result they are not suitable for studying space amplification on such drives. We therefore extend KVell [45], a recent KV designed for NVMe SSDs.

KVell has two main components: an ordered index residing in RAM, and an unsorted data structure on disk similar to a slab memory allocator, which groups items with similar sizes in the same file. Reads are either served from a cache (0 I/O), or from disk (1 I/O). Updates fetch a 4KB block from disk, modify it in memory, and then write the dirty block back to disk (1 or 2 I/Os, depending on whether the block was cached or not). The index and the disk data structure are partitioned among multiple worker threads, with each worker handling a range of the key space.

Ideally, analytical queries should not slow down OLTP transactions. Even on modern drives, a fine balance has to be maintained between sending too few simultaneous requests (resulting in sub-optimal bandwidth) and sending too many (resulting in high latency). In its original implementation, KVell scans ranges by reading all items of the range in parallel. We change the implementation of scans to ensure that scans do not overwhelm the disk with requests. Scans

request batches of items from the store, with the size of a batch adjusted depending on the current disk utilization. In practice, we aim at having between 32-64 pending disk I/O requests at all time. When reading the next batch, we adjust the batch size to keep the number of disk I/Os within this bound.

In its original implementation, KVell did not support transactions. We first describe our conventional implementation of SI in KVell+ and the extension to reduce space amplification proposed in Steam [8]. We then describe our implementation of OLCP in KVell+.

4.2 Conventional SI

Our implementation of SI is inspired by those of RocksDB and WiredTiger, two KVs that are widely used in industry.

Timestamps: We add a global logical timestamp in KVell. The global timestamp is incremented every time it is read. When a transaction *commits*, it is given a commit timestamp t_{commit} equal to the current global timestamp. When a transaction *starts*, it is given a snapshot timestamp, $t_{snapshot}$. The snapshot timestamp is chosen so that a transaction can only read data that has already been committed, using the following formula: $t_{snapshot} = \min_{active}(t_{commit}) - 1$. If no transaction is committing, the $t_{snapshot}$ is set to the current global timestamp.

In the original version of KVell, persisted items are already timestamped; we use these timestamps in the read and writing path: a transaction can only read or write an item with a timestamp less than or equal to its $t_{snapshot}$.

Writing data: To perform a *write* on a key, a transaction locks the index entry for that key in the main memory index. If the key is not present in the store, a new locked index entry is created. To prevent write-write conflicts, a transaction that fails to lock an item aborts. It also removes all previously acquired locks and any newly created index entries. Before commit, only the in-memory index is updated. The new item versions are kept in a private in-memory buffer (similarly to RocksDB).

Reading data: When *reading* an item, the worker first checks if the item is in its private buffer. If not, the item is read from the main store. If the memory index contains multiple versions of an item, the transaction reads the most recent version that belongs to its snapshot.

Committing updated data: To commit, a transaction persists a tuple (t_{commit}, N) , where N is the number of updated items. This tuple is used in case of a crash to avoid recovering items from partially committed transactions. The transaction then writes the new items to disk, timestamped with t_{commit} . Once all new items have been persisted, the transaction deletes the (t_{commit}, N) tuple. During a commit, the transaction updates the index non-atomically: entries for the new versions are added to the index, and index entries are unlocked as they are updated. This process is safe because no other transac-

tion can read or write any of the updates before the commit ends (by the definition of $t_{snapshot}$), so transactions cannot access partially committed data. Hence, transactions appear "atomically" in the system.

KVell did not use a commit log in its original implementation, and we do not add one to support transactions. This design choice is essential for performance on modern drives. Historically, commit logs were cheap to maintain compared to the cost of updating the store – a fast sequential append vs. a slow random update to a complex data structure. NVMe drives can perform random I/Os as fast as sequential I/Os. In KVell, persisting an item is performed in as low as 1 I/O. Adding a commit log would essentially double the number of I/Os required to perform an update and halve the speed of the store. We acknowledge the usefulness of logs (e.g., for accountability, audit, etc.), and developers might choose to log store accesses via a fast logging system. Our implementation has the advantage of placing logs outside of the critical path.

Garbage collection: After commit, the location of the old versions of updated items are placed in a per-worker cleaning list. Workers periodically check the smallest active $t_{snapshot}$. When this value changes, they scan their cleaning list and delete obsolete items. Workers stop cleaning as soon as they find an item with a timestamp higher than or equal to $\min(t_{snapshot})$ (similarly to WiredTiger).

4.3 Steam

Steam [8] uses a more aggressive form of garbage collection that aims to reduce the number of old versions. When an item is updated, Steam scans that item's versions, and deletes the ones that do not belong to any active transaction. Steam was originally implemented in an in-memory database and does not handle recovery in case of a crash. In our implementation, we delay the deletion of old versions to after the commit to avoid deleting versions that might be needed during recovery. Otherwise, our implementation is similar to the original one.

4.4 OLCP in KVell+

OLCP further modifies garbage collection and implements propagation. We also describe a key optimization to avoid extra I/Os as a result of propagation.

Garbage collection: The main difference between OLCP and OLAP is the time during which old versions need to be kept in the store. Workers have two cleaning lists: one for items belonging to the scan ranges, and one for items belonging to the point ranges. GC for point ranges happens as it would under SI. GC for scan ranges happens as described in Algorithm 1.

Propagations: Key to the proper functioning of OLCP is implementing an efficient propagation mechanism. KVell uses an asynchronous interface: threads send requests to the data-

store, and the datastore enqueues answers in a per-transaction queue. We build on this mechanism for propagations. Propagating an item I to a OLCP query T consists of enqueueing I in T 's queue (as if T had requested to read the item). At the data store level, data is sharded between single threaded workers, so propagations do not introduce any data races. For instance, if an item is propagated "while" being requested by a scan, the scan request and the propagation request are serialized at the worker level and only one of the requests causes the item to be enqueued in the queue. If multiple OLCP queries are running, an item may be enqueued in multiple queues.

Concurrency: In KVell, items are sharded between multiple workers. To speed up queries, we start the scan on all workers. All workers progress in their scan concurrently and may propagate updates concurrently. No synchronization is required between workers because workers work on distinct items. In practice, the scan happens as if multiple single threaded scans were launched on disjoint sets of items.

Avoid reading old versions from disk: In Section 2, old item versions are propagated immediately after committing the new versions. This approach is sub-optimal: updates are not performed in place, and therefore propagating old versions at this time requires reading them from disk, adding an extra read to an update. To eliminate this extra read, we delay propagations and deletions. Instead of propagating and deleting the old versions in the GC (lines 18-23 in Algorithm 1), we keep the entries for them in the index, and we put their location in a list of reusable spots. When such a spot is later reused, the disk block containing that spot is read, and we take advantage of that to propagate the old version without an extra disk read.

This optimization raises the possibility that versions of the same item might not be overwritten in the order they are created. For instance, if versions of the same data item are of different size, they are allocated in different slabs, and a more recent version may be overwritten before an older version.

Figure 3 presents a case where an item has three versions (k_0 , k_1 and k_2). k_2 is the current version. k_0 and k_1 are old versions ($t_0 < t_1 < t_2$). k_0 and k_1 are in the free list of reusable spots and have not yet been overwritten. At the beginning of the execution, the in-memory index still contains all three versions. Indeed, k_0 and k_1 have not been overwritten, and so have not yet been propagated. In Figure 3 an OLCP query T executes with a snapshot timestamp equal to t_1 . Assume that the slot containing k_1 is reused before the one containing k_0 , and assume furthermore that k has not been scanned. k_1 is propagated and deleted, since it has not been scanned and it is part of T 's snapshot.

However, k_1 's index entry must not be immediately removed. In the absence of any record of k_1 in the index, if k_0 's slot is overwritten before the scan reaches k , as depicted in Figure 3, it would be propagated to T . Similarly, if T 's scan reaches k before k_0 is overwritten, it would be read by the

scan. In both cases, T would erroneously read k_0 , a version that does not belong to its snapshot. To avoid these situations, we keep k_1 in the index, but flag it as deleted. It then becomes clear that k_0 does not belong to T 's snapshot, and it is neither propagated nor read by the scan. Once k_0 has been overwritten, it is removed from the index because it is the oldest version. k_1 is then removed from the index as well because it is now the oldest version and flagged as deleted.

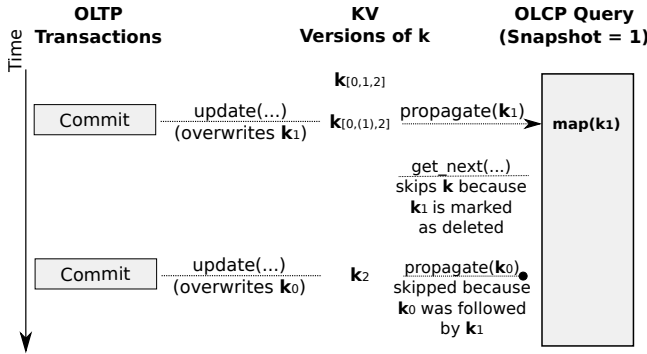

Figure 3: Under optimized OLCP old versions might not be overwritten in version order. In that case, the query must skip k_0 , even though it would appear to belong to its snapshot ($t_0 < t_1$).

4.5 OLCP in other stores

In the previous section, we focused on the implementation of OLCP in KVell, but the OLCP paradigm is general and applicable to other datastores and other storage devices. For instance, OLCP can be implemented in RocksDB and WiredTiger and on slower SSDs. In RocksDB, old items can be propagated during compactions: when merging two SSTables, old items can be propagated and discarded with no extra I/Os. Similarly, WiredTiger can propagate old items during checkpointing. OLCP can also be implemented in in-memory databases like Hyper [39]: Hyper maintains free lists of reusable spots, so it can propagate old items when reusing their spot (just as in our KVell+ implementation).

5 Evaluation

5.1 Goals

We evaluate OLCP queries on a variety of synthetic and production workloads. We seek to answer the following questions:

- **Resource utilization:** What is the space amplification of OLCP compared with existing SI implementations? What is the impact of using OLCP queries on throughput and tail latency?

- **Scalability:** How does OLCP scale with the number of concurrent scans and with the size of the store?
- **Performance:** How does OLCP perform on TPC and production workloads?

5.2 Experimental settings

Hardware: We use the following hardware configurations:

Config-AWS. An AWS i3.metal instance, with 36 CPUs (72 cores) running at 2.3GHz, 488GB of RAM, and 8 NVMe SSD drives of 1.9TB each (brand unknown, 2016 technology). The server can sustain a total of 3M read IOPS and 1.4M write IOPS (on read/write workloads, the maximum number of IOPS varies between 1.4 and 3M). The store is configured to cache 30GB of data.

Config-NVMe. A 4-core 4.2GHz Intel i7, 48GB of RAM, and a 480GB Intel Optane 905P (2018). The server can sustain 500K read or write IOPS. The store is configured to cache 20GB of data.

Workloads: We use the following workloads:

YCSB-T: YCSB-Transactional [21] is inspired by the Yahoo! Cloud Serving Benchmark [16] but groups updates in transactions. The average KV item size is 1024B, and the total data set size is approximately 100GB (100M keys) for the small test and 5TB (5B keys) for the large test. Similarly to previous work [77], we perform 16 updates per transaction and items are accessed uniformly. We use this workload to test the limit of SI and OLCP under a write-heavy workload (100% updates).

TPC-CH: The TPC-CH workload [15] mixes the widely popular TPC-C and TPC-H workloads. Currently, TPC-C is the industry standard to simulate OLTP systems [72] and TPC-H is the industry standard to simulate OLAP systems [74]. The TPC-CH workload harmonizes the representation of the data used by TPC-C and TPC-H so that TPC-C and TPC-H queries can run on the same dataset. The TPC-CH benchmarks [15] remove 3 updates that cause most TPC-C queries to fail due to write-write conflicts. Without this modification, TPC-C transactions abort 85% of the time. The abort rate goes down to less than 1% of the time with the modification. Our implementation is similar to the one for Redis [73].

In order to reach a significant database size, we configure TPC-CH to run with 300 warehouses. In that configuration, the store contains 140M items in total, 90M of which represent orders. The rest of the items represent customer data, stock, etc.

Production workloads from Nutanix: The production workloads are two write-intensive workloads, with a profile of 57:41:2 write:read:scan ratio. The KV item sizes range between 250B and 1KB, with a median of 400B. The total dataset size for the production workload is 256GB. The difference between the two workloads is the data skew: The key distribution in Production Workload 1 is close to uniform, while Production Workload 2 is more skewed. OLTP

transactions perform on average 10 requests per transaction.

Existing SI implementations: We compare OLCP to the conventional SI implementations and the Steam SI implementation presented in Section 4. In the remainder of this section, we refer to these implementations as "SI" and "Steam", respectively.

5.3 YCSB-T

In this experiment, we run scans of the store concurrently with YCSB-T transactions. The system is disk-bound. We run the experiment with the 100GB dataset on Config-NVMe.

5.3.1 Space amplification

Figure 4 presents the evolution of the number of old versions in time for a Zipfian and a uniform distribution of updates, varying the number of concurrent scans.

Figure 4(a) - 1 scan - Zipfian distribution: Unsurprisingly, the number of old versions increases linearly with time with the standard implementation of SI and, after 24 minutes of execution, the store has accumulated 350 million old versions and runs out of space. Steam keeps at most one version per active snapshot; since we only execute one scan, Steam only keeps at most one old version per item. Running a Zipfian workload concurrently with a single scan is the best case scenario for Steam because most updates are concentrated on a few items. At the end of the scan, Steam has accumulated 50M old versions. OLCP propagates old versions to the scan, and the number of old versions using OLCP is low and stable throughout the run (a maximum of 1000 old versions).

Figure 4(b) - 1 scan - Uniform distribution: Similarly to the Zipfian distribution, the number of old versions grows linearly with the standard implementation of SI. Because updates are distributed over more items, Steam keeps more versions and eventually the store doubles in size. The number of old versions using OLCP is again negligible throughout the run (a maximum of 1000 old versions).

Figure 4(c) - 3 scans - Uniform distribution: In this experiment, we launch a second scan after 500s of execution, and a third scan after 1,000s of execution. The three scans run concurrently. In this configuration, Steam has to keep up to three versions per item. At the end of the execution of the first scan (not shown in the picture), the store has accumulated 250M old versions (store tripled in size). OLCP propagates old versions to the scans and has close to zero space amplification (a maximum of 1000 old versions).

5.3.2 Throughput

In this section, we study the performance of the scans and the updates when executed with the various SI implementations. We run the uniform workload with a single scan presented in the previous section. Results are similar with the Zipfian distribution and with more scans. Figure 5(a) shows the scan throughput, and Figure 5(b) shows the update throughput.

Figure 5(a): The scan throughput is the same for the standard SI implementation and Steam. Surprisingly, scanning data is much faster using OLCP. The OLCP scan finishes after 691s. With standard SI, the scan aborts after 1460s because the store runs out of disk space (350GB space amplification). With Steam, the scan takes 1870s to complete, 2.7x as long as OLCP. OLCP queries process items just before they are overwritten, and thus when they are in memory. In contrast, with SI and Steam, queries have to fetch most of their data from disk. This advantage is especially visible at the beginning of the scan. As the scan progresses, the advantage of OLCP over SI decreases, because, statistically, as the scan progresses, most of the overwritten items have already been scanned.

Figure 5(b): OLCP scans also interfere slightly less with updates because updates make better use of the caches with OLCP. Updates happen as follows: read a 4KB block (1 I/O if the block is not cached), modify and persist the block (1 I/O). In a uniform workload, the probability of hitting the cache depends on the store size ($P(\text{hit}) = \text{cache size} / \text{store size}$). Because the database grows less with OLCP, the read has a higher probability of hitting the cache and updates are faster.

Figure 4: **Config-NVMe.** Evolution of the number of old versions for (a) a Zipfian workload with 1 scan, (b) a uniform workload with 1 scan, and (c) a uniform workload with 3 scans.

Figure 5: **Config-NVMe**. Evolution of (a) scanned items/s, and (b) updated items/s. Y-axes differ.

Table 1 shows the tail latency of the updates. At the 99th percentile, it takes 3-3.4ms to commit the 16 updates performed by an OLTP transaction (190-250us per update). Switching to OLCP for scans has no significant impact on the 99th percentile latency of OLTP transactions. In SI, the GC of the 350M old items stalls the store after the scan aborts, so the tail latency is high (18s). Cleaning the 100M old items takes 5s in Steam. A non stop-the-world GC could be used, at the expense of higher average space utilization. In OLCP, regardless of the GC implementation, cleaning overhead is negligible, and tail latency is orders of magnitude lower (9ms).

Latency	SI	Steam	OLCP
99p	3.4ms	3.1ms	3ms
Max	18s	5s	9ms

Table 1: **Config-NVMe**. Tail latency of OLTP transactions (16 updates).

Config-AWS: Trends are similar on Config-AWS. The full scan of the store finishes in 134s with OLCP and in 256s with SI and Steam. OLTP transactions have similar throughput.

5.3.3 Overhead of propagations

The overhead of propagations depends on the number of running OLCP queries: the more OLCP queries, the more enqueues in propagation queues might be done. The overhead

also depends on whether concurrent updates are done on scan ranges or not: an item is only propagated if it belongs to a scan range. We launch up to 32 concurrent scans on two stores containing 100M items (100GB) and 5B items (5TB), respectively. Each scan reads a random range of 1M items. As in the previous section, the scans run concurrently with an update intensive YCSB-T workload. We run all tests on Config-AWS, since it is the only machine able to store 5TB.

Figure 6 presents the average number of scanned items per second, varying the number of concurrent scans. On all tested configurations, OLCP is equivalent or faster than conventional SI and Steam. The difference between OLCP and conventional SI is lower than in the experiments of Section 5.3.2 because (i) the queries only scan a small percentage of the store, so updates are less likely happen in a scanned range and result in a propagation, (ii) the read bandwidth of the disks on Config-AWS is higher than the write bandwidth, so the scan progresses faster than the updates. On the 100M store, the gap between OLCP and SI increases with the number of concurrent scans. Indeed, as the number of scans increases, so does the probability that a propagation happens within a scan range and that OLCP can process items in memory. On the 5TB store this effect is less visible (statistically an update has a lower probability of being in a scan range).

The throughput on the 5TB store is lower than on the 100M store because less data is cached (30% vs. 0.6%). The total number of "scans + updates" requests per second is not constant in the experiments (i.e., adding 100K scans/s does not reduce the update rate by 100K updates/s) because (i) reads are done using at most 1 I/O (vs. 2 for updates), and (ii) Config-AWS disks can sustain a higher number of read IOPS than write IOPS.

Figure 6: **Config-AWS**. Number of scanned items per second on a (a) 100M and (b) 5TB store, varying the number of scans.

Figure 7 presents the number of updates performed per second. OLCP is slightly faster for the same reasons as those presented in the previous experiment.

Figure 7: **Config-AWS**. Number of updates per second on a (a) 100M and (b) 5TB store, varying the number of scans.

In conclusion, it is possible to propagate items to OLCP queries with negligible overhead. In all experiments, less than 2% of the time is spent propagating values.

5.4 TPC-CH performance

In this section, we measure space amplification and performance on a TPC-C workload running concurrently with a TPC-H analytical workload. We ran on average 10 TPC-C queries concurrently. Each TPC-C query does an average of 22 requests (17 reads, 5.5 writes), and 30% of the reads hit the cache. Figure 8 presents the throughput of TPC-C running concurrently with TPC-H Query 17, presented in Algorithm 9.

With OLCP, Query 17, which scans 64% of the store, completes without space overhead and creates little interference with TPC-C queries (3% slowdown compared to an execution without a scan). Under Steam, the store doubles in size. Under SI, the store runs out of space, and the query aborts.

5.5 Production workloads performance

We study the performance of conventional SI, Steam and OLCP with the production workloads running on Config-AWS. Figure 9 presents the resulting space amplification, scan throughput and update throughput. At the end of the analytical processing, in Production Workload 2, the store has accumulated 934M old versions with the conventional SI implementation, and GC takes 49s. Steam stores 310M old versions at the end of the analytical processing. OLCP queries cause no space amplification. All implementations have the same throughput.

Figure 8: **Config-NVMe**. Space amplification and throughput of TPC-CH.

Figure 9: **Config-AWS**, production workloads. Space amplification, S (scan), O (OLTP) throughput.

6 Related Work

Running mixed OLTP/OLAP workloads: OLTP/OLAP workloads are commonly handled by systems that maintain a column-oriented datastore for OLAP (e.g., Vertica [42], C-Store [67], and Hive [71]), isolated from the row-oriented OLTP system (e.g. Cassandra [26], RocksDB [24]). This approach allows to optimize each sub-system independently. The main disadvantages are running analytics on old data and space amplification caused by data replication.

A popular approach to decrease data replication overhead is to design store for OLTP/OLAP workloads from the ground-up [10, 13, 25, 38, 39, 43, 60, 80]. Typically, these systems employ hybrid vertical/horizontal data partitioning schemes, coupled with carefully chosen secondary indexing. A significant drawback of these systems is the performance impact that OLAP and OLTP workloads have on each other (e.g., up to 5x throughput decrease in SAP HANA [63]). In OLCP, the analytics workloads do not impact transactions thanks to OLCP's minimal GC overhead.

Reducing space amplification in SI: The role of SI is to provide a coherent view of the data to OLAP queries [51, 66, 69]. SI-related space amplification is one of the most challenging issues for stores that run fully in main memory and it has been addressed by many designs. Harizopoulos et al. [28] execute transactions sequentially to avoid MVCC maintenance work. IoSnap provides flash-optimized snapshots that reduce space overhead by reconstructing snapshot metadata in-memory [68]. Hyper [38, 39] runs OLTP transactions on a fork of the store. BatchDB [51] runs OLAP queries on a replica of the store. These solutions still create problematic space amplification (up to 2x), and garbage collection times at the end of the execution of OLAP queries. Furthermore, the execution of OLAP queries might be delayed to the next batch, adding possibly minutes/hours of latency to analytical queries. OLCP mitigates the space amplification and garbage collection issues. OLCP model could also be beneficial for in-memory stores.

Space amplification in KVs for fast drives: Much of the prior KVs work relies on SI to provide a consistent view of the data during range scans [2, 4, 36, 37, 47, 50, 57–59, 64, 65]. Existing systems such as PebblesDB [64], TRIAD [3], WiscKey [50], and HashKV [11] propose optimizations to decrease space amplification caused by compactions in log-structured merge KVs. SlimDB [65] decreases space for caching indexes and filters. Other KVs designed for fast drives do not support transactions [3, 5, 40, 41, 45, 48]. To the best of our knowledge, OLCP is the first work that focuses on reducing disk space amplification due to SI on fast drives.

Improving the performance of MVCC: In practice, SI is implemented through MVCC [6]. Many recent optimizations and protocols provide support for high transaction rates [8, 33, 46, 49, 55, 75]. Steam [8] trims versions that do not belong to any active transaction’s snapshot. Steam is efficient for skewed workloads. However, under a uniform load the space amplification is proportional to the number of active transactions. We go one step further by propagating old versions to avoid keeping unnecessary versions in snapshots. Silo [75] chooses provides scalable timestamps and uses RCU to garbage collect old versions. Cicada [49] batches operations to reduce protocol costs. TicToc [77] only keeps the latest version of an item in the store. All these techniques focus on improving the speed of MVCC, but do not address space amplification. They can be used to complement OLCP.

Improving the performance of transactions: Various approaches have been proposed to increase transaction performance such as transactional memory techniques [7, 18, 22, 29, 31, 54, 62], transaction support for byte-addressable persistent memory [27, 53], work stealing [79], relaxing ACID properties when possible [17, 61, 76], decreasing replication overhead [78], and reducing coordination [70]. These techniques are orthogonal to OLCP and can be used together with our model to boost the OLTP workload.

7 Conclusion

Long OLAP queries cause problematic space amplification and long transaction tail latencies when run under SI. To remedy this problem, we propose OLCP, a new query model. OLCP provides the same isolation guarantees as conventional SI implementations, but with much reduced space amplification and interference with concurrent OLTP transactions. We show how OLCP can be used to express a wide range of OLAP queries. We implement OLCP in KVell+, an extension of KVell, a state-of-the-art open-source KV for NVMe SSDs. OLCP achieves low or no space amplification, up to 2x higher throughput for OLAP queries, and order-of-magnitude improvements in tail latency for concurrent OLTP transactions.

Abstract

Machine learning inference is becoming a core building block for interactive web applications. As a result, the underlying model serving systems on which these applications depend must consistently meet low latency targets. Existing model serving architectures use well-known reactive techniques to alleviate common-case sources of latency, but cannot effectively curtail tail latency caused by unpredictable execution times. Yet the underlying execution times are not fundamentally unpredictable—on the contrary we observe that inference using Deep Neural Network (DNN) models has deterministic performance.

Here, starting with the predictable execution times of individual DNN inferences, we adopt a principled design methodology to successively build a fully distributed model serving system that achieves predictable end-to-end performance. We evaluate our implementation, Clockwork, using production trace workloads, and show that Clockwork can support thousands of models while simultaneously meeting 100 ms latency targets for 99.9999% of requests. We further demonstrate that Clockwork exploits predictable execution times to achieve tight request-level service-level objectives (SLOs) as well as a high degree of request-level performance isolation.

1 Introduction

With the proliferation of machine learning (ML), model inferences are now not only commonplace but increasingly on the critical path of web requests [29, 71]. Inference requests are handled by underlying model serving services [16, 26, 51, 58] responsible for supporting scores of different pre-trained ML models (including personalized models and experimental A/B tests), ideally at low latency, high throughput, and low cost. These are demanding goals to meet at scale—Facebook alone serves over 200 *trillion* inference requests each day [48]. Furthermore, at least 100 companies are creating hardware chips for accelerated ML inference [48], which underscores the high stakes in this industry.

Yet significant software bottlenecks continue to hamper the efficient utilization of hardware accelerators, such as GPUs, for high-performance model serving. Consider an inference request passing through a model serving system. The request has an inherent deadline after which the answer ceases to be useful to the end-user, and so the system should seek to bound the latency of the request, or even provide service level objectives (SLOs) for consistently achieving low tail latency. The canonical approach for building such a low-latency system is to reduce potential wait times for resources through over-provisioning, since a larger pool of available resources makes it more likely to find a resource on which a pending request can be immediately scheduled. Increased resource provisioning, however, comes at the expense of efficiency and utilization.

Existing systems fundamentally assume that the constituent system components have *unpredictable* latency performance [16, 58]. Moreover, the best-effort techniques employed to tolerate such variability, such as fair queuing, further cascade the unpredictability to other system components and propagate tail latency to higher layers. While some performance volatility of a model serving system is due to external factors, such as a bursty or skewed workload, much variability in execution times stems from design decisions internal to the service, ranging from caching decisions over conditional branching behavior to concurrency from other processes, the OS, and the hypervisor. The challenge, then, is to tame the internal unpredictability.

In this paper, we present the design and implementation of Clockwork, a distributed system for serving models with predictable performance. With an explicit focus on the ubiquitous deep neural network (DNNs) architectures we first show that DNN inference is fundamentally a deterministic sequence of mathematical operations that has a predictable execution time on a GPU. To leverage this observation in designing a responsive model serving system, our approach is to preserve predictability wherever possible by **consolidating choice**: eschewing reactive and best-effort mechanisms and centralizing all resource consumption and scheduling decisions. Clockwork will only execute an inference request if it is confident that the request can meet its latency SLO. To

* Equal contribution

support such proactive scheduling, Clockwork is composed of *workers* that each handle one or more GPUs, and a centralized *controller* that schedules requests. Each Clockwork worker, responsible for the exclusive model loading and inference execution on the GPUs, achieves predictable performance. If a worker cannot execute a particular schedule, because of external factors, the request is immediately aborted and the worker resumes execution of the next request at the specified time. The Clockwork controller manages the resources of each worker and maintains a minimal advance schedule for the worker's operations, including model placement and replication.

We have implemented Clockwork in C++ and evaluated it using a wide range of DNN models on production workload traces. In comparison to Clipper [16] and INFaaS [58], two prior model serving systems, Clockwork more effectively meets latency goals while providing comparable or better goodput. Clockwork more effectively shares resources between different models, and scales to thousands of models per worker. For realistic workloads comprising unpredictable, bursty, and cold-start clients, Clockwork consistently meets low-latency response times of under 100ms.

The main contributions of this paper are as follows:

- We demonstrate that predictability is a fundamental trait of DNN inference that can be exploited to build a predictable model serving system.
- We propose a system design approach, *consolidating choice*, to preserve predictable responsiveness in a larger system comprised of components with predictable performance.
- We present the design and implementation of Clockwork, a distributed model serving system that mitigates tail latency of DNN inference from the bottom up.
- We report from an experimental evaluation on Clockwork to show that the system supports thousands of models concurrently per GPU and substantially mitigates tail latency, even while supporting tight latency SLOs. Clockwork achieves close to ideal goodput even under overload, with unpredictable and bursty workloads, and with many contending users.

2 Background and Motivation

The state of machine learning. The meteoric rise of applications driven by machine learning (ML), ranging from computer vision [28, 78] to ad-targeting [3, 17] to virtual assistants [13, 64], has prompted significant interest into making both ML training and inference faster. These efforts have targeted the underlying ML models, hardware accelerators, and software infrastructure. Chief among the ML modeling approaches are *deep neural networks* (DNNs), which are composed of multiple layers of artificial neurons tuned through non-linear convolution and pooling operations [25].

A plethora of specialized hardware are being developed and deployed for ML training and inference [48], such as ASIC and FPGA chips, Google's TPUs [41], and Facebook's Big

Fig. 1: Model serving targets the narrow waist of the ML software stack (adapted from Reddi *et al.* [48]). Clockwork targets the shaded blocks on the left.

Basin [29] chips. The dominant machine learning hardware in data centers, however, is the GPU, representing a third of the global market in 2020 [5], and will be our focus here.

Interposed between the emerging DNN applications and hardware accelerators, an ecosystem of ML software frameworks is flourishing. Fig. 1 displays several prominent projects in today's ML software stack. Layered protocol stacks in complex systems and competitive environments tend to evolve into hourglass-shaped architectures [4]. We are witnessing the ONNX and NNEF graph exchange formats for DNNs [49, 52] emerging as the “narrow waist” of the ML stack, acting as an interface between high-level ML model development and low-level software and hardware concerns.

Model serving. Operators increasingly deploy machine learning on the critical path of nascent interactive applications [71]. This has elevated machine learning inference to separate, managed *model serving* services [16, 26, 58]. From the vantage point of an operator, the model serving users (customers or internal applications) upload their pre-trained DNN ahead of time (the natural format for which is ONNX/NNEF). Their applications can then submit *inference requests* to an API. The model serving back-end manages the users' models and the hardware accelerator resources, and provides timely responses to inference requests. Upon receiving an inference request, it loads the appropriate model into hardware if not already loaded, runs the DNN on the input, and returns the resulting output to the user. Model serving has similar concerns to other datacenter services [2]: it multiplexes workloads of different users concurrently and load balances requests across multiple workers and GPU hardware accelerators.

Low-latency inference. Model serving users require a timely response to their queries. Most cloud and data center services have *service-level objectives* (SLOs) that codify the performance that clients can expect from the service [40]. The most common type is a *latency SLO*, which specifies the service's acceptable request latencies, typically on the order of milliseconds [14, 32, 41]. For example, a latency SLO might specify a 10ms average response time, or a 40ms 99th percentile response time, or both. If a service fails to meet its SLOs – for example, by being too slow for too many requests – the service provider may risk a penalty.

Model serving further operates under hard cost constraints. Specialized ML hardware is necessary to achieve interactive

latencies [41], but it is comparatively expensive to procure and operate, and must thus be used efficiently [60, 65]. Existing model serving systems achieve efficient inferences for specific heavily used models by dedicating them entire GPUs and using copious batching [41]. However, many use cases cannot justify dedicated hardware resources: applications with insufficient request volume; specialization (*e.g.* location-specific search or language-to-language translation); and experimentation (*e.g.* retrained models and A/B testing) [63]. Efficiently serving models with low request rates requires a large number of models to share accelerators; no existing model serving system supports this.

While it is already difficult for model serving operators to meet latency SLOs under these constraints, the bigger challenge lies in minimizing *tail latency*, the insidious bane of interactive performance. Numerous sources of latency variability in complex individual [46] and distributed [18, 56] systems have been identified and studied, including out-of-order scheduling, interference from concurrency, power saving modes, and network queuing delays.

The crux of tail latency lies in performance variability of both the constituent system/network components and the encompassing architecture. To tame it, the system designer can either seek to (quoting Dean and Barroso [18]) “*create a predictably responsive whole out of less-predictable parts*”, or to expend significant effort to systematically unshroud and mitigate the performance variability of these underlying components. To meet tight tail-latency SLOs under resource constraints, the latter approach is necessary.

Observation: DNN inference is predictable. We observe that DNN executions exhibit negligible latency variability, a result both intuitive in concept — DNN inferences involve no conditional branches — and demonstrable in practice. Although we describe our observations in the context of GPU execution, they extend to other accelerators such as TPUs, and also to CPU execution where appropriate.

Conceptually, a DNN inference is a fully deterministic execution. Each DNN inference request carries a fixed-size *input* tensor argument; in practical terms this is a statically-sized array of bytes. A worker receives this input over the network into main memory. To execute on a GPU, the input is copied from main memory to GPU memory over the PCIe interconnect. The DNN is then executed on the GPU. Abstractly, a DNN is a pre-defined sequence of tensor multiplications and activation functions. Concretely, the DNN code applies these operations to the input tensor one-at-a-time to transform the input into an output. DNN code lacks conditional branching; input choices such as batching size and RNN sequence length are specified ahead of time as parameters. The output is also a statically-sized array of bytes, and it is copied from GPU memory back to main memory over the PCIe interconnect.

We compiled ResNet50v2 [78] with TVM 0.7 [15] and executed 11 million inferences in isolation on a state-of-the-art

(a) CDF of 1-thread latency (b) Inference throughput and latency. Whiskers show min and max.

Fig. 2: Inference is predictable in isolation (left). Running inferences concurrently gains up to 25% throughput (middle), at a cost of substantially increased latency variability (right) due to interleaved GPU and OS executions.

NVIDIA Tesla v100 GPU using random inputs and batch size 1. We measured the latencies of each inference and show the median and high-percentile latencies in Fig. 2a. The 99.99th percentile latency was within 0.03% of the median latency.

If DNN execution times can be measured and then accurately predicted for future inferences on that model, the next question is whether a distributed model serving system can preserve the predictable responsiveness of the core inference execution.

3 Predictable Performance

To build a responsive system through principled design, we further study the factors that can cause or amplify performance variability. Importantly, components at any level of the modern system stack can contribute to variable request latency, whether at the application layer, in the operating system, or even in the hardware [46]. Network effects and workload fluctuations add two more sources of unpredictability to distributed systems.

The whole is more than the sum of its parts. The overall system performance variability is primarily governed by how the system is assembled from its constituent components. We can handle variable latency of a software component in several ways. First, we can ignore the problem and allow the volatility to propagate to later requests or percolate to other components of the system. Even performance-conscious code that is optimized to improve throughput or average latency does not fix tail latency [19]. An example of this contagiousness of unpredictability, known as the “straggler” problem in data analytics frameworks [7, 56], is when a worker executes a request that takes unusually long and the other requests that were enqueued on the worker in the meantime then incur the extra delay from the unexpected wait-time. Ignoring the variability can further compound the problem across the system, such as when the request handler itself has variable latency [69].

Second, we can mitigate the volatility by ensuring all requests match the worst-case latency, thus exchanging lower resource utilization for predictability—often a steep price when worst-case latency is significantly higher than the median.

Third, we can minimize variability by expending more resources, again in trade for lower utilization. Some networked systems, for instance, are designed to submit the same job to mul-

multiple workers in parallel and then to cancel unneeded jobs upon successfully receiving a result from the fastest worker [18].

Fourth, upon detecting an unusual delay, we can notify a feedback mechanism to adjust the environment to lower the impact on future requests. Such “best-effort” methods are typically reactive and aimed at longer-term effects, such as by temporarily adding more resources (auto-scaling [23]), throttling requests, or balancing load.

Consolidating choice. We take a fundamentally different approach: *designing a predictable system from the bottom up*. Our strategy is to restrict the choices available to lower system layers as much as possible—a philosophy based on our observation that when executing an essentially predictable task, performance variability only arose when a lower layer in the system was given choices regarding how to execute its task. Examples from all layers of the systems stack abound, including:

- **Hardware level:** when a GPU is passed multiple CUDA kernels to execute in parallel, the GPU has the choice of how to allocate resources, including execution units and memory bandwidth, between kernels. The GPU makes these choices based on its internal state and undocumented, proprietary policies.
- **OS level:** when we create multiple threads that the operating system can execute on the same core, the OS has the choice of what threads to execute when, based on internal scheduling policies and state.
- **Application level:** when the worker processes of a distributed application each manage their own cache independently, the workers have the choice of what to cache and for how long, leading to unpredictable hit rates and latency variability [38]; similarly, when worker processes implement their own thread pools and queuing policies, they have the choice of which requests to execute first, leading to unpredictable queuing times.

Fig. 2b illustrates this: a standard design for building a worker would use thread pools serving inference requests in parallel to saturate the GPU. While concurrent threads indeed increase inference throughput by up to 25%, the factors above cause tail latency to increase by 100x.

Our approach is to *consolidate choices* in the upper layers: once a layer implements choices for lower layers based on internal state, it forces the lower layer to follow a narrow path of possible executions, causing the performance of the resulting layer to be nearly deterministic. The upper layer can then sufficiently predict the performance of the lower layers and reason with foresight about resource utilization and the anticipated execution times for all requests. The price of this strategy, however, is a tighter coupling of components and a less modular architecture.

Imperfect predictability. Notably, we can consolidate choice without requiring *perfect* predictability. Real systems will retain some unpredictable components, such as managing CPU caches or workload shifts, even after consolidating choices in its upper layers. Instead, the chief goal of concentrat-

Fig. 3: Clockwork comprises multiple Workers and a centralized Controller. Models (★) reside on Workers; inference requests are queued and scheduled centrally on Clockwork’s Controller. See §4.1 for a detailed description.

ing these choices is to make predictable executions the common case. This frees us from implementing best-effort mechanisms to tolerate the occasional, rare instance of unpredictability; instead unpredictability can be directly treated as an error.

4 Design

By recursively restricting choice from lower layers, we converge on a design where the most performance-critical execution choices are made in the topmost layer. In the context of a model serving service, this process converges to an architecture, which we call Clockwork, with a centralized controller and workers with predictable performance.

4.1 Overview

Architecture. Fig. 3 illustrates Clockwork’s architecture. Users submit inference requests (1) which are queued centrally on Clockwork’s controller. Each worker has a set of DNN models (★) loaded into RAM and maintains exclusive control over one or more GPUs. The centralized scheduler has a global view of system state, including all workers, and decides when to execute each request (2). To execute a request, the scheduler explicitly decides when to load models into GPU memory (3) and when to execute requests on the GPU (4). At any time, the scheduler makes accurate, high-quality caching, scheduling, and load balancing decisions. The controller can perform these actions proactively because execution on workers is highly predictable. The controller transmits continual scheduling information to the workers that, by design, will execute schedules exactly as directed.

Illustrative example. To elucidate the Clockwork architectural components with more detail, including the choices that were consigned to the controller, consider the key steps for serving the inference requests illustrated in Fig. 4.

① Upon receiving an inference request r_1 for model ★, the controller is aware that a target worker has yet to copy the model weights from RAM into GPU memory. It estimates the time required to load the model weights (LOAD), plus the time to subsequently execute the inference (INFER), and concludes that the request will complete within its specified SLO. The controller instructs the worker to copy the model weights to

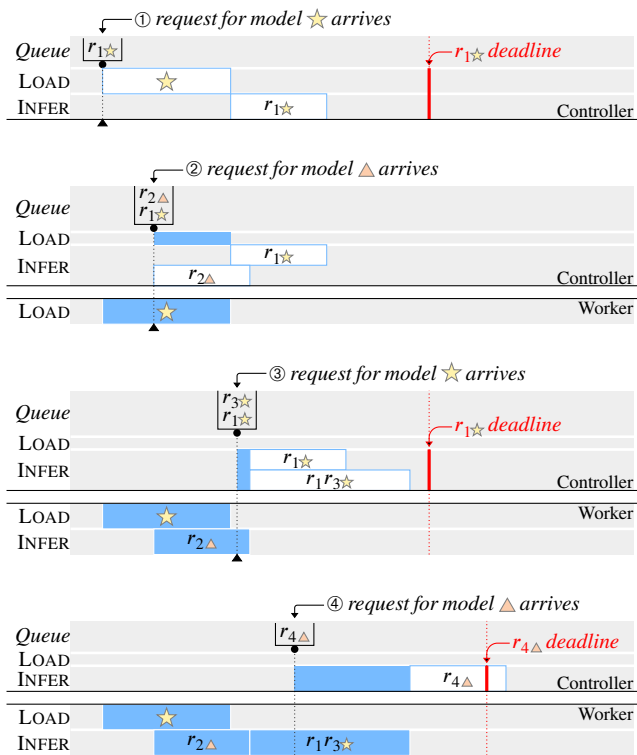

Fig. 4: Timeline of four illustrative inference requests.

GPU memory via a LOAD action. Since the controller is aware of all timings, it does not yet need to submit the subsequent INFER action until the LOAD has completed.

② While \star is loading, a request r_2 for model \triangle arrives. The controller is aware that, unlike \star , \triangle is already loaded into GPU memory. The controller can choose to either INFER r_2 immediately, or wait for \star to complete loading then INFER r_1 . Since the worker would be otherwise idle, the controller instructs the worker to execute the inference for r_2 immediately via an INFER action.

③ Clockwork workers only execute one INFER action and one LOAD action at a time, so the controller can wait until r_2 has nearly completed before submitting an INFER action for r_1 . In the meantime, another request r_3 for model \star arrives. This gives the controller a choice between INFER for r_1 by itself, or to batch r_1 and r_3 . Batched execution is more efficient, but takes longer. In this case a batched INFER action will still complete before r_1 's deadline, so the controller instructs the worker to batch the inferences for r_1 and r_3 .

④ While r_1 and r_3 execute, a request r_4 for \triangle arrives with a tight SLO. The controller is aware that r_4 will miss its deadline, even if it executes immediately after the worker becomes free. The controller does not proceed to schedule an INFER action, and cancels the request before performing any fruitless work.

Each step of the above execution is fast, *e.g.* for ResNet50, LOAD and INFER take approximately 8 ms and 3 ms respectively. Table 1 outlines representative measurements for 8 of the 61 models used for Clockwork experiments.

4.2 Consolidating Choice

Our design consolidates choice in three main ways. First, changes in the worker's state, for instance evicting a DNN from GPU memory, can influence the performance for future requests in a way that makes performance estimation complex. We therefore require that no worker operation should have implicit performance side-effects on any future operation. Second, we must ensure that a predictable component either delegates scheduling decisions that may impact performance to the centralized controller, or otherwise makes schedules deterministic. Third, when a predictable component is unable to execute a schedule as instructed, it is treated as an error to enable workers to get back on schedule. Workers do not attempt best-effort remediation, so as to avoid a cascade of mispredictions.

We enforce these three properties in Clockwork through an action command abstraction between the controller and workers that, in lieu of traditional RPC calls, either communicates a change in a worker's state or a task for a worker to execute. Each action the controller issues to a worker, such as LOAD and INFER, has predicted execution time and a designated execution window. These are derived using the known state of the worker, previously submitted actions, and known transitions in controller-maintained worker state.

4.3 Challenges for Predictable Inference

To consolidate choice we must first identify where performance-critical choices arise in system components. We have established that DNN inference itself on a GPU has deterministic performance; we next study the challenges in extending this result to a full-fledged inference system.

Managed memory and caches can be unpredictable (C1). RAM and GPU memory on a worker constitute state that impacts the performance of future requests. Additionally, some memory allocators exhibit variable timing for allocation and deallocation requests due to internal trade-offs between memory fragmentation and amortized performance. Memory that is used as a cache specifically introduces performance variability between cache hits and misses, with an internal cache replacement policy influencing performance of future items. To maintain predictability, we must instead consolidate choice by managing cache admission and eviction for each worker at the central controller. Fortunately, caching of DNN weights is coarse-grained and per-model.

Hardware interactions can be unpredictable (C2). Many system resources are implicitly administered by hardware schedulers that operate at very fine time-scales and produce different schedules under even minute shifts in the arrival times of other requests. The volatility of timing coupled with proprietary and un-documented scheduling policies make it onerous to accurately predict completion times for concurrent requests. The remedy for non-determinism is to strip away the ability for schedulers to reorder requests by forcing only a single request to be executed at a time, at the cost of spending

Model Family	Model	IO Size (kB)		Weights		GPU Execution Latency (ms)				
		Input	Output	Size (MB)	Transfer (ms)	B1	B2	B4	B8	B16
DenseNet [36]	densenet169	602	4	56.5	4.50	5.18	6.29	8.57	12.82	21.85
Inception v3 [68]	inceptionv3	1073	4	95.3	7.77	4.46	6.85	10.99	16.45	26.17
Mobile Pose [72]	mobile_pose_mobilenetv3	590	209	19.0	1.55	1.29	1.92	3.13	5.71	11.62
ResNet [30]	resnet18	602	4	46.7	3.81	1.27	1.86	2.73	4.06	7.02
	resnet50	602	4	102.3	8.33	2.61	3.78	5.61	9.13	15.67
	resnet152	602	4	240.9	19.58	7.71	11.14	16.21	26.48	44.60

Table 1: Measurements of a representative subset of the 61 models used for Clockwork experiments. Pre-trained models were sourced from the ONNX Model Zoo [53] and the GluonCV Model Zoo [28], and optimized for NVIDIA Tesla v100 GPUs using TVM v0.7 [15].

greater effort on keeping the resource fully utilized. Mercifully, one-at-a-time execution of DNN inferences on GPUs has closely comparable throughput to concurrent execution (Fig. 2b) and many classes of DNNs (*e.g.* convolutional neural networks) can saturate GPUs with small batch sizes.

External factors can trigger performance variance (C3).

Even after systematically removing the key internal sources of unpredictability by consolidating choice, there will always remain external sources outside of the controller’s purview. These include performance interference through shared network bottlenecks, thermal throttling of CPUs and GPUs, and others. The only option is to minimize their effects by building sufficient tolerance into the system.

4.4 Predictable DNN Worker

At a high-level, Clockwork workers maintain DNNs in memory and execute inference requests on one or more GPUs. The workers interface with the controller to receive actions.

Memory management. Model weights must be present in GPU memory to execute an inference. However, GPU memory capacity is small ($\leq 32\text{GB}$) relative to host memory ($\leq 4\text{TB}$), and host-to-GPU memory transfers ($\approx 8.3\text{ms}$ for ResNet50) typically take longer than running the DNN inference on the GPU ($\approx 2.9\text{ms}$). Consequently, Clockwork treats GPU memory as a cache, letting commonly or recently used models avoid expensive loads. To overcome C1, workers explicitly expose LOAD and UNLOAD actions to the controller for copying models to and removing models from worker’s GPU memory with deterministic latency. These actions also update the state that the controller tracks for the worker.

Inference execution. The controller only sends an INFER action when a model is present in GPU memory or a LOAD action will momentarily complete. The worker internally divides INFER actions into three steps. First, INPUT transfers the input vector from host to GPU memory. Next, EXEC performs the actual heavy-weight DNN GPU calculations, which dominate the total inference time. Finally, OUTPUT transfers the resulting output vector from the GPU back to host memory. These steps may coincide: the previous request’s outputs can be copied at the same time as the current request’s input is being transferred. However, multiple concurrent EXEC calls cause the GPU hardware scheduler to behave unpredictably (C2). Fortunately,

a DNN inference call by itself can efficiently utilize the GPU while also restricting the hardware scheduler to a single, predictable option (Fig. 2b). Clockwork workers therefore run a single EXEC at a time, a design choice that reduces performance variability by two orders of magnitude while only minimally decreasing inference throughput (Fig. 2b).

Interface with the controller. Clockwork workers receive LOAD, UNLOAD, and INFER actions from the controller with detailed timing expectations attached:

type	INFER, LOAD, or UNLOAD
earliest	the time when this action may begin executing
latest	when this action will be rejected

Rather than executing actions in a work-conserving, best-effort manner, workers strictly follow the schedule of actions imposed by the controller. The controller communicates two timestamps with every action, *earliest* and *latest*, to designate a time interval during which the worker may begin executing the action. Actions that cannot start within the prescribed window are cancelled and never executed. This allows workers to quickly get back on schedule after an individual action is delayed unexpectedly (C3) by skipping one or more actions, minimizing the impact of the delay on other actions. Workers communicate the result of each action back to the controller, including whether the command was successful and the measured execution time.

4.5 Central Controller

All decision-making in Clockwork occurs in the central controller. The controller receives inference requests from users and decides worker actions while striving to meet SLOs.

Modeling worker performance. The controller maintains a per-worker, per-model performance profile comprising processing time measurements of recent requests; profiles are updated continuously to tolerate shifts due to external factors (C3). The controller also tracks the outstanding actions and memory state at every worker. Since actions have inherently deterministic latency by design, the controller can deduce the earliest time that a worker could begin executing a new action (queuing time).

Action scheduler. The Clockwork controller proactively manages action schedules for workers. It utilizes a global view

of system requests, up-to-date worker performance profiles, and accurate predictions for when outstanding actions will complete. The controller attempts to pack worker schedules tightly by making narrow, realistic estimates for the `earliest` and `latest` time interval. The interval width balances a trade-off between Clockwork SLO fulfillment and system goodput. On one hand, making the interval too narrow increases the risk of an action not being executed by a worker because it could not be completed in time (C3), potentially triggering an SLO violation. On the other hand, underestimating the window length can create periods of inactivity and decrease worker utilization, thus affecting Clockwork goodput.

The scheduler lazily decides which worker should execute the inference. The controller only submits a minimal amount of work to keep workers utilized; it is in no hurry to commit because it can accurately predict action timings. Delaying choices on the controller improves schedules by providing more options, permitting the Clockwork controller to re-order and *batch* inference requests to the same model, significantly improving resource efficiency and throughput.

In our design, any worker can process any request since they all store every model in host memory; however, workers have different sets of models loaded into their GPU memory. A worker that executes only cold inferences must transfer weights for each model from host memory to the GPU and may saturate the available PCIe bandwidth, whereas a worker that executes only hot inferences may be bottlenecked by the GPU. The Clockwork scheduler balances load by mixing and matching hot and cold inferences among all workers.

5 Implementation

Clockwork’s implementation, comprising 26KLOC of C++, contains various decisions that enable Clockwork to consolidate choice on its controller.

5.1 Models

Predictable model execution. Prior model serving systems such as Clipper [16] and INFaaS [58] act as orchestration layers atop existing model execution frameworks such as TensorFlow [1] and TensorRT [50]. This decoupling makes it difficult to consolidate choice, since the model execution frameworks encapsulate scheduling and memory management decisions that we wish to make with Clockwork. Instead, Clockwork implements its own model runtime, reusing key components of the TVM optimizing compiler [15]. Clockwork’s model runtime enables fine-grained control over each stage of a model’s execution. For models provided to Clockwork (e.g. in ONNX form), we compile a binary representation using TVM and postprocess the model to produce the following:

- **Weights:** A model’s weights are a binary blob (10s to 100s of MB (cf. Table 1)).
- **Kernels:** The CUDA kernels that execute a model (10s to 100s of kB). These are not provided by the user; they are derived from the abstract model definition, and kernels

from different users can safely execute within the same process. Clockwork uses the kernels compiled by TVM. Clockwork compiles kernels for multiple configurable batch sizes; by default 1,2,4,8, and 16. Kernels for different batch sizes can use the same weights without modification.

- **Memory metadata:** At runtime, models do not directly allocate memory; instead, Clockwork will pre-allocate and manage all GPU memory and pass pointers as arguments to function calls. The memory requirements for a model are static, and Clockwork precalculates the required workspace memory and offsets required for each kernel.
- **Profiling data:** Clockwork runs a brief profiling step to produce a seed estimate for model execution times.

Model loading. Models are stored in an efficient serialized form on disk. Clockwork workers pre-load models from disk into main memory on worker startup. For the worker machines used in our evaluation, 768GB RAM can support thousands of models (cf. §6.5). Once a model is in main memory, Clockwork extracts and links the CUDA modules needed for its execution. To improve predictability, Clockwork disables JIT compilation and the caching of CUDA kernels.

5.2 DNN Workers

Each machine runs one worker process that receives and executes actions from Clockwork’s controller. We do not run Clockwork in a container or VM to avoid the performance interference such sharing can impose.

Managing model weights in memory. Clockwork pre-allocates all GPU memory and divides it into three categories:

- **Workspace:** Models require a variable amount of GPU memory for intermediate results. This memory is transient and only needed during execution; once an output has been produced, it is no longer needed. Clockwork only executes models one-at-a-time, so it allocates 512MB workspace memory.
- **IOCache:** Although Clockwork only executes models one-at-a-time, Clockwork asynchronously copies inputs to the GPU prior to execution, and outputs to host memory after execution. Clockwork allocates 512MB device memory for temporary storage of inputs and outputs before and after execution.
- **PageCache:** The remaining device memory is used for storing model weights, divided into 16MB *pages*. Multiple tensors can occupy the same 16MB page and the mapping of tensors to pages is determined statically at model-compile time. At runtime, page pointers are passed as kernel arguments and tensors are read from pre-defined offsets.

Clockwork’s PageCache has several advantages. First, avoiding repeated memory allocation calls leads to more predictable executions, since memory allocation can be an unpredictable source of overheads (C1). Second, paging *simplifies choice*: external memory fragmentation issues are

eliminated, and the controller need only track the number of total free pages to completely capture the worker’s memory state. Paging slightly increases memory utilization; however, model memory requirements are static and known ahead of time, and can be bucketed on to pages to reduce internal fragmentation. Paging does not affect the latency of memory transfers.

Actions. To orchestrate workers, the controller uses the previously described *action* abstraction. Actions contain a unique `id` and an action-dependent payload (e.g. INFER inputs). Each worker runs a dedicated *executor* for each action type and each worker-GPU. An executor runs a thread that dequeues actions chronologically by `earliest` timestamp, and waits until `earliest` is reached before proceeding with an action. Executors reject actions whose `latest` timestamp has passed. To reduce interference between threads and other processes, each executor is pinned to a dedicated core and runs at real-time priority. Both INFER and LOAD execute asynchronous work in their own CUDA streams. Each executor is bottlenecked by a different resource (e.g. GPU execution and PCIe transfers) and can run concurrently with negligible interference.

Results. A network thread maintains a persistent connection with the controller for receiving actions and sending results. A result comprises the following:

<code>status</code>	success or an error code
<code>timing</code>	start and end times, and on-device execution duration for any asynchronous work

LOAD actions acquire pages from the PageCache, then copy weights to those pages. If no pages are available then LOAD aborts. The controller explicitly frees pages with UNLOAD; this only updates in-memory metadata and always succeeds.

INFER actions comprise INPUT, EXEC and OUTPUT, each of which have dedicated executors. INPUT executes immediately on receipt of INFER; it acquires IO memory from the IOCache then copies inputs. EXEC inherits the INFER action’s `earliest` and `latest` timestamps; it checks weights and inputs are present then executes kernels on the GPU, using Workspace for intermediate calculations. OUTPUT immediately copies outputs back to main memory then releases the IO memory. To simplify controller decision making, INPUT and OUTPUT are not exposed as actions since they are orders of magnitude faster than EXEC and LOAD (10s of microseconds) for our workloads. Clockwork’s memory management allows for back-to-back INFER actions for the same model.

5.3 Central Controller

On startup, Clockwork’s controller establishes persistent connections to all workers and exchanges metadata about the size of each worker’s PageCache, the models present on each worker, and their initial pre-profiled execution times. The core duty of the controller is to satisfy requests received from clients by submitting actions to workers. This decision making is encapsulated in the *Scheduler* interface:

<code>onRequest</code>	client request received, specifying a model ID, SLO, and providing inference inputs
<code>onResult</code>	a result is received from a worker

A scheduler implements this interface, and can invoke `sendAction` to send an action to a worker, and `sendResponse` to respond to a client. A separate layer of the controller implements common tasks such as networking, forwarding inputs to workers, setting timestamps, and handling timeouts. This design concentrates all choice in a single place, and enables different scheduler implementations to be easily dropped in.

Managing worker state. The controller maintains an accurate representation of workers’ execution state, which is threefold: *memory state*, in which the scheduler tracks what models are present in the worker PageCaches and when LOAD will be required; *action profiles*, which are measurements of past 10 actions duration, stratified by model, worker, and batch size, to predict the duration of future action; and *pending actions*, which tracks submitted actions and estimates when each executor will next be available. Taken together, these enable the scheduler to accurately predict when candidate actions will complete, and avoid submitting work that cannot complete before the request’s deadline. Worker state is not a significant scalability bottleneck; action profiles require only 40 bytes for each model, worker and batch size combination.

Scheduling INFER. Upon arrival, requests are enqueued into per-model request queues. For each INFER executor, a new action must be scheduled whenever the executor has less than 5 ms of outstanding work. To schedule an INFER action, a model and batch size must be selected. The batch size can differ action-to-action, though the scheduler prioritizes larger batch sizes for efficiency.

At any point in time, a model will have zero or more queued requests. However, not every request is suitable for every batch size. Higher batch sizes take longer to execute, so a request close to its deadline might only be satisfiable using a small batch size. To handle this, each model has a request queue per batch size (we term this a *batch queue*). New requests are enqueued into *every* batch queue. Requests are dropped from batch queues when they cease to be satisfiable; e.g. a request in the batch size of 16 queue will be dropped sooner than it is dropped from the batch size of 8 queue.

To decide which model and batch size to schedule, we use *strategies*. A strategy specifies a *model*, a *latest* timestamp, and a *batch size*. Each INFER executor has a separate strategy queue, ordered by *latest*, containing only strategies for models it has loaded. The scheduler dequeues strategies until it finds one that is *valid*: *latest* has not elapsed, and the batch queue for the specified batch size has sufficient requests. If a strategy is valid, the scheduler will also speculatively increase the batch size as long as extra requests are available.

When a valid strategy is found, an INFER action is created and requests are dequeued to fill the batch. Old strategies for this model are removed from the strategy queue, and new

Fig. 5: Goodput and latency measurements for Clipper, INFaaS, and Clockwork. We deploy 15 instances of ResNet50 on 1 worker; each model submits 16 concurrent requests in a closed loop. (Left) Request goodput. Goodput only counts requests that succeed within the SLO. (Right) Request latency CDFs across all requests (including those rejected due to missed deadlines). Latency CDFs are scaled to highlight tail latency.

strategies are then created and enqueued. A strategy is created per batch queue; *latest* is calculated by subtracting the batch execution time from the deadline of the request at the head of the queue. Empty batch queues are skipped.

Scheduling LOAD. Each LOAD executor also schedules up to 5 ms of outstanding work. For a LOAD executor, the scheduler selects a model by estimating each model’s SLO violations given the model’s current state and outstanding requests. To do this efficiently, the scheduler maintains and incrementally updates *load* and *demand* statistics for models and GPUs:

- d_m the total demand for each model m
- $a_{m,g}$ the demand allocation of model m on GPU g .
- $\ell_g = \sum_m a_{m,g}$ the total load on each GPU g

A model’s total demand d_m is the total estimated execution time of m ’s outstanding requests; we update d_m when requests for that model arrive and complete. The demand allocations $a_{m,g}$ for m on GPU g are also updated when requests arrive and complete; they are calculated such that $\sum_g a_{m,g} = d_m$. Demand allocations are 0 for GPUs where the model is not loaded. On GPUs where the model is loaded, demand allocations are inversely proportional to the GPU’s load, since overloaded GPUs will be able to execute proportionally less of the total demand. Each GPU’s total load ℓ_g is the sum of its allocations across all models. With these estimates, each model’s load priority is defined as

$$p_{m,g} = d_m - \sum_g a_{m,g} \cdot \frac{\text{capacity}_g}{\ell_g}.$$

A model’s load priority estimates its unfulfilled work. For example, a model that is not loaded on any GPUs has priority equal to its outstanding work; a model loaded on a GPU that sits mostly idle has negative priority since the GPU can serve more work than the model demands.

Clockwork does not attempt to converge to a perfect demand allocation each time the system’s state changes. Rather, Clockwork incrementally updates each model’s demand allocation and load priority (i) when new requests arrive for that model; (ii) when an INFER is initiated for that model; (iii) when LOAD and UNLOAD affect a model; and (iv) when a request crosses the point where it can benefit from LOAD before its deadline.

The scheduler selects LOAD actions by choosing the highest priority model that is not already loaded. Notably, models with negative priority need not be loaded since their demands are already met. Clockwork uses a least-recently-used (LRU) eviction policy when selecting models to UNLOAD.

6 Evaluation

We next assess Clockwork’s ability to reliably serve DNNs under a variety of workload conditions. We begin our experimental evaluation with simple workloads in controlled settings, before expanding to heterogeneous models and diverse workloads. Our evaluation shows that Clockwork’s assumptions about predictability hold, and result in a system that can effectively meet SLOs and drastically reduce tail latency.

Experimental setup. We deploy Clockwork in a private cluster of 12 Dell PowerEdge R740 Servers. Each server has 32 cores, 768 GB RAM, and 2xNVIDIA Tesla v100 GPUS with 32 GB memory. The servers are connected by 2x10 Gbps Ethernet on a shared network. In all experiments, we run the controller, clients, and workers on separate machines.

6.1 How Does Clockwork Compare?

We begin with a comparison to two prior model serving systems, Clipper [16] and INFaaS [58]. For Clipper and Clockwork, we provision a single cluster machine to use 1 GPU to serve 15 separate copies of ResNet50. ResNet50 is the *de facto* model used for comparison previously by these systems; we chose 15 models as this reached the memory limit of Clipper¹. To evaluate INFaaS, we deployed an m5.24xlarge and a p3.2xlarge EC2 instance as the master and the worker, respectively. These are not identical experiment conditions; however, INFaaS is tightly integrated with EC2, and could not be deployed on our cluster infrastructure. We include these results for qualitative comparison.

Offered load. For each model, we run 16 closed-loop clients². The serving systems may batch requests for the same model instance, but requests to different instances cannot be

¹INFaaS memory limits were reached at 64 models

²Open-loop clients yielded similar results

Fig. 6: Clockwork can serve thousands of models from a single worker. From $t = 0$, the Major workload adds an additional model per second, to a total of 3,600 models at $t = 60$ (cf. §6.2.)

batched. We run multiple experiments, varying the target SLO from 10 ms to 500 ms.

Goodput. Fig. 5 plots the *goodput* achieved by each system as the target SLO varies from 10 ms to 500 ms. Goodput is the number of successful requests that completed within the target SLO; it excludes timed out requests and requests that responded after the SLO.

With a high SLO of 500 ms, Clockwork and INFaaS meet their SLOs and have comparable goodput of approximately 800 r/s. Clipper’s goodput is substantially lower, as Clipper only treats SLOs as an average latency target, not a strict threshold, and converges to this target over time without bounding latency variability. As SLOs tighten, goodput and tail latency deteriorate for both Clipper and INFaaS, and their goodput collapses below a 100 ms SLO. Like Clipper, INFaaS uses the SLO as a coarse-grained goal for reactive policies. Consequently, only Clockwork can continue serving SLOs below 100 ms.

Fig. 5 also plots latency CDFs for Clipper, INFaaS, and Clockwork. We scale the CDFs to emphasize tail latency. The figure illustrates how both Clipper and INFaaS allow latency higher than their SLOs. However, of note, with a 500 ms SLO, INFaaS successfully finds a configuration that can serve this SLO, and meets its SLO for 99% of its requests. By comparison, Clockwork’s tail latency remains very close to the SLO in all cases. For the 500 ms SLO, Clockwork’s latency remains at ≈ 300 ms because it schedules each model’s entire batch of 16 requests at a time, round-robin across models. With 15 models and a 20 ms batch-16 execution duration, Clockwork does not exceed the optimal 300 ms latency.

6.2 Can Clockwork Serve Thousands?

The previous experiment represented an idealized scenario, with only a small number of models, each with a steady sustained workload. We now examine the serving limits of a single worker. We deploy 3,601 copies of ResNet50 to a worker, and set a 100 ms SLO. We submit two workloads: a Major workload and a Minor workload. The Major workload

comprises 3,600 model instances; we vary the number of instances that are active at any point in time, and evenly distribute a workload of 1,000 r/s across all active models. The Minor workload is a single model instance that maintains a fixed 200 r/s request rate throughout the experiment.

Figure Fig. 6 (a) plots the goodput achieved by the major and minor workloads. From $t = -5$ to $t = 0$ (we denote t in minutes) only the Minor workload is present, achieving its full 200 r/s. At $t = 0$, we activate one model instance of the Major workload; the addition of 1000 r/s fully saturates the GPU (e). After that, we activate an additional model of the Major workload every 1 second. As more model instances become active, the Major workload’s goodput drops since each additional model forgoes batching opportunities. At $t = 60$ all 3,600 models are active, each submitting approximately 0.28 r/s.

By $t = 3.5$, 201 models have been activated, reaching the capacity of GPU device memory. To continue serving requests, Clockwork begins swapping models on and off GPU; Fig. 6 (d) shows PCIe utilization rapidly rises to 100%. As more models activate, an increasing number of requests in the Major workload find that their model is not loaded; Fig. 6 (c) plots the rise in *cold-starts*, reaching 70% by the end of the experiment. The minor workload, with its sustained request rate of 200 r/s, does not experience any cold starts because its demand dwarfs every other model after the first 5 seconds. As the number of cold-starts increases, the demand on GPU execution decreases, enabling the Minor workload’s goodput to gradually grow back to 200 r/s. At approximately $t = 20$, the bottleneck for the Major workload shifts to PCIe utilization, enabling the Minor workload’s latency to drop back to an average of 20 ms (b).

This experiment illustrates how bottlenecks in Clockwork can shift as workload demand changes. Clockwork can deal with shifting bottlenecks even while serving a large number of models. As illustrated in Fig. 6 (b), the maximum request latency across the experiment did not exceed the 100 ms SLO.

6.3 How Low Can Clockwork Go?

Clockwork’s predictability and centralized decision-making enables it to satisfy low-latency SLOs. In this experiment, we use six Clockwork workers and evaluate the lower limit on SLOs that Clockwork can achieve by measuring the proportion of successful requests while varying the SLO. We repeat the experiment for six different workloads, varying the number of ResNet50 instances ($N = 12$ or 48) and cumulative request rate ($R = 600$ r/s, 1200 r/s, or 2400 r/s). For each experiment run, we begin with an SLO of 2.9 ms ($1 \times$ the execution latency of batch-1 ResNet50 inference). Every 30 seconds, we extend the SLO by 50%; by the end of the experiment the SLO reaches 74ms. We run a separate open-loop client for each model with a Poisson inter-arrival time distribution, and as before, all models are independent (requests cannot be batched across models).

Workload satisfaction. Fig. 7 plots the *workload satisfaction* for each experiment run. Workload satisfaction is the ratio of goodput to offered load. A workload satisfaction of

Fig. 7: Workload satisfaction rates as we vary N , the number of clients, and R , the request rate.

Fig. 8: Workload satisfaction rates for latency-sensitive clients (top) and workload goodput for batch clients (bottom).

1 means all requests received a successful response within their SLO. For a load of $R=600$ r/s and 1200 r/s, irrespective of the number of models, Clockwork successfully satisfied tight SLOs 10 and 22 ms. Even at $R=2400$ r/s, Clockwork comfortably managed an SLO of 74ms.

6.4 Can Clockwork Isolate Performance?

Clockwork can satisfy tight SLOs for latency-sensitive clients in isolation; we next consider when the system is shared with other users serving batch requests without latency SLOs. As before, we use six Clockwork workers, and all clients use instances of ResNet50. We provision six *latency-sensitive* clients, each submitting a 200 r/s open-loop workload. We also provision several *batch clients*, which submit sustained closed-loop workloads and do not have latency SLOs. *Big-batch* clients have a concurrency of 16, while *small-batch* clients have a concurrency of 4. Varying the concurrency affects the maximum batch size Clockwork can achieve for batch client requests. We considered three scenarios: (a) baseline without batch clients; (b) 12 big-batch clients; and (c) 48 small-batch clients

Fig. 8 illustrates the workload satisfaction rates for latency-sensitive clients and the total goodput achieved for the batch clients. Clockwork successfully prioritizes latency-sensitive requests over batch requests. Through SLO-aware scheduling, it ensures that the workload satisfaction rates are unaffected by the presence of other pending, less time-critical requests. At the same time, Clockwork does not throttle batch requests entirely, but schedules them during idle times or expected idle times. However, when the SLOs are too tight (<15 ms), many latency-sensitive requests are rejected in advance, allowing pending batch requests to pass through.

6.5 Are Realistic Workloads Predictable?

We now ask whether executions remain predictable under realistic workloads that comprise many concurrent users and models. We also investigate whether Clockwork effectively

Table 2: List of models used in experiments.

exploits this predictability.

To answer these questions, we deploy Clockwork on 12 workers and replay a workload trace of Microsoft Azure Functions (MAF) [61]. The trace records approximately 46,000 function workloads, counting the number of invocations of each function, every minute, for two weeks. It interleaves a wide range of workloads, including heavy sustained workloads, low utilization cold workloads, bursty workloads that fluctuate over time, and workloads with periodic spikes [61]. We believe this to be a representative workload for evaluation since serverless platforms enable a wide range of applications and supporting ML inference on serverless is an active area of research [10, 39].

In this experiment, we replay six hours of the MAF trace in real-time. We use 61 different models (Table 2) taken from the ONNX Model Zoo [53] and the GlueCV Model Zoo [28]. We duplicate each model 66 times, resulting in a total of 4,026 instances and reaching the main-memory capacity of our worker machines. We replay ten or eleven function workloads for each model instance. We configure Clockwork with a 100 ms SLO.

Clockwork with realistic workloads. The time series in Fig. 9 (a) shows the offered load and goodput achieved across all models. For the 6 hour experiment, both the offered load and goodput averaged 9,638 r/s – out of a total of 208 million requests, only 58 failed due to action timing mispredictions, and no requests timed out. All GPUs were fully utilized throughout the experiment, yet no request exceeded the 100ms SLO.

Fig. 9 (b) plots the median, 99th percentile, and maximum request latency over the course of the experiment. Latency spikes occur every 5, 15, and 60 minutes, due to the presence of numerous periodic workloads within the trace [61]. Workload spikes do not cause SLO violations because of latency headroom; Fig. 9 (c) shows the average batch size for the experiment, and with each workload spike, Clockwork can schedule larger batches, with higher latency. To evaluate the cold-start behavior of this workload, we categorize a request as a cold-start if its model is not already loaded into GPU’s memory before arrival. For each 1-minute interval, Fig. 9 (d) counts the number of

Fig. 9: Microsoft Azure Functions (MAF) over Clockwork; see §6.5 for a description.

Fig. 10: Clockwork prediction and completion errors for MAF trace.

unique models that have at least one cold-start, and at least one warm-start. On average, 987 unique models perform cold-starts each minute; or approximately 25% of all models. However, while many models perform cold-starts, they only represent a small fraction of all requests. Fig. 9 (e) plots the throughput of cold-start requests, averaging 126 r/s, or 1.3% of all requests. These results show that Clockwork can sustain significant load for varied, realistic workloads comprising thousands of models.

Predictable executions. Clockwork’s scheduler relies on accurate predictions of action latency, so to assess Clockwork’s underlying assumptions of predictability, we next evaluate the accuracy of Clockwork’s predictions. We measure the latency of INFER and LOAD actions on Clockwork’s workers and compare it to the time estimated by Clockwork’s controller to derive a *prediction error*. Prediction errors comprise two types: *overprediction*, when the real execution latency is faster than predicted; and *underprediction*, when the real execution latency is slower than predicted. Consistent overpredictions can lead to idle resources, while consistent underpredictions can cause SLO violations. Fig. 10 (top) plots the prediction errors for INFER and LOAD actions. For INFER actions, the 99th percentile of overpredictions and underpredictions is 144 μ s and 55 μ s, respectively. Thereafter, the tail latency grows

Fig. 11: (Left) With 40 emulated workers, goodput is approximately equal to offered load; peak goodput is achieved at appx. 40,000 r/s, when all workers are fully utilized. (Right) Peak goodput achieved with different numbers of emulated workers.

to exceed 10 ms in a few extremely rare cases. Clockwork consistently overpredicts more than it underpredicts, as it uses a rolling 99th percentile measurement to make its predictions. For LOAD actions, the 99th percentile of overpredictions and underpredictions is 431 μ s and 348 μ s, respectively.

Fig. 10 (bottom) plots the *completion time error*. Clockwork must accurately predict when a given action will complete, taking into account any previously submitted actions (*i.e.* queuing time). Individual prediction errors can compound, leading to increased completion time error. For INFER actions, the error compounds 4 \times , with a 99th percentile completion error of \approx 1 ms. In extreme cases, Clockwork’s completion error also grows to more than 10 ms. However, the completion error does not substantially exceed the action duration error, implying that for Clockwork, erroneous predictions of outliers are statistically independent.

6.6 Can Clockwork Scale?

Centralized scheduling presents a potential scalability bottleneck, though prior work has demonstrated that centralized schedulers can reach impressive scale [24, 57]. Our final experiment examines the scalability of Clockwork’s controller.

To venture beyond the capacity of our testbed, we leverage a specially-developed *emulated worker* that implements Clockwork’s action interface. The emulated worker behaves identically to a bona fide Clockwork worker, except the LOAD and INFER actions perform no meaningful work; instead, they wait for a period of time according to the pre-profiled model measurements before returning a response. The emulated worker is indistinguishable from a real worker from the vantage point of Clockwork’s controller. To bypass the limited network capacity of our testbed, we modified our clients to send zero-length inputs (network is not a fundamental limitation; see §7 for discussion).

We measure the peak goodput achieved as we vary N , the number of emulated workers. We run multiple experiments, each with a different value of N , from 10 to 150 in increments of 10. We use the same models as described in §6.5, and a similar workload. Instead of replaying the trace at a fixed rate, we scale the trace and gradually offer more load in 60-second intervals. Fig. 11 (Left) illustrates one experiment run with $N=40$. Goodput follows the offered load almost perfectly up to about 40,000 r/s, at which point all workers are fully utilized and the goodput saturates.

Fig. 11 (Right) reports the peak goodput achieved with different numbers of workers. We report the median values across three experiment repetitions. The figure shows a linear increase in the peak goodput as the number of workers increases. Below $N=110$, goodput is limited by workers reaching full utilization. At $N=110$, we reach a maximum goodput of 103,387 r/s. At this point worker utilization stops being the limiting factor; instead, the bottleneck shifts to Clockwork’s controller. Beyond $N=110$ peak goodput declines.

6.7 Summary

In comparison with prior model serving systems, Clockwork achieves superior goodput, serves considerably more models concurrently, and violates substantially fewer SLOs. Owing to a lack of performance variability, Clockwork can achieve much tighter latency SLOs without sacrificing tail latency. Clockwork’s underlying assumptions about predictable executions bear out in reality: by consolidating choice, a predictable system that substantially curtails tail latency can be built.

Clockwork extends to a diverse range of workload conditions not supported by prior systems, including supporting thousands of models concurrently per GPU. Slow cold starts can run alongside high-throughput workloads without interference. Under all workload conditions, including cold starts and even under overload, Clockwork meets most SLOs without degrading service, and maintains close to maximal possible goodput. Finally, Clockwork isolates users of different models, enabling low-latency workloads to share the same system with background batch workloads.

7 Discussion

Why consolidate choice? Philosophically, the encapsulation, abstraction, and loose coupling of components are essential design practices while the building blocks and use cases of large systems are still in flux. Over time, the true use cases for the system settle and the entire system may in turn be replaced by a simpler, refined system that avoids the over-engineering and generality of its constituent parts—components that transpired to either be unnecessary in practice or to impede the common use case of the system. The squashing of layers through such specialization, effectively transforming systems into abstract units, can counteract the infamous bloat of modern software stacks. We designed Clockwork to be such an abstract unit for model serving systems.

Machine learning. Clockwork focuses on DNN inference, and excludes data preprocessing and postprocessing steps that are user-defined and CPU-bound. Safely and predictably executing these in Clockwork is a current research topic.

Individual DNN inferences are the atomic unit of work for Clockwork. Increasingly, modern ML applications are composed of pipelines or cascades of DNNs [34, 43, 62]. For these applications, performance predictability is strongly desired. We believe there are opportunities to leverage Clockwork’s

properties and perform more sophisticated pipeline scheduling that provides end-to-end guarantees. Similarly, performance predictability can influence system designs in other areas, such as large language embedding models [11] that may require dedicated or distributed accelerators. Expanding Clockwork into other ML paradigms, such as deep reinforcement learning and DNN training, raises philosophical questions about the nature and limits of predictability.

Inference accelerators. The Clockwork approach generalizes readily beyond GPUs to other inference-specific hardware accelerators [48], whose performance is arguably even more predictable. TPUs [41], for instance, are explicitly built around the idea of delegating control to software, while also eschewing general purpose processing engines with flexible control logic and generic memory hierarchies in favor of high-level operations and explicit memory hierarchies.

On the other extreme, inferences can also be executed in software on the CPU. While many models are heavily parallel in nature and execute orders of magnitude slower on CPUs, there are other models where execution on CPU is acceptable. One such example are recurrent neural networks (RNNs) which are fundamentally more sequential and often cannot effectively leverage the available parallelism on GPUs or other accelerators.

Limitations of predictability. Consolidating choice is only possible when you have control of, or guarantees about, the system’s major bottleneck resources. For example, Clockwork assumes workers have exclusive control over their machine, and dedicated GPUs. Clockwork does not assume exclusive control over the network, but does assume that the network has mostly-predictable latency between the controller and workers. In a shared setting, preserving predictability becomes more challenging – though not impossible – and this is an active area of research due to a general need to co-locate latency critical datacenter services [42, 47].

Network. Clockwork does not explicitly consider the network in its scheduling decisions; the occasional network latency spikes of dozens of ms during our experiments had negligible impact on our results. Our prototype routes all inputs and outputs through the central controller which will become a bottleneck at scale. We were able to reach the limits of our testbed network with 12 workers and a sustained, single-model workload; to test beyond this we disabled inputs as described in §6.6. This limitation is not fundamental; Clockwork’s controller only requires request *metadata* to schedule requests, and we are working to remove this limitation with a tier of load balancers.

Security. Security is important for all multi-user systems, since there are no container or hypervisor boundaries separating the workloads of different users. Clockwork does not explicitly address security; however, Clockwork does not execute arbitrary user code. Users must submit models in an abstract format that we then compile to binary code under the covers. Clockwork’s threat model resembles shared storage or database

systems, where system correctness is the chief concern; we have not verified any safety properties of Clockwork.

Fault tolerance. While Clockwork is a distributed system, we do not address the challenges of tolerating failures when serving models at large scale. This will require implementing a fault-tolerant centralized scheduler; however, we note that Clockwork’s predictable worker design will make pernicious phenomena like grey failure [27, 37] far easier to detect.

Other benefits of predictability. Concentrating choice makes it easier to implement other guarantees, such as SLOs related to burstiness or per-request cost. The Azure trace in our evaluation, for instance, contained regular, periodic spikes; exploiting advanced knowledge is an appealing future avenue for Clockwork. A further benefit of predictable system components is *performance clarity* [55]: performance bottlenecks and upcoming tasks in Clockwork are easy to reason about. Clockwork’s controller also provides a central point for *explanation*, since the controller has complete visibility of the expected and actual request behavior.

8 Related Work

Model serving. We directly compared Clockwork to Clipper [16] and INFaaS [58] in §6.1; here we provide additional comments. Both Clipper and INFaaS are designed as wrappers around existing model execution frameworks: Clipper, in order to provide a unifying abstraction; INFaaS, in order to exploit heterogeneous execution strategies. Being agnostic to the underlying execution engine sacrifices predictability and control over model execution. Both systems treat latency SLOs as long-term, reactive targets; by contrast, Clockwork is explicitly designed to consolidate choice, and exploit predictability by making proactive decisions. Clipper and INFaaS propose several orthogonal concepts that are compatible with Clockwork. Clipper’s model selection layer could be superimposed on Clockwork. INFaaS’s model variant concept could be integrated into Clockwork; we found similar predictability properties held for DNNs executing on dedicated CPU cores.

Several other projects investigate model serving in virtualized cloud environments and on serverless platforms, where predictability is in the hands of the cloud provider [10, 44, 77]. Like INFaaS, these model throughput, latency, and accuracy together for optimal model selection, but, unlike Clockwork, they do not use the backend predictability and latency SLOs for making proactive scheduling decisions. In industry, TFS² [51] is a proprietary model hosting service at Google, about which public information is not available. Amazon SageMaker [59] and Google AI Platform [26] are public cloud DNN serving systems with a similar interface to Clockwork: upload your model, then make inference requests. Both use containers under the covers as an isolation mechanism, and users suffer the associated cold-start latency. Beyond these details, further design information is not publicly known.

Real-time systems. Performance predictability, especially temporal safety, is also an important concern for safety-critical real-time systems. However in general, real-time systems are designed for *periodic* or *sporadic* workloads [8] with known minimum inter-arrival times and worst-case execution times, or for scenarios where the set of all inference requests is known in advance [66]. *Soft-real-time* systems [12] consider weaker notions of timeliness similar to the latency SLOs considered in this paper, but mainly target periodic or sporadic workloads. Clockwork, in contrast, makes no *a priori* assumptions about its workloads. Prior real-time systems work has also proposed mechanisms to tame the unpredictability inside GPUs [6, 9, 20, 22, 54]. Elliott and Anderson [21], for example, proposed interrupt handling mechanisms to circumvent the proprietary GPU drivers that ignore scheduling priorities, while Yang *et al.* [74] suggested avoiding synchronization anomalies through more careful use of CUDA synchronization primitives. These mechanisms are designed to facilitate an *a priori schedulability analysis*—mathematically bounding the blocking delays due to contention. Such bounds are orthogonal to Clockwork, which does not require strict worst-case guarantees.

9 Conclusion

As DNN inferences become increasingly central to interactive applications, the requirements for fast response tighten, the volume of requests expands, and the number of models grows. Our model serving system, Clockwork, meets these challenges. Clockwork efficiently fulfills aggressive tail-latency SLOs while supporting thousands of DNN models with different workload characteristics concurrently on each GPU, and scaling out to additional worker machines for increased capacity. The system also successfully isolates models from performance interference caused by other models served on the same system. Our results derive from our design methodology of recursively ensuring all internal architecture components have predictable performance by concentrating all choices in the centralized controller. Notably, our approach required us to either circumvent canonical best-effort mechanisms or orchestrate them to become predictable, and illustrates how consolidating choice can be applied in practice to achieve predictable performance.

A Artifact Appendix

A.1 Abstract

The artifact consists of Clockwork’s prototype source code, instructions for building from source, and directions for preparing the environment. The instructions for launching a Docker instance that has all dependencies pre-installed is provided as well. The artifact also contains scripts, descriptions, and instructions to run the experiments automatically or manually for reproducing the graphs and results presented in the paper.

A.2 Artifact check-list

- **Program:** dnn-model-serving, multi-tenant
- **Compilation:** cmake, g++
- **Binary:** worker, controller, client
- **Model:** distributed, multi-tenant
- **Data set:** azure-functions-trace-2019, poisson-distribution
- **Run-time environment:** Linux, CUDA, network
- **Hardware:** NVIDIA, Tesla-V100
- **Execution:** automated, manual
- **Metrics:** throughput, latency, SLO-violation, tail-latency
- **Output:** telemetry-measurements, table, graph
- **Experiments:** throughput-latency, scalability, predictability, SLO, tail-latency
- **Required disk space:**
Clockwork: 210MB
Total including compiled models and dataset: 12GB
- **Expected experiment run time:** About 17 hours in total
- **Public link:**
<https://gitlab.mpi-sws.org/cld/ml/clockwork>
- **Code licenses:**
Clockwork: Apache License 2.0
TVM: Apache License 2.0
CUDA Common Library: Apache License 2.0
Catch2: Boost Software License 1.0
- **Data licenses:**
Azure Functions Trace 2019: CC-BY Attribution

A.3 Description

A.3.1 How to access

The artifact is publicly available at
<https://gitlab.mpi-sws.org/cld/ml/clockwork>

A.3.2 Hardware dependencies

To reproduce the exact experiment results, worker machines must have 768GB RAM or higher, 16 CPU cores or more, at least one 32GB Tesla v100 GPU and 10Gbps network. The large-scale experiment with Azure Functions (Fig. 9) requires 12 worker machines. Most other experiments require fewer worker machines; details on the number of machines for each experiment and environment customization guide is provided in each experiment’s documentation.

A.3.3 Software dependencies

- **Clockwork:**
Ubuntu 18.04 or later, CUDA v9.0+, libtbb-dev, libasio-dev, libconfig++-dev, libboost-all-dev, g++-8, make, cmake, automake, autoconf, libtool, curl, unzip, clang, llvm, and protobuf.
- A Dockerfile is provided to facilitate the build process.
- **Data analysis and plotting scripts:**
Python 3.x and the numpy, pandas, matplotlib, and seaborn libraries.

A.3.4 Data sets

- Publicly released Azure Functions 2019 trace [61]
<https://gitlab.mpi-sws.org/cld/trace-datasets/azure-functions>

A.3.5 Models

The DNN models pre-compiled for NVIDIA Volta V100 GPUs are accessible at
<https://gitlab.mpi-sws.org/cld/ml/clockwork-modelzoo-volta>

A.4 Installation

- **Installation pre-requisites:**
<https://gitlab.mpi-sws.org/cld/ml/clockwork/-/blob/master/docs/prerequisites.md>
- **Building Clockwork:**
<https://gitlab.mpi-sws.org/cld/ml/clockwork/-/blob/master/docs/building.md>
- **Setting-up the environment:**
<https://gitlab.mpi-sws.org/cld/ml/clockwork/-/blob/master/docs/environment.md>
- **Clockwork configuration:**
<https://gitlab.mpi-sws.org/cld/ml/clockwork/-/blob/master/docs/configuration.md>

A.5 Experiment workflow

Experiments can be run using the scripts provided in the repository. We have also provided instructions to run the experiments manually. To get started with Clockwork, we recommend getting the system running manually, in order to understand the pieces involved, and to ensure the system has been configured appropriately for your machines. Afterwards, you might choose to run the experiments using the provided scripts or manually. The experiments repository is available at <https://gitlab.mpi-sws.org/cld/ml/clockwork-results>

Experiment	Related figure	Execution time (hr)	Documentation and scripts
How Does Clockwork Compare?	Fig. 5	3	https://gitlab.mpi-sws.org/cld/ml/clockwork-results/-/tree/master/sec61_fig5
Can Clockwork Serve Thousands?	Fig. 6	1.5	https://gitlab.mpi-sws.org/cld/ml/clockwork-results/-/tree/master/sec62_fig6
How Low Can Clockwork Go?	Fig. 7	1	https://gitlab.mpi-sws.org/cld/ml/clockwork-results/-/tree/master/sec63_fig7
Can Clockwork Isolate Performance?	Fig. 8	1	https://gitlab.mpi-sws.org/cld/ml/clockwork-results/-/tree/master/sec64_fig8
Are Realistic Workloads Predictable?	Fig. 10	8	https://gitlab.mpi-sws.org/cld/ml/clockwork-results/-/tree/master/sec65_fig9_fig10
Can Clockwork Scale?	Fig. 11	2	https://gitlab.mpi-sws.org/cld/ml/clockwork-results/-/tree/master/sec66_fig11

Table 3: The experiments reproducing the presented results in this paper, their related figures, execution time, and links to the extensive documentation and scripts for each experiment.

A.6 Evaluation and expected results

The experiments repository is structured based on §6. We have provided the experiment titles, their related figures on the paper, execution time of each experiment, and the links to directories containing the respective descriptions, scripts and instructions in [Table 3](#).

A.7 Experiment customization

The directions for running each experiment manually is provided in each experiment’s documentation. Instructions for customizing the experiment environment is provided at <https://gitlab.mpi-sws.org/cld/ml/clockwork/-/blob/master/docs/customizing.md>

A.8 AE Methodology

A Unified Architecture for Accelerating Distributed DNN Training in Heterogeneous GPU/CPU Clusters

Yimin Jiang^{*†}, Yibo Zhu[†], Chang Lan[‡], Bairen Yi[†], Yong Cui^{*}, Chuanxiong Guo[†]

^{*}Tsinghua University, [†]ByteDance, [‡]Google

Abstract

Data center clusters that run DNN training jobs are inherently heterogeneous. They have GPUs and CPUs for computation and network bandwidth for distributed training. However, existing distributed DNN training architectures, all-reduce and Parameter Server (PS), cannot fully utilize such heterogeneous resources. In this paper, we present a new distributed DNN training architecture called BytePS. BytePS can leverage spare CPU and bandwidth resources in the cluster to accelerate distributed DNN training tasks running on GPUs. It provides a communication framework that is both *proved optimal* and unified – existing all-reduce and PS become two special cases of BytePS. To achieve the proved optimality in practice, BytePS further splits the functionalities of a parameter optimizer. It introduces a *Summation Service* abstraction for aggregating gradients, which is common for all the optimizers. Summation Service can be accelerated by AVX instructions and can be efficiently run on CPUs, while DNN model-related optimizer algorithms are run on GPUs for computation acceleration. BytePS can accelerate DNN training for major frameworks including TensorFlow, PyTorch and MXNet. For representative DNN training jobs with up to 256 GPUs, BytePS outperforms the state-of-the-art open source all-reduce and PS by up to 84% and 245%, respectively.

1 Introduction

In recent years, research on Deep Neural Networks (DNNs) has experienced a renaissance. DNNs have brought breakthroughs to computer vision [32, 43], speech recognition and synthesis [33, 69], natural language processing (NLP) [26], and many other areas. Training these DNN models usually requires a huge amount of arithmetic computation resources. Consequently, GPUs are preferred. To run many such tasks and achieve high resource utilization, large GPU clusters with thousands or more GPUs are introduced [29, 35, 52, 71].

Such GPU clusters have not only GPUs, but also CPUs and high speed networks. GPU machines typically also have high-end CPUs [2, 11]. There may also be CPU-only machines used for training data pre-processing and generation, *e.g.*,

in reinforcement learning. These GPU/CPU machines are connected by high-speed Ethernet or Infiniband network to facilitate distributed training. Based on our experience in operating production GPU clusters (§3.1) and recent literature from others [35], GPUs are usually better utilized while there are often spare CPU and bandwidth resources.

There are two major families of distributed training architectures, all-reduce [54] and Parameter Server (PS) [44]. They are both based on data parallelism (§2). In a task that uses all-reduce, only GPU machines are involved. In an iteration, GPUs compute the gradients of the model parameters independently, and then aggregate gradients using the all-reduce primitive. In PS tasks, both GPU machines and CPU machines can be used. Different from all-reduce, the gradients are sent to PS, which typically runs on CPU machines and aggregates the received gradients. PS then runs certain DNN training optimizer, *e.g.*, SGD [76] or Adam [42] and sends back the updated model. For both all-reduce and PS, the above happens in every iteration, until the training finishes.

All-reduce and PS are quite different, in both theory and practice. Given a set of GPU machines *without* additional CPU machines, all-reduce is proved to be bandwidth optimal [54]. However, *with* additional CPU and bandwidth resources, the optimality of all-reduce no longer holds – we find that, *in theory*, PS can offer even better performance by utilizing additional CPU machines to aid the GPU machines (§2). It seems to be a good opportunity to accelerate DNN training because GPU clusters indeed have spare CPU and bandwidth resources (§3.1). Unfortunately, *in practice*, all the existing PS have inferior performance for multiple design reasons, as we shall see soon in this paper. It is therefore not a surprise to see that distributed DNN training speed records are dominated by all-reduce [27, 49, 73].

We are thus motivated to design *BytePS*¹, an architecture that is communication-optimal, both in theory and in practice. Fundamentally, both all-reduce and PS are theoretically optimal only in very specific GPU/CPU setups, while are not

¹The name BytePS was chosen in the early stage of this project [4]. However, it is conceptually different from the conventional PS architecture.

the optimal for more generic settings, *e.g.*, there are some finite additional CPU resources. By carefully allocating traffic loads, BytePS unifies the cases where PS or all-reduce is theoretically optimal, and generalizes the optimality to any given number of GPU/CPU machines with different PCIe/NVLink configurations, with analytical proofs.

On top of that, BytePS pushes its real-world performance close to the theoretical limit, by removing bottlenecks in existing PS designs. With fast high-speed networks, we found that CPUs are not fast enough for the full fledged DNN optimizers. We introduce a new abstraction, *Summation Service*, to address this issue. We split an optimizer into gradient aggregation and parameter update. We keep gradient aggregation in Summation Service running on CPUs and move parameter update, which is more computation intensive, to GPUs. In addition, in implementation, we incorporated the idea of pipelining and priority-scheduling from prior work [34, 55] and resolved multiple RDMA-related performance issues.

As a drop-in replacement for all-reduce and PS, BytePS aims to accelerate distributed training without changing the DNN algorithm or its accuracy at all. Prior work on top of all-reduce and PS, like tensor compression [21, 45], can directly apply to BytePS. Our BytePS implementation supports popular DNN training frameworks including TensorFlow [20], PyTorch [53], and MXNet [22] with Horovod-like [60] API and native APIs.

This paper makes the following contributions:

- We design a new distributed DNN training architecture, BytePS, for heterogeneous GPU/CPU clusters. With spare CPU cores and network bandwidth in the cluster, BytePS can achieve communication optimality² for DNN training acceleration. BytePS provides a unified framework which includes both all-reduce and PS as two special cases.
- We further optimize the intra-machine communication. We explain the diverse and complicated topology in GPU machines and present the optimal strategy and principles.
- We propose Summation Service, which accelerates DNN optimizers by keeping gradient summation running in CPUs, and moving parameter update, which is the more computation intensive, to GPUs. This removes the CPU bottleneck in the original PS design.

As a major online service provider, we have deployed BytePS internally and used it extensively for DNN training. We evaluate BytePS using six DNN models and three training frameworks in production data centers. The results show that with 256 GPUs, BytePS consistently outperform existing all-reduce and PS solutions by up to 84% and 245%, respectively. We also released an open source version [4], which attracted interests from thousands in the open source community, several top-tier companies and multiple research groups.

²The optimality means to achieve minimized communication time for data-parallel distributed DNN training, given a fixed number of GPUs.

2 Background

2.1 Distributed DNN Training

A DNN model consists of many *parameters*. DNN training involves three major steps: (1) *forward propagation (FP)*, which takes in a *batch* of training data, propagates it through the DNN model, and calculates the *loss function*; (2) *backward propagation (BP)*, which uses the loss value to compute the *gradients* of each parameter; (3) *parameter update*, which uses the aggregated gradients to update the parameters with a certain optimizer (*e.g.*, SGD [76], Adam [42], etc.). Training a DNN refines the model parameters with the above three steps iteratively, until the loss function reaches its minimal.

On top of it, users can optionally run distributed training. The most popular distributed DNN training approach is *data parallelism*, which partitions the dataset to multiple distributed computing devices (typically GPUs) while each GPU holds the complete DNN model. Since the data input to each GPU is different, the gradients generated by BP will also be different. Thus data parallelism demands all GPUs to synchronize during each training iteration.

In large enterprises or in public clouds, users often run these DNN training tasks in shared GPU clusters. Such clusters are built with hundreds to thousands of GPU machines connected by high-speed RDMA networks [35, 52]. Those GPU machines typically have multiple GPUs, tens of CPU cores, hundreds of GB of DRAM, and one to several 100Gb/s NICs. These clusters run many training jobs simultaneously, with many jobs using GPUs intensively while not using CPUs heavily. A public dataset on a DNN cluster [35] indicates that 50% of hosts have CPU utilization lower than 30%.

For distributed training, there are two families of data parallelism approaches, *i.e.*, all-reduce and Parameter Server (PS). In what follows, we introduce all-reduce and PS and analyze their communication overheads. We assume that we have n GPU machines for a data-parallel training job. The DNN model size is M bytes. The network bandwidth is B .

2.2 All-reduce

Originated from the HPC community, *all-reduce* aggregates every GPU's gradients in a collective manner before GPUs update their own parameters locally. In all-reduce, no additional CPU machine is involved. *Ring* is the most popular all-reduce algorithm. All-reduce has been optimized for many years, and most state-of-the-art training speed records are achieved using all-reduce, including classical CNN-based ImageNet tasks [27, 36, 49, 73], RNN-based language modeling tasks [56], and the pre-training of BERT [26, 74].

Fig. 1 shows an example of ring-based all-reduce for three nodes. We can dissect an all-reduce operation into a *reduce-scatter* and an *all-gather*. Reduce-scatter (Fig. 1(a)) partitions the whole M bytes into n parts, and use n rings with different starting and ending point to reduce the n parts, respectively. Each node will send $(n - 1)M/n$ traffic, because each node

acts as the last node for just 1 ring and thus sends 0, while for each of the other $n - 1$ rings, it must send M/n bytes.

Next, all-gather requires each node to broadcast its reduced part to all other $(n - 1)$ nodes using a ring. In the end, all nodes have identical data that have been all-reduced (Fig. 1(c)). Similar to reduce-scatter, each node also sends $(n - 1)M/n$ egress traffic during this operation.

Adding the two steps together, in an all-reduce operation, each node sends (and receives) $2(n - 1)M/n$ traffic to (and from) the network. With B network bandwidth, the time required is $2(n - 1)M/nB$, which is proved to be the optimal in topologies with uniform link bandwidth [54], assuming *no additional resources*.

In hierarchical topologies with non-uniform link bandwidth, the optimal hierarchical strategy would require at least $2(n' - 1)M/n'B'$ communication time, where B' is the slowest link bandwidth and n' is the number of nodes with the slowest links. In distributed DNN training, n' is usually the number of GPU machines and B' is usually the network bandwidth per machine. For simplicity and without impacting our analysis, below we assume each machine has just one GPU and is connected by the same network bandwidth, *i.e.*, $n = n', B = B'$.

All-reduce has no way to utilize *additional* non-worker nodes, since it was designed for homogeneous setup. Next, we will show that the $2(n - 1)M/nB$ communication time is no longer optimal with additional CPU machines.

2.3 Parameter Server (PS)

The PS architecture [44] contains two roles: *workers* and *PS*. Workers usually run on GPU machines, perform FP and BP, and *push* the gradients to PS. PS aggregates the gradients from different workers and update the parameters. Finally, workers *pull* the latest parameters from PS and start the next iteration. According to our experience in industry, the PS processes usually run on CPUs because of cost-effectiveness. Since GPUs (and GPU memory) are much more expensive than CPUs,³ we want GPUs to focus on the most computation-intensive tasks instead of storing the model parameters.

There are two placement strategies for PS. One is *non-colocated mode* (Fig. 2(a)), in which PS processes are deployed on dedicated CPU machines, separate from the GPU machines. Suppose that we have k CPU machines,⁴ the DNN model will be partitioned into k parts and stored on the k machines, respectively. In every iteration, each GPU worker must send M bytes gradients and receives M bytes parameters back. Each CPU machine must receive in total nM/k gradients from the GPU workers and send back nM/k parameters.

³AWS price sheet [18] shows that p3.16xlarge (8 NVIDIA V100 GPUs and 64 CPU cores) costs nearly \$25 per hour. However, r4.16xlarge, which is the same as p3.16xlarge minus GPUs, costs only \$4.2 per hour.

⁴In this paper, for simplicity, we assume that a CPU machine has the same network bandwidth as a GPU machine. If not, all analysis and design will remain valid as long as the number of CPU machines scales accordingly. For example, use $4 \times$ CPU machines if their bandwidth is 25% of GPU machines.

Figure 1: The communication workflow of all-reduce.

Figure 2: The communication pattern of PS. A solid arrow line indicates the network traffic. A dashed arrow line represents the loop-back (local) traffic.

Assuming $k = n$, PS would theoretically be faster than all-reduce, as summarized in Table 1. In fact, PS is communication optimal in such setting, since M is the absolute lower bound each GPU machine has to send and receive. However, with fewer CPU machines (smaller k), the communication time nM/kB on CPU machines would increase and, if $k \leq n/2$, become slower than all-reduce. The network bandwidth of GPU machines would become under-utilized because the CPU machines would be the communication bottleneck.

The other strategy is *colocated mode* (Fig. 2(b)), which does not use any CPU machines. Instead, it starts a PS process on every GPU worker and reuses its spare CPU resources. The PS and GPU worker on the same machine will communicate through loopback traffic. In this case, it is easy to calculate that communication time is the same as all-reduce (Table 1). **All-reduce vs. PS.** They have different communication patterns. PS uses a bipartite graph. Non-colocated PS can leverage additional CPU and bandwidth resources to aid GPU machines, while may under-utilize the resources of GPU machines. Colocated PS and all-reduce utilize the GPU worker resources better, while cannot use additional CPU machines.

Another difference is that PS supports *asynchronous* training, which allows GPU workers to run at different speed and mitigates the impact of stragglers, while all-reduce does not support it. However, asynchronous training is less popular because it can slow down model convergence. We will mainly focus on synchronous training in this paper while briefly address asynchronous training in §5.

3 Motivation and BytePS Architecture

3.1 Motivation

Before the deployment of BytePS in our internal GPU clusters, our users mostly used all-reduce as the distributed training architecture due to its higher performance than existing PS designs. The remaining users choose PS for tasks where asynchronous training is acceptable or preferable. With multiple years of experience and efforts on accelerating DNN tasks and improving resource utilization, we have the following observation.

Table 1: The theoretical communication time required by each training iteration. n is the number of GPU machines. k is the number of additional CPU machines. M is the model size. B is the network bandwidth. We will revisit the *Optimal?* row in §4.1.

	All-reduce	Non-Colocated PS	Colocated PS
Time	$\frac{2(n-1)M}{nB}$	$\max(\frac{M}{B}, \frac{nM}{kB})$	$\frac{2(n-1)M}{nB}$
Optimal?	Only if $k = 0$	Only if $k = n$	Only if $k = 0$

Opportunity: there are spare CPUs and bandwidth in production GPU clusters. Large-scale GPU clusters simultaneously run numerous jobs, many of which do not heavily use CPUs or network bandwidth. Fig. 3 shows a 3-month trace collected from one of our GPU clusters that have thousands of GPUs. The GPUs have been highly utilized in that period (approaching 96% allocation ratio in peak times). We find that, 55%-80% GPU machines have been assigned as GPU workers for at least one *distributed* training task. This leaves the network bandwidth of 20%-45% GPU machines unused because they are running *non-distributed* jobs.⁵ The cluster-wide average CPU utilization is only around 20%-35%. This aligns with the findings in prior work from Microsoft [35].

This observation, combined with the all-reduce vs. non-colocated PS analysis in §2.1, inspires us – if we can better utilize these spare CPUs and bandwidth, it is possible to accelerate distributed training jobs running on given GPUs.

Existing all-reduce and PS architectures are insufficient. Unfortunately, the analysis in §2.1 also shows that all-reduce and PS have a common issue: they do not utilize additional CPU and bandwidth resources well. All-reduce and colocated PS only use resources on GPU workers, and non-colocated PS may not fully utilize the CPU cores and NIC bandwidth on GPU workers. The former is communication optimal only when $k = 0$, while the latter is optimal only when $k = n$. When the number of CPU machine k is $0 < k < n$, neither would be optimal. We defer further analysis to §4.1. Here, we use an experiment to show the end-to-end performance of existing all-reduce and PS.

Fig. 4 shows the training speed of VGG-16 [63] using 32 V100 GPUs (4 GPU machines), with 100GbE RDMA network. The batch size is 32 images for each GPU. We run the latest MXNet native PS RDMA implementation [1] and (one of) the most popular all-reduce library NCCL-2.5.7 [13]. We also tested TensorFlow’s native PS, and got similar results. We vary the number of additional CPU machines for each setup. All-reduce plot is flat because additional CPU machines are of no use, while PS has the worst performance even with additional CPU machines. Both of them are far from optimal. Even with ByteScheduler [55], which is a state-of-the-art technique that can improve the communication performance, both all-reduce and PS are still far from the linear scaling, *i.e.*, $32 \times$ of single-GPU training speed. This is because ByteScheduler

⁵Our machines have dedicated but slower NIC for data I/O. This is a common practice in industry [52]. In addition, data I/O traffic is usually much smaller than the distributed training traffic between GPU machines.

Figure 3: Daily statistics of our internal DNN training clusters from 2020-01-01 to 2020-03-31.

Figure 4: VGG-16 training performance of different architectures. We use 4 GPU machines with 32 GPUs in total. *Linear Scaling* represents the maximal performance (in theory) of using 32 GPUs.

works on top of PS or all-reduce, and thus has the same limitations. BytePS outperforms all of above at any given number of CPU machines (more in §7).

Our solution: BytePS. It is a unified architecture for distributed DNN training that can leverage spare CPU and bandwidth resources. It achieves the following goals.

First, BytePS is always communication optimal with any additional CPU and bandwidth resources, *i.e.*, $0 \leq k \leq n$, allocated by the cluster scheduler. In practice, the volume of spare resources can be dynamic (Fig. 3), so BytePS must adapt well. In addition, the hardware setup of GPU machines can be diverse, especially the internal PCIe or NVLink topology. BytePS is also *proved* optimal in intra-machine communication. All-reduce and PS, when they are communication optimal, are two special cases of BytePS (§4).

Second, BytePS can achieve communication time very close to the theoretical optimal. This is important, as shown in the existing PS case – PS performance is far from its theoretical limit. We found that original PS designs have several implementation bottlenecks (which we will discuss in §6). But even after all the bottlenecks are removed, PS performance is still inferior to optimal. This leads to BytePS’s second design contribution: *Summation Service*. We find that running the full optimizers on CPU can be a bottleneck. We divide the computation of optimizers and only put summation on CPUs. We will elaborate the rationale of this design in §5.

All the BytePS designs are generic to DNN training. BytePS can therefore accelerate various DNN training frameworks including TensorFlow, PyTorch, and MXNet. We start from presenting BytePS’s architecture.

3.2 Architecture Overview

Fig. 5 shows the architecture of BytePS. BytePS has two main modules – *Communication Service (CS)* and *Summation Service (SS)*. In BytePS, we aim to leverage any CPU resources, whether on GPU machines or CPU machines, to

Figure 5: BytePS architecture. Solid lines: the connection between CPU machines and GPU machines. Dashed lines: the data flow inside GPU machines.

achieve the best communication efficiency. This is achieved by SS, which runs on the CPU of *every* machine, including the CPU machines and GPU machines. The CPU machines may not necessarily be actual CPU-only machines. For example, our in-house cluster scheduler can allocate CPUs on the GPU machines that run non-distributed jobs and have spare CPU cores and network bandwidth. This improves the overall cluster resource utilization.

Another important property of SS is that it is much simpler than common PS server processes, which run full fledged DNN algorithm optimizers. In contrast, SS is only responsible for receiving tensors that are sent by CS, summing up the tensors and sending them back to CS.

The other module, CS, is responsible for internally synchronizing the tensors among multiple (if there are) local GPUs and externally communicating with SS. Every training iteration, each CS must send in total M bytes (the DNN model size) to and receive M bytes from SS. In synchronous distributed training, the tensors are model gradients.

CS contains several design points of BytePS. First, it decides the traffic volume to each SS (both internal and external). The load assignment strategy is based on our analysis of the optimal communication strategy (§4.1). Second, it chooses the best local tensor aggregation strategy depending on different internal GPU and NIC topology (§4.2) of the GPU machines. Finally, both CS and SS should be optimized for RDMA in modern high-speed data centers (§6.2).

This architecture enables BytePS to flexibly utilize any number of additional CPU resources and network bandwidth. When the number of CPU machines is 0, *i.e.*, $k = 0$, the communication will fallback to only using SSs on GPU machines. When the number of CPU machines is the same as GPU machines, BytePS is as communication optimal as non-located PS. In other cases, BytePS can leverage SSs on all machines together. In fact, our analytical results will reveal the optimal communication strategy with any number of CPU machines, while PS and all-reduce are just two specific points in the whole problem space.

4 BytePS Communication Design

4.1 Inter-machine Communication

In BytePS, all networking communication is between CS and SS. To prevent a bottleneck node from slowing down the

whole system, we must balance the communication time of all machines. In what follows, we assume the network has full bisection bandwidth, which is a common practice in deep learning clusters [52]. We also assume that the full bisection bandwidth can be fully utilized due to the newly introduced RDMA congestion control algorithms, *e.g.*, DCQCN [75].

On each CPU machine, the summation workload of its SS determines the network traffic. For example, if a SS is responsible for summing up $x\%$ of the DNN model, the CPU machine would send and receive $x\% \times M$ bytes traffic to *every* GPU machine during each training iteration. However, the network traffic of a GPU machine is determined by the combination of CS and SS running on it. Due to this difference, BytePS classifies SS into SS_{CPU} and SS_{GPU} based on whether they run on CPU machines or GPU machines.

To minimize the communication time, BytePS assigns $M_{SS_{CPU}}$ bytes summation workload to each SS_{CPU} . $M_{SS_{CPU}}$ is given in Eq. 1, where $k \geq 1$ is the number of CPU machines and $n \geq 2$ is the number of GPU machines, and $k \leq n$. Outside these constraints, the communication time of BytePS falls back to trivial solutions like PS (when $k > n$) and all-reduce (when $k = 0$), as §4.1.1 shows.

$$M_{SS_{CPU}} = \frac{2(n-1)}{n^2 + kn - 2k} M \quad (1)$$

Similarly, BytePS assigns $M_{SS_{GPU}}$ bytes to each SS_{GPU} .

$$M_{SS_{GPU}} = \frac{n-k}{n^2 + kn - 2k} M \quad (2)$$

Eq. 1 and Eq. 2 show the workload assignment strategy that is optimal for minimizing the communication time. The analysis is in §4.1.1. In practice, the DNN model consists of tensors with variable sizes and may not allow us to perfectly assign workloads. BytePS uses an approximation method. It partitions the tensors into small parts no larger than 4MB.⁶ Then, all CSs consistently index each part and hash the indices into the range of $[0, n^2 + kn - 2k)$. CSs will send and receive tensors to SSs based on the hash value and approximate the probabilities according to Eq. 1 and Eq. 2. Consistent indexing and hashing guarantee that the same part from all GPUs will be sent to and processed by the same SS.

4.1.1 Communication Efficiency Analysis

Next, we present the communication time analysis of BytePS. To simplify the analysis, we assume that the model size M is much larger than the partition size (4MB in our case). Partitioning enables BytePS not only to better balance the summation workloads, but also to well utilize the bidirectional network bandwidth by pipelining sending and receiving, as shown in [34, 55]. So, we further assume that sending and receiving the whole M bytes can fully overlap with negligible overhead. We have the following result.

⁶While we find that 4MB partition size works reasonably well in our environment, BytePS allow users to tune the partition size value.

Theorem 1. *The SS workload assignment given by Eq. 1 and Eq. 2 is optimal for minimizing communication time.*

Proof. We first consider the network traffic of a GPU machine. It runs a CS module and an SS module. CS should send and receive M bytes in total. However, when it communicates with the SS on the same GPU machine, the traffic does not go over the network. So, a CS module will send and receive $M - M_{SSGPU}$ bytes. An SS module on a GPU machine must receive and send M_{SSGPU} from other $n - 1$ GPU machines, *i.e.*, $(n - 1)M_{SSGPU}$ in total. Adding them together, a GPU machine with network bandwidth B requires communication time t_g :

$$t_g = \frac{M + (n - 2)M_{SSGPU}}{B} \quad (3)$$

Similarly, if $k > 0$, we can get that a CPU machine with network bandwidth B requires communication time t_c :

$$t_c = M_{SSCPU} / B \quad (4)$$

In addition, the sum of all the SS workload should be equal to the total model size.

$$M = kM_{SSCPU} + nM_{SSGPU} \quad (5)$$

From Eq. 5, it is clear that the larger M_{SSCPU} is, the smaller M_{SSGPU} is. Consequently, when $n \geq 2$, the larger t_c is, the smaller t_g is (or t_g is unchanged if $n = 2$). In addition, we know that the final communication time is $\max(t_c, t_g)$.

To minimize the communication time, t_c and t_g need to be equal. If they are not equal, say $t_c > t_g$, it means the communication time can be further reduced by decreasing M_{SSCPU} and thus bring down t_c .

We let $t_c = t_g$ and combine Eq. 3, Eq. 4, and Eq. 5. Solving the equations with M_{SSGPU} and M_{SSCPU} as variables, we can get the optimal values as given by Eq. 1 and Eq. 2. \square

Based on Theorem 1, combine Eq. 3 and Eq. 2, we have the optimal communication time, which is used in Fig. 12.

$$t_{opt} = \frac{2n(n - 1)M}{(n^2 + kn - 2k)B} \quad (6)$$

From Eq. 2, we can see that when the numbers of CPU machines and GPU machines are the same, $M_{SSGPU} = 0$, which means that we do not need any $SSGPU$. This is because the CPU machines already provide enough aggregate bandwidth. BytePS falls back to non-colcated PS. Similarly, when the number of CPU machines is 0, BytePS falls back to all-reduce and colocated PS.

Of course, the more interesting case is the general case when $0 < k < n$. We use the communication time of the plain all-reduce and non-colocated PS as the two baselines. We define the acceleration ratio γ_a as the communication time of the plain all-reduce divided by that of the general case. Similarly, γ_p is defined as the acceleration ratio compared to the non-colocated PS case. We have

$$\gamma_a = \frac{n^2 + kn - 2k}{n^2}, \gamma_p = \frac{n^2 + kn - 2k}{2k(n - 1)} \quad (7)$$

Figure 6: PCIe-only machine topology and BytePS data flow. Gray boxes are GPUs. Only the outgoing direction (from GPUs to network) is shown in the data flow figure. Incoming is the opposite.

When $k = n$ and $n \rightarrow \infty$, $\gamma_a = 2$. When k is small, γ_p can be quite big, as the communication bandwidth is severely bottlenecked by the CPU machines in non-colocated PS. For example, when $n = 32$ and $k = 16$, we have $\gamma_a = 1.46$ and $\gamma_p = 1.52$, respectively. It means that BytePS can theoretically outperform all-reduce and PS by 46% and 52%, respectively.

We note that adding more CPU machines beyond $k = n$ does not help, since the communication bottleneck will become the NIC bandwidth of the GPU machines.

4.2 Intra-machine Communication

In §4.1, we design the optimal inter-machine communication strategy. In practice, we find that intra-machine communication is equally important. There are often multiple GPUs in a machine. CS must aggregate/broadcast the tensors before/after communicating with SS. This can create congestion on the PCIe links and prevent NIC from fully utilizing its bandwidth B . Moreover, the GPU machine's internal topology can be diverse in data centers. Below, we share the two most common machine setups in our environment and our corresponding solution. We present several principles that can apply to other machine setups in §4.2.3.

4.2.1 PCIe-only Topology

Fig. 6(a) shows a setup in our production environment. A GPU machine has two NUMA CPUs connected via QPI. The eight GPUs are split into two groups and connected to two PCIe switches, respectively. The NIC is 100Gbps and connected to the PCIe of one of the CPUs. All PCIe links in figure are 3.0×16 (128Gbps theoretical bandwidth). The CPU memory and QPI has $> 300Gbps$ bandwidth, which are less likely the communication bottleneck. We call this *PCIe-only topology*. For this machine model, we measure that the throughput of GPU-to-GPU memory copy is $\approx 105Gbps$ within the same PCIe switch. The throughput of GPU-to-GPU memory copy across PCIe switches, however, is only $\approx 80Gbps$.

Unfortunately, many existing training frameworks ignore such details of internal topology. For example, TensorFlow PS, MXNet PS and even the “hierarchical all-reduce” mode of Horovod use a straightforward reduce or reduce-scatter across all GPUs on the same machine. This would lead to cross-PCIe switch memory copy, which is unfortunately slower.

Figure 7: Notations of the PCIe-only topology.

In contrast, BytePS lets GPUs under the same PCIe switch sum the tensors first, then copy to CPU and let CPU do the global summation, and finally broadcast back the global sum. We call it *CPU-assisted aggregation*. Specifically, it consists of the following steps.

1. **Reduce-Scatter:** Suppose each PCIe switch has l GPUs. These l GPUs perform a reduce-scatter which incurs $(l-1)M/l$ traffic only inside the PCIe switch. When it finishes, each GPU should hold M/l aggregated data.
2. **GPU-CPU Copy:** Each GPU copies its M/l data to CPU memory, which incurs M/l traffic along the route. Every PCIe switch would generate M aggregated data.
3. **CPU-Reduce:** CPU reduces the data from all PCIe switches and generates the aggregated data across all GPUs. This reduction does not incur any PCIe traffic.
4. **Networking:** CS sends the data to SS and receives globally aggregated data from SS.
5. **CPU-GPU Copy:** Each GPU copies its M/l partition from CPU memory back to itself. This incurs M/l traffic from the CPU to each GPU.
6. **All-Gather:** Each GPU performs an all-gather operation with those that are under the same PCIe switch. This incurs $(l-1)M/l$ traffic inside the switch.

Fig. 6(b) shows the traffic of step 1 to 3. Step 4 to 6 use the same links but the opposite direction. With CPU-assisted aggregation, the PCIe switch to CPU link would carry only M traffic in each direction, much lower than doing collective operation directly on eight GPUs ($7M/4$ traffic). Meanwhile, the traffic on each PCIe switch to GPU link would be $(2l-1)M/l$. Let $l=4$ (each PCIe has four GPUs), this is $7M/4$, remaining the same as the existing approach. Fundamentally, BytePS leverages the spare CPUs on the GPU machine to avoid the slow GPU-to-GPU cross-PCIe switch memory copy.

Optimality Analysis. We now analyze the communication optimality of the above strategy. Fig. 7 shows a more generic PCIe-only topology with variable number of GPUs and PCIe switches. We do not plot the NIC as in Fig. 6(a) because under that topology, the NIC has dedicated PCIe lanes and will not compete for the PCIe bandwidth with GPUs. The system architecture is modeled as a hierarchical graph $G = (V, E)$. Denote N as the set of leaf nodes (GPUs), S as the set of intermediate nodes (switches), C as the set of CPU nodes. $V = N \cup S \cup C$. Each edge $e(v_x, v_y)$ in E represents the bandwidth from vertex v_x to v_y , and we denote $t(v_x, v_y)$ as the amount of traffic sent from v_x to v_y . We further define p as

the number of switches ($p \geq 2$), and n as the leaf nodes that each switch connects ($n \geq 2$).

We assume the following features of G : (1) Each edge in E is duplex and the bandwidth of both directions are equal. Denote $b(v_x, v_y)$ as the bandwidth of $e(v_x, v_y)$, then $b(v_x, v_y) = b(v_y, v_x)$; (2) We assume G is symmetric. The bandwidth at the same layer of the tree is equivalent. For example, $b(S_j, C_j) = b(S_k, C_k)$ and $b(N_x, S_j) = b(N_y, S_j)$ hold for any $j, k \in [0, p-1]$, $x, y \in [jn, (j+1)n-1]$; (3) The memory and QPI bandwidth is much higher than the PCIe links and is less likely to be the bottleneck. In the following, we only focus on the PCIe links.

The GPUs from N_0 to N_{pn-1} need to sum their data. We can either use *CPU-assisted aggregation* mentioned before, or use *brute-force copy* that needs each GPU to copy its entire data to C directly. In practice, the optimal solution should be a combination of these two strategies, depending on the value of $b(S_j, C_j)$ and $b(N_i, S_j)$. The intuition is that we apply brute-force copy on x of the data, and CPU-assisted aggregation on y of the data ($x+y=1$). Under certain x and y , the job completion time J can be minimized. We calculate the traffic of two links respectively. On $e(S_j, C_j)$, the traffic is composed of n times brute-force copy plus the traffic of CPU-assisted aggregation. On $e(N_i, C_j)$, the traffic is composed of one brute-force copy and the complete traffic of CPU-assisted aggregation.

$$t(S_j, C_j) = n * xM + \frac{yM}{n} * n = (nx + y)M \quad (8)$$

$$t(N_i, S_j) = xM + \left(\frac{2(n-1)}{n} + \frac{1}{n}\right)yM = \left(\frac{2n-1}{n}y + x\right)M \quad (9)$$

Since J is determined by $J = \max\left(\frac{t(N_i, S_j)}{b(N_i, S_j)}, \frac{t(S_j, C_j)}{b(S_j, C_j)}\right)$, the optimal J is highly related to the two bandwidth terms. On our own PCIe machines (Fig. 6(a)), we measure that both $b(N_i, S_j)$ and $b(S_j, C_j)$ are 13.1GB/s (105Gbps). Let $M=1$ GB and $n=4$, combining Equation (8), (9) and $x+y=1$, we are trying to find a $x \in [0, 1]$ such that $\arg \min_x J(x) = \max\left(\frac{3x+1}{13.1}, \frac{7-3x}{52.4}\right)$. Solve it and we will get the optimal solution is $x^* = 1/5$ and $J^* = 0.129s$. This means the optimal solution works like this: each GPU applies brute-force copy on its $1/5$ data, and uses CPU-assisted aggregation for the rest $4/5$ data. Therefore, we have the following key conclusions:

CPU-assisted aggregation is near-optimal. When $x=0$, the solution is our CPU-assisted aggregation, and the job completion time is $J(0) = 0.141s$. As calculated, the optimal time is $0.129s$. Thus, our strategy closely approximates the optimal solution, with 9% difference on performance. However, in practice, brute-force copy heavily stresses the CPU memory – any tensor that uses brute-force copy would consume $4 \times$ CPU memory bandwidth compared with CPU-assisted aggregation. CPU memory does not really have $4 \times$ bandwidth of PCIe links, especially for FP16 summation (Fig. 9(b)). Consequently, we choose not to use brute-force copy at all and stick

to CPU-assisted aggregation.

CPU-assisted aggregation is better than ring-based all-reduce. We have the job completion time for ring-based all-reduce as $J_{ar} = \frac{2(np-1)M}{np \cdot b_{bottleneck}}$. Similarly, for CPU-assisted aggregation we have $J_{ca} = \frac{M}{b(S_j, C_j)} * \max(1, \frac{2n-1}{kn})$, where $k = \frac{b(N_i, S_j)}{b(S_j, C_j)}$. In our case, $k = 1$ and $b_{bottleneck} < b(S_j, C_j)$, so it is easy to prove that $J_{ca} < J_{ar}$ always holds for any $n, p \geq 2$. For example, using the value from our PCIe machines, let $p = 2$, $n = 4$, $b_{bottleneck} = 80Gbps$ (bandwidth of memory copy that crosses PCIe switches) and $b(S_j, C_j) = 105Gbps$ we get that J_{ca} is 23.7% smaller than J_{ar} .

4.2.2 NVLink-based Topology

Fig. 8(a) shows the other machine model in our data center – a GPU machine with NVLinks. There are four PCIe switches, each connecting two GPU cards. The GPUs are also connected via NVLinks. The NVLinks give every GPU in total 1.2Tbps GPU-GPU bandwidth, much higher than the PCIe link. The NIC is connected to one of the PCIe switches. The problem is that the topology is not symmetric considering the NIC, which is connected to only one (out of four) PCIe switch. The NIC and the two GPUs under the same PCIe switch have to compete for the PCIe bandwidth of $P_0 - CPU_0$. Remember that not only CS uses this PCIe bandwidth, but also the SS runs on this same GPU machine uses it! $P_0 - CPU_0$ again becomes the bottleneck in the whole communication.

With NVLink, GPU-to-GPU communication can completely avoid consuming PCIe bandwidth. So, we no longer need CPU-assisted aggregation. However, we find that existing framework, including the most popular GPU all-reduce implementation NCCL (used by TensorFlow, PyTorch, MXNet and Horovod), is again sub-optimal.

The problem is that the topology is not symmetric considering the NIC, which is connected to only one (out of four) PCIe switch. The NIC and the two GPUs under the same PCIe switch have to compete for the PCIe bandwidth of $P_0 - CPU_0$. Remember that not only CS uses this PCIe bandwidth, but also the SS runs on this same GPU machine uses it! $P_0 - CPU_0$ again becomes the bottleneck in the whole communication.

Based on the analysis, we should leave as much $P_0 - CPU_0$ PCIe bandwidth as possible to the NIC during local aggregation. For this topology, BytePS uses reduce and broadcast instead of reduce-scatter and all-gather – tensors from all GPUs are first reduced to GPU_2 and the result is then copied to CPU_0 memory from GPU_2 . Fig. 8(b) shows those steps. Later, when CS gets the aggregated results from SS, GPU_2 would copy the data into GPU memory and broadcast them to other GPUs. This way, we completely prevent GPUs from using the $P_0 - CPU_0$ bandwidth for communication, so the NIC can run to full 100Gbps bandwidth.

This approach seems to create traffic hotspots on GPU_2 . However, NVLinks has much larger bandwidth than PCIe links, so inter-GPU communication is never the bottleneck even on the hotspots. Meanwhile, the $P_1 - CPU_0$ PCIe link used for GPU-CPU copy has approximately the same 100Gbps bandwidth as the NIC, so it is not a bottleneck either.

BytePS has achieved the optimal result – there is no intra-machine bandwidth bottleneck. Existing solutions like NCCL, unfortunately, tends to let GPUs use the $P_0 - CPU_0$ bottleneck link because of the proximity between GPU_0 and the NIC.

Figure 8: NVLink-based machine topology and BytePS data flow. Only the outgoing direction is shown in the data flow figure.

Consequently, its communication performance is lower than our solution in the NVLink-based machines.

4.2.3 Discussion

The solutions for PCIe-only and NVLink-based topology are quite different. This shows that there is no one-fit-all optimal solution. The intra-machine communication must adapt to different internal topologies. Admittedly, there are certainly more topologies than the above two used in our environment. However, we believe that the above two are representative, since they are similar to the reference design recommended by server vendors [15] and NVIDIA [11], respectively.

Despite the difference, we summarize two principles – 1) always avoid direct GPU-to-GPU memory copy when the two GPUs are not under the same PCIe switch because it is slow in practice. 2) Always minimize traffic on the PCIe switch to CPU link that is shared by GPUs and NIC. We propose the following best practice procedure. Let S_n be the number of PCIe switches with GPUs and NIC, and S_g be the number of PCIe switches with only GPUs.

1. If $S_n > 0$ and $S_g > 0$, the topology is asymmetric like our NVLink-based topology. CS should use reduce and broadcast, with GPUs that are not competing with NICs as reduce or broadcast roots.
2. If $S_n = 0$ or $S_g = 0$, the topology is symmetric like our PCIe-only case. CS should use reduce-scatter and all-gather to balance traffic on all PCIe switches. CPU-assisted aggregation (§4.2.1) should be used if no NVLink.

Multi-NIC topology. Although the two specific topologies we discussed have only one NIC, the above principles can directly extend to multi-NIC topology – it only changes the value of S_n and S_g .

GPU-direct RDMA (GDR). GDR can potentially reduce the PCIe traffic. However, GDR requires the GPU and the RDMA NIC to be on the same PCIe switch, otherwise the throughput can be less than 50Gbps even with 100GbE NIC [12], which is also confirmed by our own measurements. Consequently, GDR does not benefit our settings – PCIe-only topology does not satisfy the requirement, and we already avoided any PCIe bottlenecks for NVLink-based topology. In addition, most clouds like AWS do not support GDR. Therefore, BytePS does not use GDR for now.

(a) Parameter update on different devices. (Mtm: Momentum [65]) (b) Throughput of CPU summation on different floating point tensors.

Figure 9: CPU is slow for optimizers but not for summation.

We can see that the optimal intra-machine communication strategy is tightly coupled with the internal topology. Building a profiler to automatically detect the topology, probe the bandwidth, and generate the best strategy is interesting future work.

5 Summation Service

To get the optimal inter-machine communication time (§4.1), BytePS needs a module that can run on the CPU of every machine and communicate with CS. The question is, what is its role in the training algorithm? Our initial attempt was to follow the previous PS design [44], in which the PS processes are responsible for running the *optimizer*. The optimizer aggregates the gradients from all GPUs and updates the DNN model parameters using various optimizers.

The CPU bottleneck. Unfortunately, soon we found that the CPUs became a bottleneck in the system. We use an experiment to demonstrate this. We train the VGG16 DNN [63] using a typical non-co-located PS setting: using one Tesla V100 GPU machine and one CPU machine (Intel Xeon Platinum CPU, 32 cores with hyper-threading and Intel MKL [7]) connected by 100GbE Ethernet. The GPU machine runs the forward and backward propagation, and the CPU machine runs the optimizer using all the 32 CPU cores.

Fig. 9(a) shows that, even with 32 cores and MKL-enabled, running the optimizer on the CPU machine can slow down the end-to-end training speed. It means the CPU cannot match the network bandwidth and becomes a bottleneck (§6). As the optimizer algorithm gets more complicated (from simpler SGD to the more complicated RMSProp), the bottleneck effect becomes more severe.

The root cause. The CPU bottleneck is caused by the limited memory bandwidth. Popular optimizers such as Adam can easily exhaust the memory bandwidth of modern CPUs. For example, the peak transfer rate of a 6-channel DDR4-2666 memory setup is up to 1024 Gbps combining read and write [8]. It is easy to estimate that, for example, the Adam optimizer [42] requires more than 10x memory access (read+write) for applying every gradient update. Adding that 100Gbps NIC consumes 200 Gbps memory bandwidth (read+write), the 1024 Gbps memory bandwidth is simply not sufficient for Adam to process 100 Gbps gradient stream.

CPU is good at summation. The above experiment leads us to rethink the tasks placed on CPUs. The computation of an

Figure 10: Component placement comparison between all-reduce, PS and BytePS.

optimizer can be divided into two steps, *gradient summation* and *parameter update*, as Fig. 10 shows.

Fortunately, modern x86 CPUs are good at summation thanks to the highly optimized AVX instructions [47]. In Fig. 9(b), we show the summation throughput on the same CPUs as above, using synthetic floating point tensors. The throughput is more than 200Gbps for both FP16 and FP32 precision, higher than the 100Gbps NIC bandwidth. Therefore, summation on CPU will not be a bottleneck.

BytePS’s solution. Based on these observations, BytePS decouples the two steps of optimizer. We move the computation-intensive parameter update to GPUs and places only summation on CPUs – this is why we name the CPU module Summation Service (SS). SS not only prevents the CPU from being the bottleneck, but also largely reduces the CPU overhead. With carefully implementation using AVX and OpenMP, SS only consumes fewer than 3 CPU cores when it runs at 100Gbps throughput. Fig. 10 gives a high-level comparison over PS, all-reduce and BytePS on how they place different components in DNN training onto GPU and CPU resources.

Since Summation Service moves parameter update to GPU machines, all the GPU machines need to perform the same parameter update calculation, whereas parameter update needs to be done only once in traditional PS. BytePS hence uses more computation cycles for parameter update than PS. This is a tradeoff we made willingly, to accelerate end-to-end training speed. We define SS overhead ratio as the FLOPs for parameter update over the sum of FP and BP FLOPs. The ratio is 138 MFLOPs / 32 GFLOPs, 26 MFLOPs / 7.8 GFLOPs, 387 MFLOPs / 494 GFLOPs for VGG-16, ResNet-50, BERT-large using SGD as the optimizer, all are less than 0.5%. The introduced overhead is negligible, compared to the training speedup (Fig. 9(a)). The above ratio definition assumes batch size of 1. DNN training typically uses batch size of tens or hundreds. Parameter update is done once per batch, hence the additional overhead is even smaller in practice.

We note that Horovod [60] has the option to move gradient aggregation to CPUs by first copying the tensors to CPU memory and then performing CPU-only all-reduce. Since it still only relies on the CPUs and bandwidth on GPU machines, it does not provide communication-wise advantages compared with directly all-reduce on GPUs. BytePS is different: it leverages *additional* CPU machines for gradient summation, while keeps parameter update on GPUs.

Support asynchronous training. Although separating the

summation and update brings us performance benefits, it breaks an important feature of the original PS: the support of asynchronous training like Asynchronous Parallel [25]. Asynchronous Parallel relies on the PS processes keeping the most updated model parameters, which is not directly compatible with the design of SS. To bridge this gap, we re-design a new workflow that can enable asynchronous training with SS, as shown in Fig. 11(b). In short, GPU updates parameters and computes the *delta parameters* first. CS sends them and receives *latest parameters*. SS keeps adding delta parameters to the latest parameters. Next, we prove that this new training workflow is equivalent to Asynchronous Parallel in terms of algorithm convergence.

Theorem 2. *The asynchronous algorithm for BytePS is equivalent to Asynchronous Parallel [25].*

Proof. Consider one SS connected with n CSs. We say a CS stores the local model parameters, and a SS holds the latest version of parameters. The high level idea of our proof is to show that our algorithm generates identical state (*i.e.*, same parameter for the SS module and n CS modules) with Asynchronous Parallel, given the same communication order (push and pull order). We use f as a general representation of the optimizer. The optimizations thus can be represented as $w \leftarrow w + f(g_{i,t})$, where $g_{i,t}$ represents the gradients of CS _{i} ($i \in [0, n-1]$) at iteration t ($t \in [1, T]$). Denote w_{ps} and w_{byteps} as the parameter in PS and BytePS, respectively. And denote $w_{i,t}$ as the parameter on each worker _{i} (for PS) or CS (for BytePS) at iteration t . The parameter is initiated to w_0 for all CSs and the SS. After T iterations, we can obtain the updated parameter as:

$$w_{ps} = w_0 + \sum_{t=1}^T \sum_{i=0}^{n-1} f(g_{i,t}) \quad (10)$$

$$w_{byteps} = w_0 + \sum_{t=1}^T \sum_{i=0}^{n-1} \Delta w_{i,t} \quad (11)$$

Next, we use induction to prove that $\Delta w_{i,t} = f(g_{i,t})$ holds for any i and t . (1) *Base case* $t = 1$: Given initial parameter w_0 , we obtain the gradient $g_{i,1}$ from w_0 . In Parameter Server, worker _{i} pushes $g_{i,1}$ to the server and get updated as $w_{ps,1} = w_0 + f(g_{i,1})$. In BytePS, CS _{i} pushes $f(g_{i,1})$ to SS and get updated as $w_{byteps,1} = w_0 + f(g_{i,1})$. So $\Delta w_{i,t} = f(g_{i,t})$ holds for $t = 1$. Meanwhile, the parameter on worker _{i} or CS _{i} is the same on both architectures after receiving the response from the server or SS. (2) *Inductive step*: If the lemma we want to prove holds for $t = k$ ($k \geq 1$), the gradient $g_{i,k+1}$ is computed from the same w_k . Similar to the base case, we obtain $w_{ps,k+1} = w_k + f(g_{i,k+1})$ and $w_{byteps,k+1} = w_k + f(g_{i,k+1})$. So $\Delta w_{i,t} = f(g_{i,t})$ holds for $t = k + 1$. By the principle of induction, $\Delta w_{i,t} = f(g_{i,t})$ holds for all $t \in \mathbb{N}$.

Return to (10) and (11). Since $\Delta w_{i,t} = f(g_{i,t})$ holds for any i and t , we get $w_{ps} = w_{byteps}$. This completes the proof

Figure 11: Asynchronous training workflow comparison between PS and BytePS. g is the gradients. w is the parameters.

because the parameter of our algorithm and Asynchronous Parallel are equivalent after any T batches. \square

6 Implementation

While the core of BytePS is generic for any training framework, BytePS also implements plugins for TensorFlow, PyTorch and MXNet, for user-friendliness. The core is implemented in C++, while the framework plugins contain both C++ and Python. In total, BytePS consists of about 7.8K lines of Python code, and 10K lines of C++ code. As a major online service provider, we have deployed BytePS internally. BytePS has also been open-sourced [4] and attracted thousands of users.

6.1 Multi-Stage Pipeline

A common way to speed up a multi-step procedure is to build a multi-stage pipeline that overlaps the processing time of each step. We incorporated the idea of tensor partition and pipelining from prior work [34, 55]. For example, for PCIe-only topology, CS has six steps. It maps to a 6-stage pipeline in BytePS runtime. We implement BytePS to be flexible in constructing the pipeline without recompiling. Each stage in the pipeline is implemented as an independent thread with a priority queue of tensors. The priority is assigned similar to [34, 55]. As analyzed in §4.1.1, large tensors are partitioned to multiple smaller tensors no more than 4MB. Next, each small tensor is enqueued to the first queue and moves towards the next queue once a stage finishes processing it, until it is dequeued from the last one.

6.2 Address RDMA Performance Issues

For inter-machine communication, we use RDMA RoCEv2. Each machine has one 100GbE NIC, and the RDMA network provides full bisection bandwidth. To get the full benefit of RDMA, we have gone through a full design and debug journey which we share as follows.

RDMA Memory Management. To improve the performance, we aim to avoid unnecessary memory copies [72] and achieve zero-copy on CPU memory. BytePS is based on RDMA WRITE because it is the most performant among common RDMA verbs [39]. Conventional one-sided RDMA operations (WRITE and READ) require at least two round-trips: getting the remote address, and writing (reading) the value to (from) that address [39, 40, 50, 70]. We optimize the process by leveraging the fact that DNN training always sends the same set of tensors in every iteration. Only at the

Table 2: BytePS throughput with a pair of CPU machine and GPU machine running microbenchmark.

Solution	baseline	+shm	+shm +aligned	all
Throughput in Gbps	41	52 (1.27x)	76 (1.85x)	89 (2.17x)

first iteration, BytePS initializes all the required tensors, register the buffer with RDMA NIC and exchange all the remote addresses. Then BytePS stores the remote buffer information and reuse it directly in the rest iterations.

Address Slow Receiver Symptom. We also run into the slow receiver symptom as reported in [30] – the NICs are sending out many PFCs into the network. Those excessive PFCs slow down tensor transmission can cause collateral damage to other traffic. Here we report several additional causes of such symptom and how we address them.

Our first finding is that internal RDMA loopback traffic can cause internal incast, and push the NIC to generate PFC. BytePS runs both CS and SS on each GPU machine. The traffic between them, which we call loopback traffic, does not consume NIC’s external Ethernet bandwidth, but does consume internal CPU-NIC PCIe bandwidth. Initially, we did not add any special design – we stuck to RDMA verbs [9] for loopback traffic and thought the NIC DMA can handle it. However, we realize that it creates a 2:1 incast on the NIC, with RX and loopback as two ingress ports and the DMA to memory engine as one egress port!

To solve it, we implement a shared memory (*shm*) data path. When CS detects that SS is on the same machine as itself, CS simply notifies SS that the data is in shared memory. After SS finishes summation, SS copies the results from its own buffer back to CS’s shared memory. Consequently, the loopback RDMA traffic is eliminated.

Our Second finding is that we need to use *page-aligned* memory for RDMA. Otherwise PFCs may be triggered. Our hypothesis is that hardware DMA aligns the transfer unit to the page size (*e.g.*, 4096 bytes). Therefore, using a page-aligned address is more friendly to DMA engine as it reduces the number of pages needed to be written.

Our third finding is that the RDMA NIC RX performance can be impacted by how the concurrent send is implemented! In the end, we not only use page-aligned memory, but also enforce only one scatter-gather entry (*sge*) per RDMA WRITE on the sender side.⁷

After all the optimization, BytePS implementation can run as expected. Table 2 shows the performance improvement after each of the above three optimizations is applied. The NIC generates negligible PFCs.

As we have discussed in §4.1, BytePS creates many many-to-one communication patterns in the network. Many-to-one

⁷In the whole process, we contacted with the NIC vendor and had lengthy discussion with their software and hardware experts. As of writing, we have not got the official root cause of the last two problems.

is well-known for creating incast and packet loss in TCP/IP network [66]. But BytePS uses RDMA/RoCEv2 which depends on a lossless fabric and DCQCN [75] for congestion control. We do not observe incast issue in BytePS.

6.3 BytePS Usage

BytePS [4] is easy to use. We provide Python interfaces that are almost identical to Horovod, PyTorch native API and TensorFlow native API. Users can choose either of them and migrate to BytePS with minimal efforts. For example, for a Horovod-MNIST example [19], we only need to change one line of Python code, from `"import horovod"` to `"import byteps"`. In fact, we are able to convert most of our internal Horovod-based training tasks to BytePS automatically.

7 Evaluation

In this section, we show that BytePS not only achieves optimal communication performance in microbenchmarks, but also significantly accelerate training jobs in production environment. We list a few highlights regarding the high fidelity of the results.

- All resources used are allocated by the scheduler of production clusters. The scheduler uses non-preemptive resource scheduling – once a training job is scheduled, it will have a fixed number of CPU machines that will not change. Even the most large-scale tasks we show use < 5% GPUs of a cluster that runs many production tasks.
- We use large training batch sizes. Smaller batch sizes mean less GPU memory consumption but more communication, so the end-to-end improvement will be more evident. However, all our tasks use almost full GPU memory, so the speedup numbers against all-reduce and PS are the *lower bound* of BytePS.
- Although we cannot disclose any specific models that are used internally, the tasks and DNN model structures shown are highly representative of production workloads. The code is also available publicly for reproducibility [5].
- We compare BytePS with the state-of-the-art PS and all-reduce implementation without modification. For example, we do not apply the RDMA optimizations mentioned in §6.2 on native-PS and all-reduce.

The cluster we use has a RoCEv2 network with full bisection bandwidth. All the machines have one 100GbE NIC. We note that TensorFlow, PyTorch and MXNet can overlap the DNN computation and communication [34, 55], thus even a small improvement in end-to-end performance can indicate a large improvement in communication.

7.1 Inter-machine Microbenchmarks

First, we use microbenchmarks to show the pure inter-machine communication performance of different architectures. We allocate eight 1-GPU machines from the cluster scheduler. We run a dummy task in which all GPU workers

Figure 12: Communication goodput of 8×1 -GPU machines with varying number of additional CPU machines. The point-to-point RDMA goodput is $\approx 90\text{Gbps}$ in our network, so we plot the “optimal” line based on $B = 90\text{Gbps}$ and the analysis in §4.1.

(a) PCIe-only GPU machines

(b) NVLink-based GPU machines

Figure 13: End-to-end performance with different number of CPU machines. The training is run with PyTorch on 8 GPU machines each with 8 GPUs. Each CPU machine uses < 4 cores.

just keep reducing large tensors on GPU and record the communication goodput. We verify that no other distributed job is placed on the same physical machines.

Fig. 12 shows that BytePS performance is very close to the theoretical optimum (§4.1), with 1-9% difference for different number of CPU machines. All-reduce, as expected, is close to the optimal only if there is no additional CPU machine, while remain the same even if there are CPU machines. The (MXNet) PS does not run optimizer in this case, but is mainly bottlenecked by issues described in §6.2. In practice, if PS runs DNN optimizer algorithms, the performance will be worse than all-reduce even with $k = n$ CPU machines (Fig. 4). In contrast, because of the Summation Service design, BytePS would not be affected in real training tasks shown below.

7.2 Leverage CPU Machines

Next, we show that BytePS can indeed leverage different numbers of CPU machines to speed up training. In Fig. 13, we use 8 GPU machines, each with 8 Tesla V100 32GB GPUs, and is either PCIe-only or NVLink-based topology. We vary the number of CPU machines from 0 to 8. We compare BytePS end-to-end training performance against state-of-the-art all-reduce implementation (Horovod 0.19 and NCCL 2.5.7) as the baseline. We test two DNN models, UGATIT GAN [41] (one of the most popular models for image generation) and GPT-2 [57] (one of the most popular NLP models for text generation), both implemented in PyTorch. The per GPU batch

(a) PCIe-only GPU machines (b) NVLink-based GPU machines

Figure 14: Topology-aware intra-machine communication. The training is run with PyTorch on 8 GPU machines each with 8 GPUs and no additional CPU machine.

size is 2 images for UGATIT, and 80 tokens for GPT-2. We will evaluate more models, frameworks and machines in §7.4.

Fig. 13 shows that, with more CPU machines, BytePS can run faster – up to 20% than without CPU machines. The SS on each CPU machine only consumes no more than 4 CPU cores. It is usually easy for our scheduler to find sufficient CPUs that are on machines running non-distributed jobs. It is free (or $< 10\%$ costs compared with the expensive GPUs) speedup for the cluster. Compared with all-reduce, BytePS is consistently faster in any cases and can be up to 45% faster in the best case. On NVLink-based GPU machines, the speedup is higher because the communication bottleneck is more on the network instead of PCIe links. Finally, models have different speedup due to different model sizes and FLOPs. In the examples we show, GAN is more communication intensive, so the end-to-end gain of BytePS is larger.

7.3 Adapt to Intra-machine Topology

Next, we show the benefits of BytePS intra-machine communication strategy. The software and hardware configurations are the same as in §7.2. To better compare with the all-reduce baseline, we run the jobs without any CPU machines. Thus, BytePS does not take any advantages explained in §7.2. For PCIe-only GPU machines (Fig. 14(a)), we run BytePS with 1) strawman strategy, the same as common all-reduce or PS and 2) the optimal solution in §5. We see that the optimal intra-machine solution has up to 20% gain as well.

For NVLink-based GPU machines (Fig. 14(b)), we use different sets of GPUs as the local reduce roots. BytePS’s optimal solution, as explained in §4.2.2, is $root = 2$. $root = 2, 3$ means CS chooses GPU 2 and 3 as the reduce root in a round robin manner. It has almost the same performance because GPU 3 is not competing for PCIe bandwidth with the NIC, either. It is an alternatively optimal solution. However, $root = all$ has poorer performance. Communication-wise, it is equivalent to Horovod’s hierarchical mode. $root = 0$ is the worst because it competes hardest with the NIC. Unfortunately, it is equivalent to Horovod’s normal mode (plain NCCL all-reduce).

One thing to note is that even without any optimization, BytePS still outperforms all-reduce. We discuss this in §8.

Figure 15: Computer Vision models. The batch sizes are per GPU.

Figure 16: NLP models. The batch sizes are per GPU.

7.4 Scalability

To demonstrate BytePS’s performance at different scales, we run six different training jobs using 8 to 256 Tesla V100 32GB GPUs, *i.e.*, 1 GPU machine to 32 GPU machines. Due to the constraint of free resources, we only use NVLink-based GPU machines. The six different jobs cover three frameworks, TensorFlow, PyTorch and MXNet. We have introduced two of the models, UGATIT and GPT-2 in §7.2. The rest four models are ResNet-50 [32], VGG-16 [63] (two of the most popular models for image classification and extraction), Transformer [67] (one of the most popular models for machine translation) and BERT [26] (one of the most popular models for natural language understanding). We take the official implementation of these models and slightly modify them (no more than 20 lines of code) to use PS, all-reduce and BytePS, respectively.

For BytePS, we evaluate its performance with and without CPU machines. When there are CPU machines, the number of CPU machines is equal to GPU machines. For all-reduce, we use Horovod with NCCL for all cases. For PS, we show the native implementation from TensorFlow and MXNet with RDMA support enabled. PS uses the same resources as BytePS with CPU machines. PyTorch does not have official PS implementation, so it does not have PS results. We also provide the speed of linear scaling as the upper bound. We use trained images per second as the speed metric for computer vision models, and tokens per second for NLP models.

Fig. 15 and Fig. 16 show very consistent results – BytePS with CPU machines is always the best and BytePS without CPU machines is the second. The native PS of both TensorFlow or MXNet are always the poorest. All-reduce always has a clear advantage over PS, but is inferior to BytePS. When training with 256 GPUs, the speedup of BytePS over all-reduce is 10% to 84% with CPU machines, and 9% to 53% without CPU machines. From 8 GPUs to 256 GPUs, the speedup becomes larger. We expect that with even more

GPUs, BytePS will have even larger advantage.

We see that models have different system scalability,⁸ which is determined by the model sizes and FLOPs. The most scalable model is ResNet-50. BytePS achieves 97.5% scaling efficiency with 256 GPUs. All-reduce also performs well, achieving 88% scaling efficiency. It is not surprising that prior work is fond of training ResNet at large scale [49, 73] with all-reduce. Nevertheless, other models are more challenging, with UGATIT as the least scalable one. Even BytePS only achieves 74% scaling efficiency. For such communication intensive models, BytePS has the most gain over all-reduce (84% with 256 GPUs). Despite UGATIT, BytePS has at least 91.6% scaling factor for the rest five 256-GPU training jobs.

We analyze the breakdown of performance improvement by comparing native-PS and BytePS, since they both use the same number of additional CPU machines. For example, BytePS outperforms native-PS by 52% with 256 GPUs on VGG-16 (Fig. 15(b)). Among the 52% improvement, we find that 19% comes from optimal communication design (intra-server), 18% comes from Summation Service, and the rest 15% comes from better implementation mentioned in §6.

8 Observations and Discussion

In this section, we share several of our observations and discussions, with the aim to inspire future research.

BytePS outperforms all-reduce even without extra CPU machines. Theoretically, the communication time is the same for all-reduce and BytePS when no additional CPU machines are available (§4.1). In practice, we observe that BytePS still outperforms all-reduce significantly in this case. One reason is that BytePS has a better intra-machine communication strategy than all-reduce. However, even without intra-machine optimization, BytePS still outperforms all-reduce (see Fig. 14 in §7). We hypothesize that BytePS has the advantage of

⁸We focus on system scalability and do not discuss algorithm scalability, *i.e.* the hyperparameter tuning and convergence speed with more GPUs.

allowing more “asynchronicity” than all-reduce. All-reduce usually requires additional out-of-band synchronization to ensure the consistent order across nodes, while BytePS does not have this overhead. However, to analyze it, we need a distributed profiler that can build the complete timeline of the execution and communication across all nodes in distributed training.

GPU cluster scheduler should consider dynamic CPU resources. By leveraging additional CPU machines, BytePS can speedup DNN training. Since BytePS can adapt to any number of CPU machines, it enables elasticity – the cluster scheduler can scale in or out CPU machines for existing jobs based on real time conditions. Most existing schedulers keep the number of GPUs of a job *static* because of convergence problems [16, 74]. Fortunately, the number of CPU machines in BytePS only impacts system performance but not model convergence. We plan to add elasticity support to BytePS, which will enable BytePS to *dynamically* schedule CPU resources during the training process.

Model-parallelism support. BytePS can accelerate the communication when reducing tensors across GPUs. Some model parallelism methods, such as Megatron-LM [62] and Mesh-TensorFlow [61], also rely on the all-reduce primitive for communication. Therefore, BytePS can also accelerate them by replacing the all-reduce operations.

9 Related Work

Acceleration of computation: To accelerate the forward propagation and backward propagation, the community has worked out many advanced compilers and libraries, including cuDNN [10], MKL [7], TVM [23], XLA [17], Astra [64] and other computation graph optimization, *e.g.*, Tensor Fusion [14] and graph substitution [37]. They focus on speeding up DNN computation. They are complementary to and can be used with BytePS.

Acceleration of communication: There are several directions for accelerating communication: (1) *Gradient compression* [21, 45] is proposed to reduce the communication traffic, *i.e.*, using half precision for gradient transmission, at the cost of potential degradation of accuracy. (2) *Communication scheduling and pipelining:* Recent work explores to better overlap the computation and communication by priority-based scheduling and tensor partition [31, 34, 55]. The ideas are that tensor partition enables simultaneous bidirectional communication, and that during communication, the former layers have higher priority because they are needed sooner for FP of the next iteration. Those ideas are complementary to BytePS, and they have been integrated into our implementation. Pipedream [51] adds parallelism between multiple batches. BytePS can also potentially accelerate its data parallel stages.

Hierarchical all-reduce: Some work proposes to leverage the hierarchical topology [24, 49] during all-reduce, in order to minimize the traffic at bottleneck links. However, they still

rely on the assumption that resources are homogeneous while overlooking CPU resources. BytePS can outperform them by leveraging the heterogeneous resources. In fact, the latest NCCL includes hierarchical, tree-based all-reduce, which does not differ much from the results in §7.

Intra-machine optimization: Blink [68] also optimizes multiple GPU communication inside a single machine, by leveraging hybrid transfers on NVLinks and PCIe links. However, Blink does not optimize the distributed training cases, where the main communication bottleneck is the NIC and its PCIe connection instead of the much faster NVLinks. BytePS carefully schedules the intra-machine traffic to utilize the bottleneck bandwidth better – the NIC bandwidth. Our intra-machine design also considers the PCIe bandwidth consumed by the NIC, while Blink is only focused on GPU’s PCIe connections.

New hardware chips or architecture for accelerating DNN training: Recently, there are many new chips, like TPU [38] and Habana [6], that are specifically designed for DNN training. In fact, the design of BytePS is not GPU-specific, and should apply to them as long as they are also PCIe devices. Some also propose using InfiniBand switch ASIC [28] to accelerate all-reduce, or using P4 switches [58, 59] to accelerate PS. E3 [46] leverages SmartNICs to accelerate network applications, and can potentially benefit BytePS by offloading the gradient summation from CPUs to SmartNICs. PHub [48] proposes a rack-scale hardware architecture with customized network configurations, *e.g.*, 10 NICs on one server. BytePS focuses on using generally available CPU and GPU servers in commodity data centers.

10 Conclusion

BytePS is a unified distributed DNN training acceleration system that achieves optimal communication efficiency in heterogeneous GPU/CPU clusters. BytePS handles cases with varying number of CPU machines and makes traditional all-reduce and PS as two special cases of its framework. To further accelerate DNN training, BytePS proposes Summation Service and splits a DNN optimizer into two parts: gradient summation and parameter update. It keeps the CPU-friendly part, gradient summation, in CPUs, and moves parameter update, which is more computation heavy, to GPUs. We have implemented BytePS and addressed numerous implementation issues, including those that affect RDMA performance. BytePS has been deployed, extensively used and open sourced [4]. Multiple external projects have been developed based on it. The Artifact Appendix to reproduce the evaluation is at [3].

Heterogeneity-Aware Cluster Scheduling Policies for Deep Learning Workloads

Abstract

Specialized accelerators such as GPUs, TPUs, FPGAs, and custom ASICs have been increasingly deployed to train deep learning models. These accelerators exhibit heterogeneous performance behavior across model architectures. Existing schedulers for clusters of accelerators, which are used to arbitrate these expensive training resources across many users, have shown how to optimize for various multi-job, multi-user objectives, like fairness and makespan. Unfortunately, existing schedulers largely do not consider performance heterogeneity. In this paper, we propose Gavel, a heterogeneity-aware scheduler that systematically generalizes a wide range of existing scheduling policies. Gavel expresses these policies as optimization problems and then systematically transforms these problems into heterogeneity-aware versions using an abstraction we call effective throughput. Gavel then uses a round-based scheduling mechanism to ensure jobs receive their ideal allocation given the target scheduling policy. Gavel’s heterogeneity-aware policies allow a heterogeneous cluster to sustain higher input load, and improve end objectives such as makespan and average job completion time by $1.4\times$ and $3.5\times$ compared to heterogeneity-agnostic policies.

1 Introduction

As Moore’s law comes to an end, specialized accelerators such as GPUs, TPUs, FPGAs, and other domain-specific architectures have emerged as an alternative to more general-purpose CPUs. These accelerators have been deployed to great effect [25, 35] to train state-of-the-art deep neural network (DNN) models for many domains, including language, image and video [14, 30, 31, 51, 55].

Consequently, users today must choose from a wide variety of accelerators to train their DNN models. For example, public cloud users can rent several generations of NVIDIA GPUs and Google TPUs from cloud providers [1–3]. Even organizations with private clusters have accumulated different accelerator types over time [34]; anecdotally, our research group has NVIDIA Titan V, Titan X, and P100 GPUs in its private cluster. Resources in these multi-tenant settings are typically arbitrated by a scheduler. GPU cluster schedulers such as Themis [40], Tiresias [28], AlloX [37], and Gandiva [58] thus need to decide how to allocate diverse resources to many users while implementing complex cluster-wide *scheduling*

Figure 1: Throughputs and dollar-normalized throughputs of training for various ML models. Dollar-normalized throughputs are computed by dividing the corresponding throughput by the relevant GCP on-demand price. The magnitude of speedup across GPU generations varies significantly across models.

policies, optimizing objectives such as fairness or makespan. Unfortunately, choosing the most effective accelerator types in this context is difficult for three reasons:

Performance Heterogeneity. Commonly used models show heterogeneous performance behavior across accelerator types due to various architectural differences. For example, Figure 1a shows that a ResNet-50 model sees a nearly $10\times$ speedup from an NVIDIA V100 GPU compared to a K80 GPU, while an A3C Deep Reinforcement Learning model only sees a $2\times$ speedup. However, as shown in Figure 1b, the V100 is no longer the optimal choice for all models when we consider the number of samples trained per dollar – for many models, the older P100 GPU is competitive or cheaper on a per-dollar basis. Some scheduling policies can also benefit from splitting a job between *multiple* resource types: for example, minimizing a job’s cost subject to a latency SLO (e.g., complete a job in 10 hours) might involve using a cheaper accelerator to begin training and then switching to a faster, more expensive device to meet the SLO. Thus, for even simple *single-job* settings, the choice of accelerator type is non-trivial and depends on *both* the job and the policy. This gets more complicated in *multi-job* settings as granting all jobs their

*Work done in part as interns at Microsoft Research.

preferred accelerator simultaneously might not be possible. Existing schedulers like Gandiva, Tiresias, and Themis do not consider this heterogeneous performance behavior.

Generality across Policies. Cluster operators might want to implement different scheduling policies based on their business goals, such as optimizing for time to complete a set of batch jobs (makespan), fairness for ad-hoc jobs, or more sophisticated *hierarchical* policies that divide resources among high-level entities (e.g., departments) using one policy, and then individual jobs within the entity using another [34]. In data analytics clusters, many job schedulers have support for hierarchical allocation policies [6, 7, 12, 59] already. The two recently proposed GPU schedulers that do consider heterogeneous resources, AlloX [37] and Gandiva_{fair} [18], optimize for a single scheduling objective, and tightly couple their scheduling mechanism to that objective (e.g., max-min fairness). Thus, they cannot easily support the more sophisticated policies often used in practice.

Colocation and Placement Optimizations. To improve cluster utilization, existing GPU schedulers often deploy optimizations such as space sharing as in Gandiva [58], where multiple jobs can use the same accelerator concurrently, and placement sensitivity as in Themis and Tiresias [28, 40], which involves the careful placement of tasks in a distributed job to ensure good scaling performance. The performance benefits of these optimizations should be considered explicitly while optimizing for global scheduling objectives, since these optimizations are more effective when deployed in a heterogeneity-aware way. We show that explicit modeling for space sharing can improve objectives by $2.2\times$ compared to Gandiva’s ad-hoc approach.

In this paper, we present Gavel, a new cluster scheduler designed for DNN training in both on-premise and cloud deployments, that effectively incorporates heterogeneity in both hardware accelerators and workloads to generalize a wide range of existing scheduling policies. For example, Gavel can provide heterogeneity-aware versions of fair sharing / least attained service [28], FIFO, minimum makespan, minimum cost subject to SLOs, finish-time fairness [40], shortest job first, and hierarchical policies [12, 59].

Gavel’s key observation is that many widely used scheduling policies, including hierarchical ones, can be expressed as *optimization problems* whose objective is a function of the jobs’ achieved throughputs. For example, least attained service is equivalent to maximizing the minimum scaled throughput among the jobs, makespan is equivalent to minimizing the maximum duration (computed as the ratio of number of iterations to achieved throughput), and so on. Given the optimization problem for a scheduling policy, Gavel introduces a general way to transform the problem to make it heterogeneity-, colocation- and placement-aware. In particular, Gavel changes the problem to search over a *heterogeneous allocation* for each job, the fraction of time spent in various

resource configurations (e.g., 60% of time running alone on a V100 GPU and 40% of time space-sharing an A100 GPU with another job), and changes the throughput terms in the objective function to *effective throughput*, i.e. the average throughput of the job over the mix of resources in its allocation. Additional constraints need to be added to ensure that the returned allocation is valid. We show that Gavel’s transformed optimization problems are efficient to execute even for clusters with hundreds of GPUs and jobs, and can support a wide range of policies. Many of these problems can be solved using a sequence of one or more linear programs.

Gavel’s heterogeneity-aware allocations for each job need to be mapped to actual scheduling decisions (placement of jobs on specific resources in the cluster for a specified duration of time). To achieve this, Gavel uses a preemptive *round-based scheduling mechanism* to ensure that jobs receive resources in fractions similar to the computed target allocation. Gavel’s scheduling mechanism needs to be able to schedule both distributed training jobs, which request multiple accelerators at once, as well as combinations of jobs running concurrently on a given accelerator due to space sharing.

Gavel makes these scheduling decisions transparently: it specifies an API between the scheduler and applications that allow jobs written in existing deep learning frameworks like PyTorch [48] and TensorFlow [13] to be moved between resources with minimal code changes, and uses a mechanism similar to Quasar [21] to estimate performance measurements of colocated jobs, which are needed as inputs to Gavel’s policies, when not available *a priori*.

By explicitly considering performance heterogeneity, Gavel improves various policy objectives (e.g., average job completion time or makespan): on a smaller physical cluster, it improves average JCT by $1.5\times$, and on a larger simulated cluster, it increases the maximum input load a cluster can support, while improving objectives such as average job completion time by $3.5\times$, makespan by $2.5\times$, and cost by $1.4\times$.

To summarize, our main contributions are:

- A systematic method to convert existing cluster scheduling policies into equivalent policies that consider heterogeneity and colocation; these equivalent optimization problems are practical for current DNN clusters.
- A round-based scheduling mechanism to ensure that the cluster realizes the allocations returned by these policies.
- Generalizations of many existing policies in our framework that improve corresponding objectives.

Gavel is open sourced at <https://github.com/stanford-futuredata/gavel>.

2 Background

In this section, we provide a brief overview of DNN training (§2.1), and discuss performance optimizations used in existing schedulers that Gavel can help deploy more effectively (§2.2).

Figure 2: Gavel overview. Jobs are written in frameworks like PyTorch or TensorFlow. Gavel’s throughput estimator obtains performance measurements for each runnable job on each available accelerator type if necessary; its policy then computes an allocation that optimizes a user-specified objective such as fairness. Gavel’s scheduling mechanism accepts this computed allocation as an input, and makes per-round placement decisions in proportions that faithfully mimic the computed allocation.

2.1 Deep Neural Network (DNN) Training

DNN training proceeds in iterations. In each iteration, the DNN processes a collection of inputs (called a minibatch) and subsequently updates the model parameters using gradients derived from the input minibatch. Each minibatch is typically of similar size, which means model training throughput using short profiling runs (order of minutes). Gavel leverages this fact in its throughput estimator. Jobs are typically fairly long-running (on the order of hours to days), and can be distributed over many workers [9, 58].

Modern DNN schedulers leverage the fact that DNN training is iterative to suspend and resume training at iteration boundaries [28, 58]; this ensures that jobs can be time multiplexed over the existing physical resources. The latest model parameters need to be checkpointed to stable storage when a job is suspended to ensure training progress is not lost. In this work, we show how *time sharing* should be deployed to optimize various single- and multi-job objectives.

2.2 Performance Optimizations

Prior work has shown that GPUs can be severely underutilized in multi-tenant clusters [34]; for example, average GPU utilization (measured as the percentage of GPU Streaming Multiprocessors active over time) was as low as 52% on a Microsoft cluster. Prior work has also shown the placement of tasks for a distributed training job can have significant impact on performance. Gavel can *optionally* deploy these optimizations systematically, as we show in §3.1.

Space Sharing. Smaller models often do not leverage the full computational capacity of modern GPUs. In such cases, concurrently executing multiple models on the same GPU using NVIDIA’s Multi Process Service (MPS) or CUDA streams can help improve utilization [10, 47].

Placement Sensitivity. DNN models show heterogeneity in their distributed scaling behavior depending on the size of the tensors that need to be exchanged between workers during training: some models have compact weight representations and can scale well even when workers are not on the same server, while other models scale poorly when workers are spread over many servers. Existing schedulers like Tiresias use heuristics for placement sensitivity.

3 System Overview

Given a collection of jobs, Gavel arbitrates cluster resources (in the form of accelerators of different types) among the resident jobs, while optimizing for the desired cluster objective. This is accomplished in a two-step process: first, a *heterogeneity-aware policy* computes the fraction of time different jobs (and combinations) should run on different accelerator types to optimize the desired objective. These policies require as input the performance behavior (in terms of throughputs) for each job on each accelerator type, which can either be provided by the user, or can be measured on the fly by Gavel’s throughput estimator. Allocations are intended to be respected only between allocation recomputation events; for example, if job 1 is much longer than job 2, the allocation will be recomputed once job 2 completes. Gavel can recompute its policy either when a *reset event* occurs (job arrives or completes, worker in the cluster fails), or at periodic intervals of time. Given the policy’s output allocation, Gavel’s *scheduling mechanism* grants jobs time on the different resources, and moves jobs between workers as necessary to ensure that the true fraction of time each job spends on different resources closely resembles the optimal allocation returned by the policy. Gavel’s workflow is shown in Figure 2.

3.1 Heterogeneity-Aware Policies

Gavel expresses scheduling policies as optimization problems for various objectives of interest, such as fairness or makespan, and allocations as matrices that specify the fraction of wall-clock time a job should spend on each accelerator type *between* allocation recomputations. A matrix X can represent allocations on a single accelerator type (homogeneous setting), on multiple accelerator types (heterogeneous setting), as well as with other optimizations. Consider X^{example} :

$$X^{\text{example}} = \begin{pmatrix} & V100 & P100 & K80 \\ \begin{matrix} \text{job 0} \\ \text{job 1} \\ \text{job 2} \end{matrix} & \begin{pmatrix} 0.6 & 0.4 & 0.0 \\ 0.2 & 0.6 & 0.2 \\ 0.2 & 0.0 & 0.8 \end{pmatrix} \end{pmatrix}$$

According to this allocation specified over three jobs and three accelerator types, job 0 should spend 60% of the time this

Figure 3: The *cumulative* time each job spends on accelerator types between allocation recomputations for allocation X^{example} .

	CycleGAN	ResNet-18	ResNet-50	Transformer
A3C	(1.00, 1.00)	(0.92, 0.87)	(1.00, 0.81)	(0.64, 0.97)
CycleGAN		(0.59, 0.59)	(0.84, 0.49)	(0.69, 0.48)
LSTM			(0.60, 0.63)	(0.61, 0.76)
ResNet-18				(0.23, 0.60)
ResNet-50				(1.00, 0.36)
Transformer				(0.66, 0.65)

Figure 4: Performance of several DNN models when run concurrently on a single P100 GPU. The cell at row i and column j reports the normalized throughput (iterations/second) achieved by co-located models i and j . Throughputs are normalized with respect to the throughput achieved by each model when run in isolation. Black squares show jobs that cannot co-locate due to memory constraints.

allocation is valid on a V100 GPU, and the remaining 40% of time on a P100 GPU. This is shown visually in Figure 3.

Gavel finds an optimal value for the matrix X given a policy expressed as an optimization problem. To construct the optimization problem for a given policy, Gavel requires a *throughput matrix* T with each job's throughput (in training iterations per second) on different accelerators. T_{mj} can be set to $-\infty$ if job m does not run on accelerator type j (for example, due to memory constraints).

Given T and X , we define the *effective throughput* of a model m as the time-weighted average throughput across accelerators and jobs. We denote this quantity $\text{throughput}_T(m, X)$ or simply $\text{throughput}(m, X)$ (dropping the T) for brevity. For allocations X without space sharing,

$$\text{throughput}(m, X) = \sum_{j \in \text{accelerator types}} T_{mj} \cdot X_{mj}$$

Different cluster scheduling policies can be expressed as optimization problems for X while maximizing or minimizing an appropriate objective function. Constraints need to be specified to ensure that X is a valid allocation. A hypothetical policy that maximizes total effective throughput looks like,

$$\text{Maximize}_X \sum_{m \in \text{jobs}} \text{throughput}(m, X)$$

Subject to the following constraints:

$$0 \leq X_{mj} \leq 1 \quad \forall (m, j) \quad (1)$$

$$\sum_j X_{mj} \leq 1 \quad \forall m \quad (2)$$

$$\sum_m X_{mj} \cdot \text{scale_factor}_m \leq \text{num_workers}_j \quad \forall j \quad (3)$$

These constraints ensure that each job-worker allocation is non-negative and between 0 and 1 (equation 1), that the total allocation for a job does not exceed 1 (equation 2), and that the allocation does not oversubscribe workers (equation 3).

Space Sharing. Gavel's allocation matrices can also incorporate space sharing (SS). While previous work has used greedy algorithms for space sharing, we found that different pairs of DNN applications in practice have vastly different performance when colocated together, based on the resources they consume (Figure 4). When using space sharing, X needs to contain rows for each viable combination of jobs, and T needs to have throughputs of the job combinations, like:

$$T = \begin{pmatrix} \text{V100} & \text{P100} & \text{K80} \\ 40.0 & 20.0 & 10.0 \\ 15.0 & 10.0 & 5.0 \\ (20.0, 7.5) & 0.0 & 0.0 \end{pmatrix} \begin{matrix} \text{job 0} \\ \text{job 1} \\ \text{jobs (0, 1)} \end{matrix}$$

The SS-aware allocation X dictates the fraction of time that each *job combination* should spend on each accelerator type.

We limit entries of T to combinations of at most 2 jobs; we found empirically that larger combinations rarely increase net throughput. Additionally, although the size of T grows quadratically with the number of jobs even with job combinations of size 2, we found that in practice we only need to consider combinations that actually perform well. We evaluate the scaling behavior of these SS-aware policies in §7.4.

Objectives in terms of $\text{throughput}(m, X)$ remain the same; however, $\text{throughput}(m, X)$ now needs to be computed to include the throughputs of co-located jobs:

$$\text{throughput}(m, X) = \sum_{j \in \text{accelerator types}} \sum_{k \in C_m} T_{kjm} \cdot X_{kjm}$$

The constraints need to be slightly modified as well to ensure that X is a valid allocation in this new regime:

$$0 \leq X_{kj} \leq 1 \quad \forall (k, j)$$

$$\sum_{k \in C_m} \sum_j X_{kj} \leq 1 \quad \forall m$$

$$\sum_k X_{kj} \cdot \text{scale_factor}_m \leq \text{num_workers}_j \quad \forall j$$

C_m is the set of all job combinations that contain job m .

Placement Sensitivity. Similarly, Gavel's allocation matrices can also be extended to incorporate placement sensitivity. The observed throughput for distributed jobs depends on the location of tasks, as well as the model and accelerator type (slower workers are less likely to be communication-bound,

Figure 5: Priorities are used to move the received allocation towards the intended allocation (in this case, X^{example}). priorities_n is computed as $X / \text{rounds_received}_n$ (element-wise division).

which means consolidation of tasks is less effective). We can make our policies *placement-sensitive* by considering the performance of distributed jobs in: 1) a consolidated setting, where as many accelerators are on the same server as possible (for example, 8 GPUs per server if using 8-GPU servers), and 2) an unconsolidated setting, where accelerators are on independent servers. These are extreme points in the placement space, and are upper and lower bounds on performance. We can model this in our policies by having two different worker types (consolidated and unconsolidated) with corresponding throughput values in T and allocation values in X .

3.2 Round-based Scheduling Mechanism

After computing the optimal allocation, Gavel’s next step is to assign jobs (or job combinations, in the case of SS) to accelerator types while matching the optimal allocation as closely as possible. That is, to realize the allocation X^{example} above, the scheduling mechanism needs to make sure that in the time period where jobs 0, 1, and 2 are the only three runnable jobs in the cluster, jobs should receive resources according to their computed optimal time fractions.

To do this, the scheduler computes a priority score for every job and accelerator type combination that is high when a job has received a smaller time fraction than the optimal allocation. Scheduling is performed in rounds; in each round, the scheduler runs jobs in decreasing priority order, while ensuring that a given job is not scheduled on multiple workers (or accelerators) in a given round. This is shown in Figure 5. Priorities are updated as rounds complete. We have found empirically that round durations of around 6 minutes allow Gavel to effectively approximate the ideal allocation (§7.5).

3.3 Throughput Estimator

To estimate the throughputs of concurrent jobs (e.g., in the case of space sharing), Gavel employs a throughput estimator, similar to those found in prior work such as Quasar [21]. Gavel’s throughput estimator maps a new job to a set of pre-profiled reference jobs. The throughputs of the closest reference job can then be used as the initial performance estimate for the new job’s combinations. For individual jobs, the throughput estimator is not needed, since throughputs can be

estimated on the fly as jobs run on different resource types.

3.4 Limitations and Non-Goals

While Gavel exposes a flexible API that supports a variety of policies and objectives, we do not propose new scheduling policies or performance optimizations in this work. Instead, Gavel’s main goal is to determine how best to share resources amongst many different users and jobs in a heterogeneity-aware way, while supporting many existing cluster-wide objectives. Gavel accomplishes these goals with a policy framework that easily allows policies to be made heterogeneity-, colocation-, and placement-aware (§4), a reusable scheduling mechanism (§5), and a narrow scheduler API that allows users to deploy their applications with minimal code changes (§6).

4 Scheduling Policies

In this section, we show how various scheduling policies such as max-min fairness (Least Attained Service or LAS) and multi-level fairness can be expressed as optimization problems in terms of effective throughput. We describe some properties of the resulting heterogeneity-aware allocations at the end of this section.

4.1 Max-Min Fairness as an Optimization Problem

The classical Least Attained Service (LAS) policy, used by Tiresias [28], implements max-min fairness across active users in the cluster, by round-robinning resources across jobs according to the total number of accelerator hours consumed. This can be modified into a weighted max-min fairness policy with per-user weights w_m . On a homogeneous cluster, if a job m with weight w_m receives a fraction X_m (which is a scalar since there is only one resource type), LAS can be expressed as the following optimization problem:

$$\text{Maximize}_X \min_m \frac{1}{w_m} X_m$$

We need to add an additional constraint to ensure that the cluster is not overprovisioned ($\sum_m X_m \leq 1$).

However, this vanilla LAS policy is not fair in a heterogeneous setting; jobs might see unequal reductions in throughput due to variations in performance across accelerator types. For example, giving one job a K80 and another job a V100 would equalize their number of resources, but could result in very low performance for the job with the K80.

To compute a more fair allocation, we can compute max-min fairness over the weighted normalized effective throughputs, as defined in §3.1. Let X_m^{equal} be the allocation given to job m assuming it receives equal time share on each worker in the cluster. For example, if the cluster had 1 V100 and 1 K80, $X_m^{\text{equal}} = [0.5, 0.5]$. X_m^{equal} scales the effective throughputs to make them comparable across jobs.

$$\text{Maximize}_X \min_m \frac{1}{w_m} \frac{\text{throughput}(m, X)}{\text{throughput}(m, X_m^{\text{equal}})}$$

Policy	Description
Makespan	Minimize time taken by batch of jobs.
LAS [28]	Max-min fairness by total compute time.
LAS w/ weights	Max-min fairness with weights.
Finish Time Fairness [40]	Maximize minimum job speedup.
FIFO	First in, first out.
Shortest Job First	Minimize time taken by shortest job.
Minimize cost	Minimize total cost in public cloud.
Minimize cost w/ SLOs	Minimize total cost subject to SLOs.
Hierarchical [59]	Multi-level policy: FIFO, fairness, etc.

Table 1: Policies that can be expressed in Gavel.

As specified in §3.1, additional constraints need to be specified to ensure that allocations are valid.

As an example, consider 3 jobs which benefit differently when moved from a K80 GPU to a V100 GPU:

$$T = \begin{pmatrix} \text{V100} & \text{K80} \\ 40.0 & 10.0 \\ 12.0 & 4.0 \\ 100.0 & 50.0 \end{pmatrix} \begin{matrix} \text{job 0} \\ \text{job 1} \\ \text{job 2} \end{matrix}$$

Solving the above optimization problem with $w_m = 1$, and a cluster with 1 V100 and 1 K80 yields the following allocation:

$$X^{\text{het.}} = \begin{pmatrix} \text{V100} & \text{K80} \\ 0.45 & 0.0 \\ 0.45 & 0.09 \\ 0.09 & 0.91 \end{pmatrix} \begin{matrix} \text{job 0} \\ \text{job 1} \\ \text{job 2} \end{matrix}$$

Jobs receive about 10% higher throughput compared to an allocation where every user is given $1/n$ of the time on each accelerator (here, $n = 3$), also called an *isolated allocation* [26].

Fairness policy objective functions need to be modified to take into account multi-resource jobs with $\text{scale_factor}_m > 1$, since these multi-resource jobs occupy a larger share of the cluster per unit time. An easy way to do this is to multiply the max-min objectives from before by scale_factor_m . Concretely, the LAS objective from before now becomes,

$$\text{Maximize}_X \min_m \frac{1}{w_m} \frac{\text{throughput}(m, X)}{\text{throughput}(m, X_m^{\text{equal}})} \cdot \text{scale_factor}_m$$

4.2 Other Policies as Optimization Problems

We can express many other common cluster scheduling policies, some proposed by recent papers, using $\text{throughput}(m, X)$; we list these policies in Table 1. Most of these policies can be expressed using a single linear program, with a few exceptions: the cost policies are formulated as a linear-fractional program [8], which can be reduced to a sequence of linear programs. These optimization problems yield corresponding heterogeneity-aware allocations. The optimal allocation can be computed using off-the-shelf solvers.

Minimize Makespan. The makespan minimization policy tries to complete all active jobs as soon as possible. Gandiva uses a version of this policy to finish higher-level tasks such as hyperparameter tuning and AutoML, which involve training a large number of variants of a model. If num_steps_m is the number of iterations remaining to train model m , then the makespan is the maximum of the durations of all active jobs, where the duration of job m is the ratio of the number of iterations to $\text{throughput}(m, X)$ (expressed in iterations / second). Overall, this can be framed as,

$$\text{Minimize}_X \max_m \frac{\text{num_steps}_m}{\text{throughput}(m, X)}$$

Minimize Finish-Time Fairness (Themis). Themis [40] proposes a new metric called finish-time fairness (represented as ρ), which is the ratio of the time taken to finish a job using a given allocation and the time taken to finish the job using $1/n$ of the cluster (X^{isolated}), assuming n users using the cluster. This can be expressed in terms of $\text{throughput}(m, X)$ as follows (num_steps_m is the number of iterations remaining to train model m , t_m is the time elapsed since the start of training for model m , and t_m^{isolated} is the hypothetical time elapsed since the start of training if model m had $1/n$ of the cluster to itself),

$$\rho_T(m, X) = \frac{t_m + \frac{\text{num_steps}_m}{\text{throughput}(m, X)}}{t_m^{\text{isolated}} + \frac{\text{num_steps}_m}{\text{throughput}(m, X^{\text{isolated}})}}$$

The final optimization problem is then,

$$\text{Minimize}_X \max_m \rho_T(m, X)$$

FIFO. The First-In-First-Out (FIFO) policy schedules jobs in the order they arrive. In a heterogeneous regime, jobs should be placed on the fastest available accelerator type. Mathematically, we can write this as maximizing the throughput of job m relative to its throughput on the fastest type ($\text{throughput}(m, X^{\text{fastest}})$). Assuming that jobs are enumerated in order of their arrival time (m arrived before $m+1$), a FIFO allocation can be computed with the following objective:

$$\text{Maximize}_X \sum_m \frac{\text{throughput}(m, X)}{\text{throughput}(m, X^{\text{fastest}})} (M - m)$$

where M is the total number of jobs.

Shortest Job First. The Shortest Job First policy finds the allocation that minimizes the duration of the shortest job,

$$\text{Minimize}_X \min_m \frac{\text{num_steps}_m}{\text{throughput}(m, X)}$$

Minimizing Total Cost and Cost subject to SLOs. We can express policies for deployments that use elastic public cloud resources. Since cloud VMs are charged on a per-time basis, we can express policies that explicitly optimize for total cost, speed, or both.

Figure 6: Example of a hierarchical policy: weighted fairness across two entities: a product and research team, fairness across jobs within the product team, and FIFO within the research team.

Consider a simple policy that maximizes total throughput,

$$\text{Minimize}_X \sum_m \text{throughput}(m, X)$$

The above policy can be extended to incorporate cost by optimizing the following cost-adjusted objective,

$$\text{Maximize}_X \frac{\sum_m \text{throughput}(m, X)}{\sum_m (\sum_j \text{cost}_j \cdot X_{mj})}$$

where cost_j is the cost of accelerator type j . The numerator in the above objective is the time-averaged effective throughput, and the denominator is the time-averaged cost. When using space sharing, care must be taken to not double count the cost of instances running job combinations (all jobs in a job combination derive value in the form of some throughput).

Jobs can have time SLOs as well, e.g., certain high-priority jobs might need to complete every 12 hours. We can add additional constraints: given SLO_m for each model m (models without SLOs can have $\text{SLO}_m = \infty$),

$$\text{throughput}(m, X) \geq \text{num_steps}_m / \text{SLO}_m$$

4.3 Hierarchical Scheduling Policies

Modern cluster schedulers do not only deploy “single-level” policies. Hierarchical policies are common [6, 12, 59]: a large organization might share a single physical cluster among many sub-organizations (or entities) using a fairness policy. In turn, each entity can share resources among individual jobs according to a distinct per-entity policy, such as per-user fairness or FIFO. We give an example in Figure 6, where a research and product team share the same physical cluster. The research team runs ad-hoc experiments that can be executed in FIFO order, but the product team needs to ensure that all its jobs receive a fair share of the cluster.

Gavel can currently support fairness in the upper levels and fairness or FIFO in the lower levels, which matches the hierarchical policies supported by the Hadoop scheduler [6]. Determining how to extend this to other hierarchical policy sets (for example, with finish time fairness) is future work.

Gavel solves hierarchical objectives using a procedure called water filling [15], which is used in other max-min fairness problems such as link allocation in networks [49]. At a high level, the water-filling algorithm increases the allocation given to all parties at an equal rate to respect max-min fairness,

until a party saturates. The saturated party is then taken out, and the procedure repeated iteratively until all commodities are saturated. We adapt this procedure to our setting, solving a series of optimization problems iteratively: an LP that computes a fair allocation across entities while respecting each entity’s internal policy, and an MILP that identifies *bottlenecked jobs*, i.e., jobs whose effective throughputs cannot be improved without lowering other jobs’ effective throughput.

We assume that each entity s is associated with a weight w_s ; the jobs belonging to this entity receive a total cluster share proportional to this weight. We denote w_m^{job} to be the weight of job m , set such that $\sum_{m \in s} w_m^{\text{job}} = w_s$. Jobs are assigned priorities in accordance to the relevant entity’s policy; for example, a fairness policy within an entity would assign each job a weight proportional to its individual weight within the entity, while for FIFO, the first job in the queue would initially receive the entire weight of the entity.

In each iteration, we solve the following modified LP (assuming $\text{scale_factor}_m = 1$ for all m for simplicity):

$$\text{Maximize}_X \min_{\{m: w_m^{\text{job}} > 0\}} \frac{1}{w_m^{\text{job}}} \left(\frac{\text{throughput}(m, X)}{\text{throughput}(m, X_m^{\text{equal}})} - t_m \right)$$

t_m is the normalized effective throughput of job m in the previous iteration ($t_m := 0$ in the first iteration). The above objective can be appropriately modified for $\text{scale_factor}_m > 1$. Bottlenecked jobs are given priority 0 and no longer considered in future iterations. Priorities are redistributed among non-bottlenecked jobs according to the entity’s policy at the end of every iteration. For instance, in the example shown in Figure 6, if job 4 is bottlenecked, then its weight is reassigned to job 5 in accordance to the FIFO policy, while if job 2 is bottlenecked, its weight is distributed equally between jobs 1 and 3 in accordance with the entity’s fairness policy. The LP then solves the max-min problem on the resources remaining while ensuring each job’s throughput does not drop compared to the previous iteration’s allocation X^{prev} , expressed as $\text{throughput}(m, X) \geq \text{throughput}(m, X^{\text{prev}})$ for all m . Iterations continue until all jobs are bottlenecked. To make this procedure more concrete, consider an example with 4 identical jobs: job 1 with a weight of 3.0, and jobs 2 to 4 with a weight of 1.0; and 4 identical GPUs. In the first iteration, job 1 is assigned resources such that its throughput is 1.0, and jobs 2, 3, and 4 are assigned resources such that their throughput is 0.33 to respect weights. Job 1 is a bottleneck; the throughput of the remaining jobs can still be increased. In the next iteration, jobs 2 to 4 are given full-GPU allocations.

The final allocation satisfies both inter-entity and intra-entity policies. We note that the above water-filling procedure can also be used for single-level fairness policies such as the one described in §4.1 to improve the throughput of non-bottlenecked jobs.

4.4 Properties of Gavel's Policies

Existing scheduling schemes have been analyzed in terms of properties like sharing incentive, Pareto efficiency, and strategy proofness [26]. We formalize Gavel's heterogeneity-aware policies in the context of these properties as well.

Homogeneous Clusters. For homogeneous clusters, Gavel's heterogeneity-aware policies are equivalent to the baseline policies ($\text{throughput}(m, X) = X_m \cdot T_m$), since the heterogeneity-aware optimization problems reduce to the original optimization problems with one accelerator type.

Sharing Incentive. For heterogeneous clusters, the policy's objective metric (maximize least job share in LAS, completion time of first job in FIFO, or makespan) is at least as well off as it would be under a policy that naïvely splits all resources equally among all runnable jobs. This is because the allocation corresponding to giving each user $1/n$ of each resource is a feasible solution to Gavel's optimization problem, so Gavel's solution will be at least as good. All Gavel policies have *sharing incentive* [26], which encourages users to use the shared cluster rather than a static private share.

Colocation. Solutions with colocation are always at least as good as without colocation.

Pareto Efficiency. Allocations of max-min fairness policies with water filling are Pareto efficient: that is, the allocation for a particular job cannot be increased without decreasing the allocation for another job.

Note that some of Gavel's policies may not satisfy other desirable properties. For example, Sun et al. [53] showed that no fair-sharing policy can simultaneously satisfy Pareto efficiency, sharing incentive and strategy proofness in a setting with interchangeable resources. If users manipulate their throughputs, then they can possibly obtain larger shares of the cluster (e.g., jobs can be placed on a faster accelerator type) for certain objectives. Exploring how to make Gavel's policies strategy-proof is interesting future work.

5 Scheduling Mechanism

Gavel's scheduling mechanism schedules training iterations of runnable jobs on the available workers (with possibly different accelerators), such that for each schedulable job (or combination), the fraction of wall-clock time it spends on each accelerator type is approximately equal to the computed optimal allocation X^{opt} between allocation recomputation events. This is challenging for two main reasons: 1) Jobs can run on multiple accelerators. Moreover, since distributed training can be communication intensive [19, 46], jobs should be placed on accelerators "close" to each other (for example, on accelerators on the same server, or on accelerators in servers in the same rack). 2) Combinations of up to two jobs can run on a set of accelerators in order to improve resource utilization (space sharing). Each distinct job can have ≤ 1 job combination running in a given round to prevent work duplication.

Gavel makes its scheduling decisions in *rounds*. This is similar in spirit to Tiresias's [28] priority discretization in some respects. However, Gavel's scheduling mechanism differs from Tiresias's in three ways:

- Gavel needs to schedule jobs on different accelerator types: it needs to decide which job should be active in any round *and* which accelerator type to use.
- Gavel needs to grant resources to jobs while respecting an *arbitrary allocation* returned by the policy.
- Gavel's round-based scheduler grants time to jobs while ensuring that multiple job combinations sharing a job do not run in the same round; Tiresias does not consider job combinations and does not need to deal with this.

Gavel's scheduler tries to place work on all available workers for a specific duration (this time period is configurable; we use 6 minutes in our experiments). We call the work handed to each worker in a given round a *micro-task*. Without rounds, jobs that request many accelerators can suffer from starvation. For example, consider a cluster with 8 total accelerators and 4 available. The scheduler can handle a 8-accelerator job waiting for resources in one of two ways: a) wait for 8 accelerators to become available; 4 accelerators will be unused until the full quota of 8 accelerators becomes available, b) keep the 8-accelerator job in the queue, and give 4 accelerators to another job that requests a fewer number of resources. However, this situation can repeat itself, leading to starvation [59]. Scheduling is thus performed in rounds to limit resource under-utilization, simplify scheduling logic, and ensure that jobs with large scale factors do not experience prolonged starvation.

Since the number of active, *schedulable* jobs might far exceed the total number of workers, Gavel first determines the job combinations that should run in the upcoming round. To do this, Gavel maintains the time t_{mj} spent by a job (or combination) m on accelerator type j , which is updated as jobs run on different accelerator types every round. Given t_{mj} , Gavel's scheduler can then compute the fraction of total wall-clock time spent by each job (or combination) m on each accelerator type j as $f_{mj} = t_{mj} / (\sum_{m'} t_{m'j})$. The matrix of priorities is then just the element-wise division of X^{opt} by f .

Algorithm. In every round, we want to move f_{mj} closer to X_{mj}^{opt} . This can be achieved by giving high-priority jobs time on accelerator type j .

This problem can be solved exactly if jobs only request single accelerators and if space sharing is not deployed by finding the num_workers_j jobs with highest priority (for example, using a heap). However, jobs submitted to Gavel can be distributed, and space sharing can be used to improve resource utilization. Solving this problem exactly with these added requirements makes the problem similar to a multiple-choice knapsack problem [52], which is NP-hard.

Figure 7: Round-based scheduling mechanism in action to achieve an allocation $X^{\text{het.+SS}}$. Space sharing is shown with vertically split boxes. Each round is denoted by a box.

Algorithm 1 Algorithm for Gavel’s scheduling mechanism

```

1: function SCHEDULE_JOBS
2:   active_combinations  $\leftarrow$  all active job combinations
3:   num_workers_rem.  $\leftarrow$  number of total workers
4:   while num_workers_rem.g > 0 do
5:      $j \leftarrow$  job combination with highest priority
6:     Remove  $j$  from active_combinations
7:     if  $j$ .scale_factor > num_workers_rem. then
8:       continue
9:     for all  $j'$  that conflict (share a job  $k$ ) with  $j$  do
10:      Remove  $j'$  from active_combinations
11:   num_workers_rem.  $- = j$ .scale_factor

```

To overcome these challenges, we observe that it is acceptable to make greedy sub-optimal *scheduling* decisions occasionally in any given round, since we can recover from these sub-optimal decisions in subsequent rounds: our goal is to ensure that the average allocation each job receives *over multiple rounds* resemble the computed allocation (the allocations returned by policies are optimal, which follows from how policies in Gavel are expressed as optimization problems). We study the impact of this design choice in §7.5. A job (combination) not run in a particular round will have increased priority in subsequent rounds until it receives accelerator time, while a job that runs in a particular round will have decreased priority. This ensures that jobs do not suffer from starvation if they have a non-zero optimal allocation.

Gavel uses a greedy algorithm to pick the highest-priority job combinations that fit in the provided resource budget. The algorithm maintains a set of eligible job combinations (eligible_job_combinations) that can be scheduled in the upcoming scheduling round. The scheduling mechanism then tries to add job combinations with highest priority into a job_combinations_to_schedule set. Once a job combination is added to this set, all *conflicting* job combinations are removed from the set of eligible combinations to ensure that a given job is not run more than once in a given scheduling round. Job combinations that cannot fit in the current round due to space limitations (required number of accelerators unavailable) are also removed from the set of eligible combinations. This procedure is detailed in Algorithm 1. Gavel’s scheduling mechanism is decoupled from its policies, ensuring that the same scheduling mechanism can be used for

Figure 8: Gavel’s throughput estimator. Profiling is combined with matrix completion to obtain a fingerprint for every new job. The fingerprint is then used to find the closest reference job.

many different policies. Figure 7 shows Gavel’s scheduling mechanism in action.

Once Gavel has decided what jobs (and combinations) should run in a given round on different accelerator types, Gavel must decide how to *place* these jobs. Gavel’s scheduler places jobs in decreasing order of the number of requested workers, and tries to give jobs accelerators on the same physical server to minimize fragmentation.

6 Implementation

We implemented a prototype of Gavel in approximately 9000 lines of Python code, and implemented a simulator in about 500 LOC. We used `cvxpy` [23] to implement Gavel’s heterogeneity-aware policies, and `gRPC` [4] to communicate control messages between the scheduler and workers.

Interface between Scheduler and Applications. Gavel currently supports user applications written in PyTorch [48]; support for TensorFlow [13] is left for future work. The scheduler and user applications then interact through a narrow API. Gavel ships with a Python library that users can import into their code. This library provides an implementation for a wrapper around existing framework-provided data iterators (`GavelIterator`). `GavelIterator` ensures that each task in a distributed job runs for the same number of iterations, and synchronizes the conclusion of rounds between the scheduler and workers. `GavelIterator` is instantiated with arguments `train_loader` (base data loader), `load_checkpoint`, `save_checkpoint`, and a configuration object. `load_checkpoint` is a pointer to a function that loads all necessary parameters and metadata from a checkpoint at the start of a round, and `save_checkpoint` is a pointer to a function that creates a checkpoint at the end of a round; these need to call appropriate framework methods (< 5 LOC).

`GavelIterator` contacts the scheduler near a round end to see if the same job will run in the next round on the same worker. We call this a *lease renewal*. If the lease is not renewed, the iterator calls `save_checkpoint` at round end. The scheduler can then launch another job on the worker.

Throughput Estimation. Gavel uses a similar technique to Quasar [21] to estimate colocated throughputs when using the optional space sharing optimization (if they are not available a priori), mixing profiling with matrix completion.

Model	Task	Dataset / Application	Batch size(s)
ResNet-50 [5, 31]	Image Classification	ImageNet [22]	16, 32, 64, 128
ResNet-18 [31, 39]	Image Classification	CIFAR-10 [36]	16, 32, 64, 128, 256
A3C [27, 44]	Deep RL	Pong	4
LSTM [11]	Language Modeling	Wikitext-2 [42]	5, 10, 20, 40, 80
Transformer [33, 55]	Language Translation	Multi30k [24] (de-en)	16, 32, 64, 128, 256
CycleGAN [38, 60]	Image-to-Image Translation	monet2photo [60]	1
Recoder [45] (Autoencoder)	Recommendation	ML-20M [29]	512, 1024, 2048, 4096, 8192

Table 2: Models used in the evaluation.

Trace	System	Objective	Physical	Simulation
Continuous	Gavel	Average JCT	3.4 hrs	3.7 hrs
Continuous	LAS	Average JCT	5.1 hrs	5.4 hrs
Static	Gavel	Makespan	17.7 hrs	17.6 hrs
Static	Gandiva	Makespan	21.3 hrs	22.1 hrs

Table 3: Comparison of end objective between physical experiment and simulation for two different traces. For the continuous trace, we measure the average JCT of 25 jobs in a steady-state cluster. For the static trace, we measure the total time needed to complete 100 jobs submitted at the start of the run. The heterogeneity-aware policies improve target objectives, and results on the physical cluster are in agreement with results on simulated cluster ($< 8\%$).

Model	Overhead without lease renewals	Overhead with lease renewals
ResNet-18	0.94%	0.17%
ResNet-50	1.58%	0.25%
A3C	0.22%	0%
LSTM	2.91%	0.47%
Transformer	0.77%	0.11%
CycleGAN	0.77%	0.11%

Table 4: Overhead of using preemptive scheduling in Gavel, with and without lease renewals, and with a round duration of 6 minutes.

Matrix completion enables sparse low rank matrices to be reconstructed with low error [17, 43]. With matrix completion, Gavel is able to extrapolate measurements obtained through direct profiling on separate workers dedicated to profiling, and determine the job’s most similar pre-profiled reference job. The throughput estimator can then use the reference job’s throughput measurements as an initial throughput estimate. Gavel’s throughput estimator is diagrammed in Figure 8.

7 Evaluation

In this section, we seek to answer the following questions:

- Do Gavel’s heterogeneity-aware policies improve objective metrics in a physical cluster (§7.2) and in simulations of larger clusters (§7.3)?
- How do Gavel’s policies scale? (§7.4)

(a) Average job completion time vs. cluster load.

(b) CDF of job completion times (input job rate = 5.6 jobs/hr).

Figure 9: Comparison of heterogeneity-agnostic least attained service (LAS) policy to a heterogeneity-aware LAS policy (Gavel), in simulation on the continuous-single trace.

- How well does Gavel’s scheduling mechanism realize Gavel’s heterogeneity-aware allocations? (§7.5)
- Is Gavel able to accurately estimate the throughputs of co-located jobs when using space sharing? (§7.6)

7.1 Experiment Setup

We run experiments on both a physical and simulated cluster.

Clusters. We run physical cluster experiments on a cluster with 8 V100s, 16 P100s, and 24 K80s. Simulated cluster experiments are run on a cluster with 36 GPUs of each type.

Traces. We run physical and simulated experiments on two types of traces: one where all jobs are available at the start of the trace and jobs are *not* subsequently added (“static”), and another where jobs are continuously added to the cluster (“continuous”). For the continuous trace, job arrival times are generated according to a Poisson arrival process with an inter-arrival rate λ . For the simulated experiments, we vary λ to show the extra load each heterogeneity-aware policy is able to sustain in steady state. We run 3 seeds for every λ , and show standard deviations. For the physical cluster experiments, we use a single λ that keeps the cluster well-utilized in steady state. The online traces used in the simulated experiments have a variable number of jobs (at least 5000) and span 20-30 days. We measure the completion times of jobs with ID 4000 to 5000 to study steady state behavior (new jobs continue to be added until jobs of interest complete). Job types are uniformly sampled from the job table with 26 distinct job (or model) types, shown in Table 2. The online traces used in the physical experiments span a day and have 100 jobs.

(a) Average job completion time vs. cluster load.

(b) CDF of job completion times (input job rate = 2.6 jobs/hr).

Figure 10: Comparison of heterogeneity-agnostic least attained service (LAS) policy to a heterogeneity-aware LAS policy (Gavel), in simulation on the continuous-multiple trace. Each input job rate is run with 3 seeds; shaded regions show the standard deviation.

The duration of each job *on a V100 GPU* is sampled from an exponential distribution: jobs have duration 10^x minutes, where x is drawn uniformly from $[1.5, 3]$ with 80% probability, and from $[3, 4]$ with 20% probability. Given the job’s observed throughput on the V100 GPU, the number of training steps is then inferred by multiplying the throughput (in steps/sec) by the duration. This matches the process used by Gandiva [58]. For the simulated experiments, we show results in two regimes: one where all jobs use a single worker (“continuous-single”), and another where 70% of jobs request a single worker, another 25% request between 2 and 4 workers, and the remaining 5% request 8 workers, as observed in published traces from Microsoft [9] (“continuous-multiple”).

Metrics. For fairness and FIFO policies, our target metric is average job completion time of steady-state jobs, which is the same metric used by related work [28, 41]. We also show finish time fairness (FTF) for policies that explicitly optimize for FTF. For makespan policies, our target metric is the time needed to complete a job batch. For cost-related policies, the metric is cost (in dollars), and the percentage of jobs that violate time SLOs.

7.2 End-to-End Results on Physical Cluster

For our physical cluster experiments, we run a heterogeneity-aware and a heterogeneity-agnostic fairness policy on a continuous trace, and a heterogeneity-aware makespan policy against a baseline that uses Gandiva’s ad-hoc space sharing on a static trace. Results are shown in Table 3. Gavel’s heterogeneity-aware policies improved average job completion time by $1.5\times$ and makespan by $1.2\times$. For the makespan

objective, we do not run Gavel with space sharing; in theory, space sharing would additionally reduce makespan.

We also compare the real performance to simulations and observe that for both policies, the difference between metrics in simulation and on the physical cluster is small ($< 8\%$), indicating that our simulator has high fidelity.

Table 4 shows the overhead of using Gavel’s preemptive scheduler with a round duration of 6 minutes, with and without lease renewals. Allocations and worker assignments can be computed asynchronously. The only synchronous overhead is the loading and saving of checkpoints, which is dependent on the size of the model. Lease renewals decrease this overhead by allowing jobs to run on the same worker for extra rounds. The overhead of preemption, even without lease renewals and with a short round duration, is low ($< 3\%$).

7.3 End-to-End Results in Simulation

We use a larger simulated cluster to evaluate the efficacy of Gavel’s heterogeneity-aware policies across a range of objectives, and compare with heterogeneity-agnostic versions from previous work using a round duration of 6 minutes. As appropriate, we compare to other baselines like AlloX. Magnitudes of speedups are higher for these experiments compared to the physical cluster experiments since the simulated traces show job behavior over weeks, while the physical cluster traces are only a day long; consequently, queue buildups are less extreme for the traces used in the physical cluster experiments.

Least Attained Service (LAS). Figures 9 and 10 compare the vanilla LAS policy with its heterogeneity-aware variants. We compare with two other baselines: a modified LAS policy that uses Gandiva’s ad-hoc space sharing, and an AlloX policy that explicitly optimizes average job completion time (but only for single-worker jobs). We make three observations.

First, the heterogeneity-aware policies support higher load on the *same* cluster, reduce average JCT by $3.5\times$ for the continuous-single trace, and by $2.2\times$ for the continuous-multiple trace (graph can be read by comparing average JCT value for a given input job rate or x -intercept) at high load (5.6 jobs/hr for continuous-single, 2.6 jobs/hr for continuous-multiple). Second, the heterogeneity-aware LAS policy supports higher load than AlloX, since AlloX can give short jobs preferential treatment in the interest of optimizing average JCT, leading to long jobs experiencing starvation (long tail in JCT CDF). At moderate load, AlloX represents a best-case scenario since it explicitly optimizes for average JCT on a heterogeneous cluster. Gavel is able to essentially match this best case scenario, while also supporting other objectives. Third, Gandiva-style packing, which randomly explores job combinations until a combination that improves performance is found, is ineffective compared to Gavel’s principled packing ($2.2\times$ better average JCT for both traces at high load).

Finish Time Fairness (FTF). We compare the heterogeneity-aware version of Finish Time Fairness

(a) Average job completion time vs. cluster load.

(b) CDF of finish time fairness metric (input job rate = 2.6 jobs/hr).

Figure 11: Comparison of a heterogeneity-agnostic policy that optimizes for finish time fairness (“Minimize FTF”) to a heterogeneity-aware one (Gavel), in simulation with the continuous-multiple trace.

(FTF) to its heterogeneity-agnostic counterpart in Figure 11. The heterogeneity-aware policy reduces average JCTs by $3\times$ and improves average FTF by $2.8\times$. FTF is the ratio of the time taken to finish a job using a given allocation and the time taken to finish the job using $1/n$ of the cluster (X^{isolated}), assuming n users use the cluster. Lower FTF means jobs take less time with the provided allocation compared to X^{isolated} .

Makespan. Gavel’s heterogeneity-aware makespan policy reduces makespan by $2.5\times$ compared to a FIFO baseline, and by $1.4\times$ compared to a baseline that uses Gandiva’s ad-hoc space sharing. Makespan is reduced by a further 8% when the number of jobs in the trace is high when using space sharing.

FIFO. The heterogeneity-aware versions of FIFO allow the cluster to support average input job rate. At high load, the heterogeneity-aware version without space sharing reduces average JCT by $2.7\times$, and the heterogeneity-aware version with space sharing reduces average JCT by $3.8\times$ at high load. Space sharing is less effective for distributed jobs: it reduces average JCT by $1.1\times$ with distributed jobs, compared to $1.4\times$ for the continuous-single trace.

LAS with priorities. We also run an experiment with the LAS policies where 20% of jobs have higher priority. At high load, Gavel reduces the average JCT of high-priority jobs by $1.5\times$ and the average JCT of low-priority jobs by $2.7\times$.

Cost. We simulate each of the cost policies on a 500-job workload comprised of ResNet-50 and A3C jobs. As we observe in Figure 1b, the ResNet-50 job has the best cost-normalized throughput on the V100 while the A3C job has

(a) Fraction of total throughput for each job with time.

(b) Total throughput vs. time.

Figure 12: Behavior of a multi-level fairness policy with time as jobs are added to a small cluster with 3 V100 GPUs, 3 P100 GPUs, and 3 K80 GPUs. Each line represents a separate job, and jobs are added every 4 timesteps. The first 6 jobs belong to entity 0 (weight of entity, $w_0 = 1$), the next 6 jobs belong to entity 1 ($w_1 = 2$), and the last 6 jobs belong to entity 2 ($w_2 = 3$).

the best cost-normalized throughput on the K80. Each job’s duration is chosen from $\{0.5, 1, 2, 4, 8\}$ days, and each job’s SLO is chosen from $\{1.2\times, 2\times, 10\times\}$ its duration.

The policy that minimizes cost reduces the total cost compared to the policy that maximizes throughput by a factor of roughly $1.4\times$. However, approximately 35% of jobs violate their SLO as this policy prioritizes cheaper but slower GPUs; in particular, the A3C jobs are scheduled on K80 GPUs which results in violations for tight SLOs. In comparison, the policy that includes SLOs as well eliminates all violations for a small increase in cost (a cost reduction of $1.2\times$ compared to the baseline policy), by ensuring that A3C jobs with tight SLOs are run on instances with V100 GPUs.

Multi-level Hierarchical Policies. Figure 12 shows the behavior of a multi-level fairness policy as new jobs belonging to multiple entities are added to a heterogeneous cluster with equal numbers of K80, P100, and V100 GPUs. Resources are granted to jobs in a way that respects both the higher-level and lower-level policies: in Figure 12a, fairness is enforced both within and across entities (as can be seen by the widths of the colored bands, which represents cross-entity fairness, and the widths of bands within a color, which represents fairness across jobs within an entity), and allocations are adjusted as new jobs come in. Figure 13 shows results with a fairness+FIFO policy; later jobs in each entity 0 do not receive any GPU time to respect the per-entity FIFO policy.

The multi-level fairness policy can also be implemented in a heterogeneity-agnostic manner by statically partitioning

Figure 13: Behavior of a hierarchical policy (weighted fairness as top-level policy, FIFO as bottom-level policy) with time as jobs are added to a small cluster with 3 V100 GPUs, 3 P100 GPUs, and 3 K80 GPUs. Each line represents a separate job, and jobs are added every 4 timesteps. The first 6 jobs belong to entity 0 (weight of entity, $w_0 = 1$), the next 6 jobs belong to entity 1 ($w_1 = 2$), and the last 6 jobs belong to entity 2 ($w_2 = 3$).

Figure 14: Scaling of LAS and hierarchical policies with the number of active jobs on a heterogeneous cluster with an equal number of V100, P100, and K80 GPUs. The size of the cluster is increased as the number of active jobs is increased.

resources across users while respecting per-entity and per-user weights. While this results in a fair allocation as well, we observe that total effective throughput is about 17% lower compared to the heterogeneity-aware policy (Figure 12b).

7.4 Scalability of Heterogeneity-Aware Policies

Figure 14 shows the scaling behavior of the heterogeneity-aware LAS and multi-level fairness policies with and without space sharing. We observe that even with 2048 active jobs, the hierarchical policy without space sharing can be run in < 10 minutes. With space sharing, the policy can be run with 512 jobs in < 10 minutes. The single-level LAS policy is much cheaper to compute in comparison. We note that allocations do not need to be recomputed every scheduling round – however, the longer the policy takes to run, the longer it takes for the new allocation to be acted upon (jobs can still be given heterogeneity-agnostic allocations in the interim, and consequently time on resources). We believe latencies of < 30 minutes for large clusters are still preferable to non-preemptive schedulers where jobs experience large queuing delays, or preemptive schedulers with heterogeneity-agnostic policies which lead to worse objective values, as shown above.

7.5 Efficacy of Scheduling Mechanism

Figure 15a shows the effect of the round length on average JCT for the heterogeneity-aware LAS policy with a single-

(a) Effect of round length. **(b)** Mechanism vs. ideal.

Figure 15: (a) Effect of round length on average JCT for the heterogeneity-aware LAS policy. (b) Comparison of scheduling mechanism to an ideal baseline that allocates resources to jobs *exactly* according to the computed allocation for the same policy.

Figure 16: Comparison of SS-aware LAS policy with estimated throughputs, compared to the SS-aware with oracle throughputs and LAS without space sharing on a heterogeneous 12-GPU cluster.

GPU trace. We observed similar behavior on traces with multi-GPU jobs, as well as other policies. A smaller round length gives Gavel’s scheduling mechanism more rounds to course correct, allowing the true allocation and computed optimal allocation to more closely match. We found that the time needed to load and save checkpoints for our target models is < 5 seconds, which means that a round length of 6 minutes gives a good tradeoff between fidelity with the optimal allocation and preemption overhead (preemption overhead with 6-minute rounds shown in Table 4).

We compare this to an ideal baseline that allocates resources to jobs *exactly* according to their computed allocation. As shown in Figure 15b, Gavel’s scheduling mechanism with a round duration of 6 minutes behaves almost identically to this ideal baseline with a single-GPU trace (behavior with a multi-GPU trace is similar). We note that the ideal baseline is impractical to use in practice, since jobs with different scale factors can complete at different times (leading to starvation), and preemptions can be often since allocations for some (job, accelerator type) pairs are small, leading to high overhead.

7.6 Impact of Throughput Estimation

Figure 16 shows the effect of Gavel’s throughput estimator on average JCT when using the space sharing-aware LAS policy compared to the LAS policy without space sharing, and the LAS policy with space sharing and oracle throughputs. The throughput estimator is able to determine missing throughputs in an online fashion accurately enough to observe a very small decrease in average JCT at high load (orange and blue lines).

8 Related Work and Discussion

In this section, we compare Gavel to related work.

Existing DNN Training Schedulers. Several recent papers have proposed schedulers targeting DNN training workloads.

Gandiva [58] uses time and space sharing to reduce queuing delay and improve resource utilization, but does not specify an explicit scheduling policy and does not support configurable objectives. It uses a profiling-based methodology to determine whether to co-locate jobs on an accelerator. However, it does not incorporate model performance data (isolated or co-located performance) explicitly into its scheduling policy, resorting to random exploration of job combinations until a combination that improves performance is found.

Tiresias [28] and Themis [40] use different objectives to achieve multi-job fairness. However, both do not incorporate jobs’ affinities for different accelerator types in their scheduling objectives, and have scheduling mechanisms strongly coupled with the target policy, making it hard to support other more sophisticated policies like multi-level fairness.

AlloX [37] and Gandiva_{fair} [18] are recent DNN schedulers that do consider worker and model heterogeneity. However, both only work for single policies (average job completion time for AlloX, max-min fairness for Gandiva_{fair}). Moreover, Gandiva_{fair} uses a second-price auction mechanism to improve the performance of a heterogeneity-agnostic max-min fairness scheme, but does not provide guarantees as to the optimality of the final allocation. On the other hand, Gavel formalizes each policy as an optimization problem, and can provide a guarantee that the returned solution is “optimal” according to the provided objective. Gavel is also able to support more sophisticated policies such as multi-level fairness.

Traditional Cluster Schedulers. Traditional schedulers such as Mesos [32], Borg [57], TetriSched [54], and YARN [56] support workloads with fixed heterogeneous resource requests, but do not reason about the diverse performance characteristics of jobs across accelerators. Mesos and YARN do not reason about interchangeable resource types that can run the same computation: for example, Mesos’s DRF multi-resource sharing policy [26] decides how to give jobs allocations of distinct resource types, such as RAM and CPUs, but assumes that each job has declared which resources it needs to use and in what ratio (unlike our case, where we consider heterogeneity over accelerators themselves).

The multi-interchangeable resource allocation (MIRA) problem [53] also introduces the notion of effective throughput similar to Gavel, but does not demonstrate how this can be used to specify policies as optimization problems, does not consider performance optimizations like space sharing and placement sensitivity, and does not discuss how computed allocations can be realized on physical resources.

Omega [50], Apollo [16], and Hydra [20] are schedulers that take into account the fact that the target workload shows heterogeneity in the number and duration of constituent tasks.

However, tasks largely take the same time on different CPUs, and heterogeneity in memory capacities only impacts the number and size of tasks that can be placed on a server. In our work, the compute devices themselves are interchangeable with sometimes large performance differences, and policies decide the time fractions of resources each job should receive while optimizing for various end objectives.

Dynamic Performance Estimation. As detailed in §6, Gavel uses the approach proposed by Quasar [21] to estimate co-located job performance online. In particular, Gavel uses a mix of profiling and matrix completion to compute a “fingerprint” against a set of reference models profiled offline. In this work, we show that the techniques used by Quasar can be successfully applied to this new setting.

Applicability to Other Settings. Even though we focused this paper on allocating heterogeneous resources for DNN training workloads, we believe that Gavel can be used for non-DNN workloads as well. Other workloads that are amenable to GPU execution, such as simulations, can be considered, even though performance estimates for these applications will be needed. We also believe the main technical insight presented in this paper – formulating diverse scheduling policies as optimization problems – is broadly applicable, and can be used to more easily deploy policies on homogeneous deep learning clusters, and on CPU clusters as well.

9 Conclusion

In this paper, we proposed Gavel, a heterogeneity-aware cluster scheduler that is able to optimize for many high-level metrics like fairness, makespan, and cost. Gavel demonstrates how existing policies can be expressed as optimization problems, and extends these policies to be heterogeneity-aware. Gavel then uses a decoupled round-based scheduling mechanism to ensure that the computed optimal allocation is realized. Gavel’s heterogeneity-aware policies improve end objectives both on a physical and simulated cluster. It can support a higher average input job rate, while improving objectives such as average job completion time by $3.5\times$, makespan by $2.5\times$, and cost by $1.4\times$.

A Artifact Appendix

A.1 Abstract

Gavel is open sourced at <https://github.com/stanford-futuredata/gavel>. We provide implementations for Gavel’s heterogeneity-aware policies, its round-based scheduling mechanism, and the **GavelIterator** interface, as well as implementations of relevant baselines such as AlloX [37], a simulator, and code to reproduce the graphs and other quantitative results shown in this paper.

A.2 Artifact check-list

- **Algorithm:** Heterogeneity-aware policies are expressed as optimization problems over allocations. Scheduling is performed using a greedy round-based scheduling mechanism.
- **Hardware:** Experiments in simulation can run on a multi-core server with Ubuntu 16.04. Experiments on a physical cluster need Nvidia GPUs.
- **Setup instructions:** Setup instructions are available in the `README.md` and `EXPERIMENTS.md` files provided in the artifact.
- **Experiments:** All results presented in this paper can be reproduced using the provided artifact.
- **Required disk space:** About 100 GB for logfiles when running simulated cluster experiments, about 10 GB for intermediate model checkpoints for physical cluster experiments, about 150 GB for datasets.
- **Expected experiment run time:** Days to a week for full simulated experiments, shorter durations (hours to a day) for scaled-down experiments (smaller cluster and trace).
- **Public link:** <https://github.com/stanford-futuredata/gavel>.
- **Code licenses:** MIT License.

A.3 Description

A.3.1 How to access

The artifact is publicly available at <https://github.com/stanford-futuredata/gavel>.

A.3.2 Hardware dependencies

Simulated experiments can be run on any multicore server. We ran experiments on a 56-core server with Ubuntu 16.04. Physical clusters need to have Nvidia GPU accelerators; other accelerators supported by Deep Learning frameworks such as PyTorch are supported as well by the scheduler.

A.3.3 Software dependencies

Software dependencies are specified at <https://github.com/stanford-futuredata/gavel/blob/master/README.md>.

A.3.4 Datasets

Running the simulator does not require any external datasets. When running physical cluster experiments, training data for training jobs is needed. These are task-specific (for example,

image classification training jobs might use the ImageNet dataset).

A.4 Installation

Installation instructions are specified at <https://github.com/stanford-futuredata/gavel/blob/master/README.md>.

A.5 Experiment workflow

Experiments in simulation are triggered by a driver script that instantiates the scheduler, and then adds jobs to the simulated cluster either according to a pre-defined trace, or on-the-fly using distributions with input parameters specified by the user. The scheduler computes the optimal allocation for each active job based on the desired policy and target objective, and then assigns resources to jobs according to this computed allocation using its round-based scheduling mechanism. Oracle throughputs are used to estimate the progress of jobs given a specified amount of time on the given resources. At the end of a run, completion times of all jobs of interest are recorded. Jobs of interest are usually a subset of all jobs submitted to the cluster, since we want to study steady state behavior. An exception is made for makespan policies, which try to minimize the total time taken by a collection of jobs; for this policy, jobs are added once at the start of the trace, and then jobs are allowed to drain from the cluster.

Experiments on physical clusters are also triggered by a driver script run on the scheduler, but are different in one key aspect: jobs are run on real accelerators for the specified number of steps. Every round, the scheduler makes a scheduling decision to decide what resources should be given to the different jobs. As before, job completion times are recorded when a job finishes executing.

A.6 Evaluation and expected result

Each experiment run results in an output logfile that records the microtasks run every scheduling round, as well as the completion times for each job. These logfiles can then be parsed to produce the graphs and other quantitative results presented in the evaluation section of this paper. Code to parse and produce plots are available at <https://github.com/stanford-futuredata/gavel/tree/master/scheduler/notebooks/figures>.

A.7 Experiment customization

Experiments can be run with different seeds using the main sweep scripts. Experiments can also be scaled down in different ways to obtain results faster: a) smaller cluster, b) fewer traces, c) smaller traces, and d) smaller set of jobs of interest over which objectives (such as average JCT) are measured.

A.8 AE Methodology

Submission, reviewing and badging methodology is specified at <https://www.usenix.org/conference/osdi20/call-for-artifacts>.

PipeSwitch: Fast Pipelined Context Switching for Deep Learning Applications

Zhihao Bai*

Abstract

Deep learning (DL) workloads include throughput-intensive training tasks and latency-sensitive inference tasks. The dominant practice today is to provision dedicated GPU clusters for training and inference separately. Due to the need to meet strict Service-Level Objectives (SLOs), GPU clusters are often over-provisioned based on the peak load with limited sharing between applications and task types.

We present PipeSwitch, a system that enables unused cycles of an inference application to be filled by training or other inference applications. It allows multiple DL applications to *time-share* the same GPU with the entire GPU memory and *millisecond-scale* switching overhead. With PipeSwitch, GPU utilization can be significantly improved without sacrificing SLOs. We achieve so by introducing *pipelined context switching*. The key idea is to leverage the *layered* structure of neural network models and their *layer-by-layer* computation pattern to *pipeline* model transmission over the PCIe and task execution in the GPU with model-aware grouping. We also design unified memory management and active-standby worker switching mechanisms to accompany the pipelining and ensure process-level isolation. We have built a PipeSwitch prototype and integrated it with PyTorch. Experiments on a variety of DL models and GPU cards show that PipeSwitch only incurs a task startup overhead of 3.6–6.6 ms and a total overhead of 5.4–34.6 ms (10–50× better than NVIDIA MPS), and achieves near 100% GPU utilization.

1 Introduction

Deep learning (DL) powers an emerging family of intelligent applications in many domains, from retail and transportation, to finance and healthcare. GPUs are one of the most widely-used classes of accelerators for DL. They provide better trade-off between performance, cost and energy consumption than CPUs for deep neural network (DNN) models.

DL workloads include throughput-intensive training tasks and latency-sensitive inference tasks. The dominant practice today is to provision dedicated GPU clusters for training and inference separately. Inference tasks cannot be served with training clusters under flash crowds, and training tasks cannot utilize inference clusters when the inference load is low. Consequently, inference clusters are often over-provisioned for

the peak load, in order to meet strict Service Level Objectives (SLOs). Even for inference itself, production systems are typically provisioned to each application on per-GPU granularity to limit the interference between applications.

Ideally, multiple DL applications should be able to be packed to the same GPU server to maximize GPU utilization via time-sharing. This is exactly how operating systems achieve high CPU utilization via task scheduling and context switching. The idea of fine-grained CPU time-sharing has been further extended to cluster scheduling. For example, Google Borg [1] packs online services and batch jobs, and saves 20%-30% machines (compared with not packing them). Why can't we use GPUs in the same way?

The gap is that GPU has high overhead when switching between tasks. Consequently, naively using GPUs in the same way as CPUs will not satisfy the requirements of DL inference that have strict SLOs in the range of tens to hundreds of milliseconds [2, 3]. If a GPU switches to a DNN model (e.g., ResNet) that has not been preloaded onto the GPU, it can take multiple seconds before serving the first inference request, even with state-of-the-art tricks like CUDA unified memory [4] (§6). In contrast, CPU applications can be switched in milliseconds or even microseconds [5].

To avoid such switching overhead, the existing solution is to spatially share the GPU memory. For example, although NVIDIA Multiple Process Sharing (MPS) [6] and Salus [7] allow multiple processes to use the same GPU, they require all processes' data (e.g., DNN models) to be preloaded into the GPU memory. Unfortunately, the GPU memory is much more limited than host memory and cannot preload many applications. Sometimes, just one single memory-intensive training task may consume all the GPU memory. Moreover, the memory footprints of inference tasks are also increasing—the models are getting larger, and request batching is prevalently used to increase throughput [3]. In addition, this approach does not provide strong GPU memory isolation between applications.

As such, we argue that a context switching design that minimizes the switching overhead, especially quickly switching the contents on GPU memory, is a better approach for efficiently time-sharing GPUs. The DNN models can be held in host memory, which is much larger and cheaper than GPU memory, and the GPU can quickly context-switch between

the models either for training or inference. This way, *the number of* applications that can be multiplexed is not limited by the GPU memory size, and each application is able to use the entire GPU compute and memory resources during its time slice. To our best knowledge, no existing solution offers such context switching abstraction for GPU.

To this end, we propose PipeSwitch, a system that (i) enables GPU-efficient multiplexing of many DL applications on GPU servers via fine-grained time-sharing, and (ii) achieves millisecond-scale latencies and high throughput as dedicated servers. PipeSwitch enables unused cycles of an inference application to be filled by training or other inference applications. We achieve so by introducing a new technology called *pipelined context switching* that exploits the characteristics of DL applications to achieve millisecond-scale overhead for switching tasks on GPUs. Such small switching overhead is critical for DL applications to satisfy strict SLO requirements.

To understand the problem, we first perform a measurement study to profile the task switching overhead and analyze the overhead of each component. We divide the switching overhead into four components, which are old task cleaning, new task initialization, GPU memory allocation, and model transmission via PCIe from CPU to GPU. Every component takes a considerable amount of time, varying from tens of milliseconds to seconds. Such overhead is significant, because an inference task itself only takes tens of milliseconds on a GPU and the latency SLOs are typically a small multiple of the inference time [3].

We take a holistic approach, and exploit the characteristics of DL applications to minimize the overhead of all the components. Our design is based on a key observation that DNN models have a *layered* structure and a *layer-by-layer* computation pattern. As such, there is no need to wait for the entire model to be transmitted to the GPU before starting computation. Based on this observation, we design a pipelined model transmission mechanism, which *pipelines* model transmission over the PCIe and model computation in the GPU. Naive pipelining on per-layer granularity introduces high overhead on tensor transmission and synchronization. We divide layers into groups, and design an optimal model-aware grouping algorithm to find the best grouping strategy for a given model.

The computation of a DL task is layer by layer, which has a simple, regular pattern for memory allocation. The default general-purpose GPU memory management (e.g., CUDA unified memory [4]) is an overkill and incurs unnecessary overhead. We design unified memory management with a dedicated memory daemon to minimize the overhead. The daemon pre-allocates the GPU memory, and re-allocates it to each task, without involving the expensive GPU memory manager. The DNN models are stored only once in the memory daemon, instead of in every worker, to minimize memory footprint. We exploit that the memory allocation for a DNN model is deterministic to eliminate extra memory copies between the daemon and the workers and reduce the IPC overhead.

We use an active-standby mechanism for fast worker switching and process-level isolation. Each server contains an active worker and multiple standby workers. The active worker executes the current task on the GPU; the standby workers stay on the CPU and wait for the next task. Our mechanism parallelizes old task cleaning in the active worker and new task initialization in the standby worker to minimize worker switching overhead. With separate worker processes, PipeSwitch enforces process-level isolation.

Pipelining is a canonical technique widely used in computer systems to improve system performance and maximize resource utilization. Prior work in DL systems such as PipeDream [8] and ByteScheduler [9] has applied pipelining to distributed training. These solutions focus on *inter-batch* pipelining to overlap computation and *gradient* transmission of different batches for *training* workloads of the *same* DNN model. The key novelty of PipeSwitch is that it introduces *intra-batch* pipelining to overlap *model* transmission and computation to reduce the overhead of switching between *different* DNN models, which can be *either inference or training*. Unlike pipelining for the same task, PipeSwitch requires us to address new technical challenges on memory management and worker switching across *different* processes. We design new techniques to not only support training, but also inference that has strict SLOs.

In summary, we make the following contributions.

- We propose PipeSwitch, a system that enables GPU-efficient fine-grained time-sharing for multiple DL applications, and achieves millisecond-scale context switching latencies and high throughput.
- We introduce *pipelined context switching*, which exploits the characteristics of DL applications, and leverages pipelined model transmission, unified memory management, and active-standby worker switching to minimize switching overhead and enforce process-level isolation.
- We implement a system prototype and integrate it with PyTorch. Experiments on a variety of DL models and GPU cards show that PipeSwitch only incurs a task startup overhead of 3.6–6.6 ms and a total overhead of 5.4–34.6 ms (10–50× better than NVIDIA MPS), and achieves near 100% GPU utilization.

2 Motivation

In this section, we identify the inefficiencies in today’s shared GPU clusters, and motivate running DL workloads on GPUs in the fine-grained time-sharing model.

2.1 GPU Clusters

Shared GPU clusters. To run DNN workloads in a large scale, enterprises build GPU clusters that are either privately [10, 11] or publicly [12–14] shared by multiple users. Such GPU clusters are usually specifically designed with dedicated physical forms and power supplies, along with high speed networks and specialized task schedulers.

Why build a shared cluster instead of a dedicated one for each user? The main reason is to bring down the cost. The demand of training is not well predictable—it would depend on the progress of different developers. The demand of inference is more predictable, e.g., an inference task for a particular application usually has a daily periodical pattern based on the application usage. Nevertheless, the patterns can still vary across different tasks. Like traditional CPU workloads, a shared cluster by different tasks would increase the resource utilization via time-sharing.

No sharing between training and inference. However, such “shared” clusters are not shared between training and inference. Even though training and inference both use GPUs, the current practice is to build dedicated clusters for training and inference separately. This brings several inefficiencies.

- Inference clusters are over-provisioned for the peak load, because they directly serve user requests and need to meet strict SLOs. Although inference clusters are not always running at high utilization, they cannot be utilized by training.
- Training clusters are equipped with powerful GPUs to run training tasks, which are often elastic and do not have strict deadlines. However, when there is a flash crowd (e.g., an application suddenly becomes popular and the demand grows beyond the operator’s expectation), the training cluster cannot preempt the training tasks for inference tasks.
- Even for inference tasks, production systems often allocate GPUs to applications on per-GPU granularity (e.g., binding GPUs to the VMs, containers or processes of an application), in order to limit the interference between different applications and satisfy the SLO requirements.

One of the reasons for separately provisioning is that GPUs designed for inference tasks might be too wimpy for training tasks. This, however, has started to change with the arrival of new GPU hardware, most notably NVIDIA T4. Compared with NVIDIA V100 which has up to 32GB GPU memory and 15.7 TFLOPS (single-precision), NVIDIA T4 has comparable performance with 16GB GPU memory and 8.1 TFLOPS (single-precision). Also, new algorithms and systems for distributed training [8, 9, 15, 16] enable multiple GPUs to accelerate training, if one GPU is not fast enough.

Our industry collaborator, a leading online service provider, confirms this observation. This service provider currently runs more than 10K V100 GPUs for training, and at least $5\times$ as many T4 GPUs for inference. The computation power on both sides is within the same order of magnitude. The inference workload fluctuates in correlation with the number of active users, and shows clear peaks and valleys within each day—the peak demand during daytime is $> 2\times$ of the valley at midnight. It would be a great match to utilize inference GPUs during less busy times for training models that require daily updates with latest data. A good example is to fine-tune BERT using daily news. This means great opportunity in improving GPU utilization by Borg-like [1] systems for GPUs.

2.2 Fine-Grained Time-Sharing GPU

We envision to build GPU clusters that can be shared across different applications including training and inference. We propose to pack multiple DL applications onto the same GPU via fine-grained time-sharing abstraction to maximize GPU utilization. This is inspired by the OS scheduler and context switching in the CPU world. It has the following advantages.

- It would dramatically improve the resource utilization, especially because inference and training workloads have complementary usage patterns. Online inference services are often more idle during midnight, while many training developers would start a time-consuming job at night. Besides, inference loads on different models have different patterns, which also benefits from the time sharing.
- Similar to CPU workloads, fine-grained time-sharing can provide better utilization than provisioning dedicated resources, while providing necessary process-level isolation.
- It would greatly simplify the design of load balancers and schedulers as any server would be able to run any task with low overhead to switch between different applications.

The gap: the precious GPU memory and slow switching.

To achieve this goal, however, we face a major challenge—fast GPU context switching between different processes. A modern server can be equipped with several TB of host memory, enabling it to load many applications. However, task execution on GPUs require GPU memory, which is very limited even on high-end GPUs, e.g., 16 GB for T4 and 32 GB for V100. More importantly, GPU memory is purposed for task execution, not for storing the state of idle applications. DL tasks, especially training, require a large amount, or even all of the memory on a GPU.

Storing the models in the GPU like Salus [7] cannot support training tasks which are memory-intensive or even multiple inference tasks which have large models. This is particularly important as state-of-the-art models are getting deeper and larger, and thus even idle applications can occupy large memory space. In addition, request batching is prevalently used to increase throughput [3], which further increases the GPU memory requirement of inference applications. Ideally, the active application should be able to utilize the entire GPU memory for its purpose, and the number of applications that can be served by a GPU server should only be limited by its host memory size. Consequently, switching a task would require heavy memory swapping.

Unfortunately, many online inference workloads require strict SLOs that naive memory swapping between the host memory and the GPU memory cannot meet. For example, we test the strawman scenario where we stop a training task and then start an inference task. The first inference batch would require several seconds to finish (§4.1). Existing support such as NVIDIA MPS is not optimized for DL workloads, and incurs hundreds of milliseconds overhead (§6).

Figure 1: PipeSwitch architecture.

The opportunity: DL workloads have well-defined structures. Fortunately, the structure and computation pattern of DNN models allow us to highly optimize task switching and achieve millisecond-scale overhead. DNN models are usually *deep*, consisting of multiple layers stacking one on another. Furthermore, the computation of DNN models takes place layer by layer as well. Thus, it is possible to build a pipeline that overlaps the computation and GPU memory swapping for fast context switching.

In the following sections, we will show that such pipeline is indeed feasible and effective. In addition, we will also need to resolve other challenges like memory management and worker switching. Combining all the ideas into our system, PipeSwitch, we close the gap of GPU memory sharing and switching, and enable the design of an efficient time-sharing GPU cluster for DL workloads.

3 PipeSwitch Overview

PipeSwitch enables GPU-efficient multiplexing of multiple DL applications on GPU servers. It exploits the characteristics of DL applications to achieve *millisecond-scale* task switching overhead in order to satisfy SLO requirements. Such fast task switching enables more flexible fine-grained scheduling to improve GPU utilization for dynamic workloads. It benefits switching not only between inference and training, but also between inference on different models. Here we provide an overview of the architecture and task execution.

System architecture. Figure 1 shows the architecture of a PipeSwitch server. This server contains four types of components: a controller, a memory daemon, an active worker, and multiple standby workers.

- **Controller.** The controller is the central component. It receives tasks from clients, and controls the memory daemon and the workers to execute the tasks.
- **Memory daemon.** The memory daemon manages the GPU memory and the DNN models. It allocates the GPU memory to the active worker, and transfers the model from the host memory to the GPU memory.
- **Active worker.** The active worker is the worker that currently executes a task in the GPU. Here a worker is a process that executes tasks on one GPU.

Instance Type	g4dn.2xlarge	p3.2xlarge
GPU Type	NVIDIA T4	NVIDIA V100
Task Cleaning	155 ms	165 ms
Task Initialization	5530 ms	7290 ms
Memory Allocation	10 ms	13 ms
Model Transmission	91 ms	81 ms
Total Overhead	5787 ms	7551 ms
Inference Time	105 ms	32 ms

Table 1: Measurement results of task switching overhead and the breakdown of individual components. *All* components should be optimized to meet the SLOs.

- **Standby worker.** A server has one or more standby workers. A standby worker is idle, is initializing a new task, or is cleaning its environment for the previous task.

Task execution. The controller queues a set of tasks received from the clients. It uses a scheduling policy to decide which task to execute next. It supports canonical scheduling policies such as first come first serve (FCFS) and earliest deadline first (EDF), and can be easily extended to support new policies. We focus on fast context switching, and the specific scheduling algorithm is orthogonal to this paper. The scheduling is *preemptive*, i.e., the controller can preempt the current task for the next one based on the scheduling policy. For example, if the current task is a training task, the controller can preempt it for an inference task that has a strict latency SLO.

To start a new task, the controller either waits for the current task to finish (e.g., if it is inference) or preempts it by notifying the active worker to stop (e.g., if it is training). At the same time, the controller notifies an idle standby worker to initialize its environment for the new task. After the active worker completes or stops the current task, the controller notifies the memory daemon and the standby worker to load the task to GPU to execute with pipelined model transmission (§4.2). The memory daemon allocates the memory to the standby worker (§4.3), and transmits the model used by the new task from the host memory to the GPU memory. The standby worker becomes the new active worker to execute the new task, and the active worker becomes a standby worker and cleans the environment for the previous task (§4.4). The primary goal of this paper is to design a set of techniques based on the characteristics of DL applications to minimize the task switching overhead in this process.

4 PipeSwitch Design

We first perform a measurement study to profile the task switching overhead and break it down to individual components. Then we describe our design to systematically minimize the overhead of each component.

4.1 Profiling Task Switching Overhead

In order to understand the problem, we perform a measurement study to profile the task switching overhead. The mea-

surement considers a typical scenario that a server stops a training task running on the GPU, and then starts an inference task. The DNN model used in the measurement is ResNet152 [17]. The measurement covers two types of instances on Amazon AWS, which are g4dn.2xlarge with NVIDIA T4 and p3.2xlarge with NVIDIA V100. We assume the inference task has arrived at the server, and focus on measuring the time to start and execute it on the GPU. We exclude the network time and the task queueing time.

Table 1 shows the results. The total times to start the inference task on the GPUs are 5787 ms and 7551 ms, respectively. We break the overhead down into the four components.

- **Task cleaning.** The training task stops and cleans its GPU environment, such as freeing the GPU memory.
- **Task initialization.** The inference task creates and initializes its environment (i.e., process launching, PyTorch CUDA runtime loading, and CUDA context initialization).
- **Memory allocation.** The inference task allocates GPU memory for its neural network model.
- **Model transmission.** The inference task transmits the model from the host memory to the GPU memory.

The inference time on V100 is lower than that on T4, and both of them are significantly lower than the total overheads. The reason for lower overhead on T4 is that task switching largely depends on CPU, and g4dn.2xlarge is equipped with better CPU than p3.2xlarge (Intel Platinum 8259CL vs. Intel Xeon E5-2686 v4). A strawman solution that simply stops the old task and starts the new task would easily violate SLOs.

Because all the components take considerable time compared to the inference time, we emphasize that *all* the components should be optimized to achieve minimal switching overhead and meet the SLOs.

4.2 Pipelined Model Transmission

Transmitting a task from CPU to GPU is bounded by the PCIe bandwidth. The PCIe bandwidth is the physical limit on how fast an arbitrary task can be loaded to the GPU. We exploit the characteristics of DL applications to *circumvent* this physical limit. Our key observation is that DNN models have a *layered* structure. The computation is performed layer by layer. An inference task only performs a forward pass from the first layer to the final layer to make a prediction; each iteration in a training task performs a forward pass and then a backward pass. In both cases, a task does not need to wait for the entire model to be transmitted to the GPU before beginning the computation. Instead, the task can start the computation of a layer as soon as the layer is loaded in the GPU and the input of the layer is ready (i.e., the previous layers have finished their computation), regardless of its following layers. Figure 2 illustrates the advantage of pipelining over the strawman solution.

PipeSwitch requires the knowledge of models. PipeSwitch does not modify the model structure, and only adds hooks for PyTorch to wait for transmission or synchronize the execution.

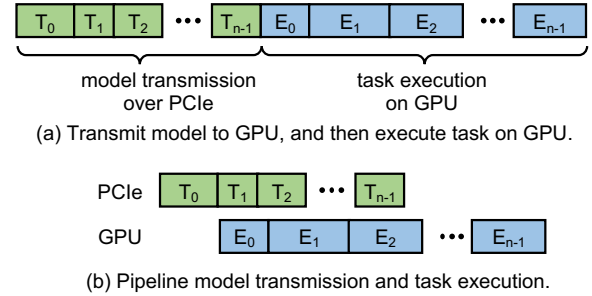

Figure 2: PipeSwitch pipelines model transmission and task execution. The example shows an inference task that only has a forward pass in task execution.

Adding hooks can be automated, and PipeSwitch can be implemented as a part of the DNN framework, e.g., PyTorch, so it can gather the model structure information while remaining transparent to users and cluster managers.

Optimal model-aware grouping. The basic way for pipelining is to pipeline on *per-layer* granularity, i.e., the system transmits the layers to the GPU memory one by one, and the computation for a layer is blocked before the layer is transmitted. Pipelining brings two sources of system overheads. One is the overhead to invoke multiple calls to PCIe to transmit the data. For a large amount of data (e.g., combining the entire model to a large tensor to transmit together), the transmission overhead is dominated by the data size. But when we divide the model into many layers, invoking a PCIe call for each layer, especially given that some layers can be very small, would cause significant extra overhead. The other is the synchronization overhead between transmission and computation, which is necessary for the computation to know when a layer is ready to compute. Pipelining on per-layer granularity requires synchronization for every layer.

We use grouping to minimize these two sources of overhead. We combine multiple layers into a group, and the pipelining is performed on *per-group* granularity. In this way, the pipelining overhead is paid once for each group, instead of each layer. Grouping introduces a trade-off between pipelining efficiency and pipelining overhead. On one hand, using small groups (e.g., per-layer in the extreme case) enables more overlap between transmission and computation, which improves pipelining efficiency, but it also pays more pipelining overhead. On the other hand, using big groups (e.g., the entire model in one group in the extreme case) has minimal pipelining overhead, but reduces the chance for overlapping.

Grouping must be model-aware, because models have different structures in terms of the number of layers and the size of each layer. Naively, we can enumerate all possible combinations to find the optimal grouping strategy. This is not amenable because large models can have hundreds of layers and the time complexity for enumeration is exponential.

In order to find the optimal grouping strategy efficiently, we introduce two pruning techniques based on two insights.

Figure 3: Examples for two pruning techniques.

Before we dive into the details, we first formulate the problem. Let the number of layers be n . Let $F(B, i)$ be a function that returns the total time of the optimal grouping strategy from layer i to $n-1$ given that layer 0 to $i-1$ have formed groups represented by B . Then we have the following recursive formula.

$$F(\{\}, 0) = \min_i F(\{group(0, i)\}, i+1) \quad (1)$$

Specifically, to find the optimal grouping strategy for the entire model (i.e., $F(\{\}, 0)$), we divide all possible combinations into n cases based on how the first group is formed, i.e., case i means the first group contains layer 0 to i . This formula can be applied recursively to compute $F(\{group(0, i)\}, i+1)$.

Our first insight is that it is not necessary to examine all the n cases, because if the first group contains too many layers, the computation of the first group would be delayed too much to compensate the pipeline efficiency. Let $T(i, j)$ and $E(i, j)$ be the transmission and execution times for a group from layer i to j respectively, where $T(i, j)$ is calculated based on the size of layer i to j and PCIe bandwidth, and $E(i, j)$ is profiled on the GPU. Note that the overhead of invoking multiple calls is included in $T(i, j)$. As illustrated by Figure 3(a), we compute a lower bound for the total time for each case in Equation 1.

$$F(\{group(0, i)\}, i+1) \geq \min(T(0, i) + T(i+1, n-1), T(0, i) + E(0, i) + E(i+1, n-1)) \quad (2)$$

The lower bound considers the best case that all the remaining layers are combined in one group for transmission and computation, and that the computation and communication can be perfectly overlapped, i.e., its computation can happen right after the computation of the first group finishes. If the lower bound of case i is already larger than the total time of the best grouping strategy found so far, then case i (i.e., the recursive computation for $F(\{group(0, i)\}, i+1)$) can be pruned.

Our second insight is that other than the first group, we can safely pack multiple layers in a group based on the progress of computation without affecting pipeline efficiency. Figure 3(b) shows an example for this insight. Suppose that we have already fixed the first group to be from layer 0 to i , and we apply Equation 1 recursively to enumerate the cases for the

Figure 4: General case for the two pruning techniques.

second group. We can hide the transmission of the second group into the computation of the first group, as long as the transmission finishes no later than the computation of the first group. The least number of layers to group can be computed using the following equation.

$$j^* = \arg \max_j T(i+1, j) \leq E(0, i) \quad (3)$$

Group from layer $(i+1)$ to $j < j^*$ is no better than grouping from $(i+1)$ to j^* because it does not increase the pipeline efficiency and has higher pipeline overhead. Therefore, we can prune the cases that group from layer $(i+1)$ to $j < j^*$ and only search for $j \geq j^*$.

Algorithm. Based on these two insights, we design an algorithm to find the optimal grouping strategy for a given model. We emphasize that this algorithm runs *offline* to find the strategy, and the resulting strategy is used online by PipeSwitch for context switching. Algorithm 1 shows the pseudo code. The function *FindOptGrouping* recursively finds the optimal grouping strategy based on Equation 1 (line 1-27). It takes two inputs: B represents the groups that have already formed, x is the first layer that have not formed a group. It uses *opt_groups* to store the best grouping strategy from layer x given B , which is initialized to none (line 2). The algorithm applies the second pruning insight to form the first group from layer x (line 3-9). Equation 3 and Figure 3(b) illustrate this insight with a special example that B only contains one group from layer 0 to i . In general, B can contain multiple groups formed by previous layers, and we use $B.delay$ to denote the time to which the group can be formed, as shown in Figure 4. The algorithm finds j^* based on $B.delay$ (line 4-9), and the enumeration for i can skip the layers from x to j^*-1 (line 11). For case i , the algorithm applies the first insight to compute the lower bound (line 12-17). Again, the example in Equation 2 and Figure 3(a) is a special case when x is 0. For the general case, the computation from x has to wait for both its transmission (i.e., $T(x, i)$) and the computation of the previous groups (i.e., $B.delay$), as shown in Figure 4. If the lower bound is already bigger than the current optimal time, then case i is pruned (line 18-19). Given the group from layer x to i is formed, the function recursively applies itself to find the optimal groups from layer $i+1$ to $n-1$ (line 21-23), and updates *opt_groups* if the current strategy is better (line 24-26). Finally, it returns *opt_groups* (line 27). In practice, we use a heuristic that bootstraps *opt_groups* with a relative

Algorithm 1 Optimal Model-Aware Grouping

```
1: function FINDOPTGROUPING( $B, x$ )
2:    $opt\_groups \leftarrow \emptyset, opt\_groups.time \leftarrow \infty$ 
3:   // find first group from layer  $i$  to  $j^*$ 
4:    $j^* \leftarrow x$ 
5:   for layer  $i$  from  $x$  to  $n - 1$  do
6:     if  $T(x, i) \leq B.delay$  then
7:        $j^* \leftarrow i$ 
8:     else
9:       break
10:  // recursively find the optimal grouping
11:  for layer  $i$  from  $j^*$  to  $n - 1$  do
12:    if  $opt\_groups \neq \emptyset$  then
13:      // compute lower bound
14:       $trans\_time \leftarrow T(x, i) + T(i + 1, n - 1)$ 
15:       $exec\_time \leftarrow \max(T(x, i), B.delay)$ 
16:         $+ E(x, i) + E(i + 1, n - 1)$ 
17:       $lower\_bound \leftarrow \min(trans\_time, exec\_time)$ 
18:      if  $lower\_bound > opt\_groups.time$  then
19:        continue
20:    // recursively find rest groups
21:     $first\_group \leftarrow Group(x, i)$ 
22:     $rest\_groups \leftarrow FindOptGrouping($ 
23:       $B + first\_group, i + 1)$ 
24:     $cur\_groups \leftarrow first\_group + rest\_groups$ 
25:    if  $cur\_groups.time < opt\_groups.time$  then
26:       $opt\_groups \leftarrow cur\_groups$ 
27:  return  $opt\_groups$ 
```

good strategy (e.g., group every ten layers). Given n layers, there are 2^{n-1} different grouping strategies, so the time complexity of Algorithm 1 is $O(2^n)$, as in the worst case it needs to enumerate all strategies. The two pruning techniques are able to prune most of the strategies, and can quickly find the optimal one as we will show in §6. We have the following theorem for the algorithm.

Theorem 1. *Algorithm 1 finds the optimal grouping strategy that minimizes the total time for the pipeline.*

Proof. Algorithm 1 computes the recursive function $FindOptGrouping(B, x)$. Let $m = n - x$, which is the number of layers the function considers. We use induction on m to show that $FindOptGrouping(B, x)$ outputs the optimal grouping strategy from layer x to $n - 1$ given that previous layers have formed groups represented by B .

Base case. When $m = 1$, the function only examines one layer. Because there is only one strategy which is layer x itself is one group, this strategy is the optimal strategy.

Inductive step. Assume that for some $k \geq 1$ and any $m \leq k$, $FindOptGrouping(B, x)$ outputs the optimal strategy. Consider $m = k + 1$, i.e., the algorithm now considers $k + 1$ layers. The algorithm divides the problem into $k + 1$ cases, where case i ($0 \leq i \leq k$) forms the first group from layer x to $x + i$.

For case i where $0 \leq i \leq k - 1$, because $FindOptGrouping(B + Group(x, x + i), x + i + 1)$ only considers $k - i \leq k$ layers, it outputs the optimal grouping strategy for case i based on the assumption.

For case $i = k$, the first group contains all layers from x to $n - 1$. The optimal strategy for this case is one group.

Because these cases are exclusive and cover the entire search space, by choosing the optimal grouping strategy from these cases, the algorithm outputs the optimal grouping strategy for $m = k + 1$.

The algorithm uses two pruning techniques. The first technique prunes the cases if their lower bounds are no better than the current found optimal. It is obvious that this technique does not affect the optimality. The second technique prunes the case if their first groups are from layer x to $j < j^*$. Because these cases cannot advance the computation to an earlier point than grouping from x to at least j^* , pruning these cases also do not affect the optimality. \square

Generality. Algorithm 1 achieves optimality for a given list of layers. This, however, does not require the models to be linear. In general, the layers or operators in a DNN model can be connected as an arbitrary computation graph, instead of a simple chain. Models like ResNet and Inception are technically non-linear directed acyclic graph (DAGs). Yet, there is an execution order that the layers/operators in the DAG are issued to the GPU one by one. Algorithm 1 does not have any special assumptions on the execution order. It is only interested in finding out how to group the layers given the execution order (and corresponding data dependencies) to achieve high pipelining efficiency and low pipelining overhead. It even applies for graphs with loops, in which the order is based on the first time an operator is executed. The order does not affect correctness, because an operator can be executed only when it is transmitted to the GPU and the input is ready. Thus, our pipelined model transmission is applicable to the general case.

4.3 Unified Memory Management

Task execution in a GPU requires GPU memory. A GPU has its own memory management system, and provides a `malloc` function (e.g., `cudaMalloc` for NVIDIA GPUs) similar to CPUs for memory allocation. NVIDIA also provides CUDA unified memory [4] to automatically handle memory movement between the host memory and the GPU memory for applications. A naive solution for GPU memory management is that each task uses the native `cudaMallocManaged` function for GPU memory allocation, and delegates model transmission to CUDA unified memory. This solution incurs high overhead for DL applications because of two reasons. First, DL applications have large models and generate large amounts of intermediate results, which require a lot of GPU memory. Second, the native `cudaMalloc` function and CUDA unified memory are designed for general-purpose applications, and may incur unnecessary overhead for DL applications.

We exploit two characteristics of DL applications to minimize GPU memory management overhead. A DL task stores two important types of data in the GPU memory: the DNN model (including the model parameters), and the intermediate results. First, the amount of memory allocated to the DNN model is *fixed*, and does not change during task execution. An

inference task only uses the model for inference, and does not change the model itself. While a training task updates the model, it only updates the model parameters (i.e., the weights of the neural network), not the DNN structure, and the amount of memory needed to store them stays the same.

Second, the intermediate results change in a simple, regular pattern, which do not cause *memory fragmentation*. For an inference task, the intermediate results are the outputs of each layer, which are used by the next layer. After the next layer is computed, they are no longer needed and can be safely freed. A training task differs in that the intermediate results generated in the forward pass cannot be immediately freed, because they are also used by the backward pass to update the weights. However, the backward pass consumes the intermediate results in the reverse order as that the forward pass generates them, i.e., the intermediate results are first-in-last-out. The memory allocation and release can be handled by a simple stack-like mechanism, without causing memory fragmentation. The general-purpose GPU memory management does not consider these characteristics, and is too heavy-weight for DL applications that require fast task switching.

Minimize memory allocation overhead. Based on these two characteristics, we design a memory management mechanism tailored for DL applications. PipeSwitch uses a dedicated memory daemon to manage the GPU memory. To be compatible with the existing system and incur minimal changes, instead of replacing the GPU memory manager, the memory daemon uses `cudaMalloc` to obtain the GPU memory when the system starts, and then dynamically allocates the memory to the workers at runtime. This eliminates the overhead for each worker to use `cudaMalloc` to get a large amount of memory to store their models and intermediate results. The memory daemon only needs to pass memory pointers to the workers, which is light-weight. The daemon ensures that each time only one worker owns the GPU memory to guarantee memory isolation between workers. Each worker uses a memory pool to allocate the memory to store its model and intermediate results, and recycles the memory to the pool after the intermediate results are no longer needed.

The memory management of PipeSwitch extends that of PyTorch. It is designed and optimized for efficient GPU memory allocation between different tasks, while the memory management in PyTorch handles memory allocation for a task itself. PipeSwitch inserts GPU memory blocks to PyTorch GPU memory pool, and PyTorch creates tensors on them.

Minimize memory footprint and avoid extra memory copies. The server stores the DNN models in the host memory. Replicating the models in each worker incurs high memory footprint, and reduces the number of models a server can store, and consequently the types of tasks the server can execute. On the other hand, storing the models in a dedicated process has minimal memory footprint as each model is only stored once, but it incurs an extra memory copy from this process to a

worker to start a task, which hurts the task switching time. We use unified memory management with the memory daemon to both achieve minimal memory footprint and eliminate extra memory copies. PipeSwitch stores the models in the memory daemon so that the server only needs to keep one copy of each model in the host memory. Because the memory daemon also manages the GPU memory, it directly transmits the model from the host memory to the GPU memory for task startup, which eliminates the extra memory copy from the memory daemon to the worker.

Minimize IPC overhead. After the model is transmitted to the GPU, the memory daemon needs to notify the worker and export the relevant GPU memory handlers to the worker, so that the worker can access the model to execute its task. This can be implemented by IPC APIs provided by GPUs, e.g., `cudaIpcOpenMemHandle` for NVIDIA GPUs. We have measured the performance of these IPC APIs and found that they incur high overhead (§6). The overhead is exacerbated by the pipeline because the pipeline needs to invoke the IPCs frequently to synchronize model transmission and task execution for *every pipeline group*, instead of invoking the IPC only once for the entire model transmission.

We leverage a property of DL applications to minimize the IPC overhead. The property is that the memory allocation process for a neural network model is *deterministic*. Specifically, given the same GPU memory region and the same model, as long as the memory daemon and the worker uses the same *order* to allocate memory for the model parameters, the memory pointers for the parameters would be the *same*. It is easy to keep the same order for the memory daemon and the worker because the neural network model is known and given, and the memory daemon only needs to use the same order to transmit the model as the worker would. As a result, the memory daemon can minimize the usage of expensive GPU IPCs. It only uses the GPU IPC once to initialize the worker, and then uses cheap CPU IPCs to notify the worker which pipeline group has been transmitted.

Pin memory. The OS would swap a memory page to disk if the page is inactive for a certain amount of time. GPUs require a page in the host memory to be pinned (or page-locked) in order to transmit the data in the page to the GPU memory. Otherwise, a temporary pinned page is created for the transmission. We pin the pages of the memory daemon to the host memory, to eliminate this overhead.

4.4 Active-Standby Worker Switching

PipeSwitch aims to provide fast task switching and ensure process-level isolation. Process-level isolation is desirable because it ensures that one task cannot read the memory of another task, and that the crashing of one task, e.g., because of a bug, does not affect other tasks or the entire system.

A naive solution is to use separate processes and start the new task after the current task is stopped. As we have profiled

	No Task Cleaning Overhead	No Task Initialization Overhead	Process- Level Isolation
Two Processes	×	×	✓
One Process	×	✓	×
Active-Standby	✓	✓	✓

Table 2: Comparison of worker switching mechanisms.

in Table 1, such sequential execution incurs long delay due to old task cleaning and new task initialization.

Another possible solution is to let the current and new tasks share the same process with a warm CUDA context, so that the new task can reuse the GPU environment of the current task. This avoids the new task initialization, but it still has the overhead for the current task to clean its status. In addition, it does not provide process-level isolation between tasks.

We design an active and standby worker switching mechanism that hides the overhead of both task cleaning and task initialization, and also ensures process-level isolation. Similar to the naive solution, we use separate processes to achieve process-level isolation. PipeSwitch has an active worker and multiple standby workers. Each worker is a separate process, and initializes its own GPU environment (i.e., CUDA context) when it is first created. This eliminates the GPU environment initialization overhead when a new task is assigned to a worker. When a current task is stopped, a major job is to clear asynchronous CUDA functions queued on the GPU. We insert synchronization points into training tasks, so the number of queued functions are limited and can be quickly cleared. Synchronization points are not needed for inference tasks as they are short and not preempted. Another job is to free its GPU memory. An important property of the cleaning procedure is that it does not modify the content of the memory, but only cleans the metadata, i.e., GPU memory pointers. As the GPU memory is managed by PipeSwitch, the cleaning procedure deletes the pointers pointing to the tensor data rather than freeing the actual data. Therefore, it is safe for the new task to transmit its model to the GPU memory at the same time. In other words, we can parallelize the task cleaning of the current task and the pipelined model transmission of the new task, to hide the task cleaning overhead. This choice is optimized for performance, and is not a problem for a trusted environment. It is possible that a latter process can read the memory data of a previous process. If this is a concern, an additional zero-out operation can be added. GPU has high memory bandwidth (e.g., 900GB/s for V100). It would incur sub-millisecond overhead for zeroing-out most models like ResNet-152 (around 240MB). On the other hand, for a trusted environment, it is unnecessary to release all allocated memory for the preempted process if the new process does not require entire GPU memory, and this could be achieved by some simple coordination. Table 2 summarizes the differences between these three solutions.

In summary, to switch workers, the controller signals the current active worker to stop, deletes the GPU memory allocated to it, and allocates the GPU memory to the new active worker. The controller ensures only one active worker to guarantee exclusive occupation of the GPU.

There is a trade-off between the number of standby workers and their GPU memory consumption. On one hand, task cleaning takes time. If a new task arrives before a standby worker finishes cleaning a previous task, the new task needs to wait, which increases its startup time. On the other hand, it is possible to have many standby workers so that there is always at least one idle standby worker. However, every standby worker needs to maintain its own CUDA context, which consumes a few hundred MB GPU memory. Our experience is that two standby workers are sufficient to ensure at least one idle worker, which eliminates the waiting time and has moderate GPU memory consumption.

4.5 Discussion

PipeSwitch is focused on single-GPU tasks for training and inference. For inference tasks, strict SLOs require requests to be handled in small batches for low latency, so it is common to execute an inference task with a single GPU [18]. Multi-GPU inference tasks can be supported by performing PipeSwitch on each GPU with *transactions*. A transaction here means a model is switched in or out on all of its GPUs to enable or disable inference on this model.

For training tasks, PipeSwitch supports single-GPU training and asynchronous multi-GPU training for data parallel strategies, as preempting one GPU does not affect other GPUs. However, it does not work out of the box with synchronous multi-GPU training. We have analyzed a production GPU training trace from Microsoft [19, 20]. Among 111,883 tasks in this trace, 96,662 tasks (or 86% of all the tasks) are single-GPU training tasks. Thus, a significant fraction of tasks in real-world workloads currently use a single GPU, and PipeSwitch is applicable to them out of the box. However, these jobs only account for 18% of total GPU hours and we expect the share of multi-GPU jobs to increase in the future. One way to seamlessly use PipeSwitch for synchronous multi-GPU training is to use elastic synchronous training, which allows the dynamic changing of the number of GPUs used for training. Unfortunately, current training frameworks do not have mature support of elastic training. This remains an active research topic and is orthogonal to PipeSwitch.

5 Implementation

We have implemented a system prototype for PipeSwitch with ~3600 lines of code in C++ and Python, and we have integrated it with PyTorch [21].

PyTorch Plugins. We add C++ and Python functions to the GPU memory management module of PyTorch. To share GPU memory between the controller and the workers, we add functions for allocating GPU memory, sharing the GPU

memory to workers through CUDA IPC API, and getting the shared GPU memory. We also add functions which insert the received GPU memory into PyTorch GPU memory pool for a specific CUDA stream or clear the GPU memory from the pool. Note that the shared GPU memory can be inserted into the PyTorch GPU memory pool for multiple times for different CUDA streams, and the controller guarantees that only one of these CUDA streams is active.

Controller and memory daemon. The controller process consists of a TCP thread and a scheduler thread. For better performance, the scheduler and the memory daemon are implemented together. The TCP thread accepts task through TCP from clients, and sends the task to the scheduler thread. The scheduler thread allocates and shares the GPU memory with workers, activates or deactivates workers, sends the task to a worker, and transfers parameters for the corresponding model to the GPU memory. Before starting a task, the user should register the model in the scheduler to notify the controller to load the model from the disk to the CPU memory. When the controller schedules a task, it determines whether to switch to another worker. There is no need for context switching if the application is already loaded in the GPU. If a new model should be loaded to the GPU, the controller will notify the current active worker to stop, and transfers the parameters of the new model to the GPU after receiving the current active worker's reply. Parameters are transmitted to the GPU memory in groups in a pipeline. After each group is transferred, the controller notifies the worker to start computing the corresponding layers.

Worker. The worker process consists of two threads. The termination thread waits for the termination signal from the controller, and notifies the main thread. The main thread manages the DNN models and performs the computation for inference or training. Similar to the controller, the worker also requires the user to register the model before starting a task, so the worker can load the models and add the hooks to wait for parameter transmission or terminate on notification. Note that the worker only loads the model structures, which is small, not the model parameters. The parameters are only stored once in the memory daemon for minimal memory footprint. When the models are loaded, they are attached to different CUDA streams, and their parameters are assigned to locations in the shared GPU memory. Different models might use the same GPU memory location, but the value is not valid until the controller transfers the corresponding parameters to these locations. After loading the models, the worker waits for the scheduler to transfer required parameters for DNN models, and performs inference or training.

6 Evaluation

In this section, we first use end-to-end experiments to demonstrate the benefits of PipeSwitch, and then show the effectiveness of the design choices on each component.

Setup. All experiments are conducted on AWS. We use two EC2 instance types. One is p3.2xlarge, which is configured with 8 vCPUs (Intel Xeon E5-2686 v4), 1 GPU (NVIDIA V100 with 16 GB GPU memory), PCIe 3.0 \times 16, and 61 GB memory. The other is g4dn.2xlarge, which is configured with 8 vCPUs (Intel Platinum 8259CL), 1 GPU (NVIDIA T4 with 16 GB GPU memory), PCIe 3.0 \times 8, and 32 GB memory. The software environment includes PyTorch-1.3.0, torchvision-0.4.2, scipy-1.3.2, and CUDA-10.1. We use PyTorch with our plugins for all mechanisms in comparison for consistency, which provides better results for stop-and-start than native PyTorch from Python-PyPI used in Table 1.

Workloads. The models include ResNet152 [17], Inception_v3 [22] and Bert_base [23], which are standard benchmarks for evaluating DL systems. We use representative configurations for each model. The experiments cover both training and inference. We use single-GPU inference and training tasks as discussed in §4.5. Training tasks periodically checkpoint their models to the host memory, and restart from the latest checkpoint after preemption. The checkpointing frequency of training tasks is set according to the scheduling cycle to minimize checkpointing overhead. The default batch size for training is 32, and that for inference is 8.

Metrics. We use throughput and latency as evaluation metrics. Each number is reported with the *average* of 100 runs. For Figure 6(b), we additionally report the minimum and maximum latencies using the error bar, because the latency of the first batch and those of later batches in one scheduling cycle can differ significantly due to switching overhead.

6.1 End-to-End Experiments

Minimizing end-to-end overhead. In this experiment, a client sends an inference task to a GPU server, and the GPU server preempts the training task to execute the inference task and sends a reply back to the client. We measure the end-to-end latency experienced by the client. We compare the following mechanisms.

- **Ready model.** There is no training task. The process with the required model is already loaded in the GPU. This solution provides the lower bound, which is the lowest latency we can achieve for an inference task.
- **Stop-and-start.** It stops the training task in the GPU, and then starts the inference task. This solution is used by existing systems like Gandiva [24] for task switching, which reported similar *second-scale* overhead.
- **NVIDIA MPS.** This is the multi-process support from NVIDIA which allows the inference process to share the GPU with the training process. We initialize separate processes in advance. The training task occupies the entire GPU memory and does not stop when inference tasks come. CUDA unified memory is used for memory swapping.
- **PipeSwitch.** This is the proposed system. The properties are described in §4.

(a) p3.2xlarge (NVIDIA V100, PCIe 3.0 \times 16).

(b) g4dn.2xlarge (NVIDIA T4, PCIe 3.0 \times 8).

Figure 5: Total latency experienced by the client for different mechanisms.

	p3.2xlarge (NVIDIA V100, PCIe 3.0 \times 16)			g4dn.2xlarge (NVIDIA T4, PCIe 3.0 \times 8)		
	ResNet152	Inception_v3	Bert_base	ResNet152	Inception_v3	Bert_base
Stop-and-start	6475.40 ms	7536.07 ms	6371.32 ms	5486.74 ms	6558.76 ms	5355.95 ms
NVIDIA MPS	307.02 ms	232.25 ms	204.52 ms	259.20 ms	193.05 ms	338.25 ms
PipeSwitch	6.01 ms	5.40 ms	10.27 ms	5.57 ms	7.66 ms	34.56 ms

Table 3: Total overhead, i.e., the difference on total latency between different mechanisms and ready model.

	ResNet152	Inception_v3	Bert_base
p3.2xlarge	3.62 ms	4.82 ms	3.62 ms
g4dn.2xlarge	2.53 ms	5.49 ms	6.57 ms

Table 4: The startup overhead for PipeSwitch to start computing the first layer.

Salus [7] is not directly comparable because it requires the models to be preloaded to the GPU, and has several limitations described in §2.2. Its performance is similar to the ready model when the model is preloaded, and is similar to NVIDIA MPS when the model is in the host memory. Figure 5 shows the latency experienced by the client, and Table 3 shows the total overhead. The total overhead is the difference between the latency of a mechanism and that of the *ready model*. It is obvious that stop-and-start performs the worst, which takes several seconds. The main source of the overhead is CUDA context initialization and first-time library loading operations in PyTorch. NVIDIA MPS has lower overhead compared to stop-and-start, but still incurs several hundred milliseconds overhead, which prevents MPS from meeting strict SLOs. One source of the overhead is the contentions both on the computation and memory of the GPU, as the training task do not stop when an inference task comes. Another source is GPU memory swapping. PipeSwitch performs the best and is close to the lower bound. The overhead of PipeSwitch for most configurations is up to 10ms, except for BERT on T4, which is due to the large model size and the smaller PCIe bandwidth on T4 than that on V100. Since it also takes longer (120ms) to compute BERT on T4 even with the ready model, the relative overhead is acceptable.

We also show the task startup overhead for PipeSwitch in Table 4, which is the difference between the time for

	ResNet152	Inception_v3	Bert_base
# of Layers	464	189	139
Algorithm 1	1.33 s	0.18 s	0.34 s
Only Pruning 1	2.09 s	0.30 s	0.88 s
Only Pruning 2	3.44 h	5.07 s	> 24 h
No Pruning	> 24 h	> 24 h	> 24 h

Table 5: Effectiveness of two pruning techniques.

PipeSwitch to start computing the first layer and that for the ready model to start computing. The startup overhead of PipeSwitch is only a few milliseconds.

Enabling fine-grained scheduling cycles. In this experiment, we compare throughput and end-to-end latency of different mechanisms under different scheduling cycles. We use ResNet152 for both training and inference on eight p3.2xlarge instances, and switch between these two tasks after each scheduling cycle. Figure 6(a) shows the inference throughput. The dashed line is the upper bound, which is the throughput of the ready model assuming no task switching. The throughput of stop-and-start is nearly zero for scheduling cycles smaller than 10 s, because it takes several seconds for task switching. MPS keeps poor throughput around 100 batches per second. We define GPU utilization as the ratio to the upper bound. PipeSwitch has high throughput close to the upper bound, achieving near 100% GPU utilization.

Figure 6(b) shows the average latency of the inference tasks. The dashed line is the lower bound, which is the average latency of the ready model assuming no task switching. The error bar indicates the minimum and maximum latency. Stop-and-start has poor latency because the first batch has several seconds overhead. MPS has about 80 ms average latency, and has several hundred milliseconds latency for the first batch.

(a) Throughput (eight p3.2xlarge instances).

(b) Latency.

Figure 6: Throughput and latency under different scheduling cycles for ResNet on p3.2xlarge.

PipeSwitch incurs only a few milliseconds overhead for task switching, and achieves low latency close to the lower bound.

6.2 Pipelined Model Transmission

To evaluate the effectiveness of pipelined model transmission, we keep all other components of PipeSwitch the same, and compare the following mechanisms discussed in §4.2.

- **No optimization.** It transmits the model layer by layer (with many PCIe calls), and then executes the task.
- **Grouped transmission.** It groups the entire model in one transmission, and then executes the task.
- **Per-layer pipeline.** It transmits model parameters layer by layer. Computation starts, once parameters are transmitted.
- **PipeSwitch.** It is the pipelining mechanism with optimal model-aware grouping in PipeSwitch.

Figure 7 shows the total time measured by the client for an inference task to preempt a training task and finish its inference. No optimization performs the worst in most cases. Grouped transmission improves no optimization by combining the layers of the model into one big tensor and transmitting it in one group. Per-layer pipeline overlaps transmission and computation at the granularity of layer. But because it has PCIe overhead and synchronization overhead for every layer, for the models with many layers but relatively light computation such as ResNet152 and Inception, it can perform worse than grouped transmission and sometimes even no pipeline. PipeSwitch uses model-aware grouping and achieves the best trade-off between pipeline overhead and efficiency. It reduces the total time by up to 38.2 ms compared to other solutions.

(a) p3.2xlarge (NVIDIA V100, PCIe 3.0 × 16).

(b) g4dn.2xlarge (NVIDIA T4, PCIe 3.0 × 8).

Figure 7: Effectiveness of pipelined model transmission.

Note that this reduction is significant, especially considering that it is evaluated when the optimizations on memory management and worker switching have already been applied. We would like to emphasize that to meet strict SLOs, it is important to reduce all overheads for task switching, not only the most significant one.

Table 5 shows the running time of Algorithm 1, as well as the effects of the two pruning techniques mentioned in §4.2. Note that the number of layers includes both weighted and unweighted layers, as both contribute to the computation time. We measure the parameter size and running time for each layer in advance. Algorithm 1 takes only several seconds to compute an optimal grouping strategy, even for ResNet152 which has hundreds of layers. On the contrary, no pruning does not finish for all three models after running for 24 hours.

6.3 Unified Memory Management

To evaluate the effectiveness of unified memory management, we keep all other components of PipeSwitch the same, and compare the following five mechanisms discussed in §4.3.

- **No unified memory management.** Each worker uses `cudaMalloc` to allocate GPU memory, and transmits the model to GPU by its own.
- **No IPC optimization.** The memory daemon handles GPU memory allocation and model transmission, but creates and sends GPU memory handlers to workers. To compare, PipeSwitch simply sends a 64-bit integer offset for the shared GPU memory to workers.
- **No pin memory.** It has all optimizations on unified memory management except that the pages of the memory daemon are not pinned to the main memory.

Figure 8: Effectiveness of unified memory management.

- **CUDA unified memory.** Each worker allocates GPU memory with `cudaMallocManaged`, and CUDA automatically transmits the model to GPU when needed.
- **PipeSwitch.** It is the unified memory management mechanism used by PipeSwitch.

Figure 8 shows the total time measured by the client. First, compared to no unified memory management, PipeSwitch saves 2–23 ms by eliminating the memory allocation overhead with the memory daemon. It is also important to note that no unified memory management requires each worker to keep a copy for each DNN model, which increases the memory footprint. Second, IPC optimization is important, which reduces the latency by 16–48 ms. Without IPC optimization, the latency is even higher than no unified memory management. Third, pinning the pages to the host memory can reduce the latency with a few milliseconds. Finally, CUDA unified memory is not optimized for DL applications, and introduces more than one hundred milliseconds overhead than PipeSwitch. Overall, this experiment demonstrates that all the optimizations on memory management are effective.

6.4 Active-Standby Worker Switching

To evaluate the effectiveness of active-standby worker switching, we keep all other components of PipeSwitch the same, and compare the following mechanisms discussed in §4.4.

- **Two processes.** The process of the old task cleans the GPU environment, and then another process is created and initialized for the new task.
- **One process.** The process cleans the GPU environment for the old task, and reuses the environment for the new task.

Figure 9: Effectiveness of active-standby switching.

- **PipeSwitch** It is the active-standby worker switching mechanism used by PipeSwitch.

Figure 9 shows the results. Two processes perform the worst as it stops the training task and initializes a new process for the new task. The new process needs to create a new CUDA environment, which dominates the total time. One process reuses the CUDA environment, but still pays the overhead to clean the environment. PipeSwitch uses an active-standby worker switching mechanism to parallelize old task cleaning and new task initialization, and incurs minimal overhead. It reduces the latency by 116–307 ms compared to one process, and 5–7 s compared to two processes.

7 Related Work

Many frameworks have been developed for deep learning, such as TensorFlow [25], PyTorch [21] and MXNet [26]. Several algorithms and systems have been designed for executing and scheduling deep learning tasks on clusters, including both training and inference tasks [3, 10, 24, 27–32]. These scheduling solutions are orthogonal and complementary to PipeSwitch. They focus on what scheduling decisions to make, while PipeSwitch focuses on how to realize a scheduling decision. Importantly, PipeSwitch enables the scheduler to change the resource allocation more often with millisecond-scale task switching. Many techniques and systems have been proposed to optimize communication and improve distributed training [8, 9, 15, 33–42]. The most relevant ones are PipeDream [8], ByteScheduler [9] and Poseidon [40]. They use inter-batch pipelining for training of the same task, while PipeSwitch introduces intra-batch pipelining to fast start both

training and inference tasks and enables fast switching across tasks. Other works like vDNN [43] and SwapAdvisor [44] also have GPU memory management module, but they focus on memory management for a single training task of large models, which are not directly comparable to PipeSwitch.

Cluster managers [45–48] typically allocate GPUs to VMs or containers at device granularity. Several solutions have been proposed to share a GPU at application granularity using techniques like library interception [6, 49–53]. They are general-purpose and focus on sharing only a few kernels. As such, they are not suitable for deep learning applications that typically require hundreds of kernels. NVIDIA MPS [6] provides official support for sharing a GPU between multiple processes. It is also not specially designed for deep learning and thus cannot meet strict SLOs of inference tasks as shown in §6. There are many efforts on GPU optimization to improve the performance of running a single task, such as tensor fusion and kernel-level concurrency and scheduling [54–58]. These solutions are complementary to PipeSwitch.

8 Conclusion

We present PipeSwitch, a system that enables GPU-efficient fine-grained time-sharing for multiple DL applications. We introduce pipelined context switching to minimize task switching overhead on GPUs for DL applications. Pipelined context switching includes three key techniques, which are pipelined model transmission, unified memory management and active-standby worker switching. With these techniques, PipeSwitch is able to achieve millisecond-scale task switching time, and enables DL applications on time-sharing GPUs to meet strict SLOs. We demonstrate the performance of PipeSwitch with experiments on a variety of DNN models and GPU cards. PipeSwitch can significantly increase GPU utilization and improve the agility of DL applications.

Abstract

Deep learning training on a shared GPU cluster is becoming a common practice. However, we observe severe sharing anomaly in production multi-tenant clusters where jobs in some tenants experience worse queuing delay than they would have in a private cluster with their allocated shares of GPUs. This is because tenants use *quota*, the number of GPUs, to reserve resources, whereas deep learning jobs often use GPUs with a desirable *GPU affinity*, which quota cannot guarantee.

HiveD is the first framework to share a GPU cluster *safely*, so that such anomaly would never happen by design. In HiveD, each tenant reserves resources through a Virtual Private Cluster (VC), defined in terms of multi-level *cell* structures corresponding to different levels of GPU affinity in a cluster. This design allows HiveD to incorporate any existing schedulers within each VC to achieve their respective design goals while sharing the cluster safely.

HiveD develops an elegant *buddy cell allocation* algorithm to ensure *sharing safety* by efficiently managing the dynamic binding of cells from VCs to those in a physical cluster. A straightforward extension of buddy cell allocation can further support low-priority jobs to scavenge the unused GPU resources to improve cluster utilization.

With a combination of real deployment and trace-driven simulation, we show that: (i) sharing anomaly exists in three state-of-the-art deep learning schedulers, incurring extra queuing delay of up to 1,000 minutes; (ii) HiveD can incorporate these schedulers and eliminate the sharing anomaly in all of them, achieving separation of concerns that allows the schedulers to focus on their own scheduling goals without violating sharing safety.

1 Introduction

Deep learning training is becoming a major computing workload on a GPU cluster. It is a common practice for an organization to train deep learning models in a multi-tenant GPU cluster, where each tenant reserves resources using a quota that consists of the number of GPUs and other associated resources such as CPU and memory [52].

Surprisingly, in a production multi-tenant GPU cluster, we have observed unexpected anomalies where a tenant's deep learning training jobs wait significantly longer for GPUs than

they would do in a private cluster whose size equals to the tenant's quota. This is because the current resource reservation mechanism is based on *quota*, i.e., the number of GPUs. Quota cannot capture the GPU *affinity* requirement of training jobs: e.g., an 8-GPU job on one node usually runs significantly faster than on eight nodes [41, 52, 86]. Quota cannot guarantee a tenant's GPU affinity like the tenant's private cluster does. As a result, multi-GPU jobs often have to wait in a queue or run at a relaxed affinity, both resulting in worse performance (longer queuing delay or slower training speed).

In this paper, we present HiveD, a resource reservation framework to share a GPU cluster for deep learning training that guarantees *sharing safety* by completely eliminating sharing anomalies. Instead of using quota, HiveD presents each tenant a virtual private cluster (abbreviated as VC) defined by a new abstraction: *cell*. Cell uses a multi-level structure to capture the different levels of affinity that a group of GPUs could satisfy. Those cell structures naturally form a hierarchy in a typical GPU cluster; e.g., from a single GPU, to GPUs attached to a PCIe switch, to GPUs connected to a CPU socket, to GPUs in a node, to GPUs in a rack, and so on.

With cell, HiveD virtualizes a physical GPU cluster as a VC for each tenant, where the VC preserves the necessary affinity structure in a physical cluster. This allows any state-of-the-art deep learning scheduler to make scheduling decisions within the boundary defined by the VC, without affecting the affinity requirement from other VCs, hence ensuring sharing safety. In this way, HiveD achieves the separation of concerns [47]: It focuses on the resource reservation mechanism and leaves other resource allocation goals to VC schedulers (e.g., cluster utilization and job completion time).

HiveD develops an elegant and efficient *buddy cell allocation* algorithm to bind cells from a VC to a physical cluster. Buddy cell allocation advocates dynamic cell binding over static binding for flexibility. It dynamically creates and releases the binding of cells in a VC to GPUs in the physical cluster, while providing *proven* sharing safety despite unpredictable workloads. Moreover, the algorithm can be naturally extended to support preemptible low-priority jobs to scavenge unused cells opportunistically to improve overall utilization. Combined, HiveD achieves the best of both a private cluster (for guaranteed availability of cells independent of other tenants) and a shared cluster (for improved utilization and access to more resources when other tenants are not using them).

We evaluate HiveD using experiments on a 96-GPU real

*Equal contribution.

cluster and trace-driven simulations. The evaluation shows that (i) sharing anomaly exists in all the evaluated state-of-the-art deep learning schedulers [41, 52, 86]; (ii) HiveD eliminates all sharing anomalies, decreases excessive queuing delay from 1,000 minutes to zero, while preserving these schedulers’ design goals; (iii) HiveD guarantees sharing safety regardless of cluster loads, whereas a quota-based cluster can result in $7\times$ excessive queuing delay for a tenant under a high load.

We have open-sourced HiveD [17], and integrated it in OpenPAI [20], a Kubernetes-based deep learning training platform. It has been deployed in multiple GPU clusters serving research and production workloads at scale, including a cluster of 800 GPUs where HiveD has been up and running reliably for more than 12 months (as of Nov. 2020).

In summary, this paper makes the following contributions:

- We are the first to observe and identify sharing anomaly in production multi-tenant GPU clusters for deep learning training.
- We define the notion of sharing safety against the anomaly and propose a new resource abstraction, i.e., multi-level cells, to model virtual private clusters.
- We develop an elegant and efficient buddy cell allocation algorithm to manage cells with proven sharing safety, and to support low-priority jobs.
- We perform extensive evaluations both on a real cluster and through simulation, driven by a production trace, to show that HiveD achieves the design goals in terms of sharing safety, queuing delay, and utilization.

2 Background and Motivation

The current approach of managing a multi-tenant GPU cluster. In large corporations, a large-scale GPU cluster is usually shared by multiple business teams, each being a tenant contributing their resources (budget or hardware). The tenants share the GPU cluster in a way similar to sharing a CPU cluster [1, 52]: Each tenant is assigned a number of tokens as its *quota*. Each token corresponds to the right to use a GPU along with other types of resource. The quota denotes an expectation that the tenant can access “at least” the share of resources it contributes.

To improve training speed in the cluster, a user usually specifies a *GPU affinity requirement* for a deep learning job [52, 86]. For example, it is often desirable for a 64-GPU job to run in the 8×8 affinity, i.e., to run the job on 8 nodes each with 8 GPUs, instead of 64×1 , i.e., 64 nodes each using 1 GPU. Given the affinity requirements, the resource manager will satisfy them in a guaranteed (hard) or best-effort (soft) manner. If there is no placement satisfying a job’s affinity requirement, the job will wait in the queue if it has a hard

Figure 1: Sharing anomaly: a tenant suffers longer queuing delay in a shared cluster than in its own private cluster.

affinity requirement or will be scheduled with relaxed affinity if the requirement is soft (e.g., 64×1 as opposed to 8×8).

Sharing anomaly. In a production GPU cluster described in [52], we observe an anomaly from user complaints: a tenant is assigned a quota of 64 GPUs but reports that it cannot run a single (and the only) 8×8 deep learning job. Such anomaly arises because the tenant’s assigned affinity has been fragmented, not by its own job(s) but by jobs from other tenants. Even though the tenant has enough GPU quota, the 64-GPU job has to wait in a queue or execute with degraded performance with relaxed affinity. The promise to the tenant that it can access at least its share of resource is broken.

Sharing anomaly appears similar to external fragmentation in memory management [54], if we liken a tenant to a program. The important difference however is that, in a shared GPU cluster, tenants expect their resource shares to be guaranteed. In the above real-world example, the fragmentation is due to other tenants, and the suffering tenant can hardly do anything except to complain to the cluster operator. Sharing anomaly can easily happen when jobs with lower affinity requirement (e.g., single-GPU jobs) from a tenant add to the fragmentation of global resources (due to varying job arrival and completion times), making jobs with higher affinity requirement (e.g., 8×8 -GPU jobs) from other tenant(s) not able to run, even with sufficient quota. Apparently, quota can reserve only the quantity of resources, but not the affinity of resources. Hence it cannot automatically get around the external fragmentation across tenants. We call this phenomenon “sharing anomaly” because the sharing of a tenant’s resource impacts the tenant negatively. Therefore, in the above case, rather than sharing with others, the wised up tenant would prefer to run a private cluster with eight 8-GPU nodes to adhere to its 8×8 GPU affinity with zero queuing delay.

A multi-tenant cluster is said to suffer from *sharing anomaly* if a tenant’s sequence of GPU requests (possibly with affinity requirement) cannot be satisfied in this shared cluster; whereas it can be satisfied in a private cluster whose size equals to the tenant’s quota. Figure 1 highlights how severe sharing anomaly could become, selected from a trace-driven simulation in a setup similar to [52] (more details in §5). The figure shows the job queuing anomaly of one tenant in a shared cluster when jobs have hard affinity requirement. In the 10-day submission window (denoted as X-axis), the

tenant's average job queuing delay (denoted as Y-axis) in the shared cluster is significantly higher than that in its own private cluster.¹ In particular, the jobs submitted around Day 1 have to stay in the queue for more than 8,000 minutes (5 days) while they have zero queuing delay in the private cluster! Moreover, tenants having reserved large resources tend to suffer the most. Consequently, we have witnessed important corporate users reverting to private clusters, after experiencing high queuing delay brought by severe sharing anomalies.

One approach to reducing sharing anomaly is to devise a scheduling policy to minimize global resource fragmentation. This makes the design of a deep learning scheduler even more complex, which already has to manage sophisticated multi-objective optimizations. For example, minimizing global fragmentation may decrease job performance due to increased inter-job interference [86]. Therefore, we propose to separate the concern of sharing anomaly from other resource allocation objectives [47]. Instead of developing a complicated scheduler that achieves all possible goals, we design HiveD, a resource reservation framework that focuses on eliminating sharing anomaly, and provides a clean interface to incorporate any state-of-the-art deep learning schedulers to address concerns like cluster utilization [86], job completion time [41, 66], and fairness [29, 60].

3 HiveD Design

3.1 System Overview

HiveD proposes to guarantee *sharing safety* (i.e., eliminating sharing anomaly as described in §2) as a prerequisite of sharing a GPU cluster. Specifically, if a sequence of GPU requests with affinity requirements can be satisfied in a private cluster, it should be satisfied in the corresponding virtual private cluster and the shared physical cluster.

Figure 2: System architecture: a two-layer design.

Figure 2 illustrates the overall system architecture. HiveD's abstraction of GPU resources is divided into two layers, i.e., the layer of Virtual Private Clusters (VCs) and the layer of physical cluster. HiveD presents each tenant a VC. Each VC is pre-assigned a set of *cells*, a novel resource abstraction that

¹The anomaly is dominated by queuing delay in the job completion time when the affinity requirement is hard. Details discussed in §5.1.

captures not only quota, but also the affinity structure of GPUs (the number inside each cell in the figure shows the number of affinitized GPUs of the cell). The cells assigned to a VC form a VC view with the GPU affinity structure identical to that of the corresponding private cluster. Any third-party scheduler can be incorporated to work on the VC view to achieve a certain goal of resource allocation [41, 52, 60, 86]. Moreover, HiveD ensures that any scheduling decision is constrained within the boundary defined by the VC view, as if happening on its private cluster, thus guaranteeing sharing safety.

Cells in a VC are logical. When a job uses a GPU in a logical cell, e.g., one GPU in the 4-GPU cell in the VC view of Tenant A in Figure 2, the logical cell will be bound to a physical cell allocated from the physical cluster, denoted at the bottom of Figure 2. If none of the GPUs is in use, the logical cell will be unbound from the physical cluster. To improve utilization, preemptible low-priority jobs can scavenge idle GPUs opportunistically. Such dynamic binding is more flexible than static binding: a dynamic binding can avoid a physical cell whose hardware is failing; it can avoid cells used by low-priority jobs to reduce preemptions; it can also pack the cells to minimize the fragmentation of GPU affinity.

To achieve this, HiveD adopts *buddy cell allocation*, an efficient and elegant algorithm, to handle the dynamic binding. A key challenge of dynamic binding is to guarantee the safety property in response to dynamic workloads, that is, jobs arrive unpredictably and request varying levels of cells. Buddy cell allocation algorithm is proven to ensure sharing safety: any legitimate cell request within a VC is guaranteed to be satisfied. The algorithm can also support low-priority jobs. Figure 2 shows a possible cell allocation, where cells in a physical cluster are bound to those defined in two VCs, and also to a low-priority job.

In §3.2, we explain the details of cells and show how a VC can be defined by cells. And in §3.3, we introduce the buddy cell allocation algorithm, prove its sharing safety guarantee, and extend it to support low-priority jobs.

3.2 Virtual Private Cluster with Cells

To model a (private) GPU cluster, HiveD defines a *hierarchy of multi-level cell structures*. A *cell* at a certain level is the corresponding collection of affinitized GPUs with their inter-connection topology. Each virtual private cluster (VC) is then defined as number of cells at each level, modeled after the corresponding private cluster.

Figure 3 shows an example, where there are 4 levels of cell structures: at the GPU (level-1), PCIe switch (level-2), CPU socket (level-3), and node levels (level-4), respectively. The cluster has one rack that consists of four 8-GPU nodes, shared by three tenants, A, B, and C. The cell assignment for each tenant's VC is summarized in the table in Figure 3. Tenants A and B's VCs both reserve one level-3 cell (4 GPUs under the same CPU socket), one level-2 cell (2 GPUs under the same

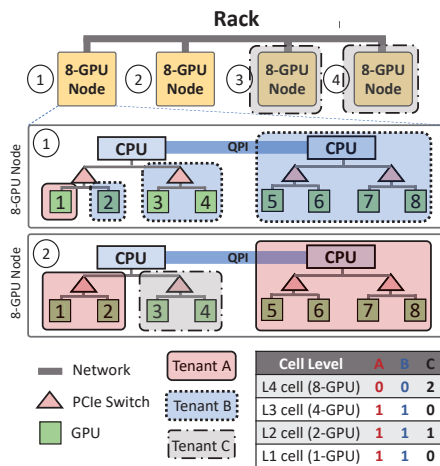

Figure 3: Multi-level cell assignment for a rack: an example.

PCIe switch), and one level-1 cell (single GPU). Tenant C is a larger tenant, which reserves two level-4 cells (node level) and one level-2 cell. Given the VC views defined in Figure 3, HiveD can adopt a third-party scheduler [41, 52, 60, 86] to work on the views. From the third-party scheduler’s point of view, the VC view is no different from a private cluster consisting of nodes with different sizes (i.e., different level of cells). For example, the scheduler can treat tenant C as a private cluster with two 8-GPU nodes and one 2-GPU node, despite the fact that the 2-GPU node is actually a level-2 cell. Note that a third-party scheduler can use any GPUs in the assigned cells. For example, it can schedule two 2-GPU jobs to a 4-GPU (level-3) cell: a cell is the granularity of resource reservation in VCs and the physical cluster, but not necessarily the job scheduling granularity of a third-party scheduler.

In the cell hierarchy, a level- k cell c consists of a set S of level- $(k-1)$ cells. The cells in S are called *buddy cells*; buddy cells can be merged into a cell at the next higher level. We assume cell demonstrates *hierarchical uniform composability*: (i) all level- k cells are equivalent in terms of satisfying a tenant request for a level- k cell, and (ii) all level- k cells can be split into the same number of level- $(k-1)$ cells.

Heterogeneity. A heterogeneous cluster can be divided into multiple homogeneous ones satisfying hierarchical uniform composability. This is logical in practice because a production cluster typically consists of sufficiently large homogeneous sub-clusters (each often a result of adding a new GPU model and/or interconnect) [52]. Users typically use homogeneous GPUs for a job for better performance and specify the desired GPU/topology type (e.g., V100 vs. K80).

Initial cell assignment. A cluster provider must figure out the number of cells at each level to be assigned to each tenant’s VC. A VC assignment is *feasible* in a physical cluster if it can accommodate all cells assigned to all VCs; that is, there exists a one-to-one mapping from the logical cells in each VC to the physical cells in the physical cluster. The initial cell

Algorithm 1 Buddy Cell Allocation Algorithm

```

1: // Initial state of free_cells: only top level has cells
2: procedure ALLOCATECELL(cell_level)
3:   if free_cells[cell_level].size() == 0 then
4:     c = AllocateCell(cell_level+1)
5:     cells = Split(c)           ▷ Split cells are buddies
6:     free_cells[cell_level].extend(cells)
7:   Return free_cells[cell_level].pop()
8:
9: procedure RELEASECELL(cell)
10:  if cell.buddies  $\subseteq$  free_cells[cell.level] then
11:    higher_cell = Merge(cell, cell.buddies)
12:    free_cells[cell.level].remove(cell.buddies)
13:    ReleaseCell(higher_cell)
14:  else
15:    free_cells[cell.level].add(cell)

```

assignment for VCs depends on factors like budget, business priority, and workload, thus it is handled outside of HiveD (§6 for further discussion). A cluster might spare more physical resources than the assigned cells to handle hardware failures.

Note that dashed lines in Figure 3 illustrate only one possible cell binding. HiveD advocates dynamic cell binding for flexibility, which reduces job preemption and fragmentation of GPU affinity. §5.3 confirms its benefits over static binding.

3.3 Buddy Cell Allocation Algorithm

HiveD manages the dynamic binding between the logical cells in VCs and the physical cells in the physical cluster, and handles requests to allocate and release cells. This is done by the *buddy cell allocation* algorithm. The algorithm maintains for each VC the information of (i) the corresponding physical cell for each allocated logical cell (i.e., the binding); (ii) a global free list at each cell level k to track all unallocated physical cells at that level. The algorithm always keeps available cells at the highest possible level: for example, if all the buddy cells at level- $(k-1)$ are available for a cell at level- k , only the cell at level- k is recorded. And the algorithm aims to keep as many higher-level cells available as possible. Algorithm 1 shows the pseudo-code of the algorithm.

To allocate a level- k cell in a VC, the algorithm starts at level- k and goes up the levels if needed: it first checks whether a free level- k cell is available and allocates one if available. If not, the algorithm will move up level-by-level, until a free level- l cell is available, where $l > k$. The algorithm will then split a free level- l cell recursively into multiple lower-level cells, until a level- k cell is available. Each splitting produces a set of buddy cells at the next lower level, which will be added to the free list at that lower level. One of those new low-level cells is again split until free level- k cells are produced.

The cell release process also works in a bottom-up manner. When a level- k cell c is released, the algorithm adds c into

the free list of level- k cells and checks the status of c 's buddy cells. If all of c 's buddy cells are free, the algorithm will merge c and its buddy cells into a level- $(k+1)$ cell. The merge process continues recursively while going up the levels, until no cells can be merged. In this way, the buddy cell allocation algorithm reduces GPU fragmentation and creates opportunities to schedule jobs that require higher-level cells.

Before processing an allocation request, the algorithm ensures the request is *legal* in that it is within the assigned quota for the VC at this cell level. HiveD stores the cell assignment in a table r , where a tenant t 's preassigned number for level- k cells is stored in $r_{t,k}$. The buddy cell allocation algorithm guarantees to satisfy all legal cell requests under a feasible initial VC assignment, which is formally stated in Theorem 1.

Theorem 1. *Buddy cell allocation algorithm satisfies any legal cell allocation, under the condition of hierarchical uniform composability, if the original VC assignment is feasible.*

Proof. Denote as $r_{t,k}$ the number of level- k cells reserved by tenant t , i.e., cell assignment for t . Denote as r_k the number of reserved level- k cells for all tenants, i.e. $r_k = \sum_t r_{t,k}$. Denote as $a_{t,k}$ the number of level- k cells that have already been allocated to t by the buddy cell allocation algorithm. Cell allocations that maintain $a_{t,k} \leq r_{t,k}$ are legal. Denote as a_k the number of allocated level- k cells for all tenants (i.e., $a_k = \sum_t a_{t,k}$), and f_k the number of free level- k cells in the physical cluster, and h_k the number of level- $(k-1)$ buddy cells that a level- k cell can be split into (hierarchical uniform composability). Define F_k as the number of level- k cells that can be obtained by splitting the higher level cells while still satisfying the safety check for the cell assignment. F_k can be calculated by Eqn. (1).

$$F_k = \begin{cases} (f_{k+1} + F_{k+1} - (r_{k+1} - a_{k+1}))h_{k+1} & k < \hat{k}; \\ 0 & k = \hat{k}, \end{cases} \quad (1)$$

where \hat{k} is the highest level.

To prove the theorem, we prove the following invariant:

$$r_k - a_k \leq f_k + F_k \quad \forall k = 1, 2, \dots, \hat{k}. \quad (2)$$

The L.H.S. is the number of level- k cells all tenants have yet to allocate, and the R.H.S. is the number of available level- k cells the cluster can provide.

We prove by induction on discrete time slots. Denote as w the sequence number of time slots. A change of the cluster state will increase w by 1. When $w = 0$, $a_k = 0$, the invariant (2) holds as long as the original VC assignment is feasible. Assuming the invariant holds at time $w = i$, we shall prove the invariant still holds at time $w = i + 1$ after a tenant allocates a legal level- k cell.

Because the allocation is legal, $a_k < r_k$ should hold at time $i + 1$. In order to satisfy the invariant (2), either $f_k > 0$ or $f_k = 0$.

When $f_k > 0$, according to Algorithm 1, $a_k = a_k + 1$ and $f_k = f_k - 1$ after an allocation of level- k cell at time $i + 1$. The gap of both sides in the invariant remains constant, thus it still holds.

When $f_k = 0$, i.e., no free cell at level- k , the algorithm will split a level- k' cell by finding the smallest k' where $k' > k$ and $f_{k'} > 0$. In this case, the invariant remains true as in the $f_k > 0$ case, while the gap of the invariant at level- k' will decrease by 1. If the invariant at the level- k' breaks after cell splitting, it would mean $r_{k'} - a_{k'} = f_{k'} + F_{k'}$ at time $w = i$. By definition, $F_{k'}$ should be 0 at time $w = i$. But since $a_k < r_k$ (because the allocation request is legal), thus the invariant (2) cannot hold true at level k . This leads to a contradiction. Therefore, the invariant must hold at level k' after splitting a level- k' cell. Following the same step, we can prove the invariant holds at level k'' when the algorithm recursively splitting a level- k'' cell, where $k'' \in [k+1, k'-1]$. Hence the invariant holds on all levels when $f_k = 0$.

Merging the buddy cells can only either increase or keep the gap of the invariant and thus it still holds. Q.E.D. \square

The buddy cell allocation algorithm has the time complexity of $O(\hat{k})$, where \hat{k} is the number of levels, and can therefore scale to a large GPU cluster efficiently: \hat{k} is usually 5, from the level of racks to the level of GPUs.

Hierarchical uniform composability ensures the algorithm's correctness and efficiency: it does not have to check explicitly after each split whether or not the subsequent legal allocation requests are satisfiable. Instead, it just needs to check whether every allocation request is legal. For the case where cells are heterogeneous (e.g., due to different GPU models or different inter-GPU connectivities), HiveD partitions the cluster into several pools within which cells at the same level are homogeneous, and applies Algorithm 1 in each pool.

The algorithm resembles buddy memory allocation [56], hence the name. Beyond reducing fragmentation efficiently [35], our key contribution here is making the non-obvious observation: GPU affinity can be modeled as cells, thus making buddy allocation applicable. Moreover, we prove that buddy cell allocation satisfies sharing safety, while traditional buddy allocation does not have such safety concern and hence does not provide this guarantee. Our algorithm also reveals the different characteristics of GPU hierarchy vs. memory regions; for example, the hierarchical uniform composability condition captures GPU hierarchy and is a generalization of the artificially-created power-of-2 rule in buddy memory allocation. Our algorithm also supports priority (elaborated next).

Allocating low-priority cells. The buddy cell allocation algorithm can be naturally extended to support low-priority jobs (a.k.a. opportunistic jobs), whose allocated cells can be preempted by high-priority jobs. Supporting such low-priority jobs helps improve overall GPU utilization, without compromising the sharing safety guarantees provided to the

VCs. HiveD maintains two cell views, one for allocating high-priority (guaranteed) cells, and the other for allocating the low-priority cells. Both views manage the same set of cells in the physical cluster using the same cell allocation algorithm (i.e., Algorithm 1). Similar to YARN [83] and Omega [73], HiveD enforces strict priority where high-priority bindings can preempt low-priority cells. Note that preempting a low-priority job could lead to loss of training progress if its checkpoint is stale. When allocating low-priority cells, HiveD chooses the cells farthest away from those occupied by high-priority jobs (e.g., a non-buddy cell of a high-priority cell) in order to minimize the chance of being preempted. Likewise, when allocating high-priority cells, HiveD chooses the free cells with the fewest GPUs used by low-priority jobs to reduce the chances of unnecessary preemptions. With a similar approach, we can extend HiveD to support multiple levels of priority.

HiveD adopts weighted max-min fairness [37,49] to decide the numbers of low-priority cells allocated to tenants. One could incorporate other state-of-the-art fairness metrics [60] to decide the fair share among tenants.

4 Implementation

HiveD has been integrated in OpenPAI, an open-source deep learning training platform [20] based on Kubernetes [28]. It has been deployed to multiple GPU clusters, managing various types of GPUs from NVIDIA Volta [19] to AMD MI50 [14]. This includes a cloud cluster with 800 heterogeneous GPUs (200 Azure GPU VMs) where HiveD has been running reliably for 12+ months (as of Nov. 2020). HiveD has served research and production workloads at scale, ranging from long-lasting training of large NLP models (e.g., BERT large [34]) to AutoML experiments that consist of hundreds of short-lived 1-GPU jobs. Next we share our experience in implementing and operating HiveD.

HiveD is implemented in 7,700+ lines of Go codes. In addition, it has a few more thousands of lines of JavaScript, Shell scripts, and YAML specifications to integrate with the training platform. It is implemented as a *scheduler extender* [9], a standalone process that works in tandem with the Kubernetes default scheduler (kube-scheduler [7]). This way, HiveD is able to reuse kube-scheduler’s basic scheduling logic.

Cell specification. HiveD relies on a cell specification to understand the cell hierarchies in a cluster and the cell assignments for VCs. Figure 4 presents an example specification for a heterogeneous GPU cluster with two racks of NVIDIA V100 GPUs and one rack of NVIDIA P100 GPUs. `cellHierarchy` describes the two types of multi-level cell structures. `physicalCluster` specifies the cell layout in a physical cluster: two V100 racks and one P100 rack, and their IP addresses. With `physicalCluster` and `cellHierarchy`, `vcAssignment` specifies the cell assignment for a VC: the only P100 rack and 4 V100 nodes are assigned to the VC `vc1`.

```
cellHierarchy:
- name: V100-RACK # cell hierarchy for V100 rack
  hierarchy:
  - cellType: V100-GPU # level-1 cell
  - cellType: V100-PCIe-SWITCH
    splitFactor: 2 # split to 2 level-1 cells
  - cellType: V100-CPU-SOCKET
    splitFactor: 2
  - cellType: V100-NODE
    splitFactor: 2
  - cellType: V100-RACK # level-5 (top-level) cell
    splitFactor: 8
- name: P100-RACK # cell hierarchy for P100 rack
  hierarchy:
  - cellType: P100-RACK # omit lower-level cells
    splitFactor: 8

physicalCluster:
- topLevelCellType: V100-RACK
  topLevelCellAddresses:
  - 10.0.1.0~7
  - 10.0.2.0~8
- topLevelCellType: P100-RACK
  topLevelCellAddresses:
  - 10.0.3.0~7

vcAssignment:
- vc: vc1 #omit other VCs
  cells:
  - subCluster: P100-RACK
    cellType: P100-RACK
    cellNumber: 1
  - subCluster: V100-RACK
    cellType: V100-NODE
    cellNumber: 4
```

Figure 4: A simplified cell specification (in .yaml format).

A third-party scheduler can leverage the VC view of `vc1` to make scheduling decisions, as if `vc1` is a physical cluster. Our release of HiveD comes with a tool to automatically detect infeasible VC assignments in the specification.

Handling faulty hardware. When multiple free cells are available, the buddy cell allocation algorithm allows HiveD to avoid using faulty hardware. It prefers binding to a healthy cell when possible. When a VC has no other choice, HiveD will proactively bind to a faulty physical cell so that the third-party scheduler in the VC can see the faulty hardware and avoid using GPUs in the cell.

Fault tolerance. The HiveD process itself is also fault-tolerant. It is deployed as a Kubernetes StatefulSet [10] to ensure a single running instance. HiveD maintains several centralized in-memory data structures to keep all the run-time information used for cell allocation (e.g., the free cell list, and the cell allocation list). To reduce overheads, these data structures are not persistent. HiveD partitions and stores the cell binding decision for each pod in its “pod annotation”, which is kept reliably by Kubernetes. If a job has multiple pods, the annotation in each pod stores the cell binding decisions for all the pods of the job. When recovering from a crash, HiveD reconstructs all the in-memory data structures like the cell allocation list and the free cell list from the pod annotation in all the running pods. Moreover, with the cell binding decisions stored in pod annotation, HiveD could detect whether or not there are unscheduled pods and resume the scheduling for the unscheduled ones. In case none of the pods of a job gets scheduled when HiveD crashes, the job manager, another single instance StatefulSet, will receive a timeout and resubmit the job. The fault tolerance of the third-party scheduler is handled by the scheduler itself.

Reconfiguration. We observe that a cluster operator may

occasionally change the cell specification on-the-fly to reconfigure a cluster: adding, removing, or upgrading hardware; adjusting cell assignment for a VC. HiveD treats reconfiguration similar to crash recovery. The difference is during a reconfiguration HiveD will check if there is any inconsistency between the old cell bindings in the pod annotations and the new cell specification. For example, the total bound cells from a VC may exceed the new cell assignment. In this case, HiveD will downgrade the jobs with the inconsistent pods to low-priority jobs and preempt them when necessary.

The failure handling and reconfiguration capabilities of HiveD have been tested and verified on all the deployed OpenPAI clusters. There are occasional hardware issues that require human intervention, e.g., power failures, GPU hardware failures. HiveD handles the decommission and recommission of hardware smoothly. To fully validate its failure handling capability, we run HiveD on an 800-GPU cluster on 200 Azure low-priority VMs [78]. The 200 Azure VMs consist of 125 NC24 [15] (NVIDIA Tesla K80) and 75 NV24 [16] (NVIDIA Tesla M60) series VMs, which could get preempted anytime. HiveD treats a preempted VM as a faulty cell. When a preempted VM resumes, HiveD will re-include it in the cluster just as a faulty cell turning normal. We observe up to 75% of the preemption rate (150 out of 200 VMs) in the cluster. And HiveD handles the preemptions well. When a VM gets preempted, the deep learning job running atop will migrate to other available GPUs or wait in a queue when GPUs are unavailable. The waiting job will get scheduled within one minute when a desired VM resumes from preemption.

5 Evaluation

We evaluate HiveD using experiments on a 96-GPU cluster on a public cloud and trace-driven simulations on a production workload. Overall, our key findings include:

- HiveD eliminates all the sharing anomalies found in all the tested schedulers. Excessive job queuing delay decreases from 1,000 minutes to zero.
- HiveD can incorporate the state-of-the-art deep learning schedulers and complement them with sharing safety, while maintaining their scheduling goals and preserving sharing benefits with low-priority jobs.
- HiveD guarantees sharing safety under various cluster load. In contrast, high cluster load in quota-based scheme can result in $7\times$ excessive queuing delay.
- HiveD’s buddy cell allocation algorithm reduces job preemption by 55% with dynamic binding and fragmentation of GPU affinity by up to 20%.

Experimental setup. We collect a 2-month trace from a production cluster of 279 8-GPU nodes (2,232 GPUs). The

Tenant	1-GPU	2-GPU	4-GPU	8-GPU	≥ 16 -GPU	Total	Quota

Table 1: Number of jobs with different GPU demands and quota assignment of tenants.

trace contains 141,950 deep learning training jobs, each specifying its submission time, training time, number of GPUs with the affinity requirement, and the associated tenant. The cluster is shared by 11 tenants. Table 1 shows each tenant’s quota assignment in the real deployment and the distribution of a job’s GPU number. Please refer to [52] for more details of the trace and its collection and analysis methodology. We run experiments in a 96-GPU cluster deployed on Azure. The cluster consists of 24 virtual machines (NC24 [15]), each with 4 NVIDIA K80 GPUs.

5.1 Sharing Safety: Cluster Experiments

In this section, we examine sharing safety in traditional quota-based scheme and HiveD on the deployed cluster.

Methodology. We collect a 10-day trace from the original 2-month production trace. To approximate the load of the 2,232-GPU cluster on a 96-GPU one, we scale down the number of jobs by randomly sampling from the 10-day trace proportionally (96 out of 2,232). Due to security reasons, we do not have access to the code and data of the jobs. Therefore, we replace the jobs with 11 popular deep learning models in domains of Natural Language Processing (NLP), Speech, and Computer Vision (CV) from GitHub (summarized in Table 2). We mix these models following a distribution of NLP:Speech:CV = 6:3:1, as reported in [86].

We test three state-of-the-art deep learning schedulers: YARN-CS [52], Gandiva [86], and Tiresias [41]. We obtained the source code of Gandiva and Tiresias [11], and use the same implementation in our experiments. YARN-CS is a modified YARN Capacity Scheduler. It packs jobs as close as possible to spare good GPU affinity, similar to [52]. We further refine the preemption policy of YARN-CS: instead of preempting the latest jobs, it preempts low-priority jobs based on the desired GPU affinity requirement. Otherwise, the baseline of YARN-CS will be much worse. To enforce quota in Tiresias, jobs exceeding the quota will get scheduled in a low-priority queue, which is also sorted by Tiresias. For each scheduler, we compare: (i) each tenant running its jobs in a private cluster with the capacity set to its quota; (ii) tenants sharing the

Type	Model	Dataset
NLP	Bi-Att-Flow [74]	SQuAD [68]
	Language Model [90]	PTB [61]

	AlexNet [57]	ImageNet
	VGG16 [77]	ImageNet
	VGG19	ImageNet

Table 2: Deep learning models used in the experiments [86].

cluster using quota; and (iii) tenants sharing the cluster using the scheduler with HiveD enabled. In a shared cluster, all schedulers will schedule jobs as high-priority ones if the tenant has sufficient resources in its quota or VC, otherwise the job will be scheduled as a low-priority one.

In HiveD’s experiments, we use a cell hierarchy with four levels: node (8-GPU), CPU socket (4-GPU), PCIe switch (2-GPU), and GPU. We assign each tenant a set of node-level cells with a total number of GPUs equal to its quota. To model the cell hierarchy after the production cluster, we treat every two contiguous 4-GPU VMs as one logical 8-GPU node (i.e., one 8-GPU node level cell). Similar to [86], to speed up replaying the 10-day trace, we “fast-forward” the experiment by instructing running jobs to skip a number of iterations whenever there are no scheduling events, including job arrival, completion, preemption, migration, etc. The time skipped is calculated by measuring job training performance in a stable state. To enable the skipping, HiveD bypasses the kube-scheduler and talks to job pods directly.

The trace shows that the GPU affinity requirements of most jobs are hard, showing that users are not willing to sacrifice training performance. In this case, queuing delay is the major source of sharing anomaly in the overall job completion time (JCT). Note that JCT consists of queuing delay and actual training time, and job training time is highly deterministic as long as GPU affinity is the same [86]. Therefore, we show the queuing delay to illustrate the sharing anomaly when job’s GPU affinity requirement is hard. We also evaluate the JCT when job’s affinity requirement is soft.

Results. Figure 5(a) shows the queuing delay of jobs from tenant prod-a using the three schedulers. The X-axis denotes the job submission time. The Y-axis denotes the queuing delay averaged in a 12-hour moving window. Figure 5(a) shows that all the three schedulers demonstrate sharing anomaly without HiveD. For YARN-CS, from Day 8 to Day 10, jobs in prod-a suffer 1,000 minutes longer queuing delay in a quota-based cluster than in its private cluster. Although YARN-CS packs jobs as compactly as possible, a large number of 1-GPU jobs from other tenants with varying durations make the available GPUs affinity highly fragmented. As a result, multi-GPU jobs have to wait a long time for the desired affinity. Since the

(a) Average queuing delay of Tenant prod-a

(b) Average job completion time across all tenants

Figure 5: The experiments for the three schedulers in a 96-GPU cluster, with and without HiveD.

majority of jobs in prod-a use multiple GPUs (Table 1), the tenant suffers more from sharing anomaly.

Similarly, in Gandiva, jobs in prod-a suffer up to 400 minutes longer queuing delay in the shared cluster on Day 2 and Day 8. The excessive queuing delay is shorter than that in YARN-CS because Gandiva can mitigate the fragmentation of GPU affinity by job migration. However, unaware of cells in a VC, Gandiva’s greedy algorithm may accidentally migrate jobs to improve the job performance in a tenant at the expense of other tenant’s GPU affinity, thus violating safety. For example, Gandiva may greedily migrate away an interfering job in a VC while increasing the fragmentation and violating the sharing safety of other VCs. In contrast, HiveD achieves separation of concerns, allowing Gandiva to migrate jobs for its own goal without worrying about sharing safety. We will discuss job migration more in §6.

In Tiresias, Tenant prod-a shows sharing anomaly on Day 2 and Day 8. With quota enforcement, Tiresias suffers over 330 minutes longer queuing delay than that in its private cluster. To reduce job completion time (JCT), Tiresias prefers running

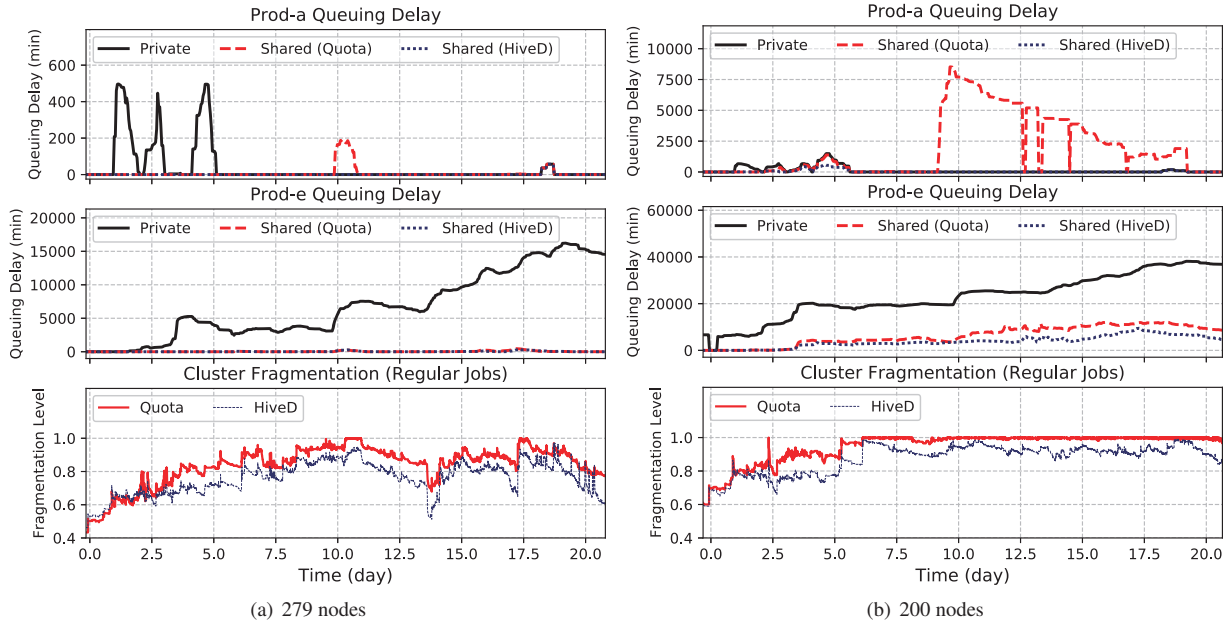

Figure 6: The average job queuing delay of Tenant prod-a and prod-e vs. the level of fragmentation of GPU affinity.

shorter and smaller jobs first. We do observe shorter queuing delay (and JCT) in Tiresias, compared to the other two schedulers. However, without HiveD, the global advantage of small jobs in a tenant might increase the fragmentation of GPU affinity in other tenants, thus resulting in sharing anomaly.

The experiment suggests that the evaluated schedulers are effective in their design objectives but they do not consider sharing safety, a factor that could severely impact user experience. HiveD complements the three schedulers with sharing safety by reserving the GPU affinity in each tenant’s VC. With HiveD, prod-a (and all the other tenants) never experiences an excessive queuing delay in the shared cluster, using each of the three schedulers. Even during Days 8~10, the multi-GPU jobs are scheduled immediately as the tenant has enough 8-GPU cells in its VC (hence the reserved cells in the physical cluster). HiveD also allows jobs to have a significantly shorter queuing delay in the shared cluster when a tenant runs out of its own capacity in the private cluster (Days 1, 3, and 6), by giving it chances to run low-priority jobs.

With sharing safety, HiveD can still preserve the scheduling efficiency. Figure 5(b) shows that HiveD exhibits similar job completion time compared to those without HiveD: at most 3% worse (for YARN-CS) and 12% better (for Gandiva).

We also evaluate the job completion time (JCT) when job’s GPU affinity requirement is soft. Without HiveD, some jobs experience worse training speed due to a relaxed affinity requirement and thus result in higher JCT in a shared cluster than in a private cluster (i.e., sharing anomaly). Again, HiveD eliminates all sharing anomalies in this case. Overall we observe a trend similar to the result when the affinity requirement is hard, hence the details are omitted in this paper.

5.2 Sharing Safety: Full Trace Simulation

We further use simulations to reveal the factors that influence sharing safety. The simulations use YARN-CS as the scheduler in the rest of this section. To validate simulation accuracy, the simulator replays the experiments in §5.1 and we compare the obtained job queuing delay to that in §5.1. The largest difference across all the experiments is within 7%. In the simulations we also observe similar sharing anomalies shown in the real experiments, so we believe the variations do not affect our main conclusion.

Queuing delay in a cluster with the original size. The top two figures in Figure 6(a) show the queuing delay for jobs from two representative tenants, prod-a and prod-e, submitted in 20 days. The jobs run in a cluster of the same size as the original production cluster (279 8-GPU nodes). The result is averaged in a 12-hour sliding window over job submission time. In the bottom figure of Figure 6(a) we also show the level of fragmentation of GPU affinity to observe its correlation with queuing delay. At any time, the level of fragmentation is defined as the proportion of 8-GPU nodes that cannot provide 8-GPU affinity for a high-priority job.

Among the three solutions, HiveD achieves the shortest queuing delay in both tenants. Tenant prod-a suffers a longer queuing delay in its private cluster in several time slots (e.g., the first 5 days) when the resource demands exceed its capacity. Both the quota-based scheme and HiveD reduce the queuing delay significantly by running low-priority jobs. However, from Day 11 to Day 12, prod-a experiences a longer queuing delay (200 minutes) in the quota-based cluster than that in the private cluster. In this period, the fact that no queuing delay

Figure 7: Average queuing delay of each tenant, normalized to that in its private cluster (200 nodes).

observed in its private cluster suggests prod-a has enough GPU quota. But the fragmentation level in the cluster reaches 100%, suggesting the quota-based scheme cannot find even one node to run an 8-GPU job for prod-a. In comparison, prod-a in HiveD has zero queuing delay since it has enough 8-GPU cells available. Overall, the fragmentation level in HiveD is lower than that in the quota-based scheme, because HiveD reserves cells for each tenant, preventing the fragmentation of reserved GPU affinity.

Queuing delay in a higher-load cluster. When a cluster is under-utilized, sharing anomaly is less likely to happen due to sufficient GPU affinity. To further understand the impact of cluster load on sharing safety, we keep the workload unchanged but reduce the cluster size to 200 8-GPU nodes (1,600 GPUs) and rerun the simulation. In this setup, around 90% of the GPUs are used by high-priority jobs. The results are shown in Figure 6(b). In the quota-based scheme, prod-a experiences more severe sharing anomaly when the cluster load is higher. The anomaly lasts from Day 9 to Day 19: the queuing delay can be 8,000 minutes longer than that in the private cluster. The higher cluster load incurs a higher level of GPU affinity fragmentation: the fragmentation level stays at 100% for most of the time, which delays the multi-GPU jobs.

For tenant prod-e, the queuing delays for both Quota and HiveD are always shorter in a shared cluster than in the private cluster. This is because its workload is dominated by a large number of 1-GPU jobs (refer to Table 1), which are immune to the fragmentation of GPU affinity. HiveD can further reduce prod-e’s queuing delay by guaranteeing its multi-GPU affinities for its multi-GPU jobs.

We also compare the average queuing delay in the three schemes for each tenant and show the result in Figure 7. The bars marked “Private” and “Quota” show that prod-a’s queuing delay in Quota is nearly $7\times$ that in its private cluster. In contrast, the bars marked “HiveD” show that every single tenant has a shorter queuing delay in HiveD than in the private cluster. Compared to Quota, HiveD reduces the queuing delay in 9 out of the 11 tenants (accounting for over 98% quota) due to lower fragmentation level. This reduction is up to 94% (for tenant prod-a), and on average 9% for all the 11 tenants.

In all the previous experiments, the cluster utilization in HiveD is similar to or slightly better than that in quota-based scheme. At some time instances, HiveD improve the utilization over quota-based scheme by up to 20% in the 200-node case and 14% in the 279-node case, as a result of reduced queuing delay. In fact, cluster utilization may depend on the “shape” of jobs (i.e., number of GPUs per job). For example, with a sufficient number of 1-GPU jobs, one can easily saturate the whole cluster. Therefore, our evaluation does not focus on cluster utilization.

Sharing anomalies leading to diminishing benefits of sharing. Figure 7 shows prod-a suffers from severe sharing anomaly ($7\times$ queuing delay). It is no longer beneficial for prod-a to contribute its GPUs to the shared cluster. We then run the experiment again to evaluate the effect of decommissioning prod-a (removing its GPUs and workload) from the cluster. The result is shown in the bars marked “Quota (w/o prod-a)” in Figure 7. This time, res-f becomes the victim of sharing anomalies, suffering over $1.7\times$ longer queuing delay. As the largest tenant, res-f previously benefits less (9% shorter queuing delay in Quota than its private cluster) from contributing GPUs to the cluster, compared to the smaller tenants. Because prod-a contains mostly multi-GPU jobs, after decommissioning prod-a, the fragmentation of GPU affinity in the whole cluster becomes worse, leading to longer queuing delay of res-f’s multi-GPU jobs and hence the sharing anomaly. This experiment shows the importance of ensuring sharing safety for large tenants. They already benefit less from the shared cluster. They will prefer not contributing their resource to the cluster if experiencing sharing anomaly.

We further decommission res-f from the cluster and rerun the experiment. The result is shown in the bars marked “Quota (w/o prod-a and res-f)” in Figure 7. This time, we do not discover further sharing anomaly. However, the decommissioning of the two tenants greatly reduces the sharing benefits of other tenants. prod-a and res-f contribute 37% of the GPUs in the original cluster. The queuing delay of other tenants in the smaller cluster is clearly longer than that in the larger clusters (before removing prod-a and res-f).

In contrast, with HiveD, not a single tenant suffers from

Figure 8: Queuing delay of *res-f* normalized by private cluster vs. workload fragmentation level (200 nodes).

sharing anomaly in all the settings. And HiveD’s queuing delay is consistently shorter than those without HiveD, across all settings. This highlights the necessity of sharing safety.

GPU affinity requirement vs. Sharing safety. We find that the distribution of the GPU affinity requirement for jobs across tenants affects sharing safety. Large number of 1-GPU jobs from other tenants may interfere (or fragment) the GPU affinity of a tenant, leading to sharing anomaly. To show this, we “reshape” the GPU affinity requirement of jobs and observe the queuing delay. In the experiment, we divide the 11 tenants into two groups: jobs in one group are reshaped to the GPU affinity of 1×8 (8-GPU), and those in the other group are changed to 1×1 (1-GPU). The reshaping does not change the total number of GPUs used in each tenant: the number of jobs N is defined by the total number of GPUs divided by the GPU number of a job (8 and 1 in this case). And the job submission time is set by randomly sampling N jobs from the original trace. We further define *workload fragmentation* as the ratio of the total number of jobs to the total number of GPUs. Jobs with higher affinity level have a lower workload fragmentation. The metric will be 1 if all jobs use 1 GPU.

Initially, only *res-f* is in the 8-GPU group, while the rest tenants go to the 1-GPU group. Figure 8 shows the queuing delay of *res-f* (normalized by that in its private cluster) and the workload fragmentation, when tenants *prod-e*, *prod-d*, and *prod-c* are moved to the 8-GPU group one by one. When only *res-f* is in the 8-GPU group, the workload is highly fragmented (0.91). This leads to severe sharing anomaly in Quota-based system: $132\times$ of the queuing delay in the private cluster. When more tenants are moved to the 8-GPU group, the workload fragmentation level goes down. This correspondingly reduces sharing anomaly. *res-f* experiences shorter queuing delay after the other three tenants are added ($4.3\times$, $1.9\times$, $0.9\times$, respectively, as shown in Figure 8). In contrast, HiveD guarantees sharing safety even under the highest fragmentation and consistently provides shorter queuing delay. Similar trends are observed in other tenants, we hence omit the detailed results here.

Soft affinity requirement. We also study the impact on sharing safety when the GPU affinity requirement of some jobs is soft, i.e., relax the affinity if it cannot be satisfied.

Figure 9: Sharing anomaly still happens when some jobs’ GPU affinity requirement is soft.

According to [86], not all training jobs will suffer from performance degradation with relaxed affinity. Hence in the study, we make the most optimistic assumption on the performance degradation: jobs with soft affinity requirement will not sacrifice the training speed. Surprisingly, sharing anomaly could still happen in this case for a quota-based scheme. Figure 9 shows the average queuing delay of tenant *prod-a* when some multi-GPU jobs in the trace are randomly selected to relax its GPU affinity. We use the 200-node setting in the experiments.

Figure 9 shows that *prod-a* still has sharing anomaly when 50% of the multi-GPU jobs are allowed to relax their affinity. The average queuing delay in the quota-based scheme is $1.3\times$ of that in its private cluster. Although no obvious anomaly found in the average queuing delay when the job ratio set to 25% and 75%, we still observe sharing anomalies in certain time instances. This is similar to the behaviors in Figures 5(a) and 6. We omit the details due to space limit. On the other hand, HiveD eliminates all the sharing anomalies and always has the shortest queuing delay. Note that Figure 9 shows the best case scenario for relaxed affinity. In reality, jobs with relaxed affinity could perform much worse than the same jobs with the desired affinity [86]. Thus sharing anomaly may happen more likely than it is described in Figure 9.

Although relaxing affinity may reduce the queuing delay for jobs with soft affinity requirement, the behavior may increase the fragmentation of GPU affinity in the cluster. This in turn will increase the queuing delay for jobs with hard affinity requirement. It becomes a complex tradeoff among queuing delay, fragmentation of GPU affinity, training performance, and cluster utilization. HiveD reserves cells to achieve sharing safety and avoids the complex tradeoff altogether.

5.3 Buddy Cell Allocation

In this section, we evaluate the buddy cell allocation algorithm through trace-driven simulations, to understand its effectiveness in reducing preemption and fragmentation of GPU affinity, and its algorithm efficiency.

Reducing preemption with dynamic binding. In the buddy cell allocation algorithm, cells are bound to those in the physical cluster dynamically. This reduces unnecessary preemption of low-priority jobs when there are idle cells. Figure 10 shows the numbers of job preemption when using dynamic

Figure 10: Preemption in dynamic and static bindings.

binding and static binding, respectively. This experiment uses the same setup as the 279-node experiment in §5.2. In total, dynamic binding reduces the number of preempted GPUs by 55%. We also measure the correlation between preemption and the proportion of bound cells in the time dimension (on a 12-hour window). When there are more cells being bound to the physical cluster (e.g., Day 10, Day 20 in dynamic binding), there are also more GPUs being preempted. This is because we have fewer choices of physical cells to bind, hence fewer opportunities to reduce preemption. This observation is also consistent with the fact that static binding, where this proportion is always 100%, incurs many more unnecessary preemptions.

Reducing fragmentation of GPU affinity with multi-level cells. Multi-level cells allow the buddy cell allocation algorithm to pack the cells at the same level across tenants to reduce the fragmentation of GPU affinity. For example, if two tenants both have a level-1 (1-GPU) cell, the algorithm prefers selecting two cells from the same physical node, i.e., buddy cells, to run a 1-GPU job. Instead, if both tenants only reserve level-4 cells (8-GPU, node level), the two tenants have to use a level-4 cell to run its 1-GPU job. Hence the two 1-GPU jobs will be placed on two different nodes, which increases the fragmentation of GPU affinity at node level.

To demonstrate this, instead of only assigning level-4 cells, we assign cells from level-1 to level-4 while keeping the total number of GPUs assigned to each tenant the same as in the above 279-node simulation. Each tenant’s assignment matches the distribution of its demands on each level of the cells. Figure 11 shows the fragmentation level of GPU affinity over time when using multi-level and single-level (level-4) cells, respectively. The fragmentation level is always lower with multi-level cells. The gap is more than 10% (up to 20%) for most of the time, which means we can spare roughly 30 more level-4 cells. HiveD therefore recommends that tenants model their job’s affinity requirements more precisely, in order for a cluster to perform more efficient cross-VC packing.

Algorithm efficiency. We profile the performance of our

Figure 11: Fragmentation with multi- and single-level cells.

implementation of buddy cell allocation in a setup of a 65,536-GPU cluster with 8 racks, each consisting of 1024 8-GPU nodes. We issued 10,000 cell allocation requests at random levels. The average time to complete a request is 2.18ms. A large part of the cost comes from ordering cells according to low-priority jobs, which accounts for 88% of the time. As the algorithm is clearly not the system bottleneck, we do not perform further optimization (e.g., lock-free operations).

6 Discussion

VC assignment. The VC assignment to a tenant, in terms of both the number of GPUs and their cell structures, has impacts on the effective VC utilization and queuing delay across tenants. The VC assignment is usually a business process, a common practice in large production clusters, e.g., Borg [84]. Factors to consider in VC assignment include overall capacity, tenant demands, composition of tenant workload, workload variation over time, business priority, and budget constraints. Therefore, HiveD leaves the choice of VC assignment to users. In most cases, a tenant can just reserve several node-level cells as a VC and adopt a deep learning scheduler for the VC. If a tenant has more details about workloads, e.g., the GPU number distribution of the jobs, the tenant can reserve different levels of cells to match the job requirement and enjoy less fragmentation and preemption, as discussed in §5.3. VC assignment is a new kind of resource reservation based on cells, and HiveD is a framework to enforce such a reservation.

Job migration. Migrating jobs between GPUs is a powerful mechanism that has been shown effective [86] in improving quality of GPU allocations. De-fragmentation via migration can in theory be used to resolve potential sharing safety violations, but our experience has shown that there are significant challenges in applying migration in production. Fully transparent migration remains challenging in practice, due to implementation issues in different deep learning frameworks (e.g., inconsistent or limited use of certain programming APIs; challenges of multi-language, multi-framework, and multi-version support [21, 30, 62, 65]). Moreover, the choice of which jobs to migrate and where could be rather complex, with different conflicting objectives to balance and a large search space. As shown in §5.1, a greedy migration algorithm [86] can still violate sharing safety. In contrast, HiveD’s cell abstraction and buddy cell allocation algorithm enable separation of con-

cerns. HiveD can also leverage migration, especially within each tenant—it will be a search space constrained to within a tenant under the sharing-safety guarantee.

HiveD in the cloud. Major cloud providers are offering GPU VMs in the cloud. Our findings in HiveD are highly relevant even in the cloud setting and can shed light on the types of offering in the cloud. Our buddy cell allocation algorithm can also be used by the cloud providers to manage their reserved [2, 6, 27] and spot [4, 8, 78] GPU instances, as our VC cells are essentially reserved instances and our low-priority cells are essentially preemptible spot instances. HiveD’s implementation already satisfies requirements of a typical cloud provider, e.g., supports different GPU models, reserves pay-as-you-go instances [70], and handles expansion in capacity. For practical deployment, HiveD can use a hybrid strategy to leverage the cloud as an extension of a multi-tenant GPU cluster when the demand temporarily exceeds the capacity, or can be deployed entirely on a cloud using reserved resources at a lower price, with the options to (i) use spot instances, (ii) buy pay-as-you-go instances when needed, and (iii) purchase and sell reserved capacity in the marketplace [3, 23].

Extending HiveD to other affinity-aware resources. Although this paper focuses on reserving affinized GPUs, HiveD’s design applies to other types of affinity-aware resources as well. For example, the cell can be used to define affinized CPU cores within the same NUMA node, or even multiple types of NUMA-aware resources like affinized GPUs and CPU cores under the same socket [18].

7 Related Work

Affinity-aware schedulers for deep learning training. Affinity has been well considered something important when scheduling deep learning jobs [22, 41, 51, 52, 59, 66, 72, 86] as well as other (big-data) jobs [36, 38, 89]. HiveD complements these schedulers by applying them in virtualized cluster views, thereby leveraging their efficiency while avoiding sharing anomalies, as identified and shown in our experiments.

Fairness in shared clusters. Identifying the fair share of resources in large clusters has been widely studied. Max-min fairness [55] has been extended in a CPU cluster to address fair allocation of multiple resource types (DRF [37]), job scheduling with locality constraints [38, 39, 48, 89], and correlated and elastic demands (HUG [31]). There are recent proposals to achieve fairness and efficiency for machine learning workloads [29, 60, 64].

In contrast, HiveD focuses on sharing safety with respect to *given* resource shares (i.e., VC assignment). As we have discussed in §6, determining the resource shares is usually a business process. HiveD assumes a pre-agreed resource partition among multiple tenants, and enforces it with the sharing safety guarantee. This is driven by witnessing that

corporate users are annoyed by the uncertain availability of GPU resources that are already assigned to them. In this sense, HiveD is a framework to guarantee a type of resource reservation [91], defined in terms of cells in VCs. HiveD can address fairness by applying the fairness schemes (e.g., Themis [60]) to determine fine-grained fair-share for jobs within a tenant (or across tenants for low-priority jobs), given the coarse-grained VC assignment enforced by HiveD.

Performance isolation. Performance in a shared cluster is sensitive to various sources of interference, including I/O, network, and cache. There are research works on performance isolation that include storage isolation [32, 42, 43, 80], appliance isolation [24, 76], network isolation [44, 58, 67, 75, 87], and GPU isolation [25, 26, 50, 53, 69, 88]. In HiveD, we identify a new source of interference: the fragmentation of GPU affinity in a tenant may affect the GPU affinity in other tenants in a shared GPU cluster. To eliminate such interference, HiveD adopts the notion of VC to encapsulate the requirement in multi-level cells and constrains the scheduling behavior within each VC.

Reducing fragmentation. Reducing fragmentation is important to cluster utilization, which has been widely studied in past decades. Tetris [40] is a multi-resource scheduler to pack tasks to avoid resource fragmentation. Feitelson [35] also proposed a buddy-based algorithm to reduce fragmentation for gang-scheduled jobs in supercomputers. There are also works using migration/preemption to reduce fragmentation for gang-scheduled jobs [63, 71, 86]. HiveD’s buddy allocation algorithm with affinity hierarchy can also effectively reduce fragmentation. More importantly, HiveD takes a step further to guarantee sharing safety, i.e., eliminate the external fragmentation across tenants. Ensuring sharing safety requires not only minimizing fragmentation but also explicitly defining cells assigned to each VC, and enforcing this assignment during physical resource allocation.

8 Conclusion

Motivated by observations from production clusters and validated through extensive evaluations, HiveD takes a new approach to meeting the challenge of sharing a multi-tenant GPU cluster for deep learning by (i) defining a simple and practical guarantee, sharing safety, that is easily appreciated by tenants, (ii) proposing an affinity-aware resource abstraction, cell, to model virtual private clusters, (iii) developing an elegant and efficient algorithm, buddy cell allocation, that is proven to guarantee sharing safety and is naturally extended to support low-priority jobs, and (iv) devising a flexible architecture, to incorporate state-of-the-art schedulers for both sharing safety and scheduling efficiency. All these combined, HiveD strikes the right balance between multiple objectives such as sharing safety and cluster utilization.

Alibaba Group

Abstract

Efficiently scheduling deep learning jobs on large-scale GPU clusters is crucial for job performance, system throughput, and hardware utilization. It is getting ever more challenging as deep learning workloads become more complex. This paper presents AntMan, a deep learning infrastructure that co-designs cluster schedulers with deep learning frameworks and has been deployed in production at Alibaba to manage tens of thousands of daily deep learning jobs across thousands of GPUs. AntMan accommodates the fluctuating resource demands of deep learning training jobs. As such, it utilizes the spare GPU resources to co-execute multiple jobs on a shared GPU. AntMan exploits unique characteristics of deep learning training to introduce dynamic scaling mechanisms for memory and computation within the deep learning frameworks. This allows fine-grained coordination between jobs and prevents job interference. Evaluations show that AntMan improves the overall GPU memory utilization by 42% and computation utilization by 34% in our multi-tenant cluster without compromising fairness, presenting a new approach to efficiently utilizing GPUs at scale.

1 Introduction

Over the past years we have witnessed the great success of Deep Learning (DL) with GPUs. DL already powers several widely-used products today, spreading across fields including computer vision, language understanding, speech recognition, recommendation, advertisement, etc. Therefore, it has become a vital workload integrated into the production pipeline at scale. Large companies often build multi-tenant GPU clusters for DL workloads, similar to shared clusters for big-data analytics.

At Alibaba, we have observed low utilization of GPU hardware in shared multi-tenant DL clusters, while queuing many jobs waiting for resources. Such low utilization of DL cluster arises from two main aspects. Firstly, most

DL-production training jobs cannot fully utilize all the GPU resources throughout their execution. Training a DL model often requires a mixture of computations, some of which can hardly be parallelized using GPU, such as graph sampling in graph neural network [21, 54], feature extraction in advertisement [15, 23], data augmentation in computer vision [56], etc. Besides, when scaled to distributed training, 90% of the time can be spent on networking [32]. Secondly, the common reservation-based approach for cluster scheduling results in significant GPU idling because DL jobs often cannot consume partial resources. For example, stochastic gradient descent (SGD) is synchronous and requires all resources to be available simultaneously for gang-scheduling [27]. The cluster scheduler thus forces partially available resources to idle in reserve until the final request is satisfied.

Packing jobs on shared GPUs can boost GPU utilization and make the same cluster accomplish more jobs overall. However, this approach is rarely used in production clusters. The reason is that although improving GPU utilization is beneficial, it is also critical to guarantee the performance of important *resource-guarantee* jobs (*i.e.*, jobs with resource quota). Co-executing multiple jobs on the same GPU can result in interference, which leads to significant performance slowdown of the resource guarantee jobs [48]. What's more, the job packing strategy can introduce memory contention on concurrent jobs, which could even cause the failure of the training jobs if the resource demands of a job abruptly increase. Therefore, it is typical in existing production GPU clusters to perform exclusive allocation of resources on jobs [27].

We present AntMan, a DL system that improves GPU cluster utilization while ensuring fairness and performance of resource-guaranteed jobs by doing cooperative resource scaling to minimize job interference. New mechanisms are introduced in DL frameworks to allocate the exact required amount of GPU memory and computation unit dynamically during the job training. Any spare GPU resources, including GPU memory and compute cycles, could be leveraged by over-subscription jobs. AntMan co-designs the cluster scheduler and DL frameworks to adapt to the inherent fluctuating re-

*Co-first author

source characteristics in production jobs, through framework information aware scheduling, transparent memory extension, and fast continuous inter-job coordination. With this architecture, AntMan opens a space for policy design of co-executing DL jobs using GPU resources. In the GPU clusters of Alibaba, AntMan adopts a simple and practical strategy to maximize the cluster throughput. While providing performance guarantee on *resource-guarantee* jobs, AntMan dispatches *opportunistic* jobs to best-effort utilize GPU resources at a low-priority without any resource guarantees.

We have implemented AntMan by modifying two most popular DL frameworks, PyTorch [35] and TensorFlow [8], to expose necessary new primitives for the cluster scheduler to leverage at runtime. Our scheduling policy is implemented in a scheduler prototype on top of Kubernetes for evaluation, and the complete system is fully implemented in Fuxi [52], the internal scheduler of Alibaba, to serve the production DL jobs in the GPU clusters.

We evaluate AntMan on a 64 V100-GPU Kubernetes cluster to show the advantages of the new scheduling primitives and policies with micro-benchmarks and real workloads. The trace evaluation shows that AntMan can preserve the performance of resource-guarantee jobs ideally without preemption. Moreover, it improves the average Job Completion Time (JCT) of all jobs by up to 2.05x compared to current production cluster scheduler, and 1.84x compared to Gandiva [48], a state-of-the-art DL cluster scheduler. We also deploy AntMan in real production clusters and report the evaluations and statistics on a heterogeneous cluster with over 5000 GPUs. The cluster statistics shows that AntMan improves the overall throughput by offering up to 17.1% more GPUs for DL jobs, significantly reduces the average queuing delay by 2.05x, and raises the GPU memory and computation unit utilization by 42% and 34% respectively.

The key contributions of this paper are as follows.

- We investigate the comprehensive characteristics of production DL clusters to understand low utilization from three aspects: hardware, cluster scheduling, and job behavior (Section 2).
- We introduce two new dynamic scaling mechanisms in both memory and computation unit management for DL frameworks to address the challenges of GPU sharing. The new mechanisms leverage DL job characteristics to dynamically adjust the resource usage of DL jobs efficiently during the job execution (Section 3.1).
- Through co-designing the cluster scheduler and DL frameworks to utilize dynamic scaling mechanisms, we introduce a new industrial method to GPU sharing. This maintains the job service-level agreement (SLA) in a multi-tenant cluster while improving the cluster utilization with opportunistic scheduling (Section 3.2 and 3.3).

- By deploying AntMan in Alibaba to serve tens of thousands of daily jobs, we conduct experiments and report the performance improvement in a cluster with more than 5000 GPUs, demonstrating a productive approach in managing multi-tenant DL cluster fairly and efficiently at scale (Section 5).

2 Motivation

In this section, we start by introducing essential DL terminologies as the background. We then highlight our observations by characterising the GPU production cluster to motivate the design of AntMan. We end by discussing opportunities to leverage the DL training characteristics.

2.1 Deep Learning Training

Deep learning training often consists of millions of iterations, and each iteration processes a few samples, called a *mini-batch*. Usually, a training mini-batch can be divided into three phases. Firstly, samples and model weights are calculated to produce a set of scores, known as a *forward* pass. Secondly, a loss error is calculated between the produced scores and the desired ones using an objective function. The loss is then spread backwards through the model to compute gradients, called a *backward* pass. Finally, the gradients are scaled by a learning rate, as defined by an optimizer, to update the model parameters. The computation output of a forward pass usually includes many data outputs, each of which is called a *tensor*. These tensors should be temporarily held in the memory and consumed by the backward pass to calculate gradients. Usually, to monitor the model quality in training, evaluations are periodically triggered.

To train models with massive data, DL generally adopts data parallelism in multiple GPUs where each GPU is responsible for processing a subset of data in parallel while performing gradient synchronizations per mini-batch before the model update.

In large companies, multi-tenant clusters are commonly used to improve hardware utilization, where users can sometimes oversubscribe GPU resource quota, especially when GPU demands burst [33].

2.2 Characterizing Production DL Cluster

We study resource usage in production clusters from three perspectives: hardware, cluster scheduling, and job behavior.

Low utilization of in-use GPUs. Figure 1 illustrates a one-week statistic of GPU memory usage and computation unit utilization. The numbers are collected from one of the production clusters with thousands of heterogeneous GPUs. GPU memory consumption is normalized by the memory capacity of the running GPU due to the heterogeneity in the GPU

Figure 1: GPU resource statistic on a GPU production cluster.

Figure 2: Average GPU idle waiting waste from gang-schedule.

Figure 3: DeepFM on Criteo dataset.

Figure 4: ESPnet on text-speech dataset.

memory capacity. As shown in the figure, only 20% of the GPUs are running applications that consume more than half of the GPU memory. With regards to the usage of computation unit, only 10% of the GPUs achieve higher than 80% GPU utilization. This statistic indicates that both the GPU memory and computation units are not being fully utilized, and are thus wasting the expensive hardware resources.

Idle waiting for gang-schedule. To train deep learning with massive amounts of data, distributed multi-GPU training is essential. Multi-GPU training jobs require gang-scheduling, which means a job will not start training unless all required GPUs are simultaneously available [19, 27]. However, in a cluster, GPU resources can hardly be satisfied simultaneously. (e.g., three GPUs might need to be held and then wait for the last one before launching a 4-GPU job, leaving the three GPUs in idle waiting mode). The more resources a job requires, the more GPU cycles are wasted when in idle waiting mode due to partial resource reservation. To understand the resource waste due to idle waiting, the timestamp of every resource grant for every gang-scheduled job was recorded. The idle waiting time of each GPU (*i.e.*, the gap between the job launching time and the resource granting time) is summed up to calculate the total resources wasted in idle waiting for a job. Figure 2 illustrates the average idle waiting resource waste for different sizes of jobs. The more GPUs a job requires, the higher the cost the cluster must pay for holding idle resources.

The unpredictable arrival of upcoming resources is the reason that reserved resources are left idle. A naïve approach to improving utilization is to launch other jobs on idle waiting resources. However, this can cause the large jobs to become starved and break the scheduling fairness. In addition, once all resources are satisfied, the burst GPU demand of this resource-guarantee job can lead to inter-job resource conflicts with the ones that are currently running in GPUs, which may cause the jobs to fail. Recently, elastic training (*e.g.*, TorchElastic [7]) is proposed to adapt to the incrementally available resources. However, it is rarely used in production because of the non-determinism it introduces to the accuracy [18, 47].

Dynamic resource demand. In addition to the idle wasting from job scheduling, our observation finds that DL jobs usually cannot fully utilize GPU resources during their life

cycle. Figure 3 illustrates the first 10 minutes of resource usage when running DeepFM [20] on Criteo dataset. At the beginning, preprocessing on the dataset only requires CPU. However, both GPU Streaming Multiprocessor (SM) utilization and memory usage are boosted at 275 seconds. Such dynamic resource demands also commonly exist in other jobs. Figure 4 illustrates a 10-minute (1200~1800 seconds) profiling on ESPnet [46], an end-to-end speech model training job. The model training pipeline could contain several phases. During the training phase, ESPnet consumes 3.6 GB GPU memory with a dynamic GPU SM utilization up to 70%. At 1400 seconds, decoding on GPU (around 1400~1600 seconds) and synthesis (around 1600~1700 seconds) on the CPU are issued in order to evaluate the model. It is worthy of note that, the decoding phase requires up to 19 GB GPU memory. After the evaluation phase, the model training continues. Such intra-job dynamic resource demand is common in production DL pipelines, making it hard to predict desired resources. We also find some jobs periodically become CPU bound, which is consistent with the observations in neural machine translation tasks [49]. We omit the result due to space limitation.

The dynamic resource demand actually conflicts with the fixed resource allocation and the potentially long running time in the training of deep learning jobs. Jobs requiring sufficient resources according to their peak usage make expensive hardware underutilized. If not granted sufficient resources, the job performance may be limited and thus the job completion time could be delayed. In addition, the memory caching design in existing DL frameworks (*e.g.*, TensorFlow and PyTorch) also conceal the temporal memory usage variations [50], which prevents GPU memory from potential sharing.

2.3 Opportunities in DL Uniqueness

The preceding characterization of the production DL cluster shows that low utilization is common for both GPU memory and GPU computation unit (*i.e.*, SM). It shows great opportunities to improve the cluster throughput with resource over-subscription. However, the unpredictable inter-job and intra-job demand burst introduces challenges to safe resource sharing. Jobs could run out of memory due to resource contention. Besides, in multi-tenant clusters, it is important to provide performance isolation for jobs holding a resource quota when the jobs are executed in a resource-sharing approach. To cater to these challenges when scheduling deep learning jobs, AntMan leverages the opportunities in the uniqueness of DL training.

We sample 10K tasks in a week of our production cluster to understand DL characteristics. We measure model size and mini-batch size during model training, both shown in Figure 5. Even though DL training could potentially use as much as 32 to 40 GB GPU memory (*e.g.*, V100 and A100), only a small portion is used to store the persistent DL model. 90% of DL models occupy only 500 MB GPU memory.¹ The majority of GPU memory is allocated and freed within the same mini-batch. Moreover, the DL training cycle is also rather small. As much as 80% of tasks consume a mini-batch within 600 *ms*.

We exploit such unique characteristics in several ways to schedule jobs on shared GPUs. Firstly, due to the small model size in common, the majority of GPU memory could be scheduled among the co-executing jobs. Secondly, mini-batch cycles are generally quite small, allowing fine-grained GPU memory and computation scheduling at every mini-batch boundary. This could further allow fast resource coordination between jobs. Thirdly, mini-batches apply mostly similar computations that can be utilized to profile the job performance, therefore their progress rate can be created as a performance metrics to quantify interference.

3 Design

AntMan deeply co-designs cluster schedulers and DL frameworks to address GPU sharing challenges. In this section, we

¹we omit the largest 2% jobs' model size as the number is business sensitive.

first describe the new mechanism extensions in DL frameworks. We then introduce the collaborative scheduling design to leverage those new primitives. Finally, we present a new productive policy enabled in the cluster scheduler of Alibaba to manage DL jobs.

3.1 Dynamic Scaling in DL Frameworks

As mentioned in Section 2.2, DL training clusters exhibit low utilization due to unsaturated GPU usage in DL workloads and unique gang-schedule requirements during job scheduling, which contains great potentials that can be exploited to execute more jobs. However, some challenges need to be addressed, such as executing jobs at their minimal requirements while preventing GPU memory usage outbreak failures, adapting to the fluctuating computation unit usage while limiting potential interference. At its core, existing DL frameworks are designed for dedicated GPU executions, which lack key capabilities when collaborating with other jobs. Such conflicts between production DL cluster characteristics and DL framework limitation motivate the design of dynamic scaling mechanisms to enhance DL frameworks. The dynamic scaling mechanisms include the fine-grained dynamic control in two aspects, GPU memory and computation unit. We elaborate them next.

3.1.1 Memory Management

A dynamic memory management mechanism is introduced in AntMan to adapt the allocated memory on the fluctuating memory demands of a DL training job. This is achieved by allocating universal memory to DL application tensors, *i.e.*, switching tensors between GPU and CPU host machine DRAM across mini-batches. Modern operating systems support *paging* in memory management at the granularity of memory pages, where they use disk as memory when they run out of physical memory. AntMan adopts a similar approach, however, this is carried out in an application-specific granularity, tensor, which can be transparently migrated in universal memory addresses at runtime. In this way, DL frameworks can support the dynamic GPU memory upper limit.

Figure 6 illustrates the memory management in existing DL frameworks as well as the differences to AntMan. The total

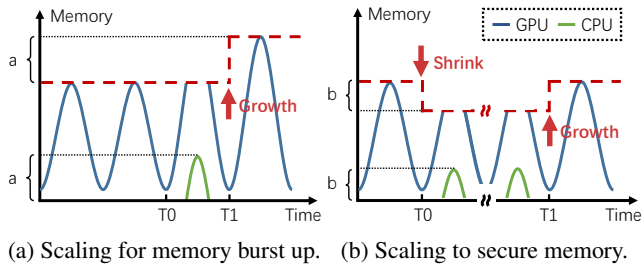

Figure 7: Leveraging mini-batch behavior to scale memory efficiently.

number of cached GPU memory size (*i.e.*, red dash line) increases with tensors created in DL frameworks (Figure 6a~b). In order to eliminate the expensive overheads in memory allocations and de-allocations, and also to speed up training among mini-batches, the GPU memory is cached in a global memory allocator inside DL frameworks after tensors are destroyed. Prevalently, some tensors are used only in certain stages of DL training (*e.g.*, data preprocessing, evaluation), which are no longer required. However, this portion of cached GPU memory is not released (Figure 6c). This cached memory design in DL frameworks optimizes individual job performance at the cost of losing sharing potentials.

AntMan turns to the approach of scaling the GPU memory upper limit. It proactively detects in-used memory to shrink the cached memory to introspectively adjust GPU memory usage to an appropriate fit. This is done by monitoring application performance and memory requirements when processing mini-batches (Figure 6d). Furthermore, new primitives are provided to shrink the upper limit of GPU memory at runtime, even below the actual GPU memory demand of a job. AntMan uses its greatest effort to allocate tensors on GPU devices, however, tensors can be allocated outside of GPU with the host memory if GPU memory is still lacking (Figure 6e). With such universal memory support, jobs can continue to process even below their actual GPU memory requirements, where we find workloads slowdown the performance differently (Section 3.3). Tensors can be allocated back to GPU automatically when the GPU memory's upper limit increases (Figure 6f).

Paging in operating systems introduces costly page copy between the memory and disk. In contrast, thanks to the unique pattern of DL, tensor copy between the GPU and CPU host DRAM is explicitly avoided. Identical tensors are created across mini-batches, and therefore, AntMan exploits this pattern to adjust the upper limit of the memory at the boundary of the mini-batches. Figure 7a illustrates how memory scaling addresses the burst demand. At T_0 , the memory requirement of a running DL training job increases, due to the limited upper-bound of GPU memory, some tensors cannot be placed in the GPU memory, and are instead created using the host memory. AntMan detects the usage of the host memory, and at T_1 , it raises the GPU memory's upper limit for that job according to the usage of the host memory, which allows

Figure 8: Computation management to run two jobs in a shared GPU without interference.

the tensors to be fully allocated in the GPU device for the next mini-batch. Note that, the performance of this running job might slowdown in a mini-batch as tensors are placed in the host memory. However, such performance overheads are negligible, considering a typical DL training often requires millions of mini-batches. The overhead of memory shrinkage and growth is quantified in Section 5. Furthermore, AntMan provides fine-grained GPU memory scheduling at runtime. A training job might shrink to secure memory resources for other jobs, and grow back after other jobs are finished, as shown in Figure 7b. It illustrates that a DL job scales down at T_0 and scales up at T_1 , at the cost of some tensors allocated on the host memory. Therefore, the usage of the remaining GPU memory between T_0 and T_1 for jobs running in the same shared GPU is secured.

3.1.2 Computation Management

Dynamic computation unit management is a mechanism introduced in AntMan to control the GPU utilization of a DL training job. Modern operating systems (*e.g.*, Linux) support cgroups, which limits, accounts for, and isolates the CPU resources that a process requires [1]. AntMan introduces a similar method of dynamically isolating the GPU computation resource access of DL-specific processes at runtime.

When multiple DL jobs are launched on the same GPU, the interference is mainly caused by the potential GPU kernel queuing delay and PCIe bus contention [14], which could

result in consistent performance downgrades across all jobs if packing jobs are running on the same model and configuration [48]. Our observation shows that jobs slowdown in different ways if different jobs are packed together (Section 5.1). This is because jobs have different capabilities at acquiring GPU computation units. Consequently, job performance can barely guarantee or predict in GPU sharing, resulting in difficulties on the deployment of GPU sharing for multi-tenant clusters. Figure 8 illustrates an example of GPU computation unit interference for two jobs that are executed on the same GPU. Figure 8a illustrates how Job-A executes on a GPU in a fine-grained manner. In short, GPU kernels will be placed in order and processed by the GPU computation unit one by one. Note that, in Figure 8, Job-A might not be able to fully saturate the GPU, resulting in idle GPU cycles and low GPU utilization which can potentially be used by other jobs. Therefore, Job-B is scheduled on this GPU (Figure 8b). The GPU operators of Job-B launch kernels (green blocks) executed in the GPU, which can fill it up, and thus delay the execution of other GPU kernels (blue blocks), leading to the poor performance of Job-A. The interference mainly comes from the lack of ability to control the execution frequency of GPU kernels. To address this issue, We introduce a GPU operator manager in DL framework(Figure 8c). Existing DL frameworks issue GPU kernels in the GPU operator once its control dependency is satisfied. In AntMan, the execution of GPU operator is dedicated to a newly-introduced module, called *GpuOpManager*. When a GPU operator is ready to execute, it is added to *GpuOpManager* instead of being directly launched. The main idea of *GpuOpManager* is to control the launching frequency by delaying the execution of GPU operators. In this way, AntMan introduces a new primitive to limit the GPU utilization of a DL training job using *GpuOpManager*. *GpuOpManager* continuously profiles the GPU operators execution time and simply distributes idle time slots before launching the GPU operators. Note that, *GpuOpManager* only delays the GPU kernel execution. Therefore, the potential dependencies among operators (including GPU operators and CPU operators) are retained, meaning that CPU operators can continue if possible. As illustrated in Figure 8c, the third CPU operator is not blocked, however, the fourth one is delayed as it depends on the second GPU operator, which has its execution delayed by the *GpuOpManager*.

3.2 Collaborative Scheduler

In this section, we describe how we co-design the cluster scheduler and DL frameworks to leverage the dynamic scaling mechanisms mentioned above for collaborative scheduling. We focus on the overall architecture of AntMan and how different modules operate. The detailed policy description is in the next section.

As shown in Figure 9, AntMan adopts a hierarchical architecture, where a global scheduler is responsible for job

Figure 9: Collaborative scheduling workflow of AntMan.

scheduling. Each working server contains a local coordinator that is responsible for managing the job execution using the primitives of dynamic resource scaling through considering the statistics reported from DL frameworks. AntMan is designed for multi-tenant GPU clusters. In a multi-tenant cluster, each tenant usually owns certain resources, annotated as a resource quota (*i.e.*, number of GPUs), which is the concurrent performance guarantee resources that can be assigned to the jobs of that tenant. The sum of the GPU resource quota of each tenant is less equal to the total capacity of a GPU cluster. In AntMan, jobs are classified into *resource-guarantee* jobs and *opportunistic* jobs by global scheduler with different scheduling policies applied (Section 3.3). Resource-guarantee jobs consume a certain amount of GPU resources quota of their corresponding tenants while opportunistic jobs do not. Therefore, AntMan ensures that the performance of the resource-guarantee jobs should be consistent with that in exclusive executions.

In AntMan, similar to conventional cluster schedulers, the scheduling decision is dispatched from the global scheduler to the local coordinator. In addition, the local coordinator introspectively schedules the GPU resources to DL training jobs using the dynamic scaling mechanisms (Section 3.1). Therefore, the scheduling decisions can be treated as a top-down control flow. In contrast, data statistic flow information is collected by statistic modules of the local coordinator and aggregated on the cluster statistic module in a bottom-up approach to help make scheduling decisions, which is similar to Apollo [10]. Alongside with the hardware information (*e.g.*, GPU utilization, GPU memory usage), AntMan also leverages detailed job information reported by DL frameworks, including mini-batch duration, peak memory usage, minimal memory usage, and host memory consumption, etc. This information can also assist job scheduling decisions made by the global scheduler. For example, peak memory and minimal memory usage are used to indicate the GPU memory size that can be made available quickly. Mini-batch time shows how soon the GPU memory can be available for another DL training job, which can affect the scheduling decisions of the global scheduler when launching jobs.

Algorithm 1 `scheduleJob(in job, out nodes)`

```
1:  $nodes0 \leftarrow findNodes(job.gpu, constraints \leftarrow job.topo)$ 
2:  $nodes1 \leftarrow findNodes(job.gpu, constraints \leftarrow M)$ 
3:  $nodes2 \leftarrow minLoadNodes(nodes1, job.gpu)$ 
4: if  $job.isResourceGuarantee$ :
5:     if  $numGPUs(nodes0) \geq job.gpu$ :
6:         return  $nodes0$ 
7:     else:
8:          $reserve(nodes0)$ 
9: else:
10:    return  $nodes2$ 
```

Once a job is launched on a GPU server, a local scheduler takes over the management of its end-to-end execution. Due to the load fluctuation of a DL training job, a local coordinator acts in an introspective mode to perform continual job control to DL frameworks. More specifically, it collects the statistics from the hardware and DL frameworks of all jobs, which is used to control job performance via resource usage adjustments (e.g., shrink GPU memory) through the new primitives we introduced in Section 3.1.

3.3 Scheduling Policy

In this section, we first present the goal of our cluster scheduler. Then we describe the detailed policies applied in global scheduler and local coordinator. Finally, we introduce the job upgrade in our system.

Goal. There is an inherent tension between providing fairness (e.g., to ensure SLAs of DL jobs with guaranteed resources) and achieving high resource utilization (e.g., GPU utilization), because of the constant fluctuation in both the load on a cluster and the resource needs of a job. Prevalent production DL cluster schedulers often trade fairness in certain ways for efficiency. For example, spare resources are allocated to over-provision tenants. However, such GPU resources can hardly get back without preemption. Generally, preemption is rarely used as it fails running jobs while wastes expensive GPU cycles. Besides, [27] also reports the out-of-order behavior which discriminates large jobs (i.e., allocating more GPUs), leading to unfairness by preferring small jobs. In AntMan, multi-tenant fairness is our primary goal, and the second priority is to improve the cluster efficiency therefore to achieve higher throughput. AntMan achieves fairness with the policies that are implemented in both the global scheduler and the local coordinator, powered by the dynamic scaling mechanisms. Furthermore, GPU opportunistic jobs are introduced in AntMan to steal idle cycles in GPUs so as to maximize cluster utilization.

Global scheduler. As a multi-tenant cluster scheduler, the global scheduler maintains multiple queues of tenants where

jobs arrive and decides GPU locations allocated for jobs. For resource-guarantee jobs and opportunistic jobs, AntMan applies different scheduling policies as shown in Algorithm 1. *findNodes* is a function that returns the node and GPU candidates which satisfy the job request with an optional parameter to specify constraints. Global scheduler fairly allocates resource-guarantee jobs given sufficient GPU resources. In addition, resource-guarantee jobs are optimized to maximize the job performance using the free GPU resources, i.e., GPUs that are not allocated to other resource-guarantee jobs (line 5-6). For instance, a distributed resource-guarantee job that uses all-reduce communication strategy (e.g., NCCL [5]) can be scheduled on one server to utilize the NVLink [6] for high-performance communication. However, if the resource request of a job can partially be satisfied, the global scheduler reserves the resources for this job, and waits for others to meet the gang-scheduling requirement (line 7-8). Such insufficient resource reservation exists mainly for resource quota (e.g., three GPUs left while there is a request for four) and resource fragmentation (e.g., request four GPUs in the same server, however only four are available spread across servers). The reserved resources will never be occupied by other resource-guarantee jobs, however, they can be utilized by opportunistic jobs.

By default, the global scheduler will estimate the queuing time for jobs without GPU quota granted. Those jobs that suffer long queuing delay will be automatically executed as opportunistic jobs. To schedule opportunistic jobs, global scheduler aims to utilize free resources to the best of its ability. It allocates opportunistic jobs on GPUs by considering the actual GPU utilization, even when some other jobs run on those GPUs. Only GPUs with a utilization of less than M (set as 80% for now) in the past 10 seconds can be selected as candidates. AntMan adopts a heuristic strategy to allocate opportunistic jobs on the freest candidates (i.e., *minLoadNodes*, line 9-10). In this way, there are some jobs allocated on the same GPU, where they are managed by the local coordinator. We will elaborate their coordinated execution next. Note that, although AntMan automatically selects opportunistic jobs by default, it also allows users to manually identify the job type at the point of submission; for example, as a resource-guarantee job explicitly to ensure SLAs. A job can also be specified as an opportunistic job that will never occupy the tenant's resource quota, and vice versa. In practice, users usually submit jobs in opportunistic mode to avoid the potential queuing delay, aiming to perform debugging and hyper-parameter tuning, which are both driven by early feedbacks [48, 51].

Local coordinator. The main responsibility of the local coordinator is to collaborate the execution of jobs on shared GPUs. Next, we first introduce how local coordinator ensures the performance of resource-guarantee jobs at shared execution. Then, we describe the approach to handle resource demand surges of a resource-guarantee job. Finally, we in-

introduce a greedy approach in AntMan to maximize the aggregated job performance when a GPU is only shared by opportunistic jobs. These approaches are achieved by utilizing the information reported from both GPU device and DL frameworks, and by instructing the memory management module (Section 3.1.1) and computation management module (Section 3.1.2) in DL frameworks.

A GPU is allocated to only one resource-guarantee job as it consumes GPU quota. However, in AntMan, it is possible that there are some opportunistic jobs executed on this GPU. As such, the local coordinator must prevent the resource-guarantee job from interfering by other co-located jobs at run-time. When a resource-guarantee job arrives on a GPU that runs with opportunistic jobs, the local coordinator first limits the opportunistic jobs in using GPU, for both GPU memory and GPU SM. By reducing the GPU usage of the opportunistic jobs, the newly launched resource-guarantee job will be capable of persistently initializing the training variables (*i.e.*, model) in the GPU memory. In addition, when launching a DL training job, the GPU device needs to be initialized by the DL framework, which takes more time if the GPU is in a high load. Once the resource-guarantee job is stably executed, the local coordinator will allocate the rest of the GPU memory to the opportunistic jobs. Furthermore, it gradually increases the GPU computation unit usage of opportunistic jobs without interfering with resource-guarantee jobs by monitoring the job performance (*i.e.*, mini-batch time). Similarly, when an opportunistic job arrives on a shared GPU, the local coordinator raises its GPU resource usage in a step-like fashion under the condition that the resource-guarantee job is not affected.

During the job execution, the resource demand of both the GPU memory and GPU computation unit might surge beyond the currently available resources (Section 2.2). To be aware of such dynamic resource demand, the local coordinator monitors the metrics that are reported by DL frameworks (*e.g.*, host memory usage, mini-batch time). Therefore, when a resource-guarantee job increases the GPU memory requirement, the tensors are temporarily stored using host memory, thanks to the universal memory (Section 3.1.1). The local coordinator shrinks the GPU memory usage of other opportunistic jobs and raises the GPU memory limit of the resource-guarantee job to recover its performance. It is similar for GPU computation unit usage coordination. Note that, AntMan relies on the application level metric (*i.e.*, mini-batch time) to indicate the job performance of resource-guarantee jobs. If it observes an unstable performance in the resource-guarantee job, it adopts a pessimistic strategy to limit the usage of GPU resources of other opportunistic jobs.

GPU resources can also be idle waiting without any resource-guarantee jobs (*e.g.*, due to gang-schedule as described in Section 2.2). In this case, if there is only one opportunistic job, the GPU resources can be fully utilized by this job without any constraints. Sometimes, it is possible that a GPU is occupied by multiple opportunistic jobs. Under this

Figure 10: Workloads show diversity in performance sensitivity given insufficient memory.

scenarios, AntMan optimizes the aggregated job performance by maximizing GPU memory efficiency. With the dynamic scaling mechanisms enabled, we find that different workloads show differences in sensitivity regarding the performance slowdown from memory limitations. The peak memory usage of a job is limited using the dynamic memory scaling mechanism, and the host memory is thereby used for the remainder of the excess. As illustrated in Figure 10, Super Resolution (SR) model suffers only around 25% performance slowdown even with a 90% reduction in its device memory. VGG16 [43] model on Cifar10 dataset (VGG) can keep most of its original performance even after reducing its device memory by half. ResNet50 [22] on ImageNet dataset (ResNet) is sensitive to memory shrinkage; a 10% memory reduction introduces more than 60% slowdown. Therefore, when the total GPU memory demand of opportunistic jobs exceeds the GPU's memory capacity, AntMan adopts a simple heuristic approach which allocates GPU memory to the job that improves the normalized aggregated job performance at best. This is carried out via an introspective trial-and-error allocation.

Job upgrade. In AntMan, opportunistic jobs are executed at best-effort level to improve the cluster utilization. However, this is done without an SLA guarantee. The global scheduler upgrades these jobs given sufficient resources to complete them quickly. For distributed synchronous DL training, the partial upgrade does not help because the performance downgrade of a worker can be broadcast to the entire job. Thus, the global scheduler checks if all GPUs are filled up in opportunistic jobs. Once all task instances are ready to upgrade and the resource quota is sufficient, AntMan prefers to upgrade the opportunistic job rather than launch a new one. Global scheduler notifies local coordinator to tag it as a resource-guarantee job and consumes the tenant's GPU quota to accomplish the job upgrade.

4 Implementation

At Alibaba, DL training jobs are executed in Docker containers with our customized versions of DL frameworks. The APIs of the DL frameworks are compatible with the community version however with AntMan’s features enhanced. A prototype custom cluster scheduler is implemented on Kubernetes [11] for evaluation. AntMan is fully implemented in our internal cluster scheduler, Fuxi [52], to serve the daily production training jobs on several clusters with thousands of GPUs each.

4.1 Deep Learning Framework

Dynamic scaling mechanisms are implemented in two popular deep learning frameworks, TensorFlow [8] and PyTorch [35], on versions v1.12 and v1.3.1 respectively. The implementation in TensorFlow takes 4000 lines of code (mostly in C++). The implementation in PyTorch takes about 2000 lines of code (500 lines in Python and 1500 lines in C++).

The modification of DL frameworks is mostly in three components: memory allocator, executor, and interfaces. As it adopts a similar implementation in both frameworks, we mainly use TensorFlow terminology to describe the details. To enable dynamic universal memory, `BFCAllocator` (`CUDACachingAllocator` in PyTorch) is modified to introduce an adjustable upper limit for memory. The memory allocator keeps track of the total bytes of memory allocation and triggers out-of-memory when total bytes exceed the upper limit. In addition, a new interface is introduced to the memory allocator to allow emptying of cached memory at any time. A new universal memory allocator, `UniversalAllocator`, is also added to wrap the GPU memory allocator and host memory allocator (*i.e.*, using `cudaHostMalloc` for memory allocation). When a memory allocation is triggered by the request of a tensor, `UniversalAllocator` tries to allocate the memory using the GPU memory allocator and treats the CPU memory allocator as a backup if there is insufficient GPU memory left over. Note that, the `UniversalAllocator` maintains a set data structure that records the pointers of memory regions allocated by GPU, which is used to classify the memory pointers for de-allocation.

To enable dynamic computation unit scaling, a `GpuOpManager` with an operator processing queue, which runs in a standalone thread, is introduced in DL frameworks. The operator executor of TensorFlow is modified accordingly to insert GPU operators to `GpuOpManager` queue in order so as to dedicate the execution of GPU operators to it. `GpuOpManager` may delay the actual execution of the GPU operators based on a limited percentage of the computation capacity.

The statistics of memory usage patterns and the execution information are aggregated for the local coordinator. The DL frameworks and local coordinator communicate through the

file system. They both have a monitor thread to check the file for receiving either job statistics or control signals. To minimize the overhead of memory management, the dynamic scaling of memory is triggered at the mini-batch boundaries (end of `session.run()`).

4.2 Cluster Scheduler

A custom scheduler is implemented on Kubernetes [11] as a prototype to evaluate AntMan. The implementation requires around 2000 lines of code in Python. Overall, Kubernetes is responsible for cluster management and for executing jobs in Docker containers. Our global scheduler uses Python APIs to monitor the events in Kubernetes’s API server for scheduling. Local coordinators are deployed as a `DaemonSet` in Kubernetes. Each coordinator monitors certain paths of the file system to collect the reported information for each job. The aggregated job and device information are stored in ETCD, a built-in distributed key-value store in Kubernetes. Therefore, global scheduler directly reads states in ETCD when making scheduling decisions.

AntMan has been fully implemented in Alibaba’s internal cluster scheduler, Fuxi [52]. The implementation of global scheduler takes about 10000 LOC, including failover support and testing. The local coordinator implementation takes about 2000 LOC. Both of them are written in C++. The DL infrastructure is coupled with the big-data infrastructure, as DL jobs are part of the data pipeline. Fuxi adopts an architecture that optimizes for high performance scheduling, and it currently does not have ETCD. Global scheduler and local coordinator shall maintain their own aggregated device and job information and use RPC for communication.

5 Evaluation

In this section, we first show micro-benchmark results to demonstrate the effectiveness and efficiency of AntMan mechanisms. We then evaluate the benefits of AntMan in a small cluster with 64 V100 GPUs to compare the policies with real workloads. Finally, we present the evaluation results on a production cluster with more than 5000 heterogeneous GPUs (V100 and P100). All the experiments are conducted on a cloud GPU cluster with 8 servers, unless explicitly stated. Every server is equipped with a 96-core Intel Xeon Platinum 8163 (Skylake) @2.50GHz with 736GB RAM, running CentOS 7.7. Each server has 8 NVIDIA V100 GPUs (32 GB GPU memory, with NVLink) powered by NVIDIA driver 418.87, CUDA 10.0, and CUDNN 7. The cloud GPU cluster is managed by Kubernetes; jobs are submitted through KubeFlow, and are executed in Docker containers. Only data-parallel is evaluated with synchronous training for jobs that require more than 1 GPU because they are common, although asynchronous training can also be supported. The trace in the experiment consists of 9 models, 2 of them implemented

	Model	Arrival	GpuMem	BS	Quota
Job-A	GCN	0 min	3.5 GB	1400	No
Job-B	ResNet	26 min	30.0 GB	360	Yes

Table 1: Setup and information of two jobs.

	Preempt	FIFO	Pack	UMem	AntMan
Job-A	Failed	43.0	43.1	43.4	43.9
Job-B	91.1	108.2	Failed	541.6	91.8

Table 2: Job status and JCT (min) of two jobs executing in different configurations.

in PyTorch 1.3.1 and 7 of them implemented in TensorFlow 1.12.

5.1 Benchmark

In this section, we evaluate the dynamic scaling mechanism of AntMan in two aspects, memory and computation unit. We first demonstrate that dynamic memory scaling is indispensable in preventing failure and ensuring job performance. We then measure the efficiency of memory shrinkage and growth on typical workloads and detail the timeline on a ResNet-50 benchmark. Finally, we demonstrate the ability of dynamic computation unit scaling on avoiding job interference, by packing two jobs in a shared GPU.

Dynamic GPU memory scaling. To demonstrate that dynamic memory scaling is essential for sharing GPUs with multiple jobs, two typical jobs are chosen to construct a typical scenario. As shown in Table 1, Job-A is a GCN model that arrives at 0 minutes. Its peak GPU memory usage is 3.5 GB and is submitted by users without a resource quota. Job-B is a ResNet-50 task that arrives 26 minutes later. In total, it consumes 30 GB GPU memory and is submitted with a resource quota guarantee, which means it should run directly to meet the SLA requirements. The cluster has only one 32 GB GPU left and both jobs are scheduled on this GPU at arrival. Both jobs are run in the setup described above multiple times, but with different action policies when Job-B arrives. Table 2 shows the job status and job completion time (JCT) in minutes for both jobs with different configurations. At Job-B’s arrival, the scheduler can choose to preempt Job-A. In this way, Job-B can be directly scheduled and finished in 91.1 minutes at the cost of Job-A’s failure. The second choice is to run Job-B in a first-in-first-out (FIFO) mode. Job-B will not be launched until Job-A is finished, which introduces an extra 17.1-minute queuing delay. The third choice is to pack two jobs in the same GPU as proposed in Gandiva [48]. In this case, Job-B eventually fails because of the insufficient GPU memory (28.5 GB) granted. UMem indicates running Job-B in packing mode with the support of AntMan’s universal memory, but without the coordinated scaling on the

(a) A shrink-growth profiling on (b) Overhead of GPU memory scaling for typical models.

Figure 11: Efficiency of GPU memory scaling in AntMan.

GPU memory limit (Section 3.1.1). Host memory are used when running out of GPU memory. Thus, Job-B will not fail from out-of-memory, however, it takes 514.6 minutes to finish and violates the SLA. AntMan leverages both universal memory and dynamic GPU memory scaling to coordinate job execution. It allocates sufficient device memory to Job-B as it runs with a resource quota, and offers the rest part of GPU memory to Job-A to allow it run as efficiently as possible. More specifically, when Job-B arrives, AntMan coordinates two jobs to shrink the GPU memory usage of Job-A and grow the GPU memory of Job-B. Job-B uses 30 GB GPU memory and Job-A uses the 2 GB left over, and 1.5 GB host memory. Note that, the performance of Job-B is still slightly slower compared to the preemptive scenario. This is because even though the required GPU memory is sufficient through dynamic scaling of AntMan, Job-B is still interfered in by the co-execution with Job-A in the computation unit.

Efficient memory shrinkage and growth. To demonstrate the efficiency of the dynamic memory scaling mechanism, a ResNet-50 job is run and the memory shrinkage and growth are manually triggered in order. As shown in Figure 11a, the performance is measured by monitoring the in-use GPU memory using both Nvidia API and memory statistics in DL frameworks. As Figure 11a indicates, the memory shrink from 17.6 GB to 1.3 GB takes only 17 ms. The GPU memory usage grows back to 17.6 GB in 143 ms, which is slower than the memory shrink. This is because GPU memory is allocated on demand with deep learning forward computation. Thus, the measured time includes both the forward computation time, which is essential to this mini-batch, and the memory allocation overhead. To understand the actual overhead, the time cost and memory usage of the next mini-batch are also plotted. The mini-batch with GPU memory growth takes 234 ms and the next mini-batch, which utilizes the cached memory, takes 119 ms to accomplish. Therefore, the growth overhead of ResNet-50 model is 115 ms. The same approach is applied to measure memory scaling overhead on other typical DL models. Figure 11b summarizes the overhead measured for VGG16 [43], Inception3 [45], and GoogleNet [44], which adjust GPU memory at a size of 17 GB, 16 GB, and 4 GB

Figure 12: The SM utilization rates of packing mode in Gandiva [48] and an adaptive computation adjustment mode in AntMan for a 500s segment of execution of ESPnet and ResNet-50.

respectively. Given a dynamic memory scaling interval of one minute, the largest overhead (*i.e.*, VGG16) is still negligible (only 0.4%).

Dynamic GPU computation unit scaling. To demonstrate the adaptive computation adjustment is essential for sharing GPU between multiple jobs, the SM utilization rates when running two typical jobs under packing mode and adaptive computation mode are characterized separately. As shown in Figure 12, the resource-guarantee job is an PyTorch job with ESPnet [46] model on the speech-text dataset. It co-executes with an opportunistic job which is a TensorFlow job with ResNet-50 [22] model on ImageNet [16]. Compared to ResNet-50, ESPnet consumes less SM and less memory. Therefore, packing these two jobs together into one GPU incurs a relatively higher GPU kernel queuing delay for the ESPnet and eventually leads to an SLA violation. Figure 12a illustrates that ESPnet is poor at competing GPU computation cycles compared to ResNet-50. The utilization of ESPnet remains mostly at 30% which is lower than in Figure 12b. ResNet-50 launches many more kernels per unit time than ESPnet, therefore, it consumes more GPU computation time. These results show that the end-to-end execution time of ESPnet increases dramatically from 20.1 minutes (when running on a dedicated GPU) to 105.2 minutes (when running together with ResNet-50).

Figure 12b illustrates that AntMan can leverage adaptive computation adjustment to utilize the left over resources as much as possible while still satisfying the SLA requirements. Specifically, AntMan introduces a feedback-based adjustment approach that continuously monitors the performance of resource guarantee jobs and uses performance feedbacks to adjust the GPU kernel launching frequency of opportunistic jobs. As shown in Figure 12b, the SM utilization rates of the training stage (the first 140 seconds) of ESPnet fluctuate between 5% and 50%. In this scenario, AntMan continuously adjusts the GPU kernel launching frequency of ResNet-50 to ensure the training performance of ESPnet. Therefore, the

	Model	Type	Dataset
20%	ResNet-50 [22]	CV	ImageNet [16]
	VGG16 [43]	CV	Cifar10 [30]
	SuperResolution [42]	CV	BSD300 [34]
20%	Bert [17]	NLP	SQuAD [38]
20%	ESPnet [46]	Speech	Corp.Data
20%	GraphSAGE [21]	Rec.	PPI [55]
	GCN [29]	Rec.	Cora [41]
20%	DIN [53]	Ad.	Corp.Data
	Wide & Deep [15]	Ad.	Corp.Data

Table 3: Deep learning models and the ratios in the trace.

results reflected in this figure is that the SM utilization rates of ResNet-50 are constantly fluctuating between 30% to 90% within the first 140 seconds of execution. In contrast, the decoding stage (between 140 and 390 seconds) of ESPnet runs without consuming GPU computation cycles. Therefore, the SM utilization rates of ResNet-50 are relatively high at this stage. As a result, by leveraging adaptive computation adjustments, the end-to-end execution time of ESPnet remains 20.8 minutes while ResNet-50 maintains 57% performance.

5.2 Trace Experiment

Workloads. Nine state-of-the-art deep learning models are selected from Github, together with open datasets, as summarized in Table 3. As the datasets of speech and advertisement are too small for evaluation, the internal datasets of Alibaba are used for the experiment. The models are classified into categories according to their application domains and they are evenly mixed up (20%). The job runtime of the trace is configured according to the distribution reported by Microsoft [48]. As a simplified multi-tenant setup, deep learning training jobs of the trace are randomly dispatched into two tenants. Tenant-A has 64-GPU quota and Tenant-B has no quota. Therefore, all Tenant-A's jobs are resource-guarantee jobs, and all jobs in Tenant-B are opportunistic jobs.

Baseline. The experiment compares AntMan to another GPU production cluster scheduler, Apache YARNs capacity scheduler (YARN-CS), which is used in Microsoft Philly [19, 28]. Gandiva [48], a state-of-the-art DL scheduling system, is also used for comparison. Gandiva introduces a series of primitives in DL for scheduling, including packing, migration, and time-slicing. The packing strategy of Gandiva is used in this experiment, which greedily schedules jobs to the GPUs with lowest GPU utilization and sufficient GPU memory. The migration and time-slicing proposed in Gandiva are to solve resource fragmentation and benefit AutoML, which are orthogonal to AntMan. Note that, Gandiva relies on job profiling information (*i.e.*, GPU utilization, GPU memory usage) for greedy packing decisions. Such profiling can hardly

(a) Comparison of YARN-CS, (b) Job completion time of Gandiva, and AntMan.

Figure 13: Trace experiment on 64 V100 GPUs.

be achieved in a production cluster, as its outputs might affect the successor tasks of DL pipeline. In the trace experiment, profiling information is unknown to both AntMan and YARN-CS.

Results. Figure 13a shows the average job completion time (JCT) and the makespan for the three schedulers when executing the same synthesized job trace in a cluster with 64 V100 GPUs. Compared to the capacity scheduler and Gandiva, AntMan improves average JCT by 2.05x and 1.84x. The total makespan is also reduced by 1.76x and 1.67x respectively. To understand the improvements brought about by AntMan, we config YARN-CS to run with preemption, which allows jobs in Tenant-A to preempt jobs in Tenant-B for execution. The JCT of resource-guarantee jobs (Tenant-A) are shown in Figure 13b. This shows the JCT of AntMan is almost the same as YARN-CS-preempt, however, YARN-CS-preempt achieves it with 46% of jobs being preempted. AntMan respects the jobs of Tenant-A and schedules them once their resource quota are satisfied, while conducting a performance control on the co-executing opportunistic jobs to avoid interference. Conversely, Gandiva delays the completion time of these jobs because of the lack of performance isolation and dynamic resource scaling.

5.3 Cluster Experiment

AntMan has been deployed on the production clusters of Alibaba to serve tens of thousands of daily deep learning training jobs. To verify the design and implementation of AntMan while ensuring it works properly, experiments and statistics are conducted on a heterogeneous GPU cluster with over 5000 GPUs.

To illustrate the cluster efficiency improvement provided by AntMan, one-week statistics were collected in December 2019, right before the deployment of AntMan, as the baseline. It is compared to the number collected in April 2020, after AntMan was fully deployed for weeks. However, as the jobs of these two weeks are different, the average JCT cannot be compared directly. Therefore, we focus on system metrics

	Avg.	90% tile	95% tile
Dec. 2019	1132	1978	5960
Apr. 2020	550	124	489

Table 4: One-week queuing delay statistic in seconds.

Interference	0%	0~1%	1~2%	2~3%	3~4%
# of jobs	9895	26	30	20	29

Table 5: Interference analysis on mini-batch time for 10K production jobs

comparison because the jobs of this cluster come from the same departments in Alibaba. The comparison shows that AntMan provides up to 17.1% extra GPUs for DL training jobs in this cluster. Hardware statistics show that AntMan achieves a 42% improvement on average for GPU memory usage and a 34% improvement on average for GPU utilization. Table 4 illustrates the queuing delay of jobs selected from a one-week period when roughly the same number of jobs arrive at the cluster. It illustrates that on average, the job queuing delay reduces by 2.05x and the tail latency significantly reduces by more than an order of magnitude, thanks to the cluster throughput improvement.

To measure the performance of resource-guarantee jobs in co-execution, 10000 jobs were randomly sampled from one week in April 2020 which both have the phases executing exclusively and co-executing with other jobs. For each job, the mini-batch time was recorded for both its dedicated execution and packing execution with other jobs. The mini-batch time difference between these two scenarios was calculated and any gaps larger than 10 ms were considered as interfered (10 ms is small enough to be considered as mini-batch fluctuation). In this way, the interference ratio for each job could be calculated. As shown in Table 5, 99% of the jobs suffer zero performance downgrades during job packing.

6 Related Work

GPU memory management. To optimize the limited and valued GPU memory for supporting larger batch-size DNN training, vDNN [39], Capuchin [36], CDMA [40], and Gist [26] adopts eviction, prefetching, and re-computation to reduce the GPU memory footprint, leveraging application-specific knowledge. Salus [50] packs multiple jobs in the same process to share the GPU memory management, however, with interference in co-execution. In addition, running multiple jobs in a process could potentially broadcast the failures, especially when given a significantly high failure ratio [27, 51]. AntMan provides a universal memory management design using dynamic GPU and CPU memory swapping at the granularity of tensors for the fluctuant load, which complements the memory swapping and re-computation policies.

Interference and performance isolation. Performance isolation is critical in modern operating systems and shared CPU clusters. Linux uses cgroups [1] to control the CPU and memory usage of a process. However, it rarely has support for general GPU applications. A series of research works, such as Quincy [25] and Entropy [24], optimize the job performance for fair sharing on CPU clusters. In AntMan, the characteristic of DL jobs is leveraged to provide fine-grained control on GPU memory and computation unit at runtime, which is similar to cgroups, but on an application level.

The interference issue of multiplexing jobs on a GPU has been well studied. Baymax [14] shares GPUs by mitigating queuing delay and PCIe contention. Prophet [13] tries to predict co-executed GPU workload performance using an analytical model. AntMan introduces an operator management module in the executor of the DL framework, leveraging the inherent periodical mini-batch iteration cycles as a metric for inter-job coordination. It controls the frequency of GPU kernel launches and resolves the contention in both the GPU computation unit and PCIe.

NVIDIA MPS can co-operate with multi-process CUDA applications in a GPU. MPS support is not production ready yet [4]. The resource limit cannot be changed at the runtime of a client process which violates the fluctuant characteristic. Moreover, MPS merges CUDA execution in only one context, resulting in the termination of all clients for any fatal GPU exceptions. rCUDA [37] and FlexDirect [3] of VMWare Bitfusion allow jobs to be remotely executed on a shared GPU.

GPU cluster scheduling Today, DL training jobs in multi-tenant production clusters are managed by infrastructures such as Kubernetes or YARN [9,28], where jobs are allocated on dedicated GPUs, leading to common low utilization [27]. Gandiva [48] proposes time-slicing, migration, and packing to allow GPU sharing. Time-slicing and migration switch the GPU usage among jobs in coarse-grained, and therefore cannot improve GPU utilization. The packing approach proposed in Gandiva [48] could potentially introduce significant unpredictable resource contention, which violates the fairness requirements of a shared multi-tenant cluster. Themis [33] addresses the unfairness of placement-sensitive characteristic in DL jobs by proposing a long term fairness object. Gandiva_{fair} [12] addresses the fairness issue of multi-size job time-slicing and proposes an automated trading mechanism. AlloX [31] efficiently and fairly schedules DL jobs in interchangeable resources by modelling the scheduling problem as a min-cost bipartite matching problem. AntMan introduces opportunistic DL jobs as low-priority jobs to best-effort utilize the GPU cycles, which is complementary to the fairness metrics and policies proposed above.

Elastic training. To utilize the idle GPUs introduced by gang-scheduling and to support fault-tolerance in DL training,

TorchElastic [7] and ElasticDL [2] are designed to start training with any number of available GPUs. A common problem of these elastic DL frameworks is that the model training accuracy can hardly be guaranteed or reproduced, and are thus rarely used in production.

7 Conclusion

We present AntMan, a deep learning infrastructure deployed in the GPU production clusters of Alibaba. AntMan introduces dynamic scaling primitives in deep learning frameworks, allowing flexible fine-grained control of GPU resources for individual deep learning jobs at runtime. By utilizing the effective primitives mentioned above, AntMan co-designs cluster scheduler and deep learning frameworks for cooperative job management, allowing GPUs to be utilized by over-provision of opportunistic jobs at best-effort while avoiding the interference to other jobs. AntMan improves the overall GPU memory utilization and the computation unit utilization of Alibaba's GPU clusters by 42% and 34% respectively without compromising fairness.

Write Dependency Disentanglement with HORAE

Xiaojian Liao, Youyou Lu*, Erci Xu, and Jiwu Shu*

Tsinghua University

Abstract

Storage systems rely on write dependency to achieve atomicity and consistency. However, enforcing write dependency comes at the expense of performance; it concatenates multiple hardware queues into a single logical queue, disables the concurrency of flash storage and serializes the access to isolated devices. Such serialization prevents the storage system from taking full advantage of high-performance drives (e.g., NVMe SSD) and storage arrays.

In this paper, we propose a new IO stack called HORAE to alleviate the write dependency overhead for high-performance drives. HORAE separates the dependency control from the data flow, and uses a dedicated interface to maintain the write dependency. Further, HORAE introduces the joint flush to enable parallel FLUSH commands on individual devices, and write redirection to handle dependency loops and parallelize in-place updates. We implement HORAE in Linux kernel and demonstrate its effectiveness through a wide variety of workloads. Evaluations show HORAE brings up to 1.8 \times and 2.1 \times performance gain in MySQL and BlueStore, respectively.

1 Introduction

The storage system has been under constant and fast evolution in recent years. At the device level, high-performance drives, such as NVMe SSD [15], are pushed onto the market with around 5 \times higher bandwidth and 6 \times lower latency against their previous generation (e.g., SATA SSD) [11, 18]. From the system perspective, developers are also proposing new ways of storage array organization to boost performance. For example, in BlueStore [23], a state-of-the-art storage backend of Ceph [45], data, metadata and journal can be separately persisted in different, or even dedicated devices.

With drastic changes from the hardware to the software, maintaining the write dependency without severely impacting the performance becomes increasingly challenging. The write dependency indicates a certain order of data blocks to be per-

sisted in the storage medium, and further underlies a variety of techniques (e.g., journaling [44], database transaction [13]) to provide ordering guarantee in the IO stack. Yet, the write order is achieved through an expensive approach, referred as *exclusive IO processing* in this paper. In the exclusive IO processing, the following IO requests can not be processed until the preceding one has been transferred through PCIe bus, then been processed by the device controller and finally returned with a completion response.

Unfortunately, this one-IO-at-a-time fashion of processing conflicts with the high parallelism of the NVMe stack, and further nullifies the concurrency potentials between multiple devices. First, it concatenates the multiple hardware queues of the NVMe SSD, thereby eliminating the concurrent processing of both host- and device-side cores [50]. Moreover, it serializes the access to physically independent drives, preventing the applications from enjoying the benefits of aggregated devices. In our motivation study, we observe that with the scaling of hardware queues and devices, the performance loss introduced by the write dependency can be up to 87%. Conversely, orderless writes without dependency can easily saturate the high bandwidth of NVMe SSDs (§3).

Therefore, to leverage the high bandwidth of NVMe SSDs while preserving dependency, we propose the *barrier translation* (§4) to convert the ordered writes into orderless data blocks and ordering metadata that describes the write dependency. The key idea of barrier translation is shifting the write dependency maintenance to the ordering metadata during normal execution and crash recovery, while concurrently dispatching the orderless data blocks.

We incarnate this idea by re-architecting modern IO stack with HORAE (§5). In a nutshell, HORAE bifurcates the traditional IO path into two dedicated ones, namely ordered control path and orderless data path. In the control path, HORAE flushes ordering metadata directly into the devices' persistent controller memory buffer (CMB), a region of general-purpose read/write memory on the controller of NVMe SSDs [15, 16], using memory-mapped IO (MMIO). On the other hand, HORAE reuses classic IO stack (i.e., block layer to device driver to

*Jiwu Shu and Youyou Lu are the corresponding authors.
{shujw, luyouyou}@tsinghua.edu.cn

device) to persist orderless writes. Note that this design is also scaling-friendly as orderless data blocks can be processed in both an asynchronous (to a single device) and pipelined (to multiple devices) manner.

Now, with a bifurcated IO path, we further develop a series of techniques to ensure both high performance and consistency in HORAE. First, we design *compact ordering metadata* and efficiently organize them in the CMB (§5.2). Second, the *joint flush* of HORAE performs parallel FLUSH commands on dependent devices (§5.3). Next, HORAE uses the write redirection to break the dependency loops, *parallelizing in-place updates* with strong consistency guarantee (§5.4). Finally, for crash recovery, HORAE reloads the ordering metadata, and further only commits the valid data blocks but discarding invalid ones that violate the write order (§5.5).

To quantify the benefits of HORAE, we build a kernel file system called HORAEFS to test applications relying on POSIX interfaces, and a user-space object store called HORAESTORE for distributed storage (§5.6). We compare HORAEFS against ext4 and BarrierFS [46], resulting in an up to 2.5× and 1.8× speedup at file system and application (e.g., MySQL [13]) level, respectively (§6). We also evaluate HORAESTORE against BlueStore [23], showing the transaction processing performance increases by up to 2.1×.

To sum up, we make the following contributions:

- We perform a study of the write dependency issue on multi-queue drives among both single and multiple devices setup. The results demonstrate considerable overhead of ensuring write dependency.
- We propose the barrier translation to decouple the ordering metadata from the dependent writes to enforce correct write order.
- We present a new IO stack called HORAE to disentangle the write dependency of both a single physical device and storage arrays. It introduces a dedicated path to control the write order, and uses joint flush and write redirection to ensure high performance and consistency.
- We adapt a kernel file system and a user-space object store to HORAE, and conduct a wide variety of experiments, showing significant performance improvement.

2 Background

This section starts with a brief introduction of enforcing write dependency under current IO stack (§2.1). Then, we illustrate state-of-the-art techniques that alleviate the overhead of enforcing the write dependency (§2.2).

2.1 Basic Ordering Guarantee Approach

In Figure 1(a), we can see that modern IO stack is a combination of software (i.e., the block layer, the device driver) and hardware (i.e., the storage device) layers. Each layer may reorder the write requests for better performance [15, 50] or fairness [4, 29]. Specifically, in the block layer, the host IO scheduler can schedule the requests in the per-core software

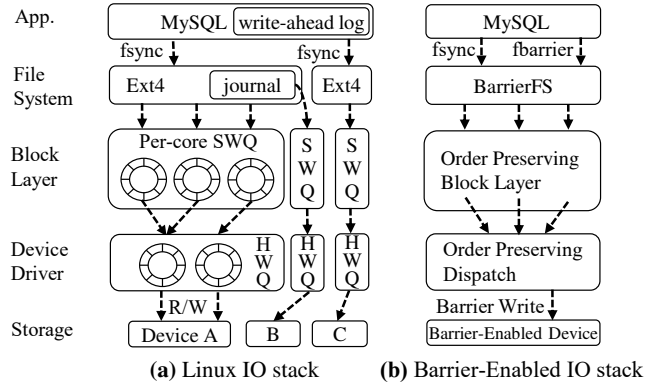

Figure 1: Existing IO Stacks with Different Order-Preserving Techniques. *SWQ: software queue. In current multi-queue block layer, each core has a software queue. HWQ: hardware queue. The storage device determines the maximum number of HWQs. Emerging NVMe drives usually have multiple HWQs.*

queues based on different algorithms (e.g., deadline). While in the storage device, the controller may fetch and process arbitrary requests due to timeouts and retries.

As a result of this design, the file system must explicitly enforce the storage order. Traditionally, the file system relies on two important steps: *synchronous transfer* and *cache barrier* (e.g., cache FLUSH). First, synchronous transfer requires the file system to process and transfer the dependent data blocks through each layer to the storage interface serially. Then, to further avoid the write reordering by the controller in the storage device layer, the file system issues a cache barrier command (e.g., FLUSH), draining out the data blocks in the volatile embedded buffer to the persistent storage. Afterwards, the file system repeats this processing the next request. Through interleaving dependent requests with exclusive IO processing, the file system ensures the write requests are made durable with the correct order.

The basic approach in guaranteeing the storage order is undoubtedly expensive. It exposes DMA transfer latency (synchronous transfer) and flash block programming delay (cache barrier) to the file system.

2.2 Ordering Guarantee Acceleration

Many techniques [25, 26, 46, 48] improve the basic approach presented in §2.1, by reducing the overhead of synchronous transfer and cache barrier. As barrier-enabled IO stack (BarrierIO [46]) is the closest competitor, we introduce it briefly.

BarrierIO reduces the storage order overhead by preserving the order throughout the entire IO stack. Specifically, the BarrierIO enforces the write dependency mainly using two techniques: the *order-preserving dispatch* to accelerate the synchronous transfer, and the *barrier write* command to improve the cache barrier. First, as shown in Figure 1(b), the order-preserving block layer ensures that the IO scheduler follows the write order specified by the file system. Further, the order-preserving dispatch maintains the write order of

Figure 2: Ordered Write VS. Orderless Write with Varying The Number of Hardware Queues and Devices. Each device has up to 32 hardware queues. Described in Section 3.1.

requests queueing in the (single) hardware queue. As a collaborator, the storage controller also fetches and serves the requests in a serialized fashion. Second, BarrierIO replaces the expensive FLUSH with a lightweight barrier write command for the storage controller to preserve the write order.

File systems provide the `fsync()` call for applications to order their write requests. Yet, it is still too expensive to preserve order by `fsync()`. Thus, like OptFS [26], BarrierIO separates the ordering from the durability, and further introduces a file system interface, i.e., `fbarrier()`, for ordering guarantee. The `fbarrier()` writes the associated data blocks in order, but returns without durability assurance.

3 Motivation

Multi-queue. The improvement of storage technologies has been continuously pushing forward the performance of solid-state drives. To meet the large internal parallelism of flash storage, SSDs are often equipped with multiple embedded processors and multiple hardware queues [33, 38]. In the host side, as shown in Figure 1(a), the IO stack employs the multicore friendly design. It statically maps the per-core software queues to the hardware queues for concurrent access. **Multi-device.** On the other hand, for higher volume capacity, performance and isolation, applications usually stripe data blocks to multiple devices as in RAID 0, or manually isolate different types of data into multiple devices. For example, as shown in Figure 1(a), the ext4 file system uses a dedicated device for journaling processing. The MySQL database redirects its write-ahead logs to a logging device.

The multi-queue and multi-device bring opportunities to enhance performance for independent write requests. Nevertheless, it still remains unknown how much overhead the write dependency introduces to the multi-queue and multi-device design. Here, we first start with a performance study of the write dependency atop multi-queue and multi-device.

3.1 Write Dependency Overhead

In this subsection, we quantify the overhead of write dependency atop Linux IO stack by comparing the IOPS of ordered writes with orderless ones. We use an NVMe SSD (spec in Table 2 Intel 750) with up to 32 hardware queues and use FIO [9] for testing. During the test, we vary the number of hardware queues and attach more devices. Further, we in-

crease the number of threads issuing 4 KB writes to gain the maximum IOPS.

For orderless random write, we use libaio [3] engine with `iodepth` of 512. In this setup, the write requests issued by libaio have no ordering constraints and can be freely reordered by the storage controller according to NVMe specification [15]. The results are shown in Figure 2. As we enable more hardware queues, the IOPS of orderless writes increases and gradually saturates the storage devices.

For ordered random write, we use libaio engine but set the `iodepth` to 1. This setup follows the principle of exclusive IO processing in guaranteeing the ordering. As shown in Figure 2, the IOPS of ordered write can hardly grow, even if we use more devices as RAID 0 to serve the write request.

The gap between orderless and ordered writes (blue area in Figure 2) indicates the overhead of the write dependency. With the increase of hardware queues, the overhead becomes more severe, and reaches up to 87%. We conclude that the Linux IO stack is not efficient in handling ordered writes.

3.2 Write Dependency Analysis

In this subsection, we analyze the write dependency overhead via explaining the behaviors of Linux IO stack.

For a single device, the physically independent hardware queues get logically dependent. The application thread firstly puts the write requests in the software queues through the IO interface (e.g., `io_submit()`). Linux IO stack supports various IO schedulers (e.g., BFQ [4]), which perform requests merging/reordering in the software queues. Next, the requests are dispatched to hardware queues, where IO commands are generated. In the hardware queues, out of consideration for hardware performance (e.g., device-side scheduling) and complexity (e.g., request retries), there are no ordering constraints of storage controller processing the commands [15]¹. Therefore, due to the orderless feature of both types of queues, to guarantee storage order, the IO stack only processes a single request or a set of independent requests at a time. As a result, the ordered write request keeps most queues idle and leaves the multi-queue drives underutilized.

For multiple devices, physically isolated devices get logically connected. The IO stack employs isolated in-memory data structures for the software environment of multi-device. In the hardware side, a device has its private DMA engine and hardware context. Despite the concurrent execution environment, the ordered writes flow through the multi-device in a serialized fashion; the application can not send a request to a different device until the on-going device finishes execution.

¹ In barrier-enabled devices, the host can queue multiple ordered writes and insert a barrier command in between. Such barrier command is available in a few eMMC products [22] with usually single hardware queue. Multi-queue-based NVMe does not have similar concept.

3.3 Limitation of Existing Work

A straightforward solution to remedy aforementioned issues is to keep the entire IO stack ordered as BarrierIO does, so as to allow more ordered writes to stay in the hardware queue. Recall that in Section 2.2, each layer in BarrierIO stack must preserve the request order spread by the upper layer. Implementing such design is quite simple in old drives with a sole command queue (e.g., mobile UFS, SATA SSD): the requests in the hardware queue are serviced in the FIFO way. However, it is quite challenging to extend this idea to multi-queue drives and multiple devices, without sacrificing the multicore designs of the host IO stack and the core/data parallelism of fast storage devices. We explain the reason in detail.

The key of BarrierIO is that each layer agrees on a specific order. While a single hardware queue structure itself can describe the order, for multi-queue and multi-device, the host IO stack must manually specify the order. Maintaining a global order among multiple queues throughout the entire IO stack potentially ruins the multi-queue and multi-device concurrency, which are vital features to fully exploit the bandwidth of high-performance drives, according to our evaluation (§6.2) and a recent study [50]. Further, the firmware design should comply with the host-specified order, which may introduce synchronization among embedded cores and may neutralize the internal core and data parallelism.

In this paper, instead of keeping the IO stack ordered, we seek a new approach that keeps most parts of current IO stack orderless while preserving correct storage order. We now present our design in the following sections.

4 The HORAE Foundation

To efficiently utilize the modern fast storage devices, we wish to keep the orderless and independent property of both the software and hardware intact. We achieve this goal via *barrier translation*, which disentangles the write dependency from original slow and ordered write requests.

4.1 Design

Here, we refer a series of ordered write requests issued by the file system or applications as a write stream. Commonly, a write stream can have multiple sets of data blocks and the inbetween barriers that serve as ordering points between two sets of data blocks. We note a set of data blocks to device A with a monotonic set ID x as A_x , and refer a barrier (write dependency) as \leq . Thus, for a write stream $A_x \leq B_{x+1}$, it shall be ensured that the data blocks of A_x must be made durable prior to ($<$) B_{x+1} or at the same time ($=$) as B_{x+1} .

Next, we move on to remove the dependency (i.e., \leq) between two write requests. We use $\{\}$ to group a set of independent write requests that can be processed concurrently. Our key issue is to translate the $A_x \leq B_{x+1}$ into $\{A_x, B_{x+1}\}$. We decouple the indexing of a write stream from its data content. The indexing (i.e., ordering metadata) keeps a minimum set of information to retain the dependency. We refer the ordering

metadata as \tilde{A}_x and the data content as \bar{A}_x , and thus we have $A_x = \tilde{A}_x \cup \bar{A}_x$. Specifically, if A_x has consecutive data blocks of n length to device A from logical block address (lba) m , $\tilde{A}_x = \{A, m, n\}$.

Given a write stream $A_x \leq B_{x+1}$, the *barrier translation* turns it into $\tilde{A}_x \leq \tilde{B}_{x+1} \leq \{\bar{A}_x, \bar{B}_{x+1}\}$. Specifically, the translated write stream guarantees the order in two steps: (1) $\{\tilde{A}_x, \tilde{B}_{x+1}\} \leq \{\bar{A}_x, \bar{B}_{x+1}\}$ and (2) $\tilde{A}_x \leq \tilde{B}_{x+1}$. First, we must ensure the ordering metadata is made durable no later than data content. Then, the write dependency of original write stream is extracted as the ordering metadata.

4.2 Proof

Now, we further discuss the correctness of barrier translation via the following proof. Our main point is to show that the translated write stream has the same effect on satisfying the ordering constraints. In other words, the following proves that if the ordering metadata is made durable in specific order, and is made durable no later than the data content, the write dependency of original write stream is maintained.

We formalize the implication as follows:

$$\tilde{A}_x \leq \tilde{B}_{x+1} \leq \{\bar{A}_x, \bar{B}_{x+1}\} \implies A_x \leq B_{x+1} \quad (1)$$

The key lies in the non-deterministic order between \bar{A}_x and \bar{B}_{x+1} . We thus discuss the proof in two situations: $\bar{A}_x \leq \bar{B}_{x+1}$ and $\bar{B}_{x+1} < \bar{A}_x$ as follows.

The first case $\bar{A}_x \leq \bar{B}_{x+1}$. Since we already have $\tilde{A}_x \leq \tilde{B}_{x+1}$, we have $(\tilde{A}_x \cup \bar{A}_x) \leq (\tilde{B}_{x+1} \cup \bar{B}_{x+1})$. Because $A_x = \tilde{A}_x \cup \bar{A}_x$ and $B_{x+1} = \tilde{B}_{x+1} \cup \bar{B}_{x+1}$, we have $A_x \leq B_{x+1}$.

The second case $\bar{B}_{x+1} < \bar{A}_x$. This case at first glance may seem to violate the write order. However, since we have $\tilde{B}_{x+1} \leq \bar{B}_{x+1}$, we can always find and discard the content \bar{B}_{x+1} via the indexing \tilde{B}_{x+1} . In this situation, the data content remains empty, i.e., \emptyset . The empty result obeys any write dependency, i.e., $\emptyset \in \{A_x \leq B_{x+1}\} = \{\emptyset, \{A_x\}, \{A_x, B_{x+1}\}\}$.

Two intuitive concerns may be raised from the second case. First, a long write stream may be at a higher risk of losing more data due to discard, although it keeps a consistent state of disk status. However, such scenario is common and acceptable in storage systems. Similar to roll-back and undo log, the discarding time window (e.g., `fsync()` delay) is determined by the file systems or applications. If applications desire data durability rather than ordering, they must synchronously wait for the durability of the write stream, e.g., calling `fsync()`.

Second, a special case of the write dependency, called discarding at a dependency loop, may erase the old but valid data content. For example, consider $A_x \leq B_{x+1} \leq A_{x+2}$, where A_x and A_{x+2} operate on the same logical block address. This would occur when storage systems perform in-place updates (IPU). Simply discarding \bar{A}_x in the second case loses the valid data. Our solution is to break the dependency loop by redirecting IPU to another location, i.e., $A_x \leq B_{x+1} \leq A'_{x+2}$, where A'_{x+2} targets on a different address from A_x . In this way, we guarantee the correctness of dependency loop as in

Figure 3: An Example of The Barrier Translation. The solid circle represents the ordering metadata. The subscript denotes the desired write order of the file system or applications.

normal case, preserving high concurrency as well as the old version of data. We show more details in §5.4.

4.3 Example

We now use an example to go through the entire process of barrier translation. Figure 3(a) presents the original write stream. As we can see, even for different devices, the block-sized (e.g., 4 KB) data is still processed in a serialized fashion. Even worse, the classic approach uses slow and coarse-grained barrier (the cloud shape, e.g., flash FLUSH) to enforce the relationship \leq , which may process unrelated data blocks (e.g., the orderless data blocks).

Figure 3(b) shows the output of the barrier translation. Original expensive barriers are replaced with faster and fine-grained barriers (the thunder shape, e.g., memory barrier). Further, the initial ordered writes are translated to orderless ones with no barriers. As a result, after processing the ordering metadata, the devices can process data blocks at their full throttle concurrently.

5 The HORAE IO stack

To demonstrate the advantage of the barrier translation, we implement HORAE by modifying the classic Linux IO stack. The following sections first give an overview of HORAE, and then present the techniques at length.

5.1 Overview

As the high level architecture shown in the Figure 4, HORAE extends the generic IO stack with an *ordering layer* targeting ordered writes. Moreover, HORAE separates the ordering control from the data flow: the ordering layer translates the ordered data writes (①) into ordering metadata (②) plus the orderless data writes (③). The ordering metadata passes through a dedicated control path (MMIO). The orderless data writes flow through the original block layer and device driver (block IO) as usual. As a result of separation, the data path is no longer bounded by the write dependency, and it thus allows the file systems to dispatch the data blocks to arbi-

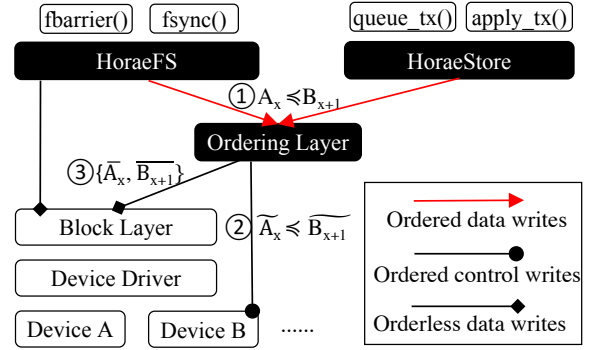

Figure 4: The HORAE IO Stack Architecture. HORAE splits the traditional IO path into ordered control path ② and orderless data path ③. HORAE persists the ordering metadata \tilde{A}_x via the control path before submitting the orderless data blocks \tilde{A}_x to the data path.

trary hardware queues or storage devices without exclusively occupying the hardware resources.

The key of HORAE is the ordering layer, to which the ordering guarantee of the entire IO stack is completely delegated (§5.2). Note that the ordering layer does not need to handle all block IOs, but instead just need to capture the write dependencies of ordered writes. Specifically, HORAE stores the ordering metadata in the persistent controller memory buffer (CMB in NVMe spec 1.2 [15], PMR in NVMe spec 1.4 [16]) of the storage device using an ordering queue structure. HORAE leverages epochs to group a set of writes with no intra-dependency, and further uses the ordering queue structure itself to reflect the order of each epoch with inter-dependency.

Separating the ordering control path from the data path provides numerous benefits; it saves the block layer, the device driver, and the devices from enforcing write order, which can sacrifice performance or particular property (e.g., scheduling). Further, this design enables HORAE to perform parallel FLUSHes despite the dependencies among multiple devices (§5.3). Yet, it also faces a challenge, the dependency loop.

As we mentioned in §4.2, the dependency loop occurs when multiple in-place updates (IPU) operate on the same address. As the data path of HORAE is totally orderless, multiple ordered in-progress (issued by the file system but the completion response is not returned) IPUs can co-exist and be freely reordered. The dependency loops, if not properly handled, can introduce data version issue (e.g., the former request overwrites the later one) and even the security issue (e.g., unauthorized data access). HORAE breaks the dependency loops by write redirection (§5.4). In other words, HORAE treats the IPUs as versioned writes, stores their ordering metadata serially, and concurrently redirects them to a pre-reserved disk location. In background, HORAE writes the redirected data blocks back to their original destination. In this way, HORAE parallels the IPUs while retaining their ordering.

Atop the ordering layer, HORAE exports block device abstraction and provides ordering control interface to the upper

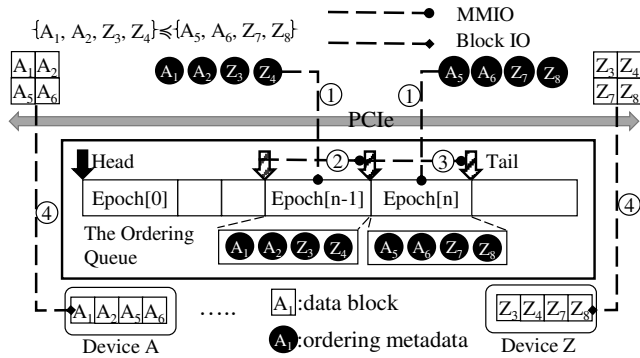

Figure 5: The Circular Ordering Queue Organization. The ordering queue is located in the persistent controller memory buffer (CMB) of SSD. HORAE groups a set of independent writes to an epoch, and enforces the ordering between epochs. Described in Section 5.2.

layer systems (§5.6). We provide APIs (application programming interfaces) and high level porting guidelines for upper layer systems to adapt to HORAE. Moreover, we build a kernel file system, HORAEFS, for applications that rely on POSIX file system interfaces, and a user-space object store, HORAESTORE, for distributed storage backend.

On top of HORAEFS and HORAESTORE, similar to previous works [23, 26, 46], we provide two interfaces, the ordering and durability interface, for upper layer systems or applications to organize the ordered data flow. The ordering interfaces (i.e., `fbarrier()`, `queue_tx()`) send the data blocks to the storage with ordering guarantee, but return without ensuring durability. The durability interfaces (i.e., `fsync()`, `apply_tx()`) deliver the intact semantics as before.

5.2 Ordering Guarantee

The major role of the ordering layer is guaranteeing the write order. Recall that the write stream $A_x \leq B_{x+1}$ is translated to $\tilde{A}_x \leq \tilde{B}_{x+1} \leq \{\tilde{A}_x, \tilde{B}_{x+1}\}$, thus the ordering layer enforces the write dependency of the ordering metadata before dispatching the translated data blocks. We first present the organization of the ordering metadata.

Ordering metadata organization. As shown in the center of Figure 5, through the PCIe base address register, HORAE uses the persistent Controller Memory Buffer (CMB) as the persistent circular ordering queue. The ordering queue is bounded by the head and tail pointers, and stores the ordering metadata of one write stream. For an incoming ordered write request, HORAE first appends its ordering metadata to the queue via MMIO. As shown in Figure 6, the ordering metadata is compact, mainly consisting of range-based destination (i.e., lba, len, devid). Storing the ordering metadata via control path is a CPU-to-device transfer with byte-addressability; unlike an interrupt-based memory-to-device DMA transfer, it does not transfer a full block nor switch context. Thus, persisting the compact ordering metadata via MMIO is efficient.

HORAE leverages the epoch to group a set of independent writes. And, HORAE only enforces the write dependency in

Format:	lba	len	devid	etag	dr	plba	rsvd
Size in bits:	32	32	8	1	1	32	22

Figure 6: The Ordering Metadata Format. lba: logical block address. len: length of continuous data blocks. devid: destination device ID. etag: epoch boundary. dr: is made durable. plba: lba of prepare write. rsvd: reserved bits.

the unit of epoch. To realize epoch, HORAE uses the etag to indicate the boundary of epochs. The etag implies \leq .

Now, we go through an example presented in Figure 5 to show how data blocks reach the storage with ordering constraints. Suppose that the ordering layer receives two sets of ordered write requests from two threads with ordering constraints $\{A_1, A_2, Z_3, Z_4\} \leq \{A_5, A_6, Z_7, Z_8\}$. The ordering layer first forms two epochs N and N-1, and constructs the ordering metadata according to the data blocks and write dependencies. Next, the two threads store the ordering metadata concurrently to the ordering queue via MMIO (①). Then, HORAE updates the 8-byte tail pointer sequentially to ensure both the update atomicity of each epoch and the write order of associated ordering metadata (②, ③). Finally, the two threads dispatch the orderless writes concurrently via block IO interface (④).

Since the size of available CMB is usually limited (e.g., 2 MB), the ordering queue may exceed the CMB region. Thus, HORAE introduces two operations, swap and dequeue, to reclaim free space of the CMB for incoming requests.

Swap. The ordering layer blocks the threads issuing ordered writes, and then invokes swap operation, when the total size of the valid ordering metadata exceeds the queue capacity. It moves the valid ordering metadata to a checkpoint region with larger capacity, e.g., a portion of flash storage. It first waits for the on-going append operations on the ordering queue to complete. Next, it copies the whole valid ordering metadata to the checkpoint region. Finally, it updates the head and tail pointers atomically with a lightweight journal.

Dequeue. The ordering layer dequeues the expired ordering metadata when its associated data blocks and the preceding ones are durable. The dequeue operation moves the 8-byte head pointer.

Optimization. We observe that the MMIO write latency through PCIe is acceptable, but MMIO read can be extremely slow (8 B read costs 0.9us, 4 KB read costs 113us). This is because MMIO read is split into small-sized (determined by CPU) non-posted read transactions to guarantee atomicity [17]. Yet, MMIO reads can be abundant on the CMB. For example, HORAE allocates free locations from the ordering queue before sending the ordering metadata, which requires frequent head and tail pointer access. Also, HORAE needs to read the whole ordering queue for a swap operation. HORAE avoids slow MMIO reads by maintaining an in-memory write-through cache for the entire CMB. The cache serves all read operations in memory. Write operations are performed to the cache, and persisted to the device CMB simultaneously via

Figure 7: The Durability and Joint FLUSH of HORAE. A FLUSH command to a single device also triggers flushings to other devices whose write requests must be made durable in advance.

MMIO. The extra memory consumption (2 MB) is negligible.

5.3 Durability Guarantee

Applications may also require instant durability. Linux IO stack uses the FLUSH command (e.g., calling `fsync()`) to enforce durability and ordering of updates in a storage device. Further, the FLUSH serves as a barrier between multiple devices, so as to ensure that the post-FLUSH requests are not made durable prior to the pre-FLUSH ones. For example, to guarantee the durability of $A_x \leq B_{x+1}$, Linux IO stack issues two FLUSHes. The first one on device A ensures the write dependency (\leq) as well as the durability of A_x , and the second one on device B for durability of B_{x+1} .

The FLUSH of HORAE no longer serves as a barrier. Thus, HORAE eliminates intermediate FLUSHes and invokes an eventual FLUSH to ensure durability. Unlike the legacy FLUSH targeting on sole device, the FLUSH of HORAE, called joint FLUSH, automatically flushes related devices whose data blocks should be persisted in advance.

Figure 7 shows an example of the joint FLUSH in detail. The states of the ordering queue are in Figure 7a, and suppose we decide to flush device C. The ordering layer firstly finds the flush point (6), the last position of the flushed device in the ordering queue. Next, it identifies the devices that need to be flushed simultaneously. A device should be flushed if it has requests prior to the flush point. To quickly locate the flush candidates, HORAE keeps the first and last position of each device (device range) in the ordering queue (e.g., <1,5> of device A), as shown in the top of Figure 7a. By checking the existence of the intersection of the device range and head-to-flush range (<1,6>), HORAE selects the flush candidates. Then, HORAE sends FLUSH commands to the candidate devices (A and B) simultaneously. When the joint FLUSH completes, HORAE moves the `flushed` pointer and resets the device range, as shown in Figure 7b.

With the `flushed` pointer, HORAE ensures the durability of the write requests between the head and `flushed` position. However, on SSDs with power loss protection (PLP), data blocks are guaranteed to durable when they reach the storage buffer, prior to a FLUSH command. Therefore, HORAE uses the `dr` bit (shown in Figure 6) to indicate the durability of the requests after the `flushed` position. For SSD with PLP, HORAE sets the `dr` bit, once the ordered write requests are

completed via interrupt handler or polling.

While the legacy FLUSH is always performed in a serialized and synchronous fashion, the joint FLUSH enables HORAE to flush concurrently and asynchronously, for devices without PLP. These devices expose extremely long flash programming latency, so async flushings on them exploit the potential parallelism. However, HORAE remains the sync flushing on the other type of devices with PLP. Since flushing such devices is returned from the block layer directly, async flushing incurs unnecessary context switches from the wakeup mechanism.

5.4 Handling Dependency Loops

To understand the motivation for resolving the dependency loops, we show two examples. First, consider a data block is overwritten repeatedly. Reordering of two overwrite operations may cause the later one to be overwritten by the former one, and results in a data version issue. Second, consider at the file system level. The file system frees a data block from owner A, and then reallocates it to owner B. Reordering of reallocating and freeing upon a sudden crash can cause a security issue: owner B can see the data content of owner A.

Classic IO stacks handle dependency loops by prohibiting multiple in-progress IPU on the same address. IPU on the same address are operated exclusively, where the next IPU can not be submitted until the preceding one is completely durable. However, this approach serializes the access to the same address, leaving the device underutilized. HORAE allows multiple in-progress parallel IPU on the same address, and resolves dependency loops through IPU detection, prepare and commit write.

IPU detection. The foremost issue is to detect IPU. In HORAE, the upper layer systems must specify the IPU explicitly because of the awareness of IPU.

Prepare write. In receiving an IPU, HORAE first allocates an available location from the preparatory area (p-area), a pre-reserved area of each device for handling dependency loops. It stores the location in the `plba` region (shown in Figure 6) of the ordering metadata. Next, it dispatches the IPU to the `plba` position of p-area, via the same routine as the classic orderless write. Further, HORAE uses an in-memory IPU radix tree to record the `plba` for following read operations to retrieve the latest data. The IPU tree accepts the logical block address (lba) as the input and outputs the newest `plba`. Compared to the IO processing, the modification on the IPU tree is performed in memory, and its overhead is thus negligible.

Commit write. HORAE applies the effects of IPU via the commit write, once the durability of the prepare write is satisfied. HORAE firstly scans the ordering queue, and merges the overlapping data blocks of the p-area. Then, it writes the merged data blocks back to their original destination concurrently. When the commit write completes, HORAE removes associated entries of the IPU tree, and dequeues the entries between the head and `flushed` pointer of the ordering queue.

HORAE introduces two commit write policies, lazy and ea-

API	Explanation
<code>olayer_init_stream(sid, param)</code>	Register an ordered write stream with ID <code>sid</code> and parameters <code>param</code>
<code>olayer_submit_bio(bio, sid)</code>	Submit an ordered block IO <code>bio</code> to stream <code>sid</code>
<code>olayer_submit_bh(bh, op, opflags, sid)</code>	Submit a buffer head <code>bh</code> to stream <code>sid</code> with specific flags <code>opflags</code> and <code>op</code>
<code>olayer_submit_bio_ipu(bio, sid)</code>	Submit an ordered in-place update block IO <code>bio</code> to stream <code>sid</code>
<code>olayer_blkdev_issue_flush(bdev, gfp_mask, error_sector, sid)</code>	Issue a joint FLUSH to device <code>bdev</code> and stream <code>sid</code>
<code>fbarrier(fd)</code>	Write the data blocks and file system metadata of file <code>fd</code> in order
<code>fdatabarrier(fd)</code>	Write the data blocks of file <code>fd</code> in order
<code>io_setup(nr_events, io_ctx, sids)</code>	Create an asynchronous I/O context <code>io_ctx</code> and a set of streams <code>sids</code>
<code>io_submit_order(io_ctx, nr, iocb, sid)</code>	Write <code>nr</code> data blocks defined in <code>iocb</code> to stream <code>sid</code>

Table 1: The APIs of HORAE. HORAE provides the *stream* (or *sequencer*) abstraction for upper layer systems. Each stream is identified by a unique *sid*, and represents a sequence of ordered IO requests. To realize multiple streams, HORAE evenly partitions the CMB area and p-area, and assigns a portion to each stream.

ger commit write. The lazy commit write is performed in background when the IO stack is idle. When HORAE runs out of p-area space, it triggers eager commit write.

Read. As the ordered IPU's are redirected to p-area, the following read operation retrieves the latest data blocks from p-area first. HORAE searches the IPU tree for the `plba`, and reads the data from the `plba` position of p-area.

With write redirection for IPU's, HORAE provides higher consistency than the data consistency, which matches the default ordered mode of ext4. The data consistency requires that (1) the file system metadata does not point to garbage data, and (2) the old data blocks do not overwrite new ones. HORAE is able to preserve the order between data and file system metadata, and thus the file system metadata always points to valid data. Also, HORAE controls the order of parallel IPU's. Therefore, HORAE supports data consistency.

However, the data consistency does not provide request atomicity. Under data consistency, the IPU's directly overwrite valid data blocks, and can sometimes leave the file system a combination of old and new data, which brings inconvenience to maintain application-level consistency [2]. This is because commodity storage does not provide atomic write operations. For a write request containing a 4 KB data block, it may be split into multiple 512 B (determined partially by `Max_Payload_Size`) PCIe atomic ops (i.e., transactions) [17]. A crash may result in partially updated 4 KB data block.

HORAE enhances data consistency with request atomicity; continuous data blocks of each write request sent to the HORAE are made durably visible atomically due to double write. Once the durability of the prepare write is satisfied, HORAE ensures request atomicity. Otherwise, the prepare write may be partially completed and its effect is thus ignored.

5.5 Crash Consistency

In the face of a sudden crash, HORAE must be able to recover the system to a correct state that the data blocks are persisted in the correct order and the already durable data blocks with a completion response are not lost. This subsection discusses the crash consistency of HORAE, including the ordering queue consistency and the data block consistency.

The ordering queue. As stated in §5.2, HORAE writes the ordering metadata via MMIO. But MMIO writes are not guaranteed to be durable because they are posted transactions without completions. After each MMIO write, HORAE issues a non-posted MMIO read of zero byte length to ensure prior writes are made durable [24].

Upon a power outage, the ordering queue, the head, flushed and tail pointers, are saved to a backup region of flash memory, with the assistance of capacitors inside the SSD. When power resumes, HORAE loads the backup region into the CMB.

The data block. HORAE recovers the storage to a correct state with the support of the ordering queue. HORAE scans the ordering queue from the head position to the flushed position, in case of the data blocks are made durable with the FLUSH response but expired entries are not dequeued. HORAE commits the data blocks of the p-area that obey the order.

Further, HORAE recovers the durable yet not flushed data blocks (e.g., in SSD with PLP). Starting from the flushed position, HORAE sequentially scans the ordering queue, and commits the prepare writes until it finds a non-durable data block (i.e., `dr` bit is not set). After that, HORAE discards the following data blocks through filling the blocks with “zeros”, because they violate the write order.

5.6 The API of HORAE and Use Cases

This subsection first describes the API of HORAE, and then presents two use cases: a file system leveraging a single write stream (i.e., a single ordering queue), and a user-space object store running with multiple write streams.

5.6.1 The API of HORAE

To enable the developers to leverage the efficient ordering control of HORAE, we provide three levels of functionalities/APIs shown in Table 1: the kernel block device, the file system and the asynchronous IO interface (i.e., `libaio` [3]).

Kernel block device interface. The kernel systems (e.g., file systems) can use `olayer_init_stream` to initialize an ordered write stream for further use. `olayer_submit_bio` and `olayer_submit_bh` deliver the same block IO sub-

mission function as classic interfaces (i.e., `submit_bio` and `submit_bh`); but they return when associated ordering metadata are persisted in the `sid` ordering queue (§5.2). `olayer_submit_bio_ipu` is for in-place updates (§5.4). `olayer_blkdev_issue_flush` is extended from classic FLUSH interface (i.e., `blkdev_issue_flush`); it keeps the same arguments and performs joint FLUSH on a given stream and target devices (§5.3).

File system interface. We offer two ordering file system interfaces, the `fbarrier` and `fdatabarrier`, for upper layer systems or applications to organize their ordered data flow. The `fbarrier` bears the same semantics as the `osync` of OptFS and `fbarrier` of BarrierFS; it writes the data blocks and journaled metadata blocks in order but returns without ensuring durability. The `fdatabarrier` is the same as that of BarrierFS; it only ensures the ordering of the application data blocks but not the journaled blocks. We further show the internals of these interfaces in the following §5.6.2.

Libaio interface. Libaio provides wrapper functions for async IO system calls, which are used for some systems (e.g., BlueStore and KVell [36]) designed on high-performance drives. We expose the ordering control path of HORAE via two new interfaces on libaio. `io_setup` allows developers to allocate a set of streams defined in `sids`. `io_submit_order` performs ordered IO submission; it bears the same semantics of `fdatabarrier`. We further show the usage of these interfaces in boosting BlueStore in §5.6.3.

Porting guidelines. We provide three guidelines. First, upper layer systems can distinguish the ordered writes from the orderless ones based on the categories of the request, and send them using HORAE’s APIs. The requests that contain metadata, the write-ahead log and the data of eager persistence (e.g., data specified by the `fsync()` thread) are treated as ordered writes. Second, due to the separation of ordering control path, upper layer system can design and implement the ordering and durability logic individually. In the ordering logic, they can use the ordering control interface (e.g., `olayer_submit_bio`) to dispatch the following ordered writes immediately after the previous one returns from the control path. This allows the ordered data blocks to be transferred in an asynchronous manner without waiting for the completion of DMA. Third, they can remove all FLUSHes that serve as ordering points in the ordering logic, and invoke an eventual joint FLUSH in the durability logic to guarantee durability.

5.6.2 The HORAEFS File System

We build HORAEFS atop the HORAE with a set of modifications of BarrierFS [46]. BarrierFS builds on Ext4, and divides the journaling thread (i.e., JBD2 in Figure 8) into submit thread and flush thread.

HORAEFS inherits this design, and the major changes are that (1) we submit ordered writes and reads to the ordering layer first, (2) we remove the FLUSH to coordinate the data and journal device and (3) we detect IPU through inspecting

Figure 8: The `fsync()` and `fbarrier()`. 4 KB data size. The number shows the latency of each operation in microseconds. *D*: application data blocks. *Pre*: prepare the journaled metadata. *JM*: journaled file system metadata. *JC*: journaled commit record. *Post*: change transaction state, calculate journal stats, etc.

the `BH_New` states of each write. Although the journal area is repeatedly overwritten, we do not treat the journaled writes as IPU, as the journal area is always cleaned before reused.

Figure 8 shows a side-by-side comparison between Ext4 and HORAE on a NVMe SSD. For each 4 KB allocating write in most cases, both file systems issue three data blocks, namely the data block (*D*), the journaled metadata block (*JM*) and the journaled commit block (*JC*). Further, both file systems order the data blocks with $\{D, JM\} \leq JC$. Ext4 enforces the ordering constraints through the exclusive IO processing. It waits for the completion of preceding data blocks (e.g., `Wait JM`) and issues a FLUSH (not shown in the figure because it is returned by the block layer quickly). HORAEFS eliminates the exclusive IO processing, and preserves the order through the ordering layer, as shown in the black rectangle. HORAEFS waits for the durability of the associated blocks in flush thread, and finally issues a FLUSH to the ordering layer for durability.

HORAEFS differs from BarrierFS in the IO dispatching (i.e., the white rectangle) and IO waiting (i.e., the gray rectangle) phase. During IO dispatching phase, BarrierFS passes through the entire order-preserving SCSI software stack. Besides, BarrierFS experiences extra waiting time due to the order-preserving hardware write, i.e., the barrier write.

5.6.3 The HORAESTORE Distributed Storage Backend

We build HORAESTORE atop the HORAE with a set of modifications of BlueStore [23], an object store engine of Ceph.

BlueStore directly manages the block device by async IO interfaces (e.g., libaio), providing transaction interfaces for distributed object storage (i.e., RADOS). Inside each write transaction, it first persists the aligned write to data storage, followed by storing the unaligned small writes and metadata in a RocksDB [1] KV transaction (KVTXN). The RocksDB first writes the write-ahead log (WAL), then applies the updates to the KV pairs. For inter-transaction ordering, it uses sequencers; the next transaction can not start a KVTXN until the preceding one has made the aligned write durable and

Figure 9: Ordered Write Performance. The throughput of randomly writing 1 GB drive space by 1 write stream (i.e., 1 thread). *vanilla*: native Linux NVMe IO stack. *horae*: HORAE IO stack. *barrier*: Barrier-enabled IO stack. Horizontal dotted lines: maximum device bandwidth.

started its KVTXN. Besides, BlueStore uses a single KV thread to serially perform KVTXNs, which blocks and waits for in-progress KVTXNs to become durable.

HORAESTORE accelerates the transaction ordering guarantee, while exporting the same transaction interfaces. For intra-transaction ordering, HORAESTORE uses the new async IO interface of HORAE, `io_submit_order()`, to control the write order of data, WAL and KV pairs. With this new interface, for each transaction, HORAESTORE processes the data, WAL and KV pairs concurrently.

For inter-transaction ordering, HORAESTORE extends the overlapping range of dependent transactions, and improves the concurrency of KVTXNs' submission. First, in HORAESTORE, the following transaction starts the KVTXN immediately after the preceding one has satisfied the ordering of its aligned writes (D) and KVTXN. In other words, HORAE can process two dependent transactions concurrently, once the ordering between them is satisfied, i.e., $\{D_1, D_2\} \leq KVTXN_1 \leq KVTXN_2$. Second, HORAESTORE separates the ordering of KVTXN from durability; it starts the KVTXNs in a KV submit thread for ordering, and ensures the durability in a KV flush thread. Hence, more KVTXNs can be queued in the KV submit thread, and can further be dispatched to RocksDB for processing.

5.7 Implementation Details and Discussion

We implement HORAE in Linux kernel as a pluggable kernel module (i.e., the ordering layer), consisting of 1288 lines of code (LOC); no changes are needed for traditional IO stack (i.e., the block layer, NVMe and SCSI driver). HORAEFS is implemented based on BarrierFS with approximately 100 LOC changes. HORAESTORE is implemented based on BlueStore with around 200 LOC change.

HORAE needs a region of byte-addressable persistent memory for efficient ordering control path. We realize this by remapping the CMB region of a capacitor-backed CMB-enabled SSD from StarBlaze [20] using `ioremap_wc()`.

Currently, CMB-enabled SSDs are already available in the market [14, 18]. Moreover, many SSDs have enabled power loss protection [10, 12, 18, 32]. Therefore, the persistent CMB (or PMR) requirement of HORAE can be achieved easily. We further discuss the alternatives of the CMB in §7.

6 Evaluation

This section evaluates the HORAE, HORAEFS and HORAESTORE by answering the following questions:

- What is the performance of HORAE in guaranteeing the ordering? (§6.2, §5.2)
- What is the performance of HORAE in guaranteeing the durability? (§6.3, §5.3)
- How does HORAE perform under in-place updates with different consistency level? (§6.4, §5.4)
- Can HORAE recover correctly after a crash and how much overhead does recovery introduce? (§6.5, §5.5)
- How much improvement does HORAE bring to applications? (§6.6, §5.6)

6.1 Experimental Setup

Hardware. We conduct all experiments with a 12-core machine running at 2.50 GHZ. Table 2 shows the specification of the candidate SSDs. We use three broadly categorized SSDs: the SATA SSD (labelled as A), the consumer-grade NVMe SSD (B), and the high-performance datacenter-grade NVMe SSD (C). The NVMe SSD B and C are with PLP. The size of CMB used by HORAE is 2 MB.

Compared Systems. We mainly compare with two types of IO stacks, Vanilla and BarrierIO [46]. Vanilla is the default Linux IO stack. Ext4 [7] is a journaling file system running upon vanilla. We setup ext4 with default options in ordered journaling mode (denoted as ext4-DR). We disable the barriers in ext4-DR (`nobarrier` option) with ext4-OD, which only guarantees the dispatch order reaching in storage buffer (not storage medium). Similar to ext4, we test BarrierFS [46] upon BarrierIO stack with durability guarantee (denoted as BFS-DR) and ordering guarantee (denoted as BFS-OD). Since we do not have barrier compliant storage

	Model	Seq. Bandwidth	Rand. IOPS (8GB span)
A	Samsung 860 PRO SATA	Read: 560MB/s Write: 530MB/s	Read: 100k Write: 90k
B	Intel 750 NVMe	Read: 2200MB/s Write: 950MB/s	Read: 430K Write: 230K
C	Intel DC P3700 NVMe	Read: 2800MB/s Write: 1900MB/s	Read: 640K Write: 475K

Table 2: SSD Specifications.

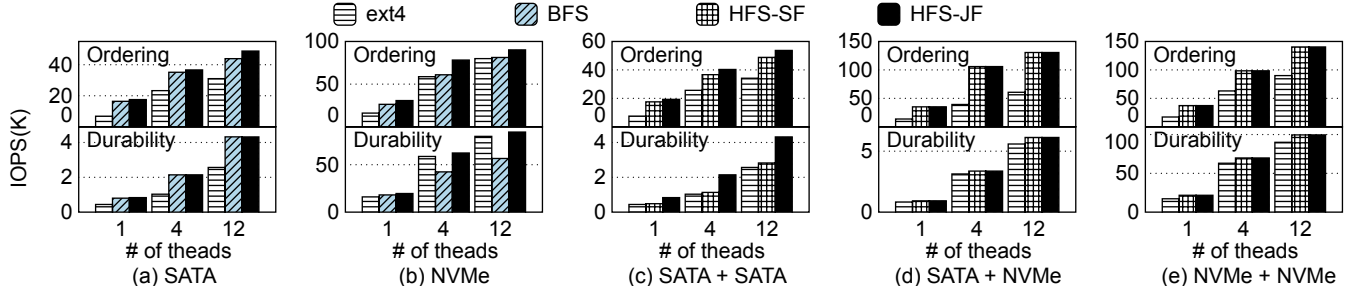

Figure 10: File System Performance under FIO Allocating Write Workload. *Ordering*: *nobarrier* option of *ext4*, but only guarantees a relaxed ordering of reaching the storage write buffer. *fbarrier()* of *BarrierFS* and *HORAEFS*. *Durability*: *fsync()*. *SF*: *serialized FLUSH*. *JF*: *joint FLUSH*.

devices, we reuse the software of *BarrierFS* and add extra 5% overhead of the hardware barrier write, following the assumption of the *BarrierFS* paper. To run *BarrierFS* correctly in multi-queue drives, we modify the NVMe driver to setup only one IO command queue. *HORAEFS* (abbreviated as *HFS*) uses just one ordering queue.

6.2 Basic Performance Evaluation

First, we demonstrate the effectiveness of *HORAE* in guarantee the ordering (§5.2), through measuring the throughput of three IO stacks on block devices. We vary the number of devices and organize them as soft-RAID 0. Specifically, we evenly distribute *X* KB random writes to different devices in a round-robin fashion. Figure 9 shows the overall throughput of ordering guarantee with varying the write size. Note that we only have the result of *BarrierIO* on a single device, because it does not support multiple drives.

Result. From the result, we find that *HORAE* outperforms vanilla and *BarrierIO* IO stack by 4.1× and 2× respectively in the case of a single device and 4 KB write unit. On multiple devices, *HORAE* achieves up to 6.8× throughput than vanilla. Further, we observe that *HORAE* can easily saturate the device bandwidth with small write units (e.g., 4 KB).

Analysis. We now decompose the IO path to better understand the performance. The overall IO path can be broken down into four parts, and we measure the overhead of each part when issuing 4 KB data blocks as follows: (1) data page preparation costs 0.8 us in our test; (2) the ordering layer processes and writes ordering metadata within 0.7 us; (3) about 1.0 us is spent on block layer, which performs request merging and *bio*(block IO data structure)-to-*request*(NVMe driver data structure) transmission; (4) data DMA, device-side processing and interrupt handler consume 8.7 us. The classic approach experiences all parts except (2), which counts up to 10.5 us in total. Thus, the maximum IOPS and throughput that a single write stream can achieve in classic IO stack are 95K and 380 MB/s. *HORAE* experiences (1) and (2) in most cases. The ordering layer delegates the submission of orderless block IO to per-CPU background submitter threads, so as to hide the overhead of block layer for foreground ordering calls. Thus, *HORAE* can achieve up to 2.6 GB/s in the case

of 4 KB writes. *BarrierIO* eliminates (4) in ordering guarantee, and thus can achieve up to 2.2 GB/s in NVMe stack theoretically. However, we observe that configuring the drive to a single IO command queue considerably decreases the available bandwidth of high-performance storage.

6.3 File System Evaluation

In this subsection, we evaluate the performance of POSIX file systems atop different IO stacks with varying the number and type of storage devices. Moreover, we demonstrate the effectiveness of *HORAE* in guaranteeing the durability (§5.3). We perform allocating write so that the file system always finds the updated metadata in the journal. We set up the file system with two modes: the internal journal that mixes data and journal blocks in a single device, and the external journal that uses a dedicated device for locating journal. The result is shown in Figure 10, and we make the following observations.

Effect of removing flush. As shown in Figure 10(a), on SATA SSD, *HFS* achieves 80% higher IOPS averagely against *ext4*, and exhibits comparable performance compared to *BFS*. Here, the major overhead is two *FLUSH*s. The former one is used to control the write order of the data blocks and the commit record, and the later one is to ensure durability. The *FLUSH* of SATA SSD exposes raw flash programming delay (1 ms). In *BFS* and *HFS*, the former *FLUSH* is eliminated.

Effect of async DMA. As shown in Figure 10(b), on NVMe SSD, *HFS* achieves 22% higher IOPS than *ext4*. Compared to the durability of *HFS*, the ordering guarantee of *HFS* can further boost IOPS by 57%. The major overhead here is shifted to the DMA transfer. Figure 8 shows the source of improvement, and the number next to each rectangle shows the single thread latency of each operation. Due to the separation of the ordering and durability, *HFS* and *BFS* can overlap the DMA transfer with CPU processing, and thus partly hide the DMA delay. *BFS* does not perform well on NVMe SSD due to the restriction of the single IO command queue, especially when we increase the number of threads.

Effect of joint flush. As shown in Figure 10(c), *HFS* outperforms *ext4* by 88% and 90% on average in durability and ordering respectively. Comparing *HFS-PF* to *HFS-SF*, we find the joint flush improves the overall performance by up to

Figure 11: In-Place Update Performance. OD: *nobarrier* option of ext4, *fbarrier()* of HFS. DR: *fsync()*. Test on SSD C.

70%. This is because joint flush allows physically independent devices to perform flushing concurrently.

Effect of parallel device access. Figure 10(d-e) plots the result when we use an NVMe SSD to accelerate the journal. In ordering, HFS improves ext4 by 150% and 76% respectively. The major contributor here is the parallel device access. In HFS, once the associated ordering metadata is processed serially by the control path, the data blocks can be transferred and processed by individual devices concurrently. While in ext4, this is done in a serialized manner.

6.4 In-Place Update Evaluation

In this subsection, we evaluate the performance of in-place update under different consistency and with varying the size of the preparatory area (p-area) (§5.4).

As shown in the X title of Figure 11(a), we first setup the file system with two modes, the ordered and data-journaling mode, representing data and version consistency, respectively. Then, we issue 10 GB overwrites to a 10 GB file. The ordered mode performs metadata journal. The data-journaling mode performs data journal to achieve the version consistency that the version of data matches that of metadata.

In the ordered mode, the double write of eager commit write enhances the data consistency at the cost of 10% IOPS loss in durability. In ordering, HFS exhibits 50% higher IOPS compared to ext4, because HFS can emit multiple IPU simultaneously without interleaving each IPU with DMA transfer and FLUSH command.

In the data-journaling mode, both file systems first put the IPU to journal area. When performing journal, HFS dispatches the commit record immediately after the journaled data, and thus provides 60% higher IOPS on average.

When HORAE runs out of p-area space, HORAE blocks incoming requests and triggers eager commit write. To investigate the performance of HORAE in such a situation, we run the same IPU workload with the scaling of p-area size. The results are shown in Figure 11(b). We find that HFS-OD performs dramatically better than ext4-OD even with small p-area. To provide request atomicity, HFS-DR delivers less IOPS than ext4-DR. As we enlarge the p-area, the IOPS gap narrows.

Figure 12: MySQL under OLTP-insert Workload. (a) Sole: mix data, redo log and undo log in device B. (b) Separate redo: data and undo log to device B, redo log to device C. (c) Separate redo & undo: data to device B, redo log to device C, undo log to another device B. DR: The *fsync()* used to control the write order of transactions is replaced with *fbarrier()*. OD: All *fsync()*s are replaced with *fbarrier()*s. Sync() the database every 1 second. R0: organize underlying devices as logical volumes using RAID 0.

6.5 Crash Recovery Evaluation

To verify the consistency guarantees of HORAE (§5.5), we run workloads, and forcibly shut down the machine at random. We restart the machine and measure the recovery performance. We choose Varmail workload of Filebench [8] for its intensive *fsync()*. Varmail contains two *fsync()*s in each flow loop, and we replace the first one with *fbarrier()*.

We repeat the test 30 times, and observe HORAEFS can always recover to a consistent state. The recovery time comes from two main parts: the ordering queue load time and commit write time. First, HORAE loads the pointers and the ordering metadata into host DRAM, which consumes 29.8 ms on average. Next, the commit write requires “read-merge-write”, and costs 497.6 ms on average.

6.6 Application Evaluation

6.6.1 MySQL

We evaluate MySQL with OLTP-insert workload [21]. The setups are described in the caption of Figure 12.

In sole configuration, HFS-DR outperforms ext4-DR and BFS-DR by 15% and 23% respectively. In ordering, HFS-OD prevails ext4-OD by 56% and achieves 36% higher TPS than BFS-OD. This evidences that HFS is more efficient in controlling the write order.

When using dedicated devices to store redo and undo logs (i.e., Figure 12(b)), HFS-DR outperforms ext4-DR by 16%, and HFS-OD performs 76% better than ext4-OD. This is because HFS can parallelize the IOs to individual devices.

Comparing Figure 12(b) with (c), we find that separating undo logs does not bring much improvement in both ext4 and HFS. Undo logs perform logical logging to retain the old version of database tables, which incurs less writes compared to physical logging (redo log). MySQL tightly embeds the undo logs in the table files, thus separating undo logs does not alleviate the write traffic to the data device.

Comparing HFS with HFS-R0, we observe that, from the performance aspect, manually distributing data flows to de-

Figure 13: SQLite Random Insert Performance. SQLite runs at WAL mode. 1M inserts in random key order. Key size 16 bytes, value size 100 bytes. DR: The first three `fdatsync()`s used to control storage order of transactions are replaced with `fdbatbarrier()`s, but the last one remains intact. OD: All `fdatsync()`s are replaced with `fdbatbarrier()`s.

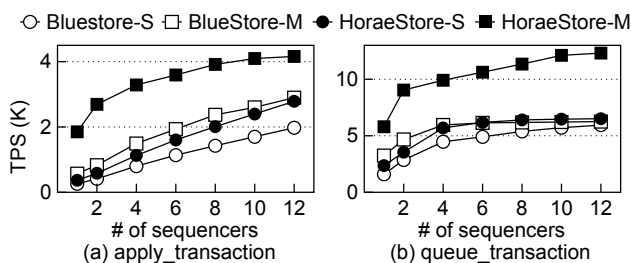

Figure 14: Object Store Performance. Store-S: mix data, metadata, WAL to device A. Store-M: data to device A, metadata to device B, WAL to device C. `apply_transaction`: durability guarantees. `queue_transaction`: ordering guarantee.

vices of particular usage is better than the automatic dispersion of logical volumes. A naive implementation of RAID 0 treats the devices equally. However, the data flows of application usually have different write traffic and locality. Therefore, uniform distribution potentially bounds the better devices and ruins the data locality.

6.6.2 SQLite

This subsection focuses on the performance of SQLite [19]. The detailed setups are presented in the caption of Figure 13.

On SATA SSD, the ordering setups (OD) outperform the durability ones (DR) by an order of magnitude due to the reduction of the prohibitive FLUSH. In ordering, both BFS and HFS exhibit over 20% performance gain against ext4 due to the separation of ordering and durability that brings chances of overlapping CPU with IOs.

On NVMe SSD, as the FLUSH becomes inexpensive, ext4-OD achieves almost the same performance as ext4-DR. HFS separates the control path from the data path, and thus SQLite can order the table files and logs through `fbarrier()`. Therefore, more IOs can be processed at the same time.

6.6.3 BlueStore

This subsection evaluates the transaction processing of object store with default options. We use the built-in object store benchmark [5] of Ceph with varying the number of

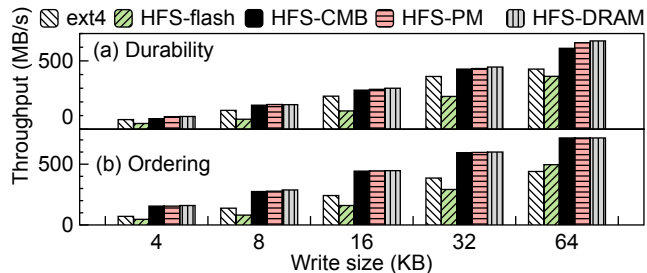

Figure 15: Comparison of The Media of The Ordering Queue. flash: block IO to SSD. CMB: MMIO to SSD's memory buffer. PM: Intel Optane persistent memory. DRAM: capacitor-back memory.

sequencers. Each sequencer serializes the transactions, and transactions of different sequencers do not have dependency. Each transaction issues 20 KB write, which is split into 16 KB aligned write to data device and 4 KB small write to RocksDB. Two interfaces are evaluated, `apply_transaction()` and `queue_transaction()`, representing ordering and durability guarantee, respectively. Figure 14 shows the results.

In Figure 14(a), HORAEStore exhibits 1.4× and 2.1× TPS gain against BlueStore, in S and M setup, respectively. To preserve order, BlueStore does not submit the small write and metadata to RocksDB until the aligned write has been completed. While in HORAEStore, once the aligned write and KV transaction have been processed serially via the control path, associated data blocks can be processed concurrently.

The `queue_transaction()` brings opportunities to apply multiple transactions. As shown in Figure 14(b), HORAEStore outperforms BlueStore averagely by 23% and 83% in S and M setup, respectively. Due to the write dependency over multiple devices, the slower data device burdens the faster metadata and WAL devices. Hence, BlueStore-M delivers similar TPS compared to BlueStore-S. In HORAEStore-M, as the control path guarantees the ordering, the synchronization between aligned write and KV transaction is alleviated. Further, HORAEStore enables more KV transactions to continuously fulfill the metadata and WAL storage.

7 Discussion

CMB Alternatives. Recall that HORAE persists the ordering metadata in the CMB for efficiency. Nevertheless, several off-the-shelf non-volatile media are capable of storing the ordering metadata: SSD (flash), Intel persistent memory (PM) and capacitor-backed DRAM. We locate the ordering queue in these media and measure the single-threaded throughput of the ordered writes, as shown in Figure 15. We find that storing the ordering metadata directly through the block-based interface to SSD (i.e., HFS-flash) significantly decreases the throughput. This is because, even the ordering metadata is 16 B, it must be padded to 4 KB, where the 4 KB synchronous PCIe transfer masks the concurrency of translated orderless writes. When the write size increases (over 64 KB), HFS-flash gradually outperforms ext4. We also find the PM and

DRAM are also satisfiable alternatives of the CMB.

8 Related Work

Storage order. Many researchers [25–28, 40, 46] have studied and mitigated the overhead of storage order guarantee. Among these studies, the closest ones are OptFS [26] and BarrierFS [46] that separate the ordering guarantee from durability guarantee and provide similar ordering primitive. OptFS, BarrierFS and HORAE are proposed under different storage technologies (HDD, SATA SSD, NVMe SSD and storage arrays), thereby mainly differing in the architecture, the scope of application and hardware requirements. First, OptFS embeds the transaction checksum in the journal commit block and detects the ordering violation during recovery, which reduces the rotational disk FLUSH overhead at runtime. BarrierFS preserves the order layer by layer, thereby aligning with the single queue structure of SCSI stack and devices. They are difficult to be extended to multiple queues or multiple devices. In contrast, HORAE stores the ordering metadata via a dedicated control path to maintain the write order. This design aims to let the ordering bypass the traditional stack to enable high throughput and easy scaling to multiple devices. Second, the checksum-based ordering approach of OptFS is limited to continuous address space (e.g., file system journaling), because the checksum can be only used to detect the ordering violation of data blocks in pre-determined locations. Alternatively, HORAE builds a more generic ordering layer which can spread data blocks to arbitrary logical locations of any device. Third, OptFS requires the disk to support asynchronous durability notification. BarrierIO requires barrier compliant storage device which is only available in a few eMMC (embedded multimedia card) products. HORAE can run on the standard NVMe devices with exposed CMB. The CMB feature is already defined in NVMe spec, and is under increasing promotion and recognition by NVMe and SPDK communities [6].

Dependency tracking. Some works use dependency tracking techniques to handle storage order. Soft updates [39] directly tracks the dependencies of the file system structures in a per-pointer basis. Similarly, Featherstitch [28] introduces the *patch* to specify how a range of bytes should be changed. HORAE also tracks the write dependencies in the ordering queue. The tracking unit of HORAE is different from prior works; each entry in HORAE describes how a range of data blocks (e.g., 4 KB) should be ordered. The block-aligned tracking introduces less complexity of both dependency tracking and file system modifications, and it is more generic in the context of block device. In addition, due to the disability of telling data versions, soft updates does not support version consistency. Featherstitch assumes single in-progress write to the same block address, and treats dependency loop as errors. Thus, the in-place updates of Featherstitch must wait for the completion of preceding one. Instead, HORAE saves the in-place updates from long DMA transfer through write

redirection with enhanced consistency.

Storage IO stack. A school of works [30, 31, 34, 35, 37, 40–43, 49, 51] improve the storage IO stack. Xsyncfs [40] uses output-triggered commits to persist a data block only when the result needs to be externally visible. IceFS [37] allocates separate journals for each container for isolation. SpanFS [31] partitions the file system at *domain* granularity for performance scalability. Built atop F2FS [34], ParaFS [51] co-designs the file system with the SSD’s FTL to bridge the semantics gap between the hardware and software. iJournaling [41] designs fine-grained journaling for each file, and thus mitigates the interference between `fsync()` threads. CCFS [42] provides similar *stream* abstraction at file system level for applications to implement correct crash consistency. Its stream is designed on individual journals and still relies on exclusive IO processing to preserve the order. HORAE exports stream at block level via the dedicated control path, not relying on exclusive IO processing nor journal. TxFS [30] leverages the file system journaling to provide transactional interface. Son *et al.* [43] propose a high-performance and parallel journal scheme. FlashShare [49] punches through the IO stack to device firmware to optimize the latency for ultra-low latency SSDs. AsyncIO [35] overlaps the CPU execution with IO processing, so as to reduce the `fsync()` latency. CoinPurse leverages the byte interface and device-assisted logic to expedite non-aligned writes [47]. However, these works still rely on exclusive IO processing to control the internal order (e.g., the order between data blocks and metadata blocks) and external order (e.g., the order of applications’ data).

NoFS [27] introduces backpointer-based consistency to remove the ordering point between two dependent data blocks. Due to the lack of ordering updates, NoFS does not support atomic operations (e.g., `rename()`).

9 Conclusion

In this paper, we revisit the write dependency issue on high-performance storage and storage arrays. Through a performance study, we notice that with the growth of performance of storage arrays, the performance loss induced by the write dependency becomes more severe. Classic IO stack is not efficient in resolving this issue. We thus propose a new IO stack called HORAE. HORAE separates the ordering control from the data flow, and uses a range of techniques to ensure both high performance and strong consistency. Evaluations show that HORAE outperforms existing IO stacks.

Abstract

We introduce Blockene, a blockchain that reduces resource usage at member nodes by orders of magnitude, requiring only a smartphone to participate in block validation and consensus. Despite being lightweight, Blockene provides a high throughput of transactions and scales to a large number of participants. Blockene consumes negligible battery and data in smartphones, enabling millions of users to participate in the blockchain without incentives, to secure transactions with their collective honesty. Blockene achieves these properties with a novel split-trust design based on delegating storage and gossip to untrusted nodes.

We show, with a prototype implementation, that Blockene provides throughput of 1045 transactions/sec, and runs with very low resource usage on smartphones, pointing to a new paradigm for building secure, decentralized applications.

1 Introduction

Blockchains provide a powerful systems abstraction: they allow mutually untrusted entities (*members*) to collectively manage a *ledger* of transactions in a decentralized manner.

All blockchains today require member nodes to run powerful servers with significant network, storage, and compute resources. Blockchains based on *proof-of-work* [5, 30] push resource usage to an extreme, requiring significant compute for puzzle-solving, but even consortium blockchains [13] and blockchains based on *proof-of-stake* [21] incur significant network and storage costs to keep the blockchain up to date at a high transaction throughput. Blockchains today are therefore limited to use-cases where members have a strong incentive to participate, and can hence afford the high resource cost. For example, in consortium blockchains [13], business efficiency improves, while in cryptocurrencies [21, 30], members earn currency.

Interestingly, the high resource requirement of blockchains also weakens *reliability* for several real-world applications. Blockchains require that majority (typically two-thirds) of members are honest, a property that is easier to guarantee when a large number of members participate. However, wide-scale adoption of a blockchain is hard given the high resource requirement, especially in scenarios where members do not have a direct incentive to participate. Not surprisingly, public

blockchains with high membership today target cryptocurrencies [5, 30].

In this paper, we present *Blockene*¹, an ultra-lightweight, large scale blockchain that provides high throughput for real-world transactions. By being lightweight and scalable, it enables wide-scale adoption by millions of users. By enabling large scale of participation, *Blockene* makes it plausible to assume honest-majority. By being high-throughput, *Blockene* supports real-world transaction rates.

The key breakthrough in *Blockene* is that instead of requiring members to run powerful servers, *Blockene* is the first blockchain that enables members to participate as first-class citizens in consensus even while running on devices as lightweight as smartphones, lowering cost by orders of magnitude.

Network: Blockchains rely on peer-to-peer gossip between members; at a high transaction rate, gossip would require tens of GBs of data transfer per day; *Blockene* requires only about 60MB of data transfer per day on a smartphone.

Storage: Member nodes in blockchains keep a copy of the entire blockchain (terabytes at high-throughput); in *Blockene*, members incur only a few hundred MBs of storage.

Compute: Even the gossip cost of typical blockchains would drain battery on mobile nodes; *Blockene* ensures that battery drain is less than 3% per day.

Thus, a user incurs no perceptible cost while running *Blockene*. As the low resource usage in *Blockene* makes it feasible even in a smartphone, *Blockene* can also run on desktops, with much lighter resource usage than state-of-the-art.

Blockene achieves three conflicting properties: large scale of participation, high throughput, and lightweight resource usage, catering to even scenarios where there is no direct incentive (e.g., altruistic participation), and handling transactions across variety of use-cases including those on public funds. A comparison of *Blockene* with other blockchain architectures is depicted in Table 1.

Example application: Audited Philanthropy. Charitable donations to non-profits are in excess of USD 500 billion annually worldwide [7, 8, 10]. However, from a donor's perspective, the lack of transparency on the end-use of funds makes donations vulnerable to sub-optimal use or mismanagement by non-profits, especially in regions where regulatory enforcement is ineffective or crippled by corruption. A sys-

^{*}Sudheesh was with Microsoft Research India while doing this work.

¹Named after *Graphene*, one of the lightest and strongest materials.

tem that provides a public, end-to-end trail of funds from the donor to the end beneficiary, will exert market pressure on non-profits, besides motivating donors. A blockchain can provide such tracking, but given the scale of funds involved, a small consortium of members cannot be trusted with operation of the blockchain. Ideally, such a blockchain should be jointly controlled by millions of citizens altruistically. Similar requirements arise in government/public spending.

Key techniques in Blockene: *Blockene* adopts a novel system design based on a split-trust architecture with a new security model. There are two types of nodes in *Blockene*: *Citizens* and *Politicians*. *Citizens* run on smartphones and are the real members of the blockchain, i.e., they have voting power in consensus protocol; hence we assume that two-thirds of the *Citizens* are honest (a reasonable assumption with millions of *Citizens*). On the other hand, *Politicians* run on servers and are untrusted, i.e., do not participate in consensus. *Politicians* are fewer in number (few hundreds), and we require only 20% of them to be honest. Although *Politicians* do the heavy work such as storing the blockchain, our protocols ensure that *Citizens* can detect and handle malicious behavior even if 80% of the *Politicians* collude with the one-third of malicious *Citizens*. *Citizens* deal with high dishonesty of *Politicians* by using a new primitive called *replicated verifiable reads*: the *Citizen* reads the same data from multiple *Politicians* and can get the correct value even if one (out of, say, 25) is honest.

Citizens perform transaction validation, and decide on the block and resulting global state to commit, by running Byzantine consensus. To make consensus feasible with millions of *Citizens*, *Blockene* borrows an idea from Algorand [21] (modified to make it battery-friendly), where a different random committee of (~2000) *Citizens* is cryptographically chosen to run consensus for each block. Unlike Algorand, *Blockene* exposes the set of committee members a few minutes before their participation: this enables *Blockene* to reduce data and battery cost at *Citizens*. While this may appear to increase the window for a targeted attack on the committee, we discuss in § 4.2 why this is not a serious concern.

To keep storage/communication costs at the *Citizens* low, only *Politicians* store the blockchain and the global state (i.e., key-value pairs), freeing *Citizens* from gossiping all blocks (~50GB/day). *Citizens* only read a small subset of data from *Politicians* (e.g., key-values for transactions for the current block), and write out the new block. Further, because *Politicians* are untrusted, *Citizens* cannot rely on the correct latest values returned by them for, say, a given key. *Blockene* uses a novel technique of *sampling-based Merkle tree read/write* that reduces communication cost while ensuring tolerance to 80% malicious *Politicians*.

When in the committee, *Citizens* reduce their communication cost by not gossiping directly, but through *Politicians*; data written by a *Citizen* gets gossiped among *Politicians*, and interested *Citizens* read from *Politicians*.

As participation in *Blockene* is lightweight, the system

needs to protect against Sybil attacks [17]; preventing an adversary from spinning up lots of virtual nodes to get disproportionate voting share. To thwart such attacks, *Blockene* requires the participant identity to be certified by the trusted hardware (TEE) available in most smartphones [6, 11], and enforces that each TEE can have at most one active identity on the blockchain, thus raising the economic cost of participation to the cost of a unique smartphone.

To limit damage that 80% malicious *Politicians* can cause to performance, *Blockene* employs several techniques to restrict their ability to lie. First, we use a technique called *pre-declared commitments* to make some malicious behaviors detectable. Second, to perform gossip among *Politicians* reliably and efficiently despite 80% dishonesty, we introduce a novel technique called *prioritized gossip*. These techniques reduce cost at *Citizens*, enabling *Blockene* to achieve high throughput despite running on smartphones.

We have built a prototype of *Blockene*; the *Citizen* node is implemented as an Android application, and *Politician* node is implemented as a cloud server. We evaluate *Blockene* along various dimensions, and show that it achieves good transaction throughput of 1045 transactions/sec (6.8 MB/min) while ensuring a commit latency of 270s in the 99th percentile. We also demonstrate very little data use (61 MB/day) and battery use (3%/day) at *Citizens*.

The key contributions of this paper are as follows:

- We present the first blockchain system where nodes can participate as first-class members in consensus while running on devices as lightweight as smartphones, supporting high scale of members and high throughput.
- We present a novel split-trust design with a new security model comprised of resource constrained *Citizens* (honest majority) and resource heavy *Politicians* (dishonest majority), and *Citizens* performing validation and consensus by offloading heavy work to untrusted *Politicians* in a verifiable way.
- We make several novel optimizations (e.g., pre-declared commitments, sampling-based Merkle tree read/write, prioritized gossip) that achieve good performance despite 80% malicious *Politicians*.
- With a thorough theoretical analysis, we prove that *Blockene* satisfies *safety*, *liveness*, and *fairness*.
- We perform a thorough empirical evaluation of this architecture, demonstrating its feasibility as a shared scalable blockchain service.

The rest of the paper is structured as follows: In § 2, we provide a background on blockchains, and discuss existing blockchain architectures in § 3. § 4 provides an overview of *Blockene*, and its threat model, and § 5 presents its design. We discuss optimizations for resource-heavy steps in § 6, present an overview of safety and liveness proofs in § 7, and describe the implementation in § 8. We evaluate *Blockene* in § 9, and conclude (§ 10).

2 Background

In this section, we discuss the key principles and abstractions in a blockchain, and its applications.

2.1 Basic properties

A blockchain is a *distributed ledger* of transactions. Without a trusted authority (*e.g.*, a bank) managing the ledger, a group of mutually untrusted parties collectively validate transactions, and maintain a consistent ledger, provided at least a threshold of participants (*e.g.*, two-thirds) are honest. A blockchain must provide *safety*, *liveness*, and *fairness*. Safety ensures that honest participants have a consistent view of the ledger. Liveness ensures that malicious participants cannot indefinitely stall the blockchain by preventing new block additions. Fairness ensures that all valid transactions submitted to the blockchain get eventually committed.

2.2 Building blocks

A blockchain is a replicated, peer-to-peer distributed system built on the following basic primitives:

Merkle tree for Global State: A key part of a blockchain is the *global state* database that tracks keys and their current values. This global state is managed in a tamper-proof manner, typically using a Merkle tree where the leaf nodes contain the key-value pairs, while each intermediate node contains a hash of the concatenated contents of child nodes. The root is a single hash value that represents the entire state. An update of a key requires recomputation of hashes only along the *path* from that leaf to the root. Given the root, the value of any key can be proved by a path of valid hashes to the root.

Signed transactions: The basic unit of work in a blockchain is a *transaction*. A transaction reads and updates a few keys in the global state (*e.g.*, transfer \$1000 from Alice to Bob). To be valid, (a) the transaction must be signed (b) the user signing the transaction must have access to the keys (c) “semantic” integrity must pass (*e.g.*, cannot overspend).

Cryptographic linkage: A blockchain is a list of *blocks*. A block is a list of transactions. The ordering of blocks is ensured by a *cryptographic linkage*; every block embeds the cryptographic hash of the previous block’s contents.

Gossip: Participants in a blockchain exchange state with each other in a peer-to-peer fashion. For example, when a new block gets committed to the ledger, it must be sent to other members. This communication happens through multi-hop *gossip*, with eventual consistency.

Consensus Protocol: The key primitive in blockchains is a *distributed consensus* protocol that handles *Byzantine failures* (*e.g.*, PBFT [15], Nakamoto [30], or BBA [21]), as minority of participants could be malicious. Byzantine consensus requires at least 2/3rd participants to be honest, and requires several *rounds* of communication.

3 Comparison with Existing Blockchains

In this section, we present a brief survey of related work on existing blockchain architectures. *Blockene* provides three properties: lightweight resource usage, large scale of participation, and high transaction throughput. We use the same three dimensions to compare *Blockene* with related work.

3.1 Resource usage by member nodes

Existing blockchains span a wide spectrum in resource usage by participating member nodes, depending on the mechanism used for consensus. We first discuss compute cost incurred by members, and then the network and storage cost.

Compute Cost. In terms of compute cost, the most expensive are blockchains based on Nakamoto consensus [30], also referred to as *proof-of-work*; examples are Bitcoin [30] and Ethereum [5]. In Nakamoto consensus, the first member node to solve a compute-intensive cryptographic puzzle is chosen as the winner in committing a new block. Such blockchains therefore require heavy compute resources at member nodes.

In order to address the high compute (and energy) costs of proof-of-work blockchains, two popular alternative architectures have emerged. The first is *consortium blockchains* (*e.g.*, HyperLedger [13]), which, by limiting the blockchain membership to a small number of nodes, can run traditional Byzantine consensus algorithms, instead of the compute-intensive proof-of-work based consensus. The second architecture is *proof-of-stake* blockchains, which tie the voting power of a member node with the amount of money the member node has on the blockchain. Examples of these blockchains are Algorand [21], Ouroboros [14, 22], PeerCoin [23], *etc.*. Inherently, proof-of-stake blockchains target cryptocurrency applications where such a “stake” is meaningful.

Network and Storage cost. While the above two architectures, *i.e.*, consortium blockchains and proof-of-stake blockchains, address the raw compute cost of member nodes, they are still too expensive for smartphones. In particular, they are heavy on network and storage resources, as they require the member nodes *to be always up-to-date* with the “current” state of the blockchain. Given the high transaction rate (1000s of transactions per second) that such blockchains enable, replication of the entire state across member nodes is expensive: at 1000 transactions/sec, the blockchain would commit roughly 9GB per day, which needs to be gossiped across member nodes, resulting in a network cost of roughly 45 GB/day (assuming a gossip fanout of 5 neighbors) that every member node has to incur. Further, such a blockchain would consume terabytes of storage on member nodes, as every member node stores a local copy of the blockchain.

Even blockchains that target smartphones [35] adopt the same philosophy of member nodes staying up to date, and thus incur the network and storage overheads.

Some blockchains address storage cost by *sharding*. OmniLedger [25] is a recent blockchain that allows participants to only store a *shard* of the blockchain. It uses a variant of Byzcoin [24] for fast consensus. RapidChain [37] also uses sharding to reduce storage cost. Both these works scale only to a few thousand participants and also require participants to store a large fraction ($\frac{1}{3}$ or $\frac{1}{16}$) of the entire blockchain.

Lightweight but Incapable Nodes. A class of “lightweight” blockchains adopt an approach of “unequal members”: only the first-tier, resource-heavy members participate in consensus and have voting power, while the second-tier members simply serve as read-only query frontends, and do not participate in consensus. In such a model, the “majority-honest” property must be met purely by the heavy nodes, as light nodes do not contribute to security. Not surprisingly, given the limited responsibility, the “light” nodes don’t consume much resources. An example of this architecture is the separation between light and heavy nodes in Ethereum [32].

Blockene. In contrast, *Blockene*, achieves lightweight resource usage for *first-class members* that participate in consensus and block validation. Further, unlike Ethereum which depends on honest majority among heavy nodes (only heavy nodes can vote), *Blockene* tolerates up to 80% of the “heavy” nodes (*i.e.*, *Politicians*) being corrupt. Members in *Blockene* require only a smartphone and negligible² data transfer (< 60 MB/day, *i.e.*, three orders of magnitude lower) and negligible compute (battery use of <3% per day). It achieves this by enabling member nodes to operate with minimal state needed for committing a particular block, and performing work only a few times a day, *i.e.*, not striving to stay up-to-date always.

3.2 Scale of participation

As the security of a blockchain fundamentally relies on a majority of the participating members being honest, blockchains need to protect against collusion of a large number of participants. Consortium blockchains [13] carefully structure the blockchain for a particular business process, such that members have a shared incentive in the success of the blockchain. It is sometimes infeasible/hard to structure a consortium with the above guarantee; in the philanthropy example, if a small number of members are in control of the blockchain, they may collude to, say, facilitate siphoning of donations meant for the poor. Moreover, a consortium blockchain is intricately tied to a specific business process among a set of entities, resulting in high setup and operational overhead, besides limiting inter-operability.

Another approach to guard against collusion among majority, is to enable large scale participation; by onboarding a large number of participants (say millions), majority-collusion can be made hard and unlikely. Most “public” blockchains such as Bitcoin [30], Ethereum [5], and Algorand [21] enable

²Cellular data costs in several countries are much cheaper than in the US [18]; in US/Europe, users are on WiFi/broadband most of the day.

large-scale participation. Blockene also supports a large number of participants, but unlike most public blockchains today that target cryptocurrencies, *Blockene* is not tied to cryptocurrency (*e.g.*, no proof-of-stake), but enables generic business transactions. Unlike consortium blockchains, *Blockene* can additionally enable real-world scenarios where there is potential for collusion among a small number of members.

3.3 Transaction throughput

Public blockchains based on proof-of-work are low in throughput (~4-10 transactions/sec). Proof-of-stake based Algorand [21] is the first public blockchain with ~1000 transactions/sec³. Consortium blockchains, due to low scale of participants and traditional consensus (*e.g.*, PBFT), provide 1000s of transactions/sec. Similar to Algorand, *Blockene* also provides a high transaction throughput. By not being tied to cryptocurrency applications, *Blockene* can serve traditional business applications similar to consortium blockchains.

<i>Blockchain</i>	<i>Scale of members</i>	<i>Trans. rate</i>	<i>Cost</i>	<i>Incentive needed?</i>
Public (<i>e.g.</i> , Bitcoin)	Millions	4-10 /sec.	Huge (PoW)	Yes
Consortium (<i>e.g.</i> , [13])	Tens	1000s /sec.	High	Yes
Algorand [21]	Millions	1000-2000/sec.	High	Yes
Blockene	Millions	1045 /sec.	Tiny	No

Table 1: Comparison of blockchain architectures.

3.4 Incentives to Participants

Because of high resource cost (compute, network, or storage), existing blockchains need an incentive for participants (*e.g.*, mining coins in cryptocurrencies, or business efficiency in consortiums). Blockchains that depend on such incentives cannot work for applications such as philanthropy (§ 1). To scale without incentives and to enable *altruistic* participation, the cost of participation has to be negligible.

Table 1 compares blockchain architectures along these dimensions. *Blockene* is the first blockchain to achieve all of the above: scale, throughput, and low cost. With low cost, *Blockene* supports real-world use-cases even where participants do not have a direct incentive, but are altruistic to run a background app with negligible battery and data usage.

3.5 Other related work

The committee-based consensus in *Blockene* is heavily inspired by Algorand [21]; Like *Blockene*, Algorand also

³Assuming 100-byte transactions and 2.2 MB in 20s, 10MB blocks @750MB/hr.

does not allow forks to occur, and one consistent view of the blockchain is always maintained. There is a tradeoff between Algorand and *Blockene* on the resilience to two kinds of targeted attacks (described in § 4.2 para 1). HoneyBadger [28] is a recent system designed for consortium blockchains with $O(100)$ participants. IOTA [19,20] is another distributed ledger system, but currently relies on a centralized co-ordinator for consensus.

Among proof-of-work-based blockchains, the most closely related work to *Blockene* is Hybrid consensus [31]. Similar to Algorand (and *Blockene*), Hybrid consensus periodically selects a group of participants and does not allow the adversary to corrupt nodes during the “participant selection interval”. However it has a long selection interval (of about 1 day) and is also open to the possibility of forks.

4 Architecture Overview

In this section, we first introduce our two-tier architecture that achieves the three conflicting properties of lightweight resource usage, large scale of participation, and high transaction throughput. We then discuss the threat model of *Blockene*.

4.1 Two-tier Architecture

Blockene employs a novel two-tier architecture with asymmetric trust. This architecture is depicted in Figure 1.

There are two kinds of nodes in *Blockene*: *Citizens* and *Politicians*. *Citizens* are resource-constrained (i.e., run on smartphones), are large in number (millions), and are the only entities having voting power in the system (i.e., participate in consensus). *Politicians* are powerful and run servers (similar to existing blockchains like Algorand), and are lot fewer in number (low hundreds), but they do not have voting power. *Politicians* only execute decisions taken by *Citizens*, and cannot take any decisions on their own.

The low resource usage enables a large number of *Citizens* to participate without incentives, while *Politicians* being few in number, will be run by large entities that have interest in the particular use-case (e.g., in the audited philanthropy case, large donors and foundations).

As *Citizens* participate in consensus, at least two-thirds of *Citizens* are required to be honest, while others can be malicious and collude. This is reasonable as *Blockene* allows millions of *Citizens*, making large-scale corruption hard. However, *Politicians* enjoy much lower trust. *Blockene* only requires 20% of politicians to be honest; the remaining 80% of the politicians can be malicious and collude among themselves, and with one-third malicious *Citizens*.

4.1.1 Offloading work to Politicians

Intuitively, given the two-tier architecture, *Citizens* can offload expensive responsibilities such as storage and commu-

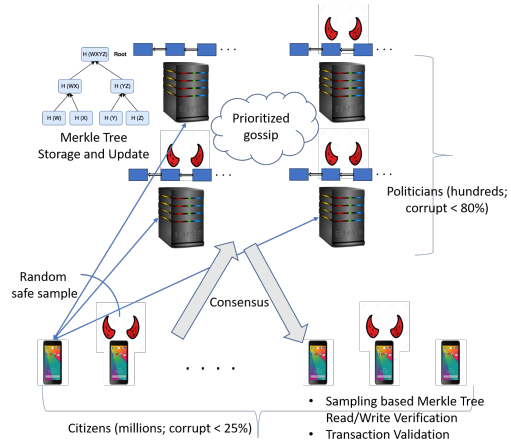

Figure 1: *Blockene*’s architecture

nication to *Politicians*. However, as 80% of *Politicians* are corrupt, a write made by a *Citizen* could just be dropped by a *Politician* or, a read could return incorrect value. To get useful work done out of *Politicians* *Blockene* uses a novel mechanism of replicated reads and writes. Reads and writes by *Citizens* to *Politicians* happen with a random *safe sample* of *Politicians*. The size of this sample is fixed such that with high probability, at least one *Politician* in the sample is honest (e.g., for a sample size of 25, this probability is $1 - (0.8)^{25} = 99.6\%$). *Blockene* is resilient to a small number of *Citizens* (0.4%) picking all dishonest *Politicians*.

4.1.2 Division of responsibilities

We now describe how the *Citizens* and *Politicians* collaborate to perform the various standard blockchain tasks:

Storage: In a traditional blockchain, every participant keeps a replica of the entire blockchain, but *Citizens* in *Blockene* cannot afford to store TBs of data. In *Blockene*, only *Politicians* store the ledger and the global state (i.e., database of key-values § 2). *Citizens* read subsets of this data from *Politicians* as needed. The only state *Citizens* store (and periodically update) is a list of valid *Citizen* identities (§ 5.3).

Transaction Validation: As *Citizens* are the actual participants in consensus, they validate transactions, ensuring that transactions are signed, and have semantic integrity (e.g., no double-spending). To perform validation, *Citizens* read transactions from *Politicians*, and lookup latest values of the keys referenced in them, from the global state with *Politicians*. *Citizens* then propose a block with valid transactions.

Gossip: To ensure that all honest participants agree on the state of the blockchain, participants need to gossip among themselves. However, as discussed in § 3, direct gossip among *Citizens* is expensive. *Blockene* solves this problem by having *Citizens* gossip through *Politicians*. When a *Citizen* needs to broadcast information to other *Citizens*, it sends a message to a *safe sample* of *Politicians*. *Politicians* then gossip data

among themselves; they can afford to do so because they have good network connectivity. Other *Citizens* then perform a replicated read from the *Politicians* when they need to, e.g., when they are in the committee⁴. For gossip through *Politicians*, we need the guarantee that a message that reaches one honest *Politician* always reaches all other honest *Politicians* via gossip, a challenging property when 80% of the *Politicians* are malicious; our custom gossip protocol is described in § 6.1). Thus, we achieve the same semantics as direct gossip among *Citizens*, but with minimal network load on *Citizens*.

Consensus: *Citizens* participate in consensus by performing gossip through *Politicians*. Given the large scale of *Citizens*, all *Citizens* cannot participate in consensus. Instead, we cryptographically select a random *committee of citizens* (roughly 2000 members) for each block (§ 5.2).

4.2 Threat Model

While our threat model is similar to Algorand [21], there is a tradeoff between Algorand and *Blockene* on the resilience to targeted attacks. On one hand, Algorand is based on proof-of-stake, which allows an adversary infinite time to target nodes with higher stake (who will appear in the committee more frequently); *Blockene* avoids this attack, as all *Citizens* have equal votes. On the other hand, Algorand protects the secrecy of the committee members until they perform their role, but *Blockene* exposes their identities a few minutes (1-2 blocks) before they participate. To conserve battery, *Citizens* normally poll *Politicians* for current state of the blockchain roughly every 10 blocks (§ 5.2), but when they are going to be in the committee, will poll again shortly (e.g., 1 block) before their expected turn, thus exposing their identity to malicious *Politicians*. This potentially provides a window for a targeted attack (e.g., by bribing the committee: § 4.2.1).

4.2.1 Attack vector of *Citizens*

Bribing attack on *Citizens*: As *Blockene* implicitly exposes the public keys of the committee a few (e.g., 2) minutes in advance, an adversary could in theory perform a targeted attack by bribing a sufficient number of committee members. However, we believe this is not a concern for the following reasons. First, with just the IP address, it is non-trivial for an adversary to “send a message” offering bribe to a *Citizen*, because of carrier-grade NAT [4] and the architecture for push notifications in smartphones; the existing channel from a malicious *Politician* to the *Citizen* cannot be misused for this, as an untampered *Blockene* app on the *Citizen* will ignore any spurious traffic on that channel. Second, as the committee is randomly chosen every block, pull-based bribing where the *Citizens* (who know of their selection up to 10 blocks in advance - § 5.2) pro-actively reach out to the adversary

⁴Direct gossip among *Citizens* would require all *Citizens* (i.e., including those outside the committee) to participate in gossip of all data.

cannot happen, as that would imply violation of the honesty assumption on *Citizens*, i.e., greater than 70% being honest.

Sybil Attack by *Citizens*: Given the lightweight cost of participation, *Blockene* needs to ensure that an adversary cannot get disproportionate share of voting by spinning up several virtual nodes (i.e., Sybil attacks [17]). A common way of addressing Sybil attacks is *Proof-of-work* which is resource-intensive and does not fit the goals of *Blockene*; another alternative is *Proof-of-stake* [21] where a participant’s voting power is proportional to the amount of “stake” (money) on the blockchain, but it is specific to cryptocurrencies.

In *Blockene*, we protect against Sybil attack by exploiting the trusted hardware (TEE) available in smartphones [6, 11], and ensuring that a smartphone can have at most one identity on the blockchain. Thus, *Blockene* imposes an economic cost to participation, i.e., the cost of a smartphone; this is sunk cost *already incurred* in owning the smartphone, but protects against Sybil as each identity is a unique smartphone.

In particular, each TEE has a unique public key that is certified by the platform (Android/iOS) vendor. The TEE can certify an EdDSA public-private keypair generated by an app; this generated public key serves as the identity on *Blockene*. The global state of *Blockene* tracks the set of valid public keys, along with the public key/certificate of the TEE that authorized it. When a transaction for adding a new member is proposed, *Blockene* looks up the TEE public key to see if that TEE (i.e., the same smartphone) already has an identity in *Blockene*; if yes, it rejects the transaction⁵. Thus, every *Citizen* on *Blockene* is tied to a unique smartphone, making it economically infeasible/unattractive for a single entity to get large participation on *Blockene*.

Note that *Blockene* only assumes that every certificate signed by Google/Apple for a TEE public-key corresponds to a unique smartphone. It does not depend on the security of an individual TEE (unlike running the blockchain consensus inside TEE, e.g. SGX [33], that opens up side-channel attacks compromising integrity and security). As a result, the TEE identity can be replaced/combined with other unique identities. In India, one-way-hash of Aadhaar-ID [1, 12] (digitally verifiable, biometric-deduped, 1.2 billion-reach) can be used. Other de-duped IDs (e.g.SSN) augmented with digital verifiability can also be used.

4.2.2 Attack vector of *Politicians*

Dealing with 80% dishonesty among the politicians is one of the main technical challenges in the design of *Blockene*. Malicious behavior by *Politicians* falls under two kinds: detectable and covert. Detectable maliciousness where there is a succinct proof of lying, can be used to improve performance by blacklisting. For example, if a *Politician* is supposed to only send one group of transactions in a round, but there are

⁵We can also support replacing the old identity with the new one for the same TEE with appropriate bookkeeping.

two versions signed by the same *Politician*, it is detectable with proof. Covert maliciousness is harder to handle, and is the focus of our techniques. We list broad (non-exhaustive) classes of covert attacks a *Politician* can employ.

Staleness Attack: When a *Citizen* node asks the *Politician* for some state (e.g., the latest committed block), the *Politician* could return a stale block. Such a response would appear to be valid because the old block would also have been signed by a quorum of *Citizens* (§ 5.3).

Split-View Attack: A *Politician* can respond selectively to some *Citizens* and not to others, causing a split in the world-view seen by honest *Citizens*. Worse, a *Politician* can respond with two different values to different subsets of *Citizens*. In a coordinated split-view attack, the malicious *Politicians* could only gossip among themselves, so that no honest *Politician* has a certain data. Malicious *Politicians* can then selectively relay this data only to some *Citizens* (e.g., § 5.5.2).

Drop Attack: A malicious *Politician* may drop data written by a *Citizen* without committing it or gossiping it to other *Politicians*. Similarly on a read, the *Politician* may choose to not respond, even though the *Politician* has the data (§ 4.1.1).

Denial-of-Service Attack: As *Politicians* are powerful servers typically hosted in the cloud, we assume that honest *Politicians* employ standard DoS protection that public clouds offer [2, 3]. For *Citizens*, most ISPs employ carrier-grade NAT to handle the explosion of IP addresses on mobile phones [4], which also provides DoS protection. Malicious *Politicians* can make our gossip protocol more expensive by asking for more data than they need (§ 6.1).

Sybil Attack: An adversary could try pushing the dishonesty fraction of *Politicians* beyond 80% by spinning up several nodes. However, given the small number (say 200), we envision that *Politician* nodes would have an out-of-band registration mechanism (e.g., mapping them to real entities, say one per Fortune-500 company) - robust because only 20% of them need to be honest (unlike *Citizens*).

Blockene protects against both detectable and covert maliciousness of the *Politicians* including the attacks listed above.

5 Design

In this section, we present in more detail how *Citizens* and *Politicians* coordinate on the key steps in *Blockene*.

5.1 System Configuration

We first outline the system configuration for *Blockene*. *Citizens* in *Blockene* run on a smartphone, so we assume that their network bandwidth is low, i.e., 1 MB/s. We choose a block size of 9MB (to amortize fixed cost per block), containing about 90k transactions (~100 bytes each including a 64-byte signature). We assume a network bandwidth of 40 MB/s between *Politicians* (representative of bandwidth in the cloud, e.g., between an Azure and a Google Cloud VM across east-US and west-US). We choose the number of *Politicians*

as 200. The work done per block only depends on committee size, so the system scales to millions of *Citizens*.

Transaction originators submit signed transactions to a safe sample or to all *Politicians*, continuously in the background. Transactions can modify keys that the originator has access to. Transactions from the same originator can depend on each other; we preserve their order by tracking a per-originator *nonce* in the global state. In this paper, (without loss of generality) each transaction accesses three keys (debits one key and credits another, third key is nonce). *Politicians* gossip transactions among each other.

5.2 Selecting Committee of *Citizens*

The committee of citizens for validating and signing each block is chosen on the basis of a *VRF* (*Verifiable Random Function*) [27], inspired by Algorand [21] but with one key modification. Algorand requires each participant to check in each round whether it is chosen in the committee. A *Citizen* on a mobile phone cannot afford to do such frequent checks because waking up the phone every round and communicating would cause significant battery drain. Therefore, instead of computing the VRF on the hash of the previous block ($N - 1$), *Blockene* uses the hash of block $N - 10$, thus allowing a *Citizen* to wake up once every 10 blocks. Note that this modification still preserves the security guarantee required from VRFs in our threat model. Specifically, for a citizen, the VRF for block N is calculated as $\text{Hash}(\text{Sign}_{\text{sk}}(\text{Hash}(\text{Block}_{N-10} || N))$ where sk is private key known to the citizen.⁶ A *Citizen* is in the committee if the VRF has 0's in the last k bits (hence a *Citizen* is part of a committee with probability 2^{-k} ; k can be set appropriately). Only the concerned *Citizen* can generate the VRF as it requires its private key, but anyone can verify its validity based on the public key given the signature.

Committee size: The size of the committee needs to balance performance and security. A small committee is good for performance, but for security of consensus protocol, we require that in any committee, at least $2/3$ *Citizens* are honest. As our committee selection is probabilistic, by the Chernoff bound [29], this security requirement cannot be met for very small committee size even if we have $2/3$ honest *Citizens* overall. Committee size increases with the fraction of dishonest *Citizens*. We calibrate this tradeoff to obtain an expected committee size of 2000 with a citizen dishonesty threshold of 25%. The details of these computations appear in the full version [34]. We give an overview below.

Proof overview: We prove several properties about the committee for a block. We call a *Citizen* that participates in a committee as *good* if the *Citizen* is honest and speaks to at least 1 honest *Politician* through m fan-out read/write. Otherwise, we say that the *Citizen* is *bad*. For a configuration with 25% corrupt *Citizens*, 80% corrupt *Politicians*, and $m = 25$,

⁶We use EdDSA signatures. ECDSA uses random number which the adversary can exploit to brute-force itself into the committee.

we show that our committee satisfies the following properties⁷: size of all committees lies in the range [1700..2300] (Lemma 1), every committee has at least 1137 good citizens (Lemma 2), every committee has at least a 2/3 fraction of good citizens (Lemma 3), and no committee has more than 772 bad citizens (Lemma 4).

5.3 Fork-proof Structural Validation

Blockene is designed to prevent forks from occurring. To enable this, each *Citizen* periodically verifies the *structural integrity* of the blockchain to enforce that the chain of hashes and VRFs are consistent and to prevent forks.

Track local state: Each *Citizen* locally remembers the block number N until which the *Citizen* validated the structural integrity of the blockchain, and the hashes of blocks N to $N - 9$. In addition, a *Citizen* stores an up to date list of public keys of other valid *Citizens*. The total storage size is <100MB for 1 million *Citizens*.

Chained ID sub-blocks: To enable *Citizens* to efficiently update local state, the public keys of new users added as part of each block B , are tracked in an *ID sub-block (SB)* within B . SBs are chained together by embedding $\text{Hash}(SB_{i-1})$ within SB_i . To aid cheap verification, committee members sign $\text{Hash}(\text{Hash}(B_i), \text{Hash}(SB_i), \text{GlobalStateRoot}(B_i))$.

Incremental Validation: Roughly every 10 blocks (12-15 mins), each *Citizen* performs a `getLedger` call to validate the incremental structural integrity (*i.e.*, from last validation point to the latest state), and to check if it will be in the committee soon (committee for a block N is a function of the hash of block $N - 10$). To find the latest block, a *Citizen* queries a safe sample of *Politicians* for the latest block number. It picks the highest number reported by *any Politician*, and asks for proof, *i.e.*, signatures of committee of that block and the corresponding VRFs. Thus, if at least one *Politician* in the safe sample is honest, the *Citizen* will know the latest block hash. If the latest block is greater than $N + 10$, it first verifies block $N + 10$. Further, it refreshes its set of valid public keys by downloading the chained sub-blocks $SB_{N+1} \dots SB_{N+10}$ that contain new *Citizens* added in each block, verifying the integrity of SB_i based on the chained hashes.

Cool-off period for new nodes: To prevent a (low-probability) attack where an adversary can manufacture public-private keypairs⁸ to increase chances of getting higher malicious fraction for a particular block N , we allow a *Citizen* to be in the committee only $k(= 40)$ blocks after the block in which the *Citizen* was added. To verify this as part of VRF checks, a *Citizen*'s local state tracks the block number of "recently" added *Citizens*. This is similar to the "look back parameter" in Algorand [21].

⁷All references to Lemma/Theorem/Algorithm numbers below and rest of this paper refer to those in the full version.

⁸Android TEE API does not allow directly signing with the private key of TEE; instead a keypair is certified by TEE.

Proof overview: Our `getLedger` protocol [34] is used for verifying ledger height $i + 10$, given the *Citizen* v has last verified height i , *without an explicit brute-force verification of signatures of all 10 blocks*. The algorithm generalizes to verifying any height $i + j$ for $1 \leq j \leq 10$. We show (Lemma 5) that if a *good Citizen* with a verified state for height i invokes the `getLedger` protocol at round $(i + 11)$ and accepts, then the *Citizen*'s updated *structural state* is consistent with the blockchain up to height $(i + 10)$. Using this, we can show that honest *Citizens* can obtain the consistent structural state of the blockchain, along with all registered public keys, for every round of the protocol (Corollary 2).

5.4 Transaction Validation

Citizens perform the task of verifying signatures of transactions, checking the transaction nonce to detect replay attacks, and verifying semantic correctness of the transaction (*e.g.*, double spending). However, only *Politicians* store the Merkle tree (§ 2.2) of the global state; keeping a large and up to date global state in *Citizens* is unaffordable. To validate a transaction, a *Citizen* must lookup the correct value of keys referenced therein. On commit, the *Citizen* must *update* the Merkle tree with new values from the transaction, and sign the new Merkle root. The challenge lies in doing so correctly given untrusted *Politicians*.

The Merkle root (along with block number) is signed by the committee of the previous block, so the *Politician* cannot lie about the Merkle root. Once the *Citizen* learns the latest block number (§ 5.3), it learns the correct Merkle root as well. To verify a value returned for a key, *Citizen* asks the *Politician* to send the *challenge path* for this key, *i.e.*, all the sibling nodes (hashes) along the path from the leaf to the root. This enables the *Citizen* to reconstruct the Merkle path and match the root hash with the signed Merkle root. By security of hashes, the *Politician* cannot present spurious challenge paths that verify. In a tree with 1 billion key-value pairs, the challenge path would contain 30 hashes.

Update of keys in the Merkle tree follows a similar protocol. The *Citizen* could build a partial Merkle tree with the new values at the leaves, and compute the new Merkle root. Both the read and update paths mentioned above are expensive, and we optimize them in § 6.

5.5 Block Proposal

Like in any blockchain, committee members can propose a new block for committing to the blockchain.

5.5.1 Pick winning proposer

For efficiency, we allow only a subset of committee members called *proposers* to actually propose a block, based on the *VRF* of the *Citizen*. For this selection, we use an additional

VRF that is based on the hash of the previous block $N - 1$ (instead of $N - 10$); only committee members who have the last k' bits of the additional VRF set to zero can propose a block, and the winner is the one with the least VRF. Using the previous block hash in this VRF ensures that the adversary does not know about the proposers until the last minute (similar to Algorand) thus preventing a targeted attack on the proposers. Any committee member can consistently determine the winning VRF among the proposers. All proposers upload their block to *Politicians* and other committee members download the block of the winning proposer.

5.5.2 Pre-declared commitments

The upload of the proposed block by a proposer needs to be done to a safe sample of 25 *Politicians*. In *Blockene*, as the blocks are ~ 9 MB in size, assuming 1MB/s bandwidth at mobile nodes, this would take 225 sec. To optimize this step, we make the transaction selection process deterministic, so that *any Citizen can reconstruct what the original proposer would have done*, without the proposer explicitly uploading the full block. Determinism is challenging, however, because the 80% malicious *Politicians* can send different transactions to different *Citizens*. Our technique of *pre-declared commitments* to transactions addresses this.

1. Freeze Transactions. At the start of block N , each *Politician* freezes the exact set of transactions it will send to *Citizens* reading from it. It does so by creating a *tx_pool*, which includes a set of (about 2000) transactions, and then generates a *commitment* which is a signed hash of the *tx_pool* along with the block number⁹. Malicious *Politicians* are forced to issue only one commitment for a given block N , because two signed commitments from a *Politician* is a proof of malicious behavior, and can be used for efficient blacklisting; *Citizens* then drop all commitments from that *Politician* in the same round. Intuitively, with frozen commitments, a *Citizen* proposing a block, need not upload the full block, but only a *digest* with the commitments that went into the block, and other *Citizens* can reconstruct that block by downloading the *tx_pools* for those commitments from *Politicians*.

2. Ensure that enough honest citizens have commitments. A malicious *Politician* can respond with its *tx_pool* only to a subset of *Citizens*, and refuse to respond to others; thus, a *tx_pool* committed in the proposed block may not be readable by all honest *Citizens*, thus thwarting consensus. To address this, we perform three steps. First, we limit the exact set of *Politicians* from whom to pull transactions for a given block to a randomly chosen set of 45 politicians based on the hash of the block number and hash of previous block. Instead of reading *tx_pools* from a random safe sample, a

⁹To reduce overlap of transactions across *tx_pools* from multiple *Politicians* (which would reduce the unique transactions in the final block), transactions are deterministically partitioned across *Politicians* using a hash on transaction identifier and round number. Given a *tx_pool* and commitment, it is easy to detect/ blacklist a *Politician* that doesn't follow this.

Citizen reads from these 45 designated *Politicians* for a block. Second, the *Citizen* uploads a *witness list* to a safe sample of *Politicians*; the witness list contains the list of *tx_pools* the *Citizen* was able to successfully download. The witness list of all *Citizens* gets gossiped between *Politicians*. Third, the proposer reads the witness list of all other *Citizens*, and picks only commitments whose *tx_pools* were successfully downloaded by at least a threshold number of *Citizens*. This threshold is fixed to be $\tilde{n}_b + \Delta$, where \tilde{n}_b is the maximum number of malicious nodes in any committee (computed to be 772, from Lemma 4), and Δ is chosen to be 350. Intuitively, all commitments (and *tx_pools*) that pass this condition are available with at least Δ honest *Citizens*. As 20% of *Politicians* are honest, in expectation, at least 9 out of the 45 commitments will pass this test.

3. Ensure that all honest citizens get commitments. The commitments available with at least Δ honest *Citizens* now need to be propagated to all honest *Citizens*. Each *Citizen* in Step 4, re-uploads 5 random *tx_pools* it has, to 1 random *Politician*. This ensures that (with high probability) each *tx_pool* (including those from malicious *Politicians*) that belongs to at least Δ honest *Citizens* reaches at least one honest *Politician* (who then gossips it to other honest politicians). Thus, other honest *Citizens* can successfully download that *tx_pool* (by querying a safe sample of politicians), preventing a *split-view* attack by malicious *Politicians*.

4. Handle malicious proposer. When the winner of block proposal is a malicious *Citizen*, it need not respect the witness list criteria, and can pick a commitment whose *tx_pool* is known to very few *Citizens*. This attack is possible only when consensus outputs the block proposed by this malicious proposer, so we can argue that at least 1/3 honest *Citizens* had all *tx_pools* at the beginning of the consensus. To ensure that all honest *Citizens* are able to download all required *tx_pools*, a second re-upload of randomly chosen *tx_pools* happens (step 9), now including the downloaded *tx_pools* from previous step. Formal proofs capturing the guarantees provided by these re-uploads needed to prove security of our system are presented in Lemmas 10 and 11.

5.6 Block Commit Protocol

The main operation in a blockchain is adding a new block to the blockchain. We list below the key steps in the process of committing block N . The protocol for block N starts once the previous block $N - 1$ gathers a threshold number of signatures (set to 850 in our case, §E.1 [34]) from the committee members for block $N - 1$.

1. A new committee of *Citizens* is chosen for block N (using Hash of block $N - 10$), denoted by C^N . The *Citizens* in C^N keep polling for the latest committed block number, and start the protocol once that number is $N - 1$.
2. Each *Citizen* C_i^N in C^N downloads *tx_pools* & commitments from $p = 45$ designated *Politicians* for the block.

3. Each C_i^N uploads a signed witness list with the commitments it downloaded, to a safe sample of *Politicians*.
4. Each *Citizen* C_i^N picks 5 random *tx_pools* it has, and re-uploads them to 1 random *Politician*.
5. Each *proposer* in C^N downloads all witness lists of C^N from a safe sample of *Politicians*, and picks commitments with at least a threshold (1122) of votes (§ 5.5.2). Then, it makes a *block proposal* with those commitments, along with its VRF to prove proposer eligibility.
6. *Politicians* gossip on block proposals/VRFs and on the *tx_pools* that were re-uploaded by *Citizens*.
7. Each *Citizen* C_i^N tries to download missing *tx_pools* in step 2 from safe sample of *Politicians*, relying on the re-upload (Step 4) by other *Citizens*.
8. Each C_i^N reads the VRFs of all proposers in C^N from a safe sample of *Politicians*, and picks the lowest correct VRF as the *local winner*. If C_i^N already has all *tx_pools* in the winning proposal, it enters consensus with that set of commitments, otherwise, NULL.
9. Each *Citizen* C_i^N performs a second re-upload of 10 random *tx_pools* it has to 1 random *Politician*.
10. *Citizens* in C^N run a consensus protocol (§ 5.6.1) with gossip through *Politicians*, where each C_i^N 's vote is decided in Step 8. At the end, all honest *Citizens* either agree on same set of commitments or an empty block. C_i^N downloads the *tx_pools* missing w.r.t. the output of consensus from safe sample of *Politicians*.
11. Each *Citizen* C_i^N performs transaction validation by downloading challenge paths for all keys from *Politicians* (§ 5.4) and drops transactions that fail validation.
12. Based on valid transactions (Step 11), each C_i^N creates a block, computes the new Merkle root of the global state using updated values of keys and signs the block hash and new Merkle root, along with block number N . It uploads the block hash, new Merkle root, and this signature to a safe sample of *Politicians*.
13. When more than a threshold number of signatures have accumulated for block N , block $N + 1$ starts.

Our complete protocol description can be found in Algorithm 4. We give an overview of various properties of *Blockene*, i.e., safety, liveness and fairness, in § 7.

5.6.1 Consensus Protocol

For consensus (Step 10), we use the Byzantine Agreement (BA) algorithm for string consensus (that is based on [36]) which calls upon the bit consensus algorithm BBA [26] in a black-box manner. These are the same consensus algorithms used by Algorand. *Citizens* enter the consensus protocol with list of commitments in local winning block, as input. Two scenarios are relevant here. If the winning proposer (i.e., the one with the lowest VRF) was honest, which would happen

at least two-thirds of the time, all honest *Citizens* in the committee would enter consensus with this proposal except with small probability (Lemma 10), and the protocol will terminate in 5 rounds. However, if the winning proposer was malicious, it can collude with malicious *Politicians* to partition the view of honest *Citizens*. In general, the consensus protocol would take an expected 11 rounds [21].

6 Optimizations

In this section, we present two key optimizations crucial to achieving high transaction throughput in *Blockene*.

6.1 Prioritized Gossip

Problem. The guarantee we require in *Blockene* is that if one honest *Politician* has a message, all honest *Politicians* receive the message. Because of the high fraction of dishonesty among *Politicians*, standard multi-hop gossip with a small number of neighbors (e.g., 10) cannot provide this guarantee, because there is a non-trivial probability that all of them were dishonest, and drop the message. Hence the safe thing to do is a full broadcast to all other *Politicians*, which is expensive; when *Politicians* need to gossip *tx_pools* that were re-uploaded by *Citizens* in the committee, each *Politician* may have up to 45 *tx_pools* to gossip; with full broadcast, it would send $0.2MB * 45 * 200 = 1.8GB$ which would take 45 seconds in the critical path (@40MB/s).

Key idea. We leverage the fact that messages being gossiped by the different *Politicians* have a high overlap; each *Politician* has a subset of the same 45 *tx_pools* as *Citizens* pick a random *Politician* to re-upload a subset of *tx_pools*. Moreover, given the nature of re-upload, in expectation, any *Politician* would be missing only a few *tx_pools*, and honest *Politicians* wouldn't lie about state.

1. Handshake. Each *Politician* asks recipients B_i which *tx_pools* they already have, and send only the missing ones. While this works with honest *Politicians*, the 80% malicious ones could always lie that don't have any, to cause a higher load/latency on the system.

2. Selfish gossip. As malicious *Politicians* can lie that they have no *tx_pools*, we assign a soft-penalty to *Politicians* that miss a lot of *tx_pools*. Each sender *Politician* A favors the peer B that has the maximum number of *tx_pools* that A needs. In each round, A sends a *tx_pool* to B , and receives one in return. Given the random re-uploads by *Citizens*, each honest *Politician* would be missing only a small number of *tx_pools*, and hence would get prioritized. The list of what B has to offer keeps getting updated as B gets *tx_pools* from other peers; note that this list can only grow, not shrink.

3. Incentivize frugal nodes. Selfish gossip loses its ability to discriminate between honest and malicious recipients, once the sender receives all *tx_pools*. To address this, after getting all *tx_pools*, the sender changes its priority function for destinations B_i to be the number of *tx_pools* that B_i claims to have;

thus honest nodes which will have large fraction of *tx_pools* are favored. Again, the list of *tx_pools* that *B* advertises can only grow, not shrink, as shrinking would mean that *B* lied. Further, each honest *B_i* requests its missing chunk from at most $k = 5$ peers simultaneously; $k = 1$ will be data-frugal, but incur high latency if the peer dishonestly delays response.

6.2 Sampling-based Merkle Tree Read/Write

Problem. The Merkle tree validation in Step 11 is expensive. In a 1-billion node Merkle-tree (30-levels deep), a challenge path is 300 bytes (10-byte hashes); downloading 270K challenge paths is 81 MB (81 sec latency) ignoring compression. The compute at *Citizens* is also high (total 16.2 million hash computations for challenge path verification during read and for computing new root post update).

Key idea. We offload most of this work to *Politicians*, in a verifiable manner. Since the Merkle tree validation is done after the conclusion of the consensus run using gossip through the *Politicians*, *Politicians* know the *tx_pools* that are considered for constructing the block. Hence, all *Citizens* in committee and *Politicians* know the keys whose values need to be read and updated. We first discuss the optimization for reading values correctly from the Merkle tree.

1. Get Values. Each *Citizen* gets just the values for all 270K keys (no challenge path, 1 MB instead of 81 MB) from one *Politician*, and then asks a safe sample of *Politicians* whether those values were correct. As at least one of these *Politicians* is honest, it alerts the *Citizen* to incorrect values through an *exception list*. The *Politician* can “prove” an incorrect value by providing a challenge path from the signed Merkle root that indicates a different value for the key.

2. Spot-checks. If many values were wrong, the exception list would be quite large and eat into the savings. To avoid this, *Citizen* picks a small random subset of $k' = 4500$ keys to initially spot-check using the challenge paths. If the spot-checks pass for a sufficiently large k' , a *Politician* could have lied only for a small number (200) of keys (except with small probability). Thus, the extra spot-checks bound the size of the exception list (Lemma 6).

3. Exception list protocol. To *cross-verify* the values with a safe sample of *Politicians*, the *Citizen* deterministically puts these values into buckets (2000) and uploads the hashes of these buckets. When a *Politician* notices a mismatch for a bucket, it sends the bucket index and the correct values for all keys in that bucket. *Citizen* gets challenge paths only for keys that disagree (from first *Politician*). Our spot-checks ensure that only a small number of buckets can mismatch.

Corner case. Even after doing the above, there is a small probability ($< 2^{-10}$) that a *Citizen* may obtain an incorrect value; we count such *Citizen* nodes as malicious and account appropriately (Lemma 7). The full protocol and all proofs are provided in Algorithm 2.

Writes: Updating the Merkle tree is a trickier problem. Due to lack of old challenge paths for the all keys being updated, the *Citizen* cannot construct the root of the updated Merkle tree T' . We solve this problem by making the *Politicians* compute T' , but now the *Citizen* must verify that the *Politicians* performed the computation correctly, i.e., T' is consistent with the new values of updated keys and old tree T for unmodified keys. We achieve this by breaking T' at a level called the *frontier level* (the nodes at this level are frontier nodes). *Citizens* obtain the values of the frontier nodes of T' from a safe sample of the *Politicians*. The *Citizens* then run a spot checking algorithm - they pick a random subset of frontier nodes and ask a *Politician* to prove the correctness of that frontier node. Next, *Citizens* create exception lists with the help of the rest of the selected *Politicians*. This list denotes which frontier nodes are incorrect with the *Citizen*. The *Citizen* then proceeds to sequentially correct the incorrect frontier nodes and then finally compute the correct root of T' from the frontier nodes.

Proof Overview: In the full paper [34], we prove (in Lemma 6) that for a *good Citizen*, after successfully spot-checking only μ fraction of key-values, only (a small number of) τ values are incorrect with probability $1 - \epsilon_1$ (here, μ , τ and ϵ_1 are appropriately chosen parameters). Moreover, these values will get corrected by processing exception lists of size at most τ . Hence, a good *Citizen* gets correct values with probability $1 - \epsilon_1$ (Corollary 3). We pick our parameters (Lemma 7) such that at most 18 *good Citizens* will obtain incorrect values during read, and account for these 18, by counting them as *bad Citizens* in the committee. In the write protocol, we can show that the sizes of exception lists can be bounded (Lemma 8) and that no more than 18 *Citizens* accept an incorrectly updated Merkle tree T' (Lemma 9), which we once again factor in to the set of *bad Citizens*. We additionally also show that our algorithms are between $3 - 18\times$ more communication efficient and between $10 - 66\times$ computationally faster than the naive algorithm for global state read/write.

7 Proofs of Safety, Liveness, and Fairness

In this section, we provide a brief overview of the proofs in the full paper [34] for the safety, liveness, and fairness guarantees of *Blockene*.

A committee round N ends when a new block gets signed and committed by a threshold number (T^*), of committee members for N . T^* will be set to be 850 (done taking into account maximum number of bad citizens in any committee as well as the 36 good citizens who might have read/written an incorrect global state).

First, we show (in Lemma 10) that for a block, if a good *Citizen* is the winning proposer, then (except with bounded constant probability) all good *Citizens* will output the proposal of this *Citizen* as the output of the consensus protocol. In Lemma 11, we show that, on the contrary, if a malicious *Citizen* is the winning proposer and the consensus results

in a non-null value, then all good *Citizens* will be able to download the transactions committed in the proposal. Using Lemmas 7 and 9 (see Proof Overview of § 6), we then show (Lemma 12) that at the end of the block commit protocol all, except 36, good citizens will sign the same block hash and new global state root and that the new block is consistent with the entire blockchain and global state. Now, using Lemma 12, safety (i.e. all honest *Citizens* agree upon all committed blocks and all blocks are consistent with a correct sequence of transactions) follows via an inductive argument. Next, to argue liveness (that adversarial entities cannot indefinitely stall the system and that the empty-block probability is bounded by a small constant), we use Lemmas 12 and 10.

Additionally, we also prove bounds on throughput in Lemma 13 (in expectation, committed blocks have a threshold number of transactions in them) and fairness in Lemma 14 (all valid transactions will eventually be committed).

8 Implementation

We have built a prototype of *Blockene*, that is spread across two components, *Citizen* nodes and *Politician* nodes.

8.1 Citizen nodes

The *Citizen* node is implemented as an Android app on SDK v23 and has 10,200 lines of code. It is built to optimize battery use and runs as a background app, without user involvement after initial setup. The application caters to two main phases of the protocol that a Citizen participates in: passive and active. In the passive phase, a service using JobScheduler [9] periodically polls *Politicians* for `getLedger` calls. In the active phase, when the *Citizen* is part of a committee, the application runs the steps of the protocol, handling failures, timeouts and retries to deal with corrupt *Politicians*. The implementation for the active phase uses a multi-threaded event-driven model and is built on top of EventBus to parallelize and pipeline network and compute intensive crypto tasks such as signature validation.

8.2 Politician nodes

The *Politician* node is implemented in C++ (11K lines of code). The implementation scales to load from thousands of *Citizens*, and handles bursty load during gossip. Given the state-machine nature of the protocol, we have built it on top of the convenient C-Actor-Framework [16], which is based on “actors” that transition the state of the *Politician* through the steps of the protocol. For instance, the BBA actor, apart from storing and serving the votes that *Citizens* submit, also reads the votes to determine the result of consensus. Based on this, it emits an event to build the updated Merkle tree.

For the global state, we have built a SparseMerkleTree (SMT), where the leaf index is deterministically computed using the SHA256 of the key. Since the tree is of bounded depth, we allow for (a small number of) collisions in the leaf

node. The challenge path of any key includes all the collisions co-located with this key, so the leaf hash can be computed. To prevent targeted flooding of a single leaf node, we reject key additions that take a leaf node beyond a threshold, forcing the transaction originator to use a different key. We also implement a DeltaMerkleTree, which allows us to efficiently create an updated version of the SMT using memory proportional only to the touched keys.

Our gossip implementation does simple broadcast for regular messages, and runs a stateful protocol for *tx_pool* gossip. We segregate these messages into different ports/queues so the bursty gossip messages are isolated from small messages (e.g., BBA votes) that are broadcast. To prevent malicious *Citizens* from flooding an honest *Politician* with the responsibility of gossiping their writes, we limit the set of *Politicians* for a *Citizen* to be deterministic based on its VRF. *Politicians* do not gossip messages from non-conforming *Citizens*.

9 Evaluation

We evaluate our *Blockene* prototype under several dimensions. The main questions we answer in our evaluation are:

- What throughput and latency does *Blockene* provide?
- How well does *Blockene* handle malicious behaviors?
- Are the optimizations on Merkle tree & gossip useful?
- What is the load on *Citizen* nodes (battery/data usage)?

9.1 Experimental setup

In our experiments, we use a setup with 2000 *Citizen* nodes and 200 *Politician* nodes. *Citizen* nodes are 1-core VMs on Azure with a Xeon E5-2673, 2GB of RAM, and are spread across three geographic regions across WAN: 700 VMs in SouthCentralUS, 600 VMs in WestUS, and 700 VMs in EastUS. Each *Citizen* runs an Android 7.1 image, and is rate-limited to 1MB/s network upload and download. *Politician* nodes run on 8-core Azure VMs with a Xeon E5-2673, 32 GB of RAM, and are spread as 100 VMs each in EastUS and WestUS. They are rate limited to 40MB/s network bandwidth. Given the random safe sampling, the *Citizen*-*Politician* communication spans across WAN regions. Similarly, the gossip between *Politicians* happens across WAN regions. As our committee size is 2000, every *Citizen* is in the committee for every block. With a higher number of *Citizens*, say 1 million, a particular *Citizen* will be in the committee only once every 500 blocks. Except the per-*Citizen* load, the system performance is independent of the total number of *Citizens* and is just a function of committee size, so the numbers are representative of a large setup.

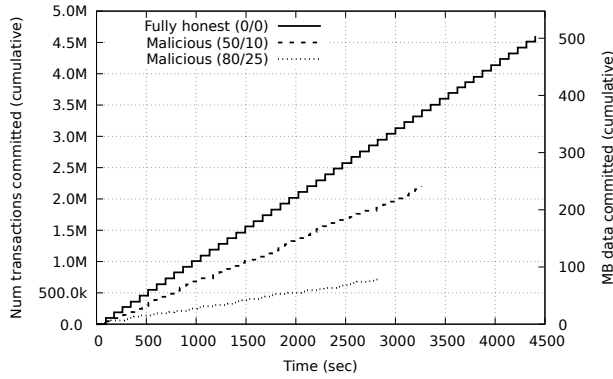

Figure 2: Throughput of *Blockene* under various configs. In 50/10, 50% *Politicians* & 10% *Citizens* are malicious.

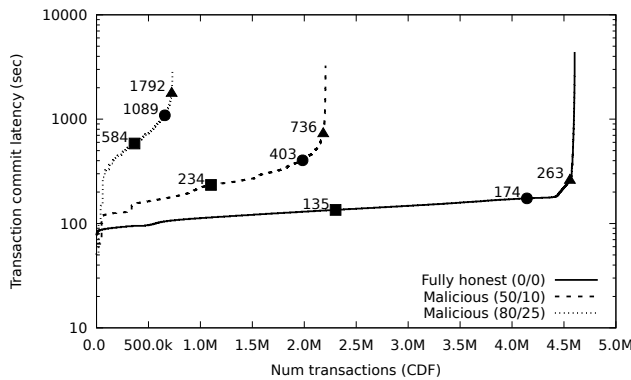

Figure 3: Transaction Latency under different malicious configs. Dots show 50th, 90th, 99th percentiles.

9.2 Transaction Throughput and Latency

Figure 2 shows the timeline of block commits in *Blockene* under fully honest and malicious configurations, for 50 consecutive blocks. In the fully honest (0/0) case, 4.6 million transactions get committed in 4403 seconds, corresponding to a throughput of 1045 transactions per second, or 114 KB/s.

Citizen dishonesty	Politician dishonesty		
	0%	50%	80%
0%	1045	757	390
10%	969	675	339
25%	813	553	257

Table 2: Transaction throughput under malicious configs.

We also evaluate *Blockene* under malicious behaviors of both *Citizens* and *Politicians*. We denote our malicious configurations in the format P/C, where P is the fraction of malicious *Politicians*, and C is the fraction of malicious *Citizens*. With our choice of parameters (e.g., committee size), *Blockene* is guaranteed to ensure safety in the presence of up to 80% malicious *Politicians* and 25% malicious *Citizens*. However,

Figure 4: Network usage at a *Politician* node.

performance can be affected because of adversarial behavior. A malicious *Citizen* in these experiments attacks in two ways (a) force an empty block by colluding with malicious *Politicians* and proposes a block with *tx_pools* that only malicious *Politicians* have. Honest *Citizens* therefore cannot download that commitment and will vote for an empty block; (b) forces additional rounds in the BBA consensus protocol by manipulating its votes. A malicious *Politician* attacks in two ways: (a) fails to give out transaction commitments, making a subset of the 45 *tx_pools* empty, potentially causing a smaller block to be committed (b) manipulates gossip by acting as sink holes and asking for same chunks from multiple peers. As Figure 2 shows, *Blockene* is quite robust to a range of malicious behaviors, and gracefully degrades in performance. With 80% dishonest *Politicians*, the effective *tx_pools* reduce to 9 out of 45, resulting in the block having only 18K transactions instead of 90K. Malicious *Citizens* cause a performance hit (empty blocks + BBA rounds) when they get chosen as the proposer (i.e., highest VRF); Table 2 shows the throughput under more configurations of malicious behaviors.

Figure 3 shows the CDF of transaction latencies of the system under different configurations, demonstrating fairness across transactions. In the fully honest case (0/0), *Blockene* ensures a median latency of 135s and a 99th%-ile latency of 263s. Under the two malicious configurations: 50/10 and 80/20, latencies are higher as expected.

9.3 Timeline of *Citizens* and *Politicians*

Figure 4 shows the network load at a typical *Politician* node during 10 blocks (each of the repetitive patterns is a block). The two large spikes in uploaded data correspond to rounds where this *Politician* was one of the 45 chosen to provide *tx_pools*. For each block, there are two small spikes of transmitted data; the first spike corresponds to gossip of *tx_pools* through prioritized gossip, and the second spike is due to gossip of votes from *Citizens* in the BBA consensus.

We also show the breakup of the 89-sec block latency by

Figure 5: Breakup of time spent at *Citizen* nodes for a single block commit. Cross indicates block commit.

plotting the time taken in *Citizen* nodes during a typical block. Figure 5 shows the progress of the 2000 *Citizen* nodes during one of the blocks, separating out the key phases of the protocol; the bulk of the time goes in the transaction validation phase, and in fetching *tx_pools* from *Politicians*.

9.4 Impact of Optimizations

We now evaluate the prioritized gossip and the sampling-based Merkle tree optimizations. For gossip, we consider how much upload/download each *Politician* incurs before all other honest *Politicians* get all the *tx_pools*. For example, in the 0/0 case, we have 10K data points (across 50 blocks and 200 *Politicians* each). Across these samples, we plot the 50th, 90th, and 99th percentiles. The malicious strategy we model in the 80/25 case is where only the bare minimum number of honest *Citizens* have *tx_pools* of malicious *Politicians* (Δ from § 5.5.2) and all malicious *Politicians* ask for the full set of *tx_pools* from all honest nodes. As Table 3 shows, the network load of prioritized gossip is robust to dishonest behavior. Even in the malicious setting, the data transmitted is quite small before all honest *Politicians* get all *tx_pools*.

Table 4 compares the performance of our sampling based Merkle-tree reads and updates, with the simple solution of downloading challenge paths for all keys referenced in the block. The simple solution incurs much higher network cost (the numbers are after gRPC compression), and a significant compute cost at the *Citizen*. With our optimization, the network cost drops by $10.8\times$ while the CPU cost drops by nearly $31\times$, thus significantly improving transaction throughput.

9.5 Load on Citizens

Finally, we evaluate the load at *Citizen* nodes due to running *Blockene*. The two metrics of interest are battery usage and data usage. To get these metrics, we run an actual Android phone (a OnePlus 5) with the *Citizen* app, as part of the committee along with the 2000 committee members on VMs,

Config	Percentile	Upload (MB)	Download (MB)	Time (sec)
0/0	50	23.1	22.4	3.6
0/0	90	30.5	27.5	4.8
0/0	99	36.7	30.1	5.2
80/25	50	35.4	23.8	3.5
80/25	90	47.6	27.6	4.1
80/25	99	53.4	28.9	4.5

Table 3: Cost of gossip per honest *Politician* before all honest *Politicians* receive all *tx_pools*.

Config	Upload (MB)	Download (MB)	Compute (s)
Naive: GS Read	0	56.16	93.5
Naive: GS Update	0	0	93.5
Optimized: GS Read	0.55	1.6	1.0
Optimized: GS Update	0.01	3	5.88

Table 4: Performance of Global State Read & Write.

and measure battery use. After being in the committee for 5 blocks, the battery drain was $\sim 3\%$. The total network traffic incurred by a *Citizen* for a single block was 19.5 MB.

Now, we can extrapolate the daily cost based on the per-block cost and the number of times a single *Citizen* is expected to be in the committee. With 1 million *Citizens*, a *Citizen* will participate roughly every 500 blocks, which at our block latency of ~ 90 s, translates to 2 times per day. Thus, the expected battery use is $< 2\%$ per day, and the data use is ~ 40 MB/day. In addition, we also measured on the same OnePlus5 that waking up the phone every 10 minutes and performing `getLedger` costs about 0.9% battery and 21MB data download. Waking up every 5 minutes costs 1.7% battery and 42MB data download. With a total of 3% battery usage and 61MB data/day, a user running the *Blockene* app will hardly notice it running.

10 Conclusion

By enabling, for the first time, a high-throughput blockchain where members perform block validation and consensus on smartphones at negligible resource usage, *Blockene* opens up a much larger class of real-world applications to benefit from the security and decentralized nature of blockchains. With a novel architecture, and several new techniques coupled with a careful security reasoning, *Blockene* is able to simultaneously provide three conflicting properties: large scale of participation, high transaction throughput, and low resource usage at member nodes.

Tolerating Slowdowns in Replicated State Machines using Copilots

Khiem Ngo^{*}, Siddhartha Sen[†], Wyatt Lloyd^{*}

^{*}Princeton University, [†]Microsoft Research

Abstract

Replicated state machines are linearizable, fault-tolerant groups of replicas that are coordinated using a consensus algorithm. Copilot replication is the first 1-slowdown-tolerant consensus protocol: it delivers normal latency despite the slowdown of any 1 replica. Copilot uses two distinguished replicas—the pilot and copilot—to proactively add redundancy to all stages of processing a client’s command. Copilot uses dependencies and deduplication to resolve potentially differing orderings proposed by the pilots. To avoid dependencies leading to either pilot being able to slow down the group, Copilot uses fast takeovers that allow a fast pilot to complete the ongoing work of a slow pilot. Copilot includes two optimizations—ping-pong batching and null dependency elimination—that improve its performance when there are 0 and 1 slow pilots respectively. Our evaluation of Copilot shows its performance is lower but competitive with Multi-Paxos and EPaxos when no replicas are slow. When a replica is slow, Copilot is the only protocol that avoids high latencies.

1 Introduction

Replicated state machines (RSMs) are linearizable, fault-tolerant groups of replicas coordinated by a consensus algorithm [46]. Linearizability gives the RSM the illusion of being a single machine that responds to client commands one by one [21]. Fault-tolerance enables the RSM to continue operating despite the failure of a minority of replicas. Together, these make RSMs operate as single machines that do not fail.

RSMs are used to implement small services that require strong consistency and fault tolerance, whose work can be handled by a single machine. They are used throughout large-scale systems, such as distributed databases [13, 14], cloud storage [6, 9], and service managers [25, 39]. While each RSM is individually small, their pervasive use at scale means that they collectively use many machines. At such scale, it is common for some machines to be slow [2, 15]. These slowdowns arise for a myriad of reasons, including misconfigurations, host-side network problems, partial hardware failures, garbage collection events, and many others. The slowdowns manifest as machines whose latency for responding to other machines is higher than usual.

Thus, RSMs should also be slowdown-tolerant, i.e., provide similar performance despite the presence of slow replicas. Unfortunately, no existing consensus protocol is slowdown-tolerant: a single slow replica can sharply increase

their latency. This increased latency decreases availability because a service that does not respond in time is not meaningfully available [5, 6, 20, 48].

Slowdowns can be transient, lasting only a few seconds to minutes, or they can be long-term, lasting hours to days. Monitoring mechanisms within and around a system should eventually detect long-term slowdowns and reconfigure the slow replica out of the RSM to restore normal performance [1, 3, 23, 24, 32, 35]. What remains unsolved is how to tolerate transient slowdowns in general and how to tolerate long-term slowdowns in the time between their onset, their eventual detection, and the end of reconfiguration.

Our ultimate goal is to develop slowdown-tolerant RSMs that continue to operate as fast RSMs despite the presence of slow replicas. Given the general rarity of slowdowns, however, it is unlikely that a single RSM will contain multiple slow replicas at the same time. Thus, we target the first and most pragmatic step toward slowdown-tolerant RSMs: *1-slowdown-tolerant* RSMs that continue to provide normal performance despite the presence of 1 slow replica.

To provide 1-slowdown-tolerance, a consensus protocol must be able to tolerate a slowdown in all stages of processing a client’s command: receive, order, execute, and reply. No existing consensus protocol is 1-slowdown-tolerant because none can handle a slow replica in the ordering stage. Existing ordering protocols all either rely on a single leader [3, 10, 28] or rely on the collaboration of multiple replicas [36, 40]. A single leader is not slowdown-tolerant because if it is slow, then it slows down the RSM. Multiple replicas collaboratively ordering commands is not slowdown-tolerant because if any of those replicas is slow, it slows down the RSM.

Copilot replication is the first 1-slowdown-tolerant consensus protocol. It avoids slowdowns using two distinguished replicas, the pilot and copilot. The two pilots do all stages of processing a client’s command in parallel. This ensures all steps happen quickly even if one pilot is slow. Clients send commands to both pilots, and both pilots order, execute, and reply to the client. This proactive redundancy protects against a slowdown but also makes it more challenging to preserve consistency and efficiency.

The key challenge for Copilot replication is making its ordering stage slowdown tolerant. To provide linearizability, it needs to ensure the pilots agree on the ordering of client commands, but that in turn would naively require each to wait on the other if it is slow. Copilot instead allows a pilot to *fast takeover* the ordering work of a slow pilot. It does so by per-

sisting its takeover and subsequent ordering to the replicas.

Each pilot has a separate log where it orders client commands. Copilot combines the logs using dependencies, e.g., pilot log entry 9 is after copilot log entry 8. Copilot's ordering protocol has two phases—FastAccept, Accept—that commit commands to the pilots' logs along with their dependencies. In the FastAccept round, a pilot proposes an initial dependency for a log entry. If a sufficient number of replicas agree to this ordering, then this entry has committed on the *fast path* and the pilot moves on to execution. Otherwise—if the replicas have already agreed to a different ordering proposed by the other pilot—then the pilot adopts a dependency suggested by the replicas that it persists in the Accept round.

Copilot provides crash fault tolerance using similar mechanisms to Multi-Paxos [28, 37] that are applied independently to the log of each pilot. Copilot combines the logs of the two pilots using mechanisms inspired by EPaxos [40]. As such, it provides the same safety and liveness guarantees as Multi-Paxos and EPaxos. It is safe under any number of crash faults, and it is live as long as a majority of replicas can communicate in a timely manner. In addition, Copilot provides slowdown tolerance even if one replica is slow or failed.

The core Copilot protocol provides slowdown tolerance. However, it would naively go to the Accept round often as the two pilot's ordering commands continuously interleave and prevent one or both from taking the fast path. This additional round of messages would increase latency and decrease throughput relative to traditional consensus protocols like Multi-Paxos, which need only 1 round in the normal case.

Copilot replication includes two optimizations that keep it on the fast path almost all the time. When both pilots are fast, *ping-pong batching* coordinates them so that they alternate their proposals, allowing both pilots to commit on the fast path. When one pilot is slow, *null dependency elimination* allows the fast pilot to avoid waiting on commits from the slow pilot. With null dependency elimination, a fast pilot only needs to fast takeover the ordering work of the slow pilot that is in-progress when the slowdown begins.

Copilot replication is implemented in Go and our evaluation compares it to Multi-Paxos and EPaxos in a datacenter setting. When no replicas are slow, Copilot's performance is competitive with Multi-Paxos and EPaxos. When there is a slow replica, Copilot is the only consensus protocol that avoids high latencies for client requests.

In summary, this work makes the following contributions:

- Defining slowdown-tolerance and identifying why existing consensus protocols are not slowdown-tolerant (§2).
- Copilot replication, the first 1-slowdown-tolerant consensus protocol. Copilot replication uses two pilots to ensure the RSM stays fast, by using proactive redundancy in all stages of processing a client command (§3).
- Ping-pong batching and null dependency elimination, which make Copilot's performance with no slowdowns or one slowdown competitive with traditional protocols (§5).

2 Slowdown Tolerance

This section explains RSMs, defines slowdown tolerance, and explains why existing protocols do not tolerate slowdowns.

2.1 Replicated State Machine Primer

RSMs are linearizable, fault-tolerant groups of machines. They implement a state machine that atomically applies deterministic commands to stored state and returns any output [46]. The machines within an RSM are *replicas*. The RSM provides fault tolerance by starting the replicas in the same initial state and then moving them through the same sequence of states by executing commands in the same order. Then, if one of the replicas fails, the remaining replicas still have the state and can continue providing the service.

RSMs provide linearizability for client commands. *Linearizability* is a consistency model that ensures that client commands are (1) executed in some total order, and (2) this order is consistent with the real-time ordering of client commands, i.e., if command *a* completes in real-time before command *b* begins, then *a* must be ordered before *b* [21].

RSMs are coordinated by *consensus protocols* that determine a consistent order of client commands that are then applied across the replicas. An RSM goes through four stages to process a client command: it receives the command, it orders the command using the consensus protocol, it executes the command, and it replies to the client with any output. Each replica executes commands in the agreed-upon order. A common way to implement and think about RSMs is that they agree to put commands in sequentially increasing log entries, and then execute them in that log order.

2.2 Defining Slowdown Tolerance

We define a slow replica, clarify the relationship between slow and failed, and then define 1-slowdown-tolerance.

Defining a slow replica. We reason about the speed of a replica based on the time it takes between when the machine receives a request over the network and sends a response back out over the network. This includes the replica's RSM processing and its host-side network processing. It does not include the time it takes messages to traverse network links.

We say a replica is *slow* when its responses to messages take more than a threshold time *t* over its normal response time. For example, if a replica typically replies to messages within 1 ms, and we consider a slowdown threshold of $t = 10$ ms, then a replica is slow if it takes more than 11 ms to send responses. The precise setting of *t* will depend on the scenario and may even vary over time. For example, if an OS upgrade increases the processing speed of all replicas, then what was considered normal performance in the past may now be considered slow. We assume the term “slow” reflects the current definition and build our notion of slowdown tolerance on top of this term—that is, our notion of slowdown tolerance is robust to changes in what is considered slow.

Failed versus slow replicas. Replicas that have failed are also slow because they will not reply to messages within the slowdown threshold time. Thus, all failed replicas are slow. However, not all slow replicas are failed. Replicas can be slow but not failed for many reasons, e.g., misconfigurations, host-side network problems, or garbage collection events. It is these slow-but-not-failed replicas that we care about most because existing fault-tolerance mechanisms do not necessarily tolerate them.

Defining s -slowdown-tolerance. Traditionally, clients use RSMs because they provide a service that does not fail despite f replicas failing. Our definition of slowdown tolerance mirrors this traditional definition of fault tolerance while accounting for the dynamic nature of what is considered “slow.” An RSM is s -slowdown-tolerant if it provides a service that is not slow despite s replicas being slow. More specifically, sort the replicas $\{r_1, \dots, r_s, \dots, r_n\}$ of an RSM according to the current definition of slow, such that $\{r_1, \dots, r_s\}$ are the s slowest replicas. Let T represent how slow the RSM is—i.e., its response time properties based on the current definition of “slow”—and let T' represent how slow the RSM would be if replicas $\{r_1, \dots, r_s\}$ were all replaced by clones of r_{s+1} . An RSM is s -slowdown-tolerant if the difference between T and T' is close to zero. In other words, the presence of s slow replicas should not appreciably slow down the RSM relative to an ideal scenario where those s replicas are not slow.

In this work, we focus on the practical case of 1-slowdown-tolerance. Designing RSMs that are s -slowdown-tolerant for $s > 1$ is an interesting avenue of future work.

2.3 Why Existing Protocols Slowdown

We explain why existing protocols are not slowdown tolerant using Multi-Paxos, EPaxos, and Aardvark as examples.

Multi-Paxos. Multi-Paxos [26, 28, 29, 37] is the canonical consensus protocol. It uses the replicas to elect a *leader*. The leader receives client commands and orders them by assigning them to the next available position in its log. It persists that order by sending Accept messages to the replicas and waiting for a majority quorum (including itself) to reply, which commits the command in that log position. It notifies other replicas of the commit using a Commit message. The replicas execute commands in the accepted prefix of the log in order, i.e., they only execute a command once its log position is committed and all previous log positions have been executed. After executing the command, the replicas reply to the client with any output. (We describe a variant of Multi-Paxos that has all replicas reply to the client, similar to PBFT [10], because it provides more redundancy.)

Figure 1a shows these steps and identifies parts of the protocol that are not slowdown tolerant. Receiving the client’s command and running the ordering protocol are not slowdown tolerant because they are only done by the leader. If the leader is slow, it slows these stages. In turn, this is evident to clients whose commands see much higher latency.

Figure 1: Message diagrams with execution for Multi-Paxos (a) and EPaxos (b). Orange components indicate parts of each protocol that are not slowdown tolerant because they lack redundancy. Blue components indicate parts with redundancy. EPaxos ordering phases that are only sometimes necessary are marked with asterisks (*).

Several parts of Multi-Paxos are individually slowdown tolerant—notably, the Accept messages sent to the replicas to persist the leader’s ordering of a command. These messages are sent to all replicas with the leader only needing to hear back from a majority (including itself). For instance, with 5 replicas the leader sends the messages to the 4 other replicas and can proceed once it hears back from 2. This makes Multi-Paxos resilient to a non-leader replica being slow.

EPaxos. EPaxos [40] avoids the single leader of Multi-Paxos with a more egalitarian approach that distributes the work of receiving, ordering, executing, and replying across all replicas. Each replica in EPaxos receives commands from a subset of clients and runs the ordering protocol. We call this specific replica the command’s *designated replica*. EPaxos’s ordering protocol uses fine-grained dependencies between commands to dynamically determine an ordering using FastAccept and SlowAccept phases. Once a replica knows the dependencies of its commands, it waits for the final dependencies of its dependencies to arrive in the DependencyWait phase. Then a replica totally orders the commands and executes them in the resulting order. When a replica executes a command for which it is the designated replica, it sends the reply to the client. EPaxos can sometimes avoid the SlowAccept and DependencyWait phases.

Figure 1b shows these steps and identifies the parts of the protocol that are not slowdown tolerant. Receiving the client’s command, running the ordering protocol, and replying to the client are all not slowdown tolerant because they are only done by a command’s designated replica. If the des-

ignated replica is slow, it will slow down all of these stages, and thus the RSM, for its subset of clients.

DependencyWait can lead to slowdowns for all clients if any replica is slow. This is because DependencyWait requires a replica to wait until it learns the dependencies of the dependencies of a command. These transitive dependencies are necessary for EPaxos to consistently order commands at different replicas. But they are only determined and then sent from a command's designated replica. Thus, a slow replica will be slow to finalize and send out the dependencies for its designated commands to other replicas. This in turn slows commands that acquire dependencies on commands ordered by the slow replica, in addition to commands that use the slow replica as their designated replica.

Leader election. Consensus protocols with leaders include a leader election sub-protocol that provides fault tolerance in case a leader fails. In this sub-protocol, replicas detect when they think a leader may have failed, elect a new leader, ensure that the new leader's log includes all the commands that have been accepted by a majority quorum, and then have the new leader start processing new commands.

Some protocols, like Aardvark [3] and SDPaxos [51], have proposed using leader election to mitigate slowdowns as well, by having replicas detect when they think a leader is slow and then trigger the leader election sub-protocol. Unfortunately, this approach does not provide slowdown tolerance for two reasons. First, leader election is a heavy-weight process that makes an RSM unavailable while it is ongoing: no new commands can be processed until a new leader is elected and brought up to date. Second, leader election is only triggered when a replica thinks the leader is slow (or failed). Thus, only the subset of slowdowns detected by the replicas will be mitigated, and only after they have been detected. In contrast, 1-slowdown-tolerance requires an RSM to deliver performance as if the slowdown did not exist.

Consider the case of Aardvark. Aardvark employs two mechanisms to detect slowdowns in the leader: the first enforces a gradually increasing lower bound on the leader's throughput based on past peak performance; the second starts a heartbeat timer between each batch to ensure the leader is proposing new batches quickly enough. If the leader's throughput drops below the lower bound or if the heartbeat timeout expires, Aardvark initiates a view change to rotate the leader among the replicas. These mechanisms provide only partial slowdown tolerance because each limits the effects of only the subset of slowdowns it detects. For example, they do not protect against a replica whose processing path is slow for client requests but fast for replicas; or a replica whose responses become gradually slower over time while maintaining a small gap between successive responses. Such replicas would still be able to slow down the RSM during their turn as leader.

Further, using view changes to react to slowdowns can itself cause slowdowns and become costly. In practice,

leader election timeouts are generally on the order of hundreds [43, 44] or thousands [8, 14, 17] of milliseconds to prevent the excess load, unavailability, and instability that occurs when leader elections are easily triggered. Thus, any leader slowdown whose severity is less than these timeouts will go undetected, as will any slowdown that is not covered by the detection mechanisms.

2.4 Summary and Insights

The fundamental problem with existing protocols is that they are *detection based*. Detection-based approaches do not protect against slowdowns until they are detected and never protect against slowdowns that are not detected. As a result, a consensus protocol cannot be 1-slowdown-tolerant if the path of a client's command includes at least one point where it goes through a single replica. If that replica is slow, the RSM will be slow (until and if the slowdown is detected). Thus, to design a 1-slowdown-tolerant replication protocol, we must *proactively* ensure there are at least 2 disjoint paths that a client's command can take at every stage. If one of these paths gets stuck at a slow replica, the other path can continue because we assume only 1 replica becomes slow.

3 Design

The core idea behind Copilot is to use two distinguished replicas, the pilot (P) and the copilot (P'), to redundantly process every client command. Figure 2 shows the life of an individual command in Copilot, which begins with a client sending the command to both pilots. By providing two disjoint paths for processing a command at every stage, Copilot prevents any single slow replica from slowing down the RSM.

This section describes the basic design of Copilot, and Section 5 describes optimizations that complete its design. This section first defines our model and then details each major part of the protocol—ordering, execution, and fast takeovers. Finally, it covers additional design details and summarizes why Copilot provides 1-slowdown-tolerance.

3.1 Model

Copilot assumes the *crash failure model*: a failed process stops executing and stops responding to messages. Copilot assumes an *asynchronous system*: there is no bound on the relative speed at which processes execute instructions, and there is no bound on the time it takes to deliver a message. Copilot requires $2f + 1$ replicas to tolerate at most f failures, and guarantees linearizability as a correctness condition despite any number of failures. Copilot provides 1-slowdown-tolerance in the presence of any one slow replica.

3.2 Ordering

Copilot's ordering protocol places client commands into the *pilot log* and the *copilot log*, which are coordinated by the pilot and copilot, respectively. The two separate logs are ordered together using *dependencies* that indicate the prefix of

Figure 2: Message diagram with execution for Copilot. All components are in blue because all have the necessary redundancy to avoid any slow replica. Phases that are only sometimes necessary are marked with asterisks (*). The takeover phase only executes when it is necessary to prevent one pilot from waiting too long on the other pilot. Copilot's optimizations (§5) keep it on the fast path when both pilots are fast and mostly avoid the need for fast takeovers when one pilot is slow.

the other log that should be executed before a given entry. Pilots propose *initial dependencies* for log entries. Replicas either agree to that ordering or reply with a *suggested dependency*. Ultimately, each entry has a *final dependency* that is used by the execution protocol. The final dependencies between the pilot and copilot log may form cycles. Copilot's execution protocol constructs a single *combined log* using the final dependencies between the pilot and copilot logs and a priority rule that orders pilot entries in a cycle ahead of copilot entries. Figure 3 shows an example of how dependencies are used to order the entries in the combined log.

Copilot's ordering protocol persists the command and final dependency for a log entry to the replicas to ensure they can be recovered if up to f replicas (including both pilots) fail. The ordering protocol always includes a FastAccept phase and sometimes includes an Accept phase. The protocol completes after the FastAccept phase if enough of the replicas have agreed with the initial dependency to ensure it will always be recovered as the final dependency. Otherwise, the pilot selects a suggested dependency that orders an entry after enough of the other pilot's log to ensure linearizability.

The remainder of this subsection follows the ordering protocol in order, starting with the client sending a command to the replicas. Our description assumes no fast takeovers (§3.4) or view-changes (§3.5) for simplicity; with fast takeovers and view-changes, replicas reject messages when entries are taken over by another pilot, and entries can be committed with a no-op as a command.

Clients submit commands to both pilots. Each client has a unique client ID *cliid*. Clients assign commands a unique, increasing command ID *cid*. Clients send each command, its client ID, and its command ID to both pilots. The $\langle cliid, cid \rangle$ tuple uniquely identifies commands and enables the replicas to deduplicate them during execution.

Pilots propose commands and an initial dependency. Upon receiving a command from a client, a pilot puts the

command into its next available log entry. It also assigns the *initial dependency* for this entry, which is the most recent entry from the other pilot it has seen. It then proposes this assignment of command and initial dependency for this entry to the other replicas by sending them FastAccept messages.

Replicas reply to FastAccepts. When a replica receives a FastAccept message it checks if the initial dependency for this entry is compatible with all previously accepted dependencies. If it is, the replica fast accepts the initial dependency. If it is not, the replica rejects the initial dependency and replies with a new suggested dependency.

A pair of dependencies are *compatible* if at least one orders its entry after the other. Figure 3a shows examples of compatible and incompatible dependencies. $P'.1$ with dependency $P.1$, and $P.2$ with dependency $P'.1$ are compatible because $P.2$ is ordered after $P'.1$. $P'.3$ with dependency $P.2$ and $P.3$ with dependency $P'.2$ are *incompatible* because neither is ordered after the other. Incompatible dependencies must be avoided because they could lead to replicas with different subsets of the pilot and copilot logs executing entries in different orders, e.g., one replica executing $P.3$ then $P'.3$ and another executing $P'.3$ then $P.3$.

A replica uses the compatibility check to determine if an initial dependency, $P.i$ with dependency $P'.j$, is compatible with all previously accepted dependencies. $P.i$ is ordered after all previous entries in the P log automatically and after all entries $P'.j$ or earlier by its dependency. Thus, the check only needs to look at later entries in the other pilot's log. The *compatibility check* passes unless the replica has already accepted a later entry $P'.k$ ($k > j$) from the other pilot P' with a dependency earlier than $P.i$, i.e., $P'.k$'s dependency is $< P.i$.

If it has not accepted a later entry, then this same check will prevent the replica from fast accepting any incompatible dependencies from the other pilot in the future. If it has accepted a later entry, but that entry's dependency is on $P.i$ or a later entry, then that entry, call it $P'.k$, is ordered after this one, i.e., $P'.j, P.i, \dots, P'.k$. Thus, in either of these cases the replica fast accepts the initial dependency and replies with a FastAcceptOk message to the pilot. Otherwise, it sends a FastAcceptReply message to the pilot with its latest entry for the other pilot, $P'.k$, as its *suggested dependency*.

Pilots try to commit on the fast path. A pilot tries to gather a *fast quorum* of $f + \lfloor \frac{f+1}{2} \rfloor$ FastAcceptOk replies (including from itself).¹ If a pilot gathers a fast quorum, then enough replicas have agreed to its initial dependency that it will always be recovered from any majority quorum of replicas. Thus, it is safe for the pilot to commit this entry on the *fast path* and continue to execution. The entry's initial dependency is now its *final dependency* that is used during execution. The pilot also sends a Commit message to the other replicas to inform them of the final dependency for this entry. (It does not wait for responses for the Commit messages.)

¹This size is 2/3, 3/5, 5/7, and 6/9 for common RSM sizes.

Figure 3: Dependencies are used to combine the pilot (P) and copilot (P') logs (a) into the combined log (b) that is deduplicated and then used for execution (c). (a) Solid black arrows indicate initial dependencies that became final dependencies because an entry was committed on the fast path. Dotted red arrows indicate initial dependencies rejected by the compatibility check because they could lead to different execution orders—e.g., $P.3$ or $P'.3$ could be executed seventh. Solid green arrows indicate final dependencies for entries whose initial dependency was rejected and thus committed on the regular path. Green arrows may contain cycles, which are consistently ordered by the execution protocol to derive a combined log. (b) The combined log has duplicates of most commands, shown in gray. (c) A command is only executed in its first position in the combined log.

A pilot might be unable to gather a fast quorum of FastAcceptOks for two reasons. First, it might receive FastAcceptReplies because replicas rejected the initial dependency as incompatible. Second, it might only receive as few as $f + 1$ replies instead of the necessary $f + \lfloor \frac{f+1}{2} \rfloor$ because up to f of the $2f + 1$ replicas have failed. In either case, the pilot waits until it receives at least $f + 1$ FastAcceptOks and FastAcceptReplies and then continues to the Accept phase.

Pilots persist the final dependency in the Accept phase.

A pilot selects the final dependency based on the suggested dependencies in the responses to the FastAccept round. All FastAcceptOk messages (including the pilot's) suggest the initial dependency. The pilot sorts the suggested dependencies in ascending order and then selects the $(f + 1)$ -th as the *final dependency*. This dependency is high enough to capture the necessary ordering constraint on this entry: it must use the $(f + 1)$ -th dependency to ensure quorum intersection with any command that has already been committed and potentially executed by the other pilot, so that this entry is ordered after that entry as required by linearizability. It is no higher to avoid creating more cycles for the other pilot: any dependency beyond the $(f + 1)$ -th will have its own dependency on this entry because this entry arrived at a majority quorum first.

Then the pilot persists this final dependency by sending it in an Accept message to all the other replicas. The ordering determined by final dependencies in Accept messages can create cycles at replicas. These cycles are acceptable because replicas will learn about them and then execute the commands in the cycles in the same order using the execution protocol. Thus, the other replicas accept this final dependency and reply with AcceptOk messages. When the pilot receives $f + 1$ AcceptOks (including from itself) it has committed the entry on the *regular path*. It then sends Commit messages to the other replicas and proceeds to execution.

3.3 Execution

Replicas execute commands in the combined log order. The combined log contains each client command twice. A replica only executes a command in its first position in the combined order. After executing a command, the pilot and copilot reply to the command's client. Figure 3 shows an example of a combined log and its executed subset.

Copilot's total order of commands. The total order of commands in the combined log is determined by the partial order of each pilot's log, the dependencies between them, and a priority rule. There are three rules that define the total order. (1) The total order includes the partial order of each pilot's log, e.g., $P.0 < P.1 < P.2$ in Figure 3a. The dependencies between the logs sometimes create cycles. (2) When the dependencies are acyclic, the total order follows the dependency order, e.g., $P.1 < P'.0 < P'.1 < P.2$ in Figure 3a. (3) When the dependencies form a cycle, the total order is determined by the *priority* of the pilots: the pilot's entries are ordered before the copilot's, e.g., $P.4 < P.5 < P'.5$ in Figure 3a.

Executing in order. Replicas learn the final dependencies for each entry and thus use the same total order. A replica executes a command once its entry is committed and all preceding entries in the total order have been executed. The following rules determine when it is safe for a replica to execute a command in entry $P.i$ with dependency $P'.j$: (0) $P.i$ is committed, and (1) it has executed $P.(i - 1)$, and then one of the following two conditions holds: (2) it has executed $P'.j$, or (3) $P.i$ and $P'.j$ are in a cycle and P is the pilot log. The rules 1–3 correspond to the rules that define the total order above.

Replicas can learn of committed entries out of order, e.g., a pilot can learn that their entries have committed before they learn of the commits for their dependencies. To ensure commands are executed in the total order, a replica must wait for the commit of all potentially preceding entries. For example, an entry in the pilot log $P.i$ must wait for the commit of all entries $< i$ in the pilot log, the commit of its dependency $P'.j$ in

the copilot log, and the commit of all entries $< j$ in the copilot log. Copilot's fast takeover protocol ensures a fast pilot need not wait long (§3.4) before executing this entry.

Deduplicating execution and replying. In the absence of failures, each command will be in the combined log twice. A replica executes each command only once in its first position. It tracks the commands from each client that have already been executed using the $\langle cliid, cid \rangle$ tuple. The first time it sees a command, it executes it. If the replica is the current pilot or copilot, it replies to the client with any output. The second time it sees a command, it simply marks it as executed and moves on. A client thus receives a response from each pilot for each command; it ignores the second response.

3.4 Fast Takeover

To execute commands in the total order determined by the ordering protocol, a pilot sometimes waits on commits from the other pilot. Waiting on the other pilot for a long time would not be slowdown tolerant. Copilot's fast takeover mechanism avoids a fast pilot waiting too long for a slow pilot by completing the necessary ordering work for that slow pilot.

All entries in the logs for both pilots have associated ballot numbers, and all messages include ballot numbers as in Paxos's proposal numbers [29]. These ballot numbers allow a fast pilot to safely takeover the work of a slow pilot using Paxos's two phases of prepare and accept. When a replica is elected as either pilot or copilot, that sets a ballot number for all entries in the corresponding log to be b . Replicas only (fast) accept entries if the included ballot number is \geq the ballot number set for that entry. When a pilot is not slow, its included ballot numbers are exactly those set for each entry, and the protocol proceeds as described above.

When a pilot is slow, the other pilot can safely takeover its work by setting higher ballot numbers on the relevant entries in the slow pilot's log. The fast pilot does this by sending Prepare messages with a higher ballot number b' for the entry to all replicas. If b' is higher than the set ballot number for that entry, the replicas reply with PrepareOk messages and update their prepared ballot number for that entry. The PrepareOk messages indicate the progress of an entry at a replica, which is one of: not-accepted, fast-accepted, accepted, or committed. The PrepareOk messages include the highest ballot number for which a replica has fast or regular accepted an entry, the command and dependency associated with that entry, and an id of the dependency's proposing pilot.

After sending the Prepare messages, the fast pilot waits for at least $f + 1$ PrepareOks (including from itself). If any of the PrepareOk messages indicate an entry is committed, the pilot short-circuits waiting and commits that entry with the same command and dependency. Otherwise, the fast pilot uses the value picking procedure described below to select a command and dependency. It then sends Accept messages for that command and final dependency, waits for $f + 1$ AcceptOk replies, and then continues the execution protocol.

Recovery value picking procedure. We use *value* to indicate the command and dependency for a log entry. The fast takeover mechanism and view-change mechanism use the recovery value picking procedure to correctly recover a command and dependency for any entry that could have been committed and thus executed. This ensures all replicas execute all commands in the same combined log order.

The recovery value picking procedure is complex and its full details appear in our accompanying technical report [41]. The procedure examines the set S of PrepareOk replies that include the highest seen ballot number. The first three cases are straightforward:

1. There are one or more replies $r \in S$ with accepted as their progress. Then pick r 's command and dependency.
2. There are $< \lfloor \frac{f+1}{2} \rfloor$ replies $r \in S$ with fast-accepted as their progress. Then pick no-op with an empty dependency.
3. There are $\geq f$ replies $r \in S$ with fast-accepted as their progress. Then pick r 's command and dependency.

In the first case, the value may have been committed with a lower ballot number in an Accept phase, so the same value must be used. In the second case, the value could not have been committed in either an Accept phase or a FastAccept phase, so it is safe to pick a no-op. In the third case, the value may have been committed with a lower ballot number in a FastAccept phase and it is safe to use the same value. It is safe because the f or more fast-accept replies plus the entry's original proposing pilot form a majority quorum of replicas that passed the compatibility check. In turn, this ensures that any incompatible entries from the other pilot's log will be ordered after this entry. Thus, it is safe to commit this entry with its initial dependency.

The remaining case is when there are in the range of $[\lfloor \frac{f+1}{2} \rfloor, f)$ replies $r \in S$ with fast-accepted as their progress. In this case, the value may have been committed with a lower ballot number in a FastAccept phase, or it might not have because an incompatible entry in the other pilot's log reached the replicas first. In the first subcase we must commit using the same value, and in the second subcase we must not. To distinguish between these subcases, the recovering replica examines the first possible incompatible entry in the other pilot's log. If that entry is not yet committed, the recovering replica recovers that entry by repeating the above procedure, which enables it to safely distinguish between the subcases.

Triggering a fast takeover. A pilot sets a takeover-timeout when it has a committed command but does not know the final dependencies of all potentially preceding entries, i.e., it has not seen a commit for this entry's final dependency. If the takeover-timeout fires, the pilot stops waiting and does the necessary ordering work itself. It starts the fast takeover of all entries in the slow pilot's log that potentially precede this entry. Our implementation does this in a parallel batch for all entries. Setting the takeover-timeout too low could result in spurious fast takeovers that could lead to dueling proposers. We avoid dueling proposers using the standard

technique of randomized exponential backoff. We avoid spurious fast takeovers by setting a medium takeover-timeout in our implementation (10 ms). This medium timeout is fine because null dependency elimination (§5.2) avoids needing to wait when a pilot is continually slow.

Fast takeovers have a superficial resemblance to leader elections because both are triggered by one replica timing out while waiting to hear from another replica. Leader elections are triggered when one replica does not hear *something* from another replica—e.g., a heartbeat or a new proposal. But a leader can still send something regularly and/or quickly while being slow in other ways (§2.3). Fast takeovers, on the other hand, are triggered when one pilot is waiting to execute a specific client command. This puts them on the processing path of every request. When combined with the proactive redundancy of having both pilots process each client command, this bounds the latency of client commands to that of the faster pilot. If one pilot is slow, the other will process any given command up until execution and then, if necessary, wait for the takeover-timeout before completing the specific ordering work of the other pilot needed to unblock execution.

3.5 Additional Design

The additional parts of Copilot’s design not described in this section all are similar to normal RSM designs. At-most-once semantics for client requests are handled using $\langle cliid, cid \rangle$ tuples and caching the output associated with a command. Non-deterministic commands can be handled by having pilots make the commands deterministic by doing the non-deterministic work (e.g., selecting a random number) and including it as input to the command. There will be two different non-deterministic versions of the command in the combined total order, but deduplication will ensure only the first is executed. State used for deduplication is garbage collected once a command is encountered in the log a second time.

Pilot and copilot election uses *view-changes*, analogous to Multi-Paxos’s leader election [37], on the pilot and copilot logs, respectively. The view-change process has a newly elected pilot or copilot use the recovery value picking procedure described above while committing all unresolved entries in the log. The two separate logs of the pilots allow Copilot to elect a new pilot to replace a failed one while the other pilot continues to order and commit commands in its own log. While this is happening, the active pilot will acquire no new dependencies. Thus, the active pilot will be able to commit on the fast path and execute commands without waiting on any entries in the other log while a new pilot is elected.

3.6 Why Copilot is 1-Slowdown-Tolerant

Copilot achieves 1-slowdown tolerance by ensuring a client command is never blocked on a single path. That is, there are always two disjoint paths in the processing of a command, from when it is received by the RSM to when a response is sent to the client, and one of the paths must be fast.

When both pilots are fast, 1-slowdown tolerance is trivially achieved even if up to f (non-pilot) replicas are slow or failed. This is because the regular path only requires a majority of replicas, allowing both pilots’ entries (and their dependencies) to commit and execute. If one of the pilots becomes slow or fails, then the other (fast) pilot can still commit its entries, but some of these entries might depend on uncommitted entries in the slow pilot’s log. In this case, the fast pilot does a fast takeover of these entries and commits them. Thus, the fast pilot is able to continue executing its own entries. Shortly after a slowdown, the fast pilot stops acquiring dependencies on uncommitted entries (or acquires only null dependencies (§5.2)), eliminating the need for any fast takeovers. Thus, the performance of the RSM reduces to that of the faster pilot, satisfying 1-slowdown-tolerance.

4 Correctness

We prove that Copilot replication is both safe, i.e., it provides linearizability (4.1), and live, i.e., all client commands eventually complete (4.2). Our technical report [41] contains the full proofs; we summarize the intuition for each proof below.

4.1 Safety

To prove linearizability, we must show that client commands are (1) executed in some total order, and (2) this order is consistent with the real-time ordering of client operations, i.e., if command a completes in real-time before command b begins, then a must be ordered before b .

Let P and P' represent the two pilots. To prove the real-time ordering property, consider a command a that completes before a command b begins. Since a completes, it must be committed in at least one pilot’s log; suppose w.l.o.g. it commits in P ’s log at entry $P.i$. Within P ’s log, a is trivially ordered before b , because b is issued only after a has been committed. In P' ’s log, a and b may commit in either order, but the key observation is that b ’s entry, call it $P'.j$, cannot have a dependency that precedes $P.i$, because this would be deemed incompatible during the FastAccept phase (cf. §3.2). Since $P'.j$ ’s dependency is $\geq P.i$ and $P.i$ ’s dependency is $< P'.j$, there are no cycles between $P.i$ and $P'.j$. Thus, $P.i$ is executed before $P'.j$, which implies that a is executed before b .

To prove the total ordering property, we first prove the following invariant: if two log entries $P.i$ and $P'.j$ commit at different pilots, either $P.i$ has a dependency $\geq P'.j$ or $P'.j$ has a dependency $\geq P.i$. This ensures that a dependency path exists from one entry to the other, preventing them from being ordered differently at different replicas. We then show that each entry in a pilot’s log commits with the same commands and dependency across all replicas, even in the presence of failures (including failures of both pilots). This relies on the recovery value picking procedure from §3.4. When an entry commits on either the fast path or regular path, it is persisted to at least a majority of replicas. During a fast takeover or view change—which occur when one or both pilots are slow

(or failed)—the prepare phase will see the entry due to majority quorum intersection, and will reuse it when committing. If the replies from the prepare phase do not show a committed entry, then we must look at them more carefully. If any reply shows the entry is accepted, or if $\geq f$ replies show it is fast-accepted, then we commit the entry with its accepted dependency because it might have committed. If $< \lfloor \frac{f+1}{2} \rfloor$ replies show it is fast-accepted, then we can safely commit a no-op because the entry did not have enough fast accepts to commit. The final case occurs when the number of replies that show fast-accepted is in the range $[\lfloor \frac{f+1}{2} \rfloor, f)$. In this case, the entry may or may not have committed, depending on whether there was an incompatible entry in the other pilot's log. The recovery value picking procedure resolves this by examining and, if needed, recovering the first possible incompatible entry in the other pilot's log. Note that this procedure does not rely on replies from either pilot, and instead reasons about any $f+1$ possible replies received during the prepare phase.

Since each pilot's log is consistent across a majority of the replicas, the entries and their dependencies are also consistent, so the commands are executed in the same total order.

4.2 Liveness

To prove liveness, we must show that a command issued by a client eventually receives a response. Due to FLP [18], we assume the system is eventually partially-synchronous [16] and that all messages are eventually delivered.

Our proof uses a double induction. Assume a replica has executed all entries in P 's log up to $P.i$ and all entries in P' 's log up to $P'.k$. We show that the replica eventually executes either $P.(i+1)$ or $P'.(k+1)$, or a fast takeover occurs, or a view change occurs. Consider the failure-free case first.

If the dependency of $P.(i+1)$ is null or points to an entry $P'.j \leq P'.k$, then $P.(i+1)$ can be executed immediately. If $P'.j > P'.k$ (i.e., $P'.j$ has not been executed), then Copilot checks if a cycle exists between $P.(i+1)$ and $P'.j$. If no cycle exists, then execution switches to the next entry in P' 's log, $P'.(k+1)$. $P'.(k+1)$ can be executed because its dependency must precede P_i (otherwise there would have been a cycle), which by our inductive assumption has been executed.

If there is a cycle and P has higher priority, Copilot breaks the cycle in favor of P and executes $P.(i+1)$. If P' has higher priority, execution switches to P' 's log. Entry $P'.(k+1)$ can execute immediately if its dependency is $\leq P_i$ (by our inductive assumption), or after Copilot breaks the cycle in favor of P' . In all cases, either $P.(i+1)$ or $P'.(k+1)$ is executed.

Now consider the case of failures. If only non-pilots fail, this reduces to the failure-free case. If P' is slow/failed, then $P.(i+1)$ may not be able to execute because its dependency $P'.j$ may not have committed. In this case, P eventually does a fast takeover of $P'.j$'s entry. If both pilots are slow/failed, then neither $P.(i+1)$ nor $P'.(k+1)$ may be able to execute. In this case, a replica eventually initiates a view change to elect new pilots. Fast takeovers and view changes cannot repeat

indefinitely by the same argument that basic Paxos and Multi-Paxos use to ensure progress, by relying on partial synchrony.

5 Optimizations

This section covers ping-pong batching and null dependency elimination, which improve Copilot's performance. Ping-pong batching coordinates the pilots so they propose compatible orderings when both are fast. Null dependency elimination allows a fast pilot to safely avoid waiting on commits from a slow pilot. Copilot includes both optimizations.

5.1 Ping-Pong Batching

Ping-pong batching coordinates the pilots so they propose compatible orderings to the replicas. The replicas fast accept these compatible orderings and thus the pilots commit on the fast path. With ping-pong batching, each pilot accumulates a batch of client commands. It assigns each command to its next available entry, so each batch is a growing assignment of client commands to consecutive entries. A pilot closes a batch and tries to FastAccept the batch when either it receives a FastAccept message from the other pilot or its ping-pong-wait timeout fires.

When both pilots are fast, they will close batches when they receive a FastAccept from the other pilot. This causes FastAccepts to ping-pong back and forth between the two pilots. The pilot closes its first batch and sends out its FastAccepts. When the copilot receives that FastAccept, it closes its first batch and sends out its FastAccepts. When the pilot receives that FastAccept, it closes its second batch, and so on.

This ping-ponging ensures that the pilots agree on the ordering of their entries. Before a pilot sends out a batch it hears about the latest batch from the copilot; and the copilot will not send out another batch until it hears about this batch from the pilot. Because the pilots agree on the ordering of their entries, the replicas can always fast accept their proposed orderings. If the replicas receive the proposed orderings in the same order that the pilots ping-pong propose them, then they agree to this ordering. Even when replicas receive the proposed ordering in a different order, they can still accept them because the dependencies will be compatible.

If one pilot is slow, the other will close its batches when the ping-pong-wait timeout fires. This timeout helps provide slowdown tolerance: even if one pilot is slow, the other need not wait on it for long.

5.2 Null Dependency Elimination

Null dependency elimination allows a fast pilot to avoid waiting on commits from a slow pilot. It looks inside a dependency to see the command it contains. If the contained command has already been executed, then execution deduplication (§3.3) will avoid executing it. We call these *null dependencies* because their execution will have no effect.

Sometimes a pilot must wait on the commit of the other pilot's earlier entries because it needs to know the finalized

dependency of that entry to know the agreed-upon total order. This is unnecessary for null dependencies because they are not executed. Thus, their final ordering information is irrelevant: a pilot need not determine when to execute them because it will not execute them. Instead, the pilot marks the null dependency as executed and continues.

When there is a continually slow pilot, null dependency elimination allows the fast pilot to avoid fast takeovers. A continually slow pilot will propose entries with a given command c after the fast pilot has already proposed an entry with that command c . Thus, the continually slow pilot's entries will be null dependencies for the fast pilot that can be safely skipped. This allows the fast pilot to never wait on commits from the slow pilot and thus avoids needing to fast takeover its entries. Fast takeovers are still necessary, however, for the cases when a pilot becomes slow *after* it proposes its ordering. Thus, when a pilot becomes slow, the other pilot does a fast takeover of the slow pilot's ongoing entries to provide 1-slowdown-tolerance. Thereafter, the fast pilot uses null dependency elimination to provide 1-slowdown-tolerance.

6 Evaluation

Copilot provides 1-slowdown-tolerant RSMs by using two pilots to provide redundancy at every stage of processing a command. Our evaluation demonstrates the benefit and quantifies the overhead of our approach. Specifically, it asks:

- §6.3 Can Copilot tolerate transient slowdowns?
- §6.4 Can Copilot tolerate slowdowns of varying severity?
- §6.5 Can it tolerate slowdowns of varying manifestations?
- §6.6 How does the throughput and latency of Copilot compare to existing consensus protocols?

Summary. We find that Copilot tolerates *any* one replica slowdown regardless of the type of slowdown, the role of the slow replica, or how slow the slow replica becomes. Copilot's latency under slowdown scenarios is comparable to its normal case latency when no replicas are slow. Copilot tolerates slowdowns better than Multi-Paxos, EPaxos, and Multi-Paxos with fast view changes. All commands in Multi-Paxos see high latencies when the leader is slow. EPaxos incurs a partial slowdown when any of the replicas is slow, and a slow replica can slow down other normal replicas under high conflict rates. Multi-Paxos with fast view changes tolerates the slowdowns that its low timeout detects, but it does not tolerate slowdowns that go undetected. Copilot achieves slowdown tolerance through redundancy. Although this incurs more messages and processing, we find that Copilot's throughput and latency are competitive with Multi-Paxos and EPaxos.

6.1 Implementation and Baseline

We implemented Copilot in Go using the framework of EPaxos [40] to enable a fair comparison with the baselines. We use the framework's implementations of *EPaxos* and *Multi-Paxos*. The Multi-Paxos implementation is representa-

tive of well optimized Multi-Paxos [11, 26, 37]. Clients send commands directly to the leader, the leader gets those commands accepted in a single round of messages to the replicas, it executes the commands in log order, and then it replies to the clients. Replicas execute commands in log order but do not reply to the client. Any performance improvement we made to Copilot's implementation we also applied to EPaxos and Multi-Paxos to ensure the comparison remains fair.

EPaxos and Multi-Paxos can use the *thrifty* optimization to send and receive messages only to the required number of other replicas. The thrifty optimization improves performance by decreasing load on all replicas in EPaxos and the leader in Multi-Paxos. It also harms slowdown-tolerance by eliminating redundancy from the ordering in these systems. Our latency slowdown experiments do not use the thrifty option for Multi-Paxos and EPaxos to show them in their best possible setting. Our throughput and latency experiments without slowdowns compare to the baselines with and without the thrifty optimization.

The EPaxos and Multi-Paxos baselines send pings every 3 s to make sure each replica has not failed. An alternative that would make them more slowdown tolerant, though less stable and unable to use some optimizations, is to use a very short view-change timeout. *Fast-View-Change* is a baseline we use to represent this alternative. Our implementation builds on the view-change implementation for Multi-Paxos in the EPaxos framework. It differs from a faithful implementation in two ways that decrease the time to complete a view change. Thus, its performance is an upper bound on that of a more faithful implementation. The first difference is that view-changes are triggered by a master process that never fails or becomes slow. The master receives heartbeats from the current leader every 1 ms and triggers a view-change as soon as 10 ms have elapsed with no heartbeats. (This timeout matches the fast-takeover timeout for Copilot.) The second difference is that a view-change immediately identifies the next leader instead of running an election, making the view-change process similar to that for viewstamped replication [34, 42]. If a client has not received a response to its command after 10 ms, it contacts the master to learn the current leader and resubmits its command to that leader.

6.2 Experimental Setup

Experiments were run on the Emulab testbed [49], where we have exclusive bare-metal access to 21 machines. Each machine has one 2.4 GHz 64-bit 8-Core processor, 64 GB RAM, and is networked with 1 Gbps Ethernet. These machines are located in the same datacenter with an average network round-trip time of about 0.1 ms. Thus, our evaluation of Copilot is focused on a datacenter setting with small latencies between replicas. Evaluation and optimization of Copilot for a geo-replicated setting is an interesting avenue of future work.

Configuration and workloads. We use 5 machines to create an RSM with 5 replicas that can tolerate at most 2 failures.

Figure 4: Client command latency for Copilot, Multi-Paxos, Fast-View-Change, and EPaxos with transient slowdowns. Transient slowdowns are injected every second starting at time 2 seconds. The severity and duration of the slowdowns in order are 0.5 ms, 1 ms, 2 ms, 5 ms, 10 ms, 20 ms, 40 ms, and 80 ms. Multi-Paxos and EPaxos have spikes in latency proportional to the slowdowns. Fast-View-Change tolerates the slowdowns using view changes to limit the maximum latency. Copilot tolerates the transient slowdowns because fast takeovers limit maximum latency.

We use 5-replica RSMs since they are a common setup for fault-tolerant services inside a datacenter [8]. Clients run on separate machines in the same facility. We use a simple workload with 8 byte commands that overwrite 4 bytes of data.

We run each experiment for 3 minutes and exclude the first and the last 30 seconds of each run to avoid experimental artifacts. To determine how to fairly configure our latency experiments, we probed the operation of each system under increasing load. For each system, we choose the number of closed-loop clients where the system operates at 50% of its peak load. This reduces the effect of queuing delays.

We enable batching for EPaxos and Multi-Paxos with a batching interval of 0.1 ms, which is similar to the effective length of Copilot’s ping-pong batches. This choice of batching interval ensures all systems have similar median latency at low and moderate load. Copilot uses a ping-pong-wait timeout of 1 ms and a fast-takeover timeout of 10 ms.

For Multi-Paxos, clients send commands to the leader. For Copilot, clients send commands to both pilots. For EPaxos, each client has a designated replica it sends commands to.

EPaxos includes an interface that allows service builders to provide specialized logic in their implementation that identifies when two commands conflict. This allows EPaxos to avoid needing to determine an order between non-conflicting commands. We compare to EPaxos with 0%, 25%, and 100% conflicts. The 0% case is EPaxos’s best case. The 100% case is EPaxos’s worst case and also represents its performance when used as a generic RSM without its specialized interface. The 25% case is a middle ground.

Severity and duration. Slowdowns vary in their severity and their duration. The *severity* of a slowdown indicates its magnitude, e.g., a replica taking an extra 10 ms or an extra 80 ms to send responses. The *duration* of a slowdown indicates how long the slowdown lasts, e.g., 1 second or 10 minutes. For example, a replica could take an extra 10 ms to respond to every message it receives during a 1-second duration. We present experiments that evaluate tolerance of slowdowns of varying

severity, duration, and manifestation.

6.3 Transient Slowdowns

Figure 4 shows the latency of client commands for Copilot, Multi-Paxos, and EPaxos as transient slowdowns of increasing severity are injected. Transient slowdowns are injected every second starting at time 2 seconds. The injected slowdowns are pauses of increasing length, i.e., the severity and duration of the slowdown are both equal to the pause length. The pause lengths are 0.5 ms, 1 ms, 2 ms, 5 ms, 10 ms, 20 ms, 40 ms, and 80 ms. The pauses are injected by stopping all processing for the specified length inside the go processes. The slowdowns are injected on a pilot for Copilot, on the leader for Multi-Paxos, and on a replica for EPaxos.

Multi-Paxos and EPaxos slow down. Multi-Paxos and EPaxos each have latency spikes that increase proportionally with the length of the injected pause. For instance, for pauses of 40 ms, Multi-Paxos and EPaxos have commands with 40.1 ms and 41.5 ms respectively.

Fast-View-Change tolerates transient slowdowns. Fast-View-Change limits the maximum latency by detecting the pause and switching to a new leader. Maximum latency is controlled by the client timeout and view-change timeout. We see a maximum latency around their sum of 20 ms when a client needs to retransmit its command twice because the view-change had not completed after its first timeout. For instance, Fast-View-Change has commands with 25 ms latency for a 40 ms pause.

Copilot tolerates transient slowdowns. The latency for Copilot remains low and close to its latency when there are no slowdowns. For very small pauses, e.g., 0.5 ms, Copilot simply waits out the pause. This does not mask the slowdown and does show up in client command latency, but its magnitude is small enough that latency remains similar. For longer pauses, Copilot’s fast-takeover timeout of 10 ms fires and the fast pilot completes the ordering work of the slow pilot. This keeps latency low and close to the timeout value. For instance, the maximum command latency is 12.6 ms for

Figure 5: CDF of command latency for Copilot, Multi-Paxos, and EPaxos in the normal case (0) and with slowdowns of varying severity in ms. Slowdowns are injected for the duration of the experiment. Multi-Paxos and EPaxos have latency that increases proportionally with the severity of the slowdown. Copilot’s latency stays low during the slowdowns because the fast pilot completes all stages of processing commands. In addition, null dependency elimination avoids having the fast pilot either wait on or fast takeover the ordering work of the slow pilot during the duration of a slowdown.

a 40 ms pause. The maximum latency during the onset of a slowdown is thus controlled by the fast-takeover timeout value. Latency as a slowdown continues, however, is even lower as our next experiment shows.

6.4 Slowdowns of Varying Severity

Figure 5 shows a CDF of latency for Copilot, Multi-Paxos, and EPaxos in the normal case (0 slowdown) and with slowdowns of varying severity that last for the duration of the experiment. A slowdown of the given severity is injected on one of the pilots for Copilot, the leader for Multi-Paxos, and a replica for EPaxos. The duration of these slowdowns is the length of the experiment (they last longer than the slowdowns evaluated in the previous subsection). The slowdowns are injected using Linux’s traffic control (tc) to add delay corresponding to the severity on the slow replica. The severity ranges from 0.5 ms to 40 ms.

Multi-Paxos and EPaxos slow down. Figure 5b shows the CDF of latency for Multi-Paxos. The latency of client commands in Multi-Paxos is proportional to $2 \times$ the severity of the slowdown. The slowdown affects latency twice because the leader appears twice on the path for client commands: the message path is client-to-leader-to-replicas-to-leader-to-client. Fast-View-Change has similar results to Multi-Paxos when the severity of the slowdown is less than the view-change timeout and it avoids the slowdown using a view-change when the severity is greater than the timeout.

Figure 5c shows the CDF of latency for EPaxos with 25% conflicts. Normal case latency is higher than Multi-Paxos because EPaxos processes batches together, and if one command in a batch acquires a dependency then the entire batch goes to the slow path and does a dependency wait. With 25% conflicts, almost all batches have at least one command with a dependency and thus almost all have higher latency than Multi-Paxos. Slowdowns have two effects for EPaxos that result in two step functions in latency. First, the upper percentiles show a slowdown proportional to $2 \times$ the severity of the slowdown. This is due to the increased latency for com-

mands whose designated replica is the slow replica. Second, the middle percentiles show a slowdown proportional to $1 \times$ the severity of the slowdown. This is due to the increased latency for commands that are ordered by a fast replica but that acquire a dependency on a command ordered by the slow replica. These commands wait on commits from the slow replica (§2.3). The CDF of latency for EPaxos with 100% conflicts (not shown) shows both effects with the latency of nearly all commands affected.

Copilot tolerates slowdowns of varying severity. Figure 5a shows the CDF of latency for Copilot. Normal case latency is similar to Multi-Paxos. Copilot’s latency under these slowdowns is related to its ping-pong-wait timeout of 1 ms. The fast pilot forms batches when either it hears from the slow pilot or its ping-pong-wait timeout fires. The fast pilot orders client commands in earlier batches than the slow pilot. Thus, null dependency elimination enables the fast pilot to avoid waiting on the slow pilot or having to fast takeover its work. The larger batches result in an increase in the latency for Copilot compared to its normal case, but this increase is small and overall performance is similar. Even in the worst case during a slowdown, median, 90th, and 99th percentile latencies are within 0.6 ms, 2 ms, and 4 ms of their values when there is no slowdown, respectively. Thus, we conclude that Copilot’s implementation is resilient to slowdowns.

6.5 Slowdowns of Varying Manifestations

Figure 6 compares latency CDFs for Copilot and Fast-View-Change for three slowdowns with varying manifestations. The slowdowns are injected on the leader for Fast-View-Change and one of the pilots for Copilot.

Figure 6a considers a slowdown manifested by a slowed processing path for client commands with a fast processing path for messages from replicas. This experiment uses tc to inject 40 ms of delay. Fast-View-Change slows down in this case with 40 ms higher latency than usual because the client command processing path on the leader is slow.

Figure 6: CDF of client command latency for Copilot and Fast-View-Change with slowdowns of varying manifestations. Fast-View-Change’s view changes are not triggered in these cases and latency spikes. Copilot’s proactive redundancy tolerates these slowdowns and delivers latency similar to the normal case.

Figure 7: Throughput and latency without the thrifty optimization of the systems when there are no slow replicas.

Figure 8: Throughput and latency with the thrifty optimization of the systems when there are no slow replicas.

Figure 6b shows a CDF of latency when the leader is slow but still quickly replies to heartbeats. This experiment injects 40 ms of delay to non-heartbeat processing directly in the Go process. Fast-View-Change slows down in this case with 80 ms higher latency than usual because the slow leader appears twice on the processing path for client commands.

Figure 6c shows a CDF of latency when the leader becomes gradually slower over time. The leader’s processing of all messages (including heartbeats) is delayed by X ms, where X starts at 5 ms and increases by 1 ms every 1 second. This delay is directly injected in the Go process. Fast-View-Change slows down in this case with a CDF of latency that mirrors the increasing slowness of its leader.

In each of these slowdowns Fast-View-Change’s low view change timeout is not triggered because the replicas are still regularly receiving messages from the leader. Multi-Paxos and EPaxos’s view changes similarly would not be triggered. In contrast, Copilot’s proactive redundancy tolerates these slowdowns and delivers latency similar to the normal case.

6.6 Performance Without Slow Replicas

Figure 7 shows the throughput and latency of the systems without the thrifty optimization as we increase load. We find that Copilot’s throughput is about 8% lower than Multi-Paxos’s. Copilot’s latency at low/moderate load is similar to Multi-Paxos’s; at high load its latency is higher but still low.

EPaxos’s best case of 0% conflicts achieves the same peak

throughput as Multi-Paxos with slightly higher latency. Under moderate and high conflict rates, EPaxos incurs another round-trip to commit on the slow path more often, and hence has higher latency and lower throughput. EPaxos processes an entire batch on the slow path if any command in the batch has a conflict. With 25% conflicts, almost all batches have at least one command with a conflict and thus almost all are processed on the slow path, resulting in similar performance to 100% conflicts. In contrast, Copilot and Multi-Paxos are not affected because they both totally order all commands.

Figure 8 shows the throughput and latency of all systems with the thrifty optimization as we increase load. Copilot does not use the thrifty optimization because its elimination of redundancy is not slowdown tolerant. Thus, Copilot’s performance is the same. Multi-Paxos and EPaxos both see their maximum throughput increase. This makes EPaxos’s best case (0% conflicts) provide clearly the highest throughput. With conflicts, however, its throughput is still lower than that of Copilot and Multi-Paxos. The thrifty optimization makes Multi-Paxos provide higher throughput than Copilot by about 35K commands/second, i.e., Copilot achieves 13% lower maximum throughput than Multi-Paxos. Multi-Paxos has higher throughput in this case because it needs to send and receive fewer messages.

Copilot’s low latency and high throughput when there are no slow replicas is due to ping-pong batching. The pilots coordinate with each other to ensure that replicas agree with

their proposed ordering, allowing them to always commit on the fast path. Committing on the fast path keeps the amount of work each pilot needs to do for its own batches similar to that of a leader in Multi-Paxos. However, a pilot also needs to do the work of a replica for the other pilot's batches. Thus, Copilot's lower but competitive performance with Multi-Paxos is as we expect, because the pilots and leader are the throughput bottlenecks in each system respectively.

7 Related Work

This section reviews related work. To the best of our knowledge, all previous consensus protocols are not 1-slowdown-tolerant. Copilot's primary distinction is thus being the first 1-slowdown-tolerant consensus protocol. We review related work in consensus protocols, Byzantine consensus protocols, and slowdown cascades.

Consensus protocols. There is a growing body of consensus protocols that started with Paxos [28] and Viewstamped Replication [42]. New consensus protocols improve latency and/or throughput on these baselines [4, 22, 30, 31, 33, 36, 45, 51]. Others are designed to be more understandable [44]. SDPaxos [51] includes a throughput-based detection mechanism, similar to that of Aardvark (§2.3), that triggers a view-change for its sequencer that orders commands. Gryff unifies shared registers and consensus [7]. Its unproxied shared register operations are slowdown tolerant while its consensus operations are not. If the network ordering from NOPaxos [33] could be made slowdown tolerant, it could be used to eliminate the need for ping-pong batching to keep the pilots on the fast path in the normal case. To the best of our knowledge, none of these protocols are 1-slowdown-tolerant.

Paxos, EPaxos, Mencius. We drew inspiration in our design from Paxos, EPaxos, and Mencius. Our fast takeover protocol uses the classic 2-phase Paxos [28] on a slow pilot's log to enable a fast pilot to complete its ordering work. Our ordering protocol is influenced by EPaxos's ordering protocol [40]. It draws its use of dependencies and a multi-round ordering protocol with a fast path from EPaxos. Copilot's ordering differs because it orders the same commands twice, totally orders all commands, has only one dependency per entry, and includes fast takeovers. Mencius has all replicas work collaboratively to avoid doing redundant work or conflicting with each other [36]. Our ping-pong batching is inspired by Mencius and lets our pilots avoid conflicting with each other.

Byzantine consensus protocols. There is also a vast body of literature on Byzantine consensus protocols [3, 10, 12, 19, 27, 47, 50]. These protocols tolerate Byzantine faults, which Copilot does not. Most use the approach that PBFT introduced for practical systems of having multiple replicas execute a command and reply to the client. Copilot's use of both pilots to execute and reply to clients is inspired by this design.

Aardvark. Aardvark focuses on ensuring reliable minimum performance in BFT environments [3]. It employs two mech-

anisms to detect slowdowns in the leader: a gradually increasing lower bound on the leader's throughput, and an inter-batch heartbeat timer that ensures the leader is proposing new batches quickly enough. Both mechanisms trigger view changes to rotate the leader among replicas. As explained in §2.3, these mechanisms are detection based and hence provide only partial slowdown tolerance for Aardvark, because each limits the effect of a subset of slowdowns and incurs view changes that themselves cause slowdowns (§2.3). Copilot, in contrast, provides 1-slowdown-tolerance, because it *proactively* provides an alternative path for processing at all times, including during a view change to replace a slow pilot.

Note that Aardvark is designed for a Byzantine environment where replicas can be malicious. Copilot assumes nodes follow its protocol and thus would not work in a malicious setting. Focusing on crash faults allows Copilot to use techniques like fast takeovers and ping-pong batching to provide slowdown tolerance with good performance, which would be vulnerable to manipulation by a Byzantine replica. An interesting question to explore is whether mechanisms from Copilot and Aardvark can be combined to provide 1-slowdown-tolerance in a Byzantine environment.

Slowdown cascades. Occult is a scalable, geo-replicated data store that is immune to slowdown cascades [38]. Slowdown cascades occur when one slow shard of a scalable system cascades and affects other shards. They are a mostly orthogonal problem to slowdown tolerance because they are about preventing slowdowns of one part (shard) of a system from affecting other parts (shards) that do different work. Slowdown tolerance, in contrast, is about preventing slowdowns *within* an RSM, which may be one part (shard) of a larger system. Slowdown tolerance within shards decreases the likelihood of slowdown cascades. But they are mostly orthogonal, because cascades can still occur if there are more than s slowdowns within a shard.

8 Conclusion

Copilot replication is the first 1-slowdown-tolerant consensus protocol. Its pilot and copilot both receive, order, execute, and reply to all client commands. It uses this proactive redundancy and a fast takeover mechanism to provide slowdown tolerance. Despite its redundancy, Copilot replication's performance is competitive with existing consensus protocols when no replicas are slow. When a replica is slow, Copilot is the only consensus protocol that avoids high latencies.

Abstract

We consider the problem of making apps fault-tolerant through replication, when apps operate at the microsecond scale, as in finance, embedded computing, and microservices apps. These apps need a replication scheme that also operates at the microsecond scale, otherwise replication becomes a burden. We propose Mu, a system that takes less than 1.3 microseconds to replicate a (small) request in memory, and less than a millisecond to fail-over the system—this cuts the replication and fail-over latencies of the prior systems by at least 61% and 90%. Mu implements bona fide state machine replication/consensus (SMR) with strong consistency for a generic app, but it really shines on microsecond apps, where even the smallest overhead is significant. To provide this performance, Mu introduces a new SMR protocol that carefully leverages RDMA. Roughly, in Mu a leader replicates a request by simply writing it directly to the log of other replicas using RDMA, without any additional communication. Doing so, however, introduces the challenge of handling concurrent leaders, changing leaders, garbage collecting the logs, and more—challenges that we address in this paper through a judicious combination of RDMA permissions and distributed algorithmic design. We implemented Mu and used it to replicate several systems: a financial exchange app called Liquibook, Redis, Memcached, and HERD [33]. Our evaluation shows that Mu incurs a small replication latency, in some cases being the only viable replication system that incurs an acceptable overhead.

1 Introduction

Enabled by modern technologies such as RDMA, Microsecond-scale computing is emerging as a must [7]. A microsecond app might be expected to process a request in 10 microseconds. Areas where software systems care about microsecond performance include finance (e.g., trading systems), embedded computing (e.g., control systems), and microservices (e.g., key-value stores). Some of these areas

are critical and it is desirable to replicate their microsecond apps across many hosts to provide high availability, due to economic, safety, or robustness reasons. Typically, a system may have hundreds of microservice apps [25], some of which are stateful and can disrupt a global execution if they fail (e.g., key-value stores)—these apps should be replicated for the sake of the whole system.

The golden standard to replicate an app is State Machine Replication (SMR) [68], whereby replicas execute requests in the same total order determined by a consensus protocol. Unfortunately, traditional SMR systems add hundreds of microseconds of overhead even on a fast network [28]. Recent work explores modern hardware in order to improve the performance of replication [30, 32, 36, 38, 61, 71]. The fastest of these (e.g., Hermes [36], DARE [61], and HovercRaft [38]) induce however an overhead of several microseconds, which is clearly high for apps that themselves take few microseconds. Furthermore, when a failure occurs, prior systems incur a prohibitively large fail-over time in the tens of *milliseconds* (not *microseconds*). For instance, HovercRaft takes 10 milliseconds, DARE 30 milliseconds, and Hermes at least 150 milliseconds. The rationale for such large latencies are timeouts that account for the natural fluctuations in the latency of modern networks. Improving replication and fail-over latencies requires fundamentally new techniques.

We propose Mu, a new SMR system that adds less than 1.3 microseconds to replicate a (small) app request, with the 99th-percentile at 1.6 microseconds. Although Mu is a general-purpose SMR scheme for a generic app, Mu really shines with microsecond apps, where even the smallest replication overhead is significant. Compared to the fastest prior system, Mu is able to cut 61% of its latency. This is the smallest latency possible with current RDMA hardware, as it corresponds to one round of *one-sided* communication.

To achieve this performance, Mu introduces a new SMR protocol that fundamentally changes how RDMA can be leveraged for replication. Our protocol reaches consensus and replicates a request with just one round of parallel RDMA write operations on a majority of replicas. This is in contrast to

prior approaches, which take multiple rounds [30,61,71] or resort to two-sided communication [28,32,39,53]. Roughly, in Mu the leader replicates a request by simply using RDMA to write it to the log of each replica, without additional rounds of communication. Doing this correctly is challenging because concurrent leaders may try to write to the logs simultaneously. In fact, the hardest part of most replication protocols is the mechanism to protect against races of concurrent leaders (e.g., Paxos proposal numbers [40]). Traditional replication implements this mechanism using send-receive communication (two-sided operations) or multiple rounds of communication. Instead, Mu uses RDMA write permissions to guarantee that a replica's log can be written by only one leader. Critical to correctness are the mechanisms to change leaders and garbage collect logs, as we describe in the paper.

Mu also improves fail-over time to just 873 microseconds, with the 99-th percentile at 945 microseconds, which cuts fail-over time of prior systems by an order of magnitude. The fact that Mu significantly improves both replication overhead and fail-over latency is perhaps surprising: folklore suggests a trade-off between the latencies of replication in the fast path, and fail-over in the slow path.

The fail-over time of Mu has two parts: failure detection and leader change. For failure detection, traditional SMR systems typically use a timeout on heartbeat messages from the leader. Due to large variances in network latencies, timeout values are in the 10–100ms even with the fastest networks. This is clearly high for microsecond apps. Mu uses a conceptually different method based on a pull-score mechanism over RDMA. The leader increments a heartbeat counter in its local memory, while other replicas use RDMA to periodically read the counter and calculate a badness score. The score is the number of successive reads that returned the same value. Replicas declare a failure if the score is above a threshold, corresponding to a timeout. Different from the traditional heartbeats, this method can use an aggressively small timeout without false positives because network delays slow down the reads rather than the heartbeat. In this way, Mu detects failures usually within ~600 microseconds. This is bottlenecked by variances in process scheduling, as we discuss later.

For leader change, the latency comes from the cost of changing RDMA write permissions, which with current NICs are hundreds of microseconds. This is higher than we expected: it is far slower than RDMA reads and writes, which go over the network. We attribute this delay to a lack of hardware optimization. RDMA has many methods to change permissions: (1) re-register memory regions, (2) change queue-pair access flags, or (3) close and reopen queue pairs. We carefully evaluate the speed of each method and propose a scheme that combines two of them using a fast-slow path to minimize latency. Despite our efforts, the best way to cut this latency further is to improve the NIC hardware.

We prove that Mu provides strong consistency in the form of linearizability [26], despite crashes and asynchrony, and it

ensures liveness under the same assumptions as Paxos [40].

We implemented Mu and used it to replicate several apps: a financial exchange app called Liquibook [50], Redis, Memcached, and an RDMA-based key-value store called HERD [33].

We evaluate Mu extensively, by studying its replication latency stand-alone or integrated into each of the above apps. We find that, for some of these apps (Liquibook, HERD), Mu is the only viable replication system that incurs a reasonable overhead. This is because Mu's latency is significantly lower by a factor of at least $2.7\times$ compared to other replication systems. We also report on our study of Mu's fail-over latency, with a breakdown of its components, suggesting ways to improve the infrastructure to further reduce the latency.

Mu has some limitations. First, Mu relies on RDMA and so it is suitable only for networks with RDMA, such as local area networks, but not across the wide area. Second, Mu is an in-memory system that does not persist data in stable storage—doing so would add additional latency dependent on the device speed.¹ However, we observe that the industry is working on extensions of RDMA for persistent memory, whereby RDMA writes can be flushed at a remote persistent memory with minimum latency [70]—once available, this extension will provide persistence for Mu.

To summarize, we make the following contributions:

- We propose Mu, a new SMR system with low replication and fail-over latencies.
- To achieve its performance, Mu leverages RDMA permissions and a scoring mechanism over heartbeat counters.
- We give the complete correctness proof of Mu [2].
- We implement Mu, and evaluate both its raw performance and its performance in microsecond apps. Results show that Mu significantly reduces replication latencies to an acceptable level for microsecond apps.
- Mu's code is available at:
<https://github.com/LPD-EPFL/mu>.

One might argue that Mu is ahead of its time, as most apps today are not yet microsecond apps. However, this situation is changing. We already have important microsecond apps in areas such as trading, and more will come as existing timing requirements become stricter and new systems emerge as the composition of a large number of microservices (§2.1).

¹For fairness, all SMR systems that we compare against also operate in-memory.

2 Background

2.1 Microsecond Apps and Computing

Apps that are consumed by humans typically work at the millisecond scale: to the human brain, the lowest reported perceptible latency is 13 milliseconds [62]. Yet, we see the emergence of apps that are consumed not by humans but by other computing systems. An increasing number of such systems must operate at the microsecond scale, for competitive, physical, or composition reasons. Schneider [67] speaks of a microsecond market where traders spend massive resources to gain a microsecond advantage in their high-frequency trading. Industrial robots must orchestrate their motors with microsecond granularity for precise movements [6]. Modern distributed systems are composed of hundreds [25] of stateless and stateful microservices, such as key-value stores, web servers, load balancers, and ad services—each operating as an independent app whose latency requirements are gradually decreasing to the microsecond level [9], as the number of composed services is increasing. With this trend, we already see the emergence of key-value stores with microsecond latency (e.g., [32, 55]).

To operate at the microsecond scale, the computing ecosystem must be improved at many layers. This is happening gradually by various recent efforts. Barroso et al [7] argue for better support of microsecond-scale events. The latest Precision Time Protocol improves clock synchronization to achieve submicrosecond accuracy [4]. And other recent work improves CPU scheduling [9, 58, 63], thread management [65], power management [64], RPC handling [18, 32], and the network stack [58]—all at the microsecond scale. Mu fits in this context, by providing microsecond SMR.

2.2 State Machine Replication

State Machine Replication (SMR) replicates a service (e.g., a key-value storage system) across multiple physical servers called *replicas*, such that the system remains available and consistent even if some servers fail. SMR provides strong consistency in the form of linearizability [26]. A common way to implement SMR, which we adopt in this paper, is as follows: each replica has a copy of the service software and a log. The log stores client requests. We consider non-durable SMR systems [29, 31, 49, 52, 57, 59], which keep state in memory only, without logging updates to stable storage. Such systems make an item of data reliable by keeping copies of it in the memory of several nodes. Thus, the data remains recoverable as long as there are fewer simultaneous node failures than data copies [61].

A consensus protocol ensures that all replicas agree on what request is stored in each slot of the log. Replicas then apply the requests in the log (i.e., execute the corresponding operations), in log order. Assuming that the service is deter-

ministic, this ensures all replicas remain in sync. We adopt a leader-based approach, in which a dynamically elected replica called the *leader* communicates with the clients and sends back responses after requests reach a majority of replicas. We assume a *crash-failure* model: servers may fail by crashing, after which they stop executing.

A consensus protocol must ensure *safety* and *liveness* properties. Safety here means (1) *agreement* (different replicas do not obtain different values for a given log slot) and (2) *validity* (replicas do not obtain spurious values). Liveness means *termination*—every live replica eventually obtains a value. We guarantee agreement and validity in an asynchronous system, while termination requires eventual synchrony and a majority of non-crashed replicas, as in typical consensus protocols. In theory, it is possible to design systems that terminate under weaker synchrony [14], but this is not our goal.

2.3 RDMA

Remote Direct Memory Access (RDMA) allows a host to access the memory of another host without involving the processor at the other host. RDMA enables low-latency communication by bypassing the OS kernel and by implementing several layers of the network stack in hardware.

RDMA supports many operations: Send/Receive, Write/Read, and Atomics (compare-and-swap, fetch-and-increment). Because of their lower latency, we use only RDMA Writes and Reads. RDMA has several transports; we use Reliable Connection (RC) to provide in-order reliable delivery.

RDMA connection endpoints are called Queue Pairs (QPs). Each QP is associated to a Completion Queue (CQ). Operations are posted to QPs as Work Requests (WRs). The RDMA hardware consumes the WR, performs the operation, and posts a Work Completion (WC) to the CQ. Applications make local memory available for remote access by registering local virtual memory regions (MRs) with the RDMA driver. Both QPs and MRs can have different access modes (e.g., read-only or read-write). The access mode is specified when initializing the QP or registering the MR, but can be changed later. MRs can overlap: the same memory can be registered multiple times, yielding multiple MRs, each with its own access mode. In this way, different remote machines can have different access rights to the same memory. The same effect can be obtained by using different access flags for the QPs used to communicate with remote machines.

3 Overview of Mu

3.1 Architecture

Figure 1 depicts the architecture of Mu. At the top, a client sends requests to an application and receives a response. We

Figure 1: Architecture of Mu. Grey color shows Mu components. A replica is either a leader or a follower, with different behaviors. The leader captures client requests and writes them to the local logs of all replicas. Followers replay the log to inject the client requests into the application. A leader election component includes a heartbeat and the identity of the current leader. A permission management component allows a leader to request write permission to the local log while revoking the permission from other nodes.

are not particularly concerned about how the client communicates with the application: it can use a network, a local pipe, a function call, etc. We do assume however that this communication is amenable to being captured and injected. That is, there is a mechanism to capture requests from the client before they reach the application, so we can forward these requests to the replicas; a request is an opaque buffer that is not interpreted by Mu. Similarly, there is a mechanism to inject requests into the app. Providing such mechanisms requires changing the application; however, in our experience, the changes are small and non-intrusive. These mechanisms are standard in any SMR system.

Each replica has an idea of which replica is currently the leader. A replica that considers itself the leader assumes that role (left of figure); otherwise, it assumes the role of a follower (right of figure). Each replica grants RDMA *write permission* to its log for its current leader and no other replica. The replicas constantly monitor their current leader to check that it is still active. The replicas might not agree on who the current leader is. But in *the common case*, all replicas have the same leader, and that leader is active. When that happens, Mu is simple and efficient. The leader captures a client request, uses an RDMA Write to append that request to the log of each follower, and then continues the application to process the request. When the followers detect a new request in their log, they inject the request into the application, thereby updating the replicas.

The main challenge in the design of SMR protocols is to handle leader failures. Of particular concern is the case when a leader appears failed (due to intermittent network delays) so

another leader takes over, but the original leader is still active.

To detect failures in Mu, the leader periodically increments a local counter: the followers periodically check the counter using an RDMA Read. If the followers do not detect an increment of the counter after a few tries, a new leader is elected.

The new leader revokes a write permission by any old leaders, thereby ensuring that old leaders cannot interfere with the operation of the new leader [3]. The new leader also reconstructs any partial work left by prior leaders.

Both the leader and the followers are internally divided into two major parts: the replication plane and the background plane. Roughly, the replication plane plays one of two mutually exclusive roles: the *leader role*, which is responsible for copying requests captured by the leader to the followers, or the *follower role*, which replays those requests to update the followers' replicas. The background plane monitors the health of the leader, determines and assigns the leader or follower role to the replication plane, and handles permission changes. Each plane has its own threads and queue pairs. This is in order to improve parallelism and provide isolation of performance and functionality. More specifically, the following components exist in each of the planes.

The replication plane has three components:

- *Replicator*. This component implements the main protocol to replicate a request from the leader to the followers, by writing the request in the followers' logs using RDMA Write.
- *Replayer*. This component replays entries from the lo-

cal log. This component and the replicator component are mutually exclusive; a replica only has one of these components active, depending on its role in the system.

- *Logging.* This component stores client requests to be replicated. Each replica has its own local log, which may be written remotely by other replicas according to previously granted permissions. Replicas also keep a copy of remote logs, which is used by a new leader to reconstruct partial log updates by older leaders.

The background plane has two components:

- *Leader election.* This component detects failures of leaders and selects other replicas to become leader. This is what determines the role a replica plays.
- *Permission management.* This component grants and revokes write access of local data by remote replicas. It maintains a permissions array, which stores access requests by remote replicas. Basically, a remote replica uses RDMA to store a 1 in this vector to request access.

We describe these planes in more detail in §4 and §5.

3.2 RDMA Communication

Each replica has two QPs for each remote replica: one QP for the replication plane and one for the background plane. The QPs for the replication plane share a completion queue, while the QPs for the background plane share another completion queue. The QPs operate in Reliable Connection (RC) mode.

Each replica also maintains two MRs, one for each plane. The MR of the replication plane contains the consensus log and the MR of the background plane contains metadata for leader election (§5.1) and permission management (§5.2). During execution, replicas may change the level of access to their log that they give to each remote replica; this is done by changing QP access flags. Note that all replicas always have remote read and write access permissions to the memory region in the background plane of each replica.

4 Replication Plane

The replication plane takes care of execution in the common case, but remains safe during leader changes. This is where we take care to optimize the latency of the common path. We do so by ensuring that, in the replication plane, only a leader replica communicates over the network, whereas all follower replicas are *silent* (i.e., only do local work).

In this section, we discuss algorithmic details related to replication in Mu. For pedagogical reasons, we first describe in §4.1 a basic version of the algorithm, which requires several round-trips to decide. Later, in §4.2, we discuss how Mu achieves its single round-trip complexity in the common

case, as we present key extensions and optimizations to improve functionality and performance. We give an intuition of why the algorithm works in this section, and we provide the complete correctness argument in the full version of the paper [2].

4.1 Basic Algorithm

The leader captures client requests, and calls *propose* to replicate these requests. It is simplest to understand our replication algorithm relative to the Paxos algorithm, which we briefly summarize; for details, we refer the reader to [40]. In Paxos, for each slot of the log, a leader first executes a *prepare phase* where it sends a proposal number to all replicas.² A replica replies with either *nack* if it has seen a higher proposal number, or otherwise with the value with the highest proposal number that it has accepted. After getting a majority of replies, the leader adopts the value with the highest proposal number. If it got no values (only *acks*), it adopts its own proposal value. In the next phase, the *accept phase*, the leader sends its proposal number and adopted value to all replicas. A replica *acks* if it has not received any prepare phase message with a higher proposal number.

In Paxos, replicas actively reply to messages from the leader, but in our algorithm, replicas are silent and communicate information passively by publishing it to their memory. Specifically, along with their log, a replica publishes a *minProposal* representing the minimum proposal number which it can accept. The correctness of our algorithm hinges on the leader reading and updating the *minProposal* number of each follower before updating anything in its log, and on updates on a replica's log happening in slot-order.

However, this by itself is not enough; Paxos relies on active participation from the followers not only for the data itself, but also to avoid races. Simply publishing the relevant data on each replica is not enough, since two competing leaders could miss each other's updates. This can be avoided if each of the leaders rereads the value after writing it [24]. However, this requires more communication. To avoid this, we shift the focus from the communication itself to the *prevention* of bad communication. A leader ℓ maintains a set of *confirmed followers*, which have granted write permission to ℓ and revoked write permission from other leaders before ℓ begins its operation. This is what prevents races among leaders in Mu. We describe these mechanisms in more detail below.

Log Structure

The main data structure used by the algorithm is the consensus log kept at each replica (Listing 1). The log consists of (1) a *minProposal* number, representing the smallest proposal number with which a leader may enter the accept phase on this

²Paxos uses proposer and acceptor terms; instead, we use leader and replica.

replica; (2) a *first undecided offset (FUO)*, representing the lowest log index which this replica believes to be undecided; and (3) a sequence of slots—each slot is a $(propNr, value)$ tuple.

Listing 1: Log Structure

```

1 struct Log {
2     minProposal = 0,
3     FUO = 0,
4     slots[] = (0, ⊥) for all slots
5 }

```

Algorithm Description

Each leader begins its propose call by constructing its *confirmed followers* set (Listing 2, lines 9–12). This step is only necessary the first time a new leader invokes propose or immediately after an abort. This step is done by sending permission requests to all replicas and waiting for a majority of acks. When a replica acks, it means that this replica has granted write permission to this leader and revoked it from other replicas. The leader then adds this replica to its confirmed followers set. During execution, if the leader ℓ fails to write to one of its confirmed followers, because that follower crashed or gave write access to another leader, ℓ aborts and, if it still thinks it is the leader, it calls propose again.

After establishing its confirmed followers set, the leader invokes the prepare phase. To do so, the leader reads the *minProposal* from its confirmed followers (line 19) and chooses a proposal number *propNum* which is larger than any that it has read or used before. Then, the leader writes its proposal number into *minProposal* for each of its confirmed followers. Recall that if this write fails at any follower, the leader aborts. It is safe to overwrite a follower f 's *minProposal* in line 22 because, if that write succeeds, then ℓ has not lost its write permission since adding f to its confirmed followers set, meaning no other leader wrote to f since then. To complete its prepare phase, the leader reads the relevant log slot of all of its confirmed followers and, as in Paxos, adopts either (a) the value with the highest proposal number, if it read any non- \perp values, or (b) its own initial value, otherwise.

The leader ℓ then enters the accept phase, in which it tries to commit its previously adopted value. To do so, ℓ writes its adopted value to its confirmed followers. If these writes succeed, then ℓ has succeeded in replicating its value. No new value or *minProposal* number could have been written on any of the confirmed followers in this case, because that would have involved a loss of write permission for ℓ . Since the confirmed followers set constitutes a majority of the replicas, this means that ℓ 's replicated value now appears in the same slot at a majority.

Finally, ℓ increments its own FUO to denote successfully replicating a value in this new slot. If the replicated value was ℓ 's own proposed value, then it returns from the *propose*

Listing 2: Basic Replication Algorithm of Mu

```

6 Propose(myValue):
7     done = false
8     If I just became leader or I just aborted:
9         For every process p in parallel:
10             Request permission from p
11             If p acks: add p to confirmedFollowers
12         Until this has been done for a majority
13     While not done:
14         Execute Prepare Phase
15         Execute Accept Phase

17 Prepare Phase:
18     For every process p in confirmedFollowers:
19         Read minProposal from p's log
20     Pick a new proposal number, propNum, higher
21         ↪ than any minProposal seen so far
22     For every process p in confirmedFollowers:
23         Write propNum into LOG[p].minProposal
24         Read LOG[p].slots[myFUO]
25         Abort if any write fails
26     If all entries read were empty:
27         value = myValue
28     Else:
29         value = entry value with the largest
30             ↪ proposal number of slots read

31 Accept Phase:
32     For every process p in confirmedFollowers:
33         Write propNum, value to p in slot myFUO
34         Abort if any write fails
35     If value == myValue:
36         done = true
37     Locally increment myFUO

```

call; otherwise it continues with the prepare phase for the new FUO.

4.2 Extensions

The basic algorithm described so far is clear and concise, but it also has downsides related to functionality and performance. We now address these downsides with some extensions, all of which are standard for Paxos-like algorithms; their correctness is discussed in the full version of our paper [2].

Bringing stragglers up to date. In the basic algorithm, if a replica r is not included in some leader's confirmed followers set, then its log will lag behind. If r later becomes leader, it can catch up by proposing new values at its current FUO, discovering previously accepted values, and re-committing them. This is correct but inefficient. Even worse, if r never becomes leader, then it will never recover the missing values. We address this problem by introducing an update phase for new leaders. After a replica becomes leader and establishes its confirmed followers set, but before attempting to replicate new values, the new leader (1) brings itself up to date with its highest-FUO confirmed follower (Listing 3) and (2) brings

its followers up to date (Listing 4). This is done by copying the contents of the more up-to-date log to the less up-to-date log.

Listing 3: Optimization: Leader Catch Up

```

1  For every process p in confirmedFollowers
2    Read p's FUO
3    Abort if any read fails
4  F = follower with max FUO
5  if F.FUO > myFUO:
6    Copy F.LOG[myFUO: F.FUO] into my log
7    myFUO = F.FUO
8    Abort if the read fails

```

Listing 4: Optimization: Update Followers

```

1  For every process p in confirmed followers:
2    Copy myLog[p.FUO: myFUO] into p.LOG
3    p.FUO = myFUO
4    Abort if any write fails

```

Followers commit in background. In the basic algorithm, followers do not know when a value is committed and thus cannot replay the requests in the application. This is easily fixed without additional communication. Since a leader will not start replicating in an index i before it knows index $i - 1$ to be committed, followers can monitor their local logs and commit all values up to (but excluding) the highest non-empty log index. This is called *commit piggybacking*, since the commit message is folded into the next replicated value. As a result, followers replicate but do not commit the $(i-1)$ -st entry until either the i -th entry is proposed by the current leader, or a new leader is elected and brings its followers up to date, whichever happens first.

Omitting the prepare phase. Once a leader finds only empty slots at a given index at all of its confirmed followers at line 23, then no higher index may contain an accepted value at any confirmed follower; thus, the leader may omit the prepare phase for higher indexes (until it aborts, after which the prepare phase becomes necessary again). This optimization concerns performance on the common path. With this optimization, the cost of a Propose call becomes a single RDMA write to a majority in the common case.

Growing confirmed followers. In the algorithm so far, the confirmed followers set remains fixed after the leader initially constructs it. This implies that processes outside the leader's confirmed followers set will miss updates, even if they are alive and timely, and that the leader will abort even if one of its followers crashes. To avoid this problem, we extend the algorithm to allow the leader to grow its confirmed followers

set by briefly waiting for responses from all replicas during its initial request for permission. The leader can also add confirmed followers later, but must bring these replicas up to date (using the mechanism described above in *Bringing stragglers up to date*) before adding them to its set. When its confirmed follower set is large, the leader cannot wait for its RDMA reads and writes to complete at all of its confirmed followers before continuing, since we require the algorithm to continue operating despite the failure of a minority of the replicas; instead, the leader waits for just a majority of the replicas to complete.

Replayer. Followers continually monitor the log for new entries. This creates a challenge: how to ensure that the follower does not read an incomplete entry that has not yet been fully written by the leader. We adopt a standard approach: we add an extra *canary byte* at the end of each log entry [51, 71]. Before issuing an RDMA Write to replicate a log entry, the leader sets the entry's canary byte to a non-zero value. The follower first checks the canary and then the entry contents. In theory, it is possible that the canary gets written before the other contents under RDMA semantics. In practice, however, NICs provide left-to-right semantics in certain cases (e.g., the memory region is in the same NUMA domain as the NIC), which ensures that the canary is written last. This assumption is made by other RDMA systems [21, 22, 33, 51, 71]. Alternatively, we could store a checksum of the data in the canary, and the follower could read the canary and wait for the checksum to match the data.

5 Background Plane

The background plane has two main roles: electing and monitoring the leader, and handling permission change requests. In this section, we describe these mechanisms.

5.1 Leader Election

The *leader election component* of the background plane maintains an estimate of the current leader, which it continually updates. The replication plane uses this estimate to determine whether to execute as leader or follower.

Each replica independently and locally decides who it considers to be leader. We opt for a simple rule: replica i decides that j is leader if j is the replica with the lowest id, among those that i considers to be alive.

To know whether a replica has failed, we employ a *pull-score* mechanism, based on a *local heartbeat* counter. A leader election thread continually increments its own counter locally and uses RDMA Reads to read the counters (heartbeats) of other replicas and check whether they have been updated. It maintains a *score* for every other replica. If a replica has updated its counter since the last time it was read,

we increment that replica's score; otherwise, we decrement it. The score is capped by configurable minimum and maximum values, chosen experimentally to be 0 and 15, respectively. Once a replica's score drops below a *failure threshold*, we consider it to have failed; if its score goes above a *recovery threshold*, we consider it to be active and timely. To avoid oscillation, we have different *failure* and *recovery* thresholds, chosen experimentally to be 2 and 6, respectively, so as to avoid false positives.

Large network delays. Mu employs two timeouts: a small timeout in our detection algorithm (scoring), and a longer timeout built into the RDMA connection mechanism. The small timeout detects crashes quickly under common failures (process crashes, host crashes) without false positives. The longer RDMA timeout fires only under larger network delays (connection breaks, counter-read failures). In theory, the RDMA timeout could use exponential back-off to handle unknown delay bounds. In practice, however, that is not necessary, since we target datacenters with small delays.

Fate sharing. Because replication and leader election run in independent threads, the replication thread could fail or be delayed, while the leader election thread remains active and timely. This scenario is problematic if it occurs on a leader, as the leader cannot commit new entries, and no other leader can be elected. To address this problem, every $X=10000$ iterations, the leader election thread checks the replication thread for activity; if the replication thread is stuck inside a call to `propose`, the replication thread stops incrementing the local counter, to allow a new leader to be elected.

5.2 Permission Management

The permission management module is used when changing leaders. Each replica maintains the invariant that only one replica at a time has write permission on its log. As explained in Section 4, when a leader changes in Mu, the new leader must request write permission from all the other replicas; this is done through a simple RDMA Write to a *permission request array* on the remote side. When a replica r sees a *permission request* from a would-be leader ℓ , r revokes write access from the current holder, grants write access to ℓ , and sends an ack to ℓ .

During the transition phase between leaders, it is possible that several replicas think themselves to be leader, and thus the permission request array may contain multiple entries. A permission management thread monitors and handles permission change requests one by one in order of requester id by spinning on the local permission request array.

RDMA provides multiple mechanisms to grant and revoke write access. The first mechanism is to register the consensus log as multiple, completely overlapping RDMA memory regions (MRs), one per remote replica. In order to grant or

Figure 2: Performance comparison of different permission switching mechanisms. *QP Flags*: change the access flags on a QP; *QP Restart*: cycle a QP through the *reset*, *init*, *RTR* and *RTS* states; *MR Rereg*: re-register an RDMA MR with different access flags.

revoke access from replica r , it suffices to re-register the MR corresponding to r with different access flags. The second mechanism is to revoke r 's write access by moving r 's QP to a non-operational state (e.g., *init*); granting r write access is then done by moving r 's QP back to the *ready-to-receive* (*RTR*) state. The third mechanism is to grant or revoke access from replica r by changing the access flags on r 's QP.

We compare the performance of these three mechanisms in Figure 2, as a function of the log size (which is the same as the RDMA MR size). We observe that the time to re-register an RDMA MR grows with the size of the MR, and can reach values close to 100ms for a log size of 4GB. On the other hand, the time to change a QPs access flags or cycle it through different states is independent of the MR size, with the former being roughly 10 times faster than the latter. However, changing a QPs access flags while RDMA operations to that QP are in flight sometimes causes the QP to go into an error state. Therefore, in Mu we use a fast-slow path approach: we first optimistically try to change permissions using the faster QP access flag method and, if that leads to an error, switch to the slower, but robust, QP state method.

5.3 Log Recycling

Conceptually, a log is an infinite data structure but in practice we need to implement a circular log with limited memory. This is done as follows. Each follower has a local *log head* variable, pointing to the first entry not yet executed in its copy of the application. The replayer thread advances the log head each time it executes an entry in the application. Periodically, the leader's background plane reads the log heads of all followers and computes *minHead*, the minimum of all log head pointers read from the followers. Log entries up to the *minHead* can be reused. Before these entries can be reused,

they must be zeroed out to ensure the correct function of the canary byte mechanism. Thus, the leader zeroes all follower logs after the leader’s first undecided offset and before min-Head, using an RDMA Write per follower. Note that this means that a new leader must first execute all leader change actions, ensuring that its first undecided offset is higher than all followers’ first undecided offsets, before it can recycle entries. To facilitate the implementation, we ensure that the log is never completely full.

5.4 Adding and Removing Replicas

Mu adopts a standard method to add or remove replicas: use consensus itself to inform replicas about the change [40]. More precisely, there is a special log entry that indicates that replicas have been removed or added. Removing replicas is easy: once a replica sees it has been removed, it stops executing, while other replicas subsequently ignore any communication with it. Adding replicas is more complicated because it requires copying the state of an existing replica into the new one. To do that, Mu uses the standard approach of check-pointing state; we do so from one of the followers [71].

6 Implementation

Mu is implemented in 7157 lines of C++17 code (CLOC [19]). It uses the *ibverbs* library for RDMA over Infiniband. We implement all features and extensions in sections 4 and 5, except adding/removing replicas and fate sharing. Moreover, we implement some standard RDMA optimizations to reduce latency. RDMA Writes and Sends with payloads below a device-specific limit (256 bytes in our setup) are inlined: their payload is written directly to their work request. We pin threads to cores in the NUMA node of the NIC.

Our implementation is modular. We create several modules on top of the *ibverbs* library, which we expose as Conan [17] packages. Our modules deal with common practical problems in RDMA-based distributed computing (e.g., writing to all and waiting for a majority, gracefully handling broken RDMA connections etc.). Each abstraction is independently reusable. Our implementation also provides a QP exchange layer, making it straightforward to create, manage, and communicate QP information.

7 Evaluation

Our goal is to evaluate whether Mu indeed provides viable replication for microsecond computing. We aim to answer the following questions in our evaluation:

- What is the replication latency of Mu? How does it change with payload size and the application being replicated? How does Mu compare to other solutions?

- What is Mu’s fail-over time?
- What is the throughput of Mu?

We evaluate Mu on a 4-node cluster, the details of which are given in Table 1. All experiments show 3-way replication, which accounts for most real deployments [28].

Table 1: Hardware details of machines.

CPU	2x Intel Xeon E5-2640 v4 @ 2.40GHz
Memory	2x 128GiB
NIC	Mellanox Connect-X 4
Links	100 Gbps Infiniband
Switch	Mellanox MSB7700 EDR 100 Gbps
OS	Ubuntu 18.04.4 LTS
Kernel	4.15.0-72-generic
RDMA Driver	Mellanox OFED 4.7-3.2.9.0

We compare against APUS [71], DARE [61], and Hermes [36] where possible. The most recent system, Hovercraft [38], also provides SMR but its latency at 30–60 microseconds is substantially higher than the other systems, so we do not consider it further. For a fair comparison, we disable APUS’s persistence to stable storage, since Mu, DARE, and Hermes all provide only in-memory replication.

We measure time using the POSIX `clock_gettime` function, with the `CLOCK_MONOTONIC` parameter. In our deployment, the resolution and overhead of `clock_gettime` is around 16–20ns [20]. In our figures, we show bars labeled with the median latency, with error bars showing 99-percentile and 1-percentile latencies. These statistics are computed over 1 million samples with a payload of 64-bytes each, unless otherwise stated.

Applications. We use Mu to replicate several microsecond apps: three key-value stores, as well as an order matching engine for a financial exchange.

The key-value stores that we replicate with Mu are Redis [66], Memcached [54], and HERD [33]. For the first two, the client is assumed to be on a different cluster, and connects to the servers over TCP. In contrast, HERD is a microsecond-scale RDMA-based key-value store. We replicate it over RDMA and use it as an example of a microsecond application. Integration with the three applications requires 183, 228, and 196 additional lines of code, respectively.

The other app is in the context of financial exchanges, in which parties unknown to each other submit buy and sell orders of stocks, commodities, derivatives, etc. At the heart of a financial exchange is an order matching engine [5], such as Liquibook [50], which is responsible for matching the buy and sell orders of the parties. We use Mu to replicate Liquibook. Liquibook’s inputs are buy and sell orders. We created an unreplicated client-server version of Liquibook

Figure 3: Replication latency of Mu integrated into different applications [Memcached (mcd), Liquibook (LiQ), Redis (rds), HERD] and payload sizes. Bar height and numerical labels show median latency; error bars show 99-percentile and 1-percentile latencies.

using eRPC [32], and then replicated this system using Mu. The eRPC integration and the replication required 611 lines of code in total.

7.1 Common-case Replication Latency

We begin by testing the overhead that Mu introduces in normal execution, when there is no leader failure. For these experiments, we first measure raw replication latency and compare Mu to other replication systems, as well as to itself under different payloads and attached applications.

Effect of Payload and Application on Latency We first study Mu in isolation, to understand its replication latency under different conditions.

We evaluate the raw replication latency of Mu in two settings: *standalone* and *attached*. In the standalone setting, Mu runs just the replication layer with no application and no client; the leader simply generates a random payload and invokes `propose()` in a tight loop. In the attached setting, Mu is integrated into one of a number of applications; the application client produces a payload and invokes `propose()` on the leader. These settings could impact latency differently, Mu and the application could interfere with each other.

Figure 3 compares standalone to attached runs as we vary payload size. Liquibook and Herd allow only one payload size (32 and 50 bytes), so they have only one bar each in the graph, while Redis and Memcached have many bars.

We see that the standalone version slightly outperforms the attached runs, for all tested applications and payload sizes. This is due to processor cache effects; in standalone runs, replication state, such as log and queue pairs, are always in cache, and the requests themselves need not be fetched from

memory. This is not the case when attaching to an application. Additionally, in attached runs, the OS can migrate application threads (even if Mu’s threads are pinned), leading to additional cache effects which can be detrimental to performance.

Mu supports two ways of attaching to an application, which have different processor cache sharing effects. The *direct* mode uses the same thread to run both the application and the replication, and so they share L1 and L2 caches. In contrast, the *handover* method places the application thread on a separate core from the replication thread, thus avoiding sharing L1 or L2 caches. Because the application must communicate the request to the replication thread, the handover method requires a cache coherence miss per replicated request. This method consistently adds ≈ 400 ns over the standalone method. For applications with large requests, this overhead might be preferable to the one caused by the direct method, where replication and application compete for CPU time. For lighter weight applications, the direct method is preferable. In our experiments, we measure both methods and show the best method for each application: Liquibook and HERD use the direct method, while Redis and Memcached use the handover method.

We see that for payloads under 256 bytes, standalone latency remains constant despite increasing payload size. This is because we can RDMA-inline requests for these payload sizes, so the amount of work needed to send a request remains practically the same. At a payload of 256 bytes, the NIC must do a DMA itself to fetch the value to be sent, which incurs a gradual increase in overhead as the payload size increases. However, we see that Mu still performs well even at larger payloads quite well; at 512B, the median latency is only 35% higher than the latency of inlined payloads.

Comparing Mu to Other Replication Systems. We now study the replication time of Mu compared to other replication systems, for various applications. This comparison is not possible for every pair of replication system and application, because some replication systems are incompatible with certain applications. In particular, APUS works only with socket-based applications (Memcached and Redis). In DARE and Hermes, the replication protocol is bolted onto a key-value store, so we cannot attach it to the apps we consider—instead, we report their performance with their key-value stores.

Figure 4 shows the replication latencies of these systems. Mu’s median latency outperforms all competitors by at least $2.7\times$, outperforming APUS on the same applications by $4\times$. Furthermore, Mu has smaller tail variation, with a difference of at most 500ns between the 1-percentile and 99-percentile latency. In contrast, Hermes and DARE both varied by more than 4μ s across our experiments, with APUS exhibiting 99-percentile executions up to 20μ s slower (cut off in the figure). We attribute this higher variance to two factors: the need to involve the CPU of many replicas in the critical path (Hermes

Figure 4: Replication latency of Mu compared with other replication solutions: DARE, Hermes, Apus on memcached (mcd), and Apus on Redis (rds). Bar height and numerical labels show median latency; error bars show 99-percentile and 1-percentile latencies.

and APUS), and sequentializing several RDMA operations so that their variance aggregates (DARE and APUS).

7.2 End-to-End Application Latency

Figure 5 shows the end-to-end latency of our tested applications, which includes the latency incurred by the application and by replication (if enabled). We show the result in three graphs corresponding to three classes of applications.

In all three graphs, we first focus on the unreplicated latency of these applications, so as to characterize the workload distribution. Subsequently, we show the latency of the same applications under replication with Mu and with competing systems, so as to exhibit the overhead of replication.

The leftmost graph is for Liquibook. The left bar is the unreplicated version, and the right bar is replicated with Mu. We can see that the median latency of Liquibook without replication is $4.08\mu s$, and therefore the overhead of replication is around 35%. There is a large variance in latency, even in the unreplicated system. This variance comes from the client-server communication of Liquibook, which is based on eRPC. This variance changes little with replication. The other replication systems cannot replicate Liquibook (as noted before, DARE and Hermes are bolted onto their app, and APUS can replicate only socket-based applications). However, extrapolating their latency from Figure 4, they would add unacceptable overheads—over 100% overhead for the best alternative (Hermes).

The middle graph in Figure 5 shows the client-to-client latency of replicated and unreplicated microsecond-scale key-value stores. The first bars in orange show HERD unreplicated and HERD replicated with Mu. The green bar shows DARE’s key-value store with its own replication system. The median unreplicated latency of HERD is $2.25\mu s$, and Mu adds $1.34\mu s$.

While this is a significant overhead (59% of the original latency), this overhead is lower than any alternative. We do not show Hermes in this graph since Hermes does not allow for a separate client, and only generates its requests on the servers themselves. HERD replicated with Mu is the best option for a replicated key-value store, with overall median latency $2\times$ lower than the next best option, and a much lower variance.

The rightmost graph in Figure 5 shows the replication of the traditional key-value stores, Memcached and Redis. The two leftmost bars show the client-to-client latencies of unreplicated Memcached and Redis, respectively. The four rightmost bars show the client-to-client latencies under replication with Mu and APUS. Note that the scale starts at $100\mu s$ to show better precision.

Mu incurs an overhead of around $1.5\mu s$ to replicate these apps, which is about $5\mu s$ faster than replicating with APUS. For these TCP/IP key-value stores, client-to-client latency under replication with Mu is around 5% lower than client-to-client latency under replication with APUS. With a faster client-to-app network, this difference would be bigger. In either case, Mu provides fault-tolerant replication with essentially no overhead for these applications.

Tail latency. From Figures 4 and 5, we see that applications replicated with DARE and APUS show large tail latencies and a skew towards lower values (the median latency is closer to the 1-st percentile than the 99-th percentile). We believe this tail latency occurs because DARE and APUS must handle several successive RDMA events on their critical path, where each event is susceptible to delay, thereby inflating the tail. Because Mu involves fewer RDMA events, its tail is smaller.

Figure 5 shows an even greater tail for the end-to-end latency of replicated applications. Liquibook has a large tail even in its unreplicated version, which we believe is due to its client-server communication, since the replication of Liquibook with Mu has a small tail (Figure 4). For Memcached and Redis, additional sources of tail latency are cache effects and thread migration, as discussed in Section 7.1. This effect is particularly pronounced when replicating with APUS (third panel of Figure 5), because the above contributors are compounded.

7.3 Fail-Over Time

We now study Mu’s fail-over time. In these experiments, we run the system and subsequently introduce a leader failure. To get a thorough understanding of the fail-over time, we repeatedly introduce leader failures (1000 times) and plot a histogram of the fail-over times we observe. We also time the latency of permission switching, which corresponds to the time to change leaders after a failure is detected. The detection time is the difference between the total fail-over time and the permission switch time.

Figure 5: End-to-end latencies of applications. The first graph shows a financial exchange app (Liquibook) unreplicated and replicated with Mu. The second graph shows microsecond key-value stores: HERD unreplicated, HERD replicated with Mu, and DARE. The third graph shows traditional key-value stores: Memcached and Redis, unreplicated, as well as replicated with Mu and APUS. Bar height and numerical labels show median latency; error bars show 99-percentile and 1-percentile latencies.

Figure 6: Fail-over time distribution.

We inject failures by delaying the leader, thus making it become temporarily unresponsive. This causes other replicas to observe that the leader’s heartbeat has stopped changing, and thus detect a failure.

Figure 6 shows the results. We first note that the total fail-over time is quite low; the median fail-over time is $873\mu s$ and the 99-percentile fail-over time is $947\mu s$, still below a millisecond. This represents an order of magnitude improvement over the best competitor at ≈ 10 ms (Hovercraft [38]).

The time to switch permissions constitutes about 30% of the total fail-over time, with mean latency at $244\mu s$, and 99-percentile at $294\mu s$. Recall that this measurement in fact encompasses two changes of permission at each replica; one to revoke write permission from the old leader and one to grant it to the new leader. Thus, improvements in the RDMA permission change protocol would be doubly amplified in Mu’s fail-over time.

The rest of the fail-over time is attributed to failure detection ($\approx 600\mu s$). Although our pull-score mechanism does not rely on network variance, there is still variance introduced by process scheduling (e.g., in rare cases, the leader process is descheduled by the OS for tens of microseconds)—this is what prevented us from using smaller timeouts/scores and it is an area under active investigation for microsecond apps [9, 58, 63, 65].

7.4 Throughput

While Mu optimizes for low latency, in this section we evaluate the throughput of Mu. In our experiment, we run a standalone microbenchmark (not attached to an application). We increase throughput in two ways: by batching requests together before replicating, and by allowing multiple outstanding requests at a time. In each experiment, we vary the maximum number of outstanding requests allowed at a time, and the batch sizes.

Figure 7 shows the results in a latency-throughput graph. Each line represents a different max number of outstanding requests, and each data point represents a different batch size. As before, we use 64-byte requests.

We see that Mu reaches high throughput with this simple technique. At its highest point, the throughput reaches 47 Ops/ μs with a batch size of 128 and 8 concurrent outstanding requests, with per-operation median latency at $17\mu s$. Since the leader is sending requests to two other replicas, this translates to a throughput of 48Gbps, around half of the NIC bandwidth.

Latency and throughput both increase as the batch size increases. Median latency is also higher with more concurrent outstanding requests. However, the latency increases slowly, remaining at under $10\mu s$ even with a batch size of 64 and 8 outstanding requests.

Figure 7: Latency vs throughput. Each line represents a different number of allowed concurrent outstanding requests. Each point on the lines represents a different batch size. Batch size shown as annotation close to each point.

There is a throughput wall at around 45 Ops/μs, with latency rising sharply. This can be traced to the transition between the client requests and the replication protocol at the leader replica. The leader must copy the request it receives into a memory region prepared for its RDMA write. This memory operation becomes a bottleneck. We could optimize throughput further by allowing direct contact between the client and the follower replicas. However, that may not be useful as the application itself might need some of the network bandwidth for its own operation, so the replication protocol should not saturate the network.

Increasing the number of outstanding requests while keeping the batch size constant substantially increases throughput at a small latency cost. The advantage of more outstanding requests is largest with two concurrent requests over one. Regardless of batch size, this allows substantially higher throughput at a negligible latency increase: allowing two outstanding requests instead of one increases latency by at most 400ns for up to a batch size of 32, and only 1.1μs at a batch size of 128, while increasing throughput by 20–50% depending on batch size. This effect grows less pronounced with higher numbers of outstanding requests.

Similarly, increasing batch size increases throughput with a low latency hit for small batch sizes, but the latency hit grows for larger batches. Notably, using 2 outstanding requests and a batch size of 32 keeps the median latency at only 3.4μs, but achieves throughput of nearly 30 Ops/μs.

8 Related Work

SMR in General. State machine replication is a common technique for building fault-tolerant, highly available services [40, 68]. Many practical SMR protocols have been designed, addressing simplicity [8, 10, 28, 44, 56], cost [39, 43],

and harsher failure assumptions [11, 12, 24, 39]. In the original scheme, which we follow, the order of all operations is agreed upon using consensus instances. At a high-level, our Mu protocol resembles the classical Paxos algorithm [40], but there are some important differences. In particular, we leverage RDMA’s ability to grant and revoke access permissions to ensure that two leader replicas cannot both write a value without recognizing each other’s presence. This allows us to optimize out participation from the follower replicas, leading to better performance. Furthermore, these dynamic permissions guide our unique leader changing mechanism.

Several implementations of Multi-Paxos avoid repeating Paxos’s prepare phase for every consensus instance, as long as the same leader remains [13, 41, 53]. Piggybacking a commit message onto the next replicated request, as is done in Mu, is also used as a latency-hiding mechanism in [53, 71].

Aguilera et al. [1] suggested the use of local heartbeats in a leader election algorithm designed for a theoretical message-and-memory model, in an approach similar to our pull-score mechanism. However, no system has so far implemented such local heartbeats for leader election in RDMA.

Single round-trip replication has been achieved in several previous works using two-sided sends and receives [23, 36, 37, 39, 43]. Theoretical work has shown that single-shot consensus can be achieved in a single one-sided round trip [3]. However, Mu is the first system to put that idea to work and implement one-sided single round trip SMR.

Alternative reliable replication schemes totally order only non-conflicting operations [16, 27, 36, 42, 59, 60, 69]. These schemes require opening the service being replicated to identify which operations commute. In contrast, we designed Mu assuming the replicated service is a black box. If desired, several parallel instances of Mu could be used to replicate concurrent operations that commute. This could be used to increase throughput in specific applications.

It is also important to notice that we consider “crash” failures. In particular, we assume nodes cannot behave in a Byzantine manner [11, 15, 39].

Improving the Stack Underlying SMR. While we propose a new SMR algorithm adapted to RDMA in order to optimize latency, other systems keep a classical algorithm but improve the underlying communication stack [32, 48]. With this approach, somewhat orthogonal to ours, the best reported replication latency is 5.5 μs [32], almost 5× slower than Mu. HovercRaft [38] shifts the SMR from the application layer to the transport layer to avoid IO and CPU bottlenecks on the leader replica. However, their request latency is more than an order of magnitude more than that of Mu, and they do not optimize fail-over time.

Some SMR systems leverage recent technologies such as programmable switches and NICs [29, 31, 49, 52]. However, programmable networks are not as widely available as RDMA, which has been commoditized with technologies

such as RoCE and iWARP.

Other RDMA Applications. More generally, RDMA has recently been the focus of many data center system designs, including key-value stores [21, 33] and transactions [35, 72]. Kalia et al. provide guidelines on the best ways to use RDMA to enhance performance [34]. Many of their suggested optimizations are employed by Mu. Kalia et al. also advocate the use of two-sided RDMA verbs (Sends/Receives) instead of RDMA Reads in situations in which a single RDMA Read might not suffice. However, this does not apply to Mu, since we know a priori which memory location should be read, and we rarely have to follow up with another read.

Failure detection. Failure detection is typically done using timeouts. Conventional wisdom is that timeouts must be large, in the seconds [47], though some systems report timeouts as low as 10 milliseconds [38]. It is possible to improve detection time using inside information [45, 47] or fine-grained reporting [46], which requires changes to apps and/or the infrastructure. This is orthogonal to our score-based mechanism and could be used to further improve Mu.

Similar RDMA-based Algorithms

A few SMR systems have recently been designed for RDMA [30, 61, 71], but used RDMA differently from Mu.

DARE [61] is the first RDMA-based SMR system. Similarly to Mu, DARE uses only one-sided RDMA verbs executed by the leader to replicate the log in normal execution, and makes use of permissions when changing leaders. However, unlike Mu, DARE requires updating the tail pointer of each replica's log in a separate RDMA Write from the one that copies over the new value, which leads to more round-trips for replication. DARE's use of permissions does not lead to a light-weight mechanism to block concurrent leaders, as in Mu. DARE has a heavier leader election protocol than Mu's, similar to that of RAFT, in which care is taken to ensure that at most one process considers itself leader at any point in time.

APUS [71] improves upon DARE's throughput. However, APUS requires active participation from the follower replicas during the replication protocol, resulting in higher latencies. Thus, it does not achieve the one-sided common-case communication of Mu. Similarly to DARE and Mu, APUS uses transitions through queue pair states to allow or deny RDMA access. However, like DARE, it does not use this mechanism to achieve a single one-sided communication round.

Derecho [30] provides durable and non-durable SMR, by combining a data movement protocol (SMC or RDMC) with a shared-state table primitive (SST) for determining when it is safe to deliver messages. This design yields high throughput

but also high latency: a minimum of $10\mu\text{s}$ for non-durable SMR [30, Figure 12(b)] and more for durable SMR. This latency results from a node delaying the delivery of a message until all nodes have confirmed its receipt using the SST, which takes additional RDMA communication steps compared to Mu. It would be interesting to explore how Mu's protocol could improve Derecho.

Aguilera et al [3] present a one-shot consensus algorithm based on RDMA that solves consensus in a single one-sided communication round in the common case. They model RDMA's one-sided verbs as shared memory primitives which operate only if granted appropriate permissions. Their one-round communication complexity relies on changing permissions, an idea we use in Mu. While that work focuses on a theoretical construction, Mu is a fully fledged SMR system that needs many other mechanisms, such as logging, managing state, coordinating instances, recycling instances, handling clients, and permission management. Because these mechanisms are non-trivial, Mu requires its own proof of correctness [2]. Mu also provides an implementation and experimental evaluation not found in [3].

9 Conclusion

Computers have progressed from batch-processing systems that operate at the time scale of minutes, to progressively lower latencies in the seconds, then milliseconds, and now we are in the microsecond revolution. Work has already started in this space at various layers of the computing stack. Our contribution fits in this context, by providing generic microsecond replication for microsecond apps.

Mu is a state machine replication system that can replicate microsecond applications with little overhead. This involved two goals: achieving low latency on the common path, and minimizing fail-over time to maintain high availability. To reach these goals, Mu relies on (a) RDMA permissions to replicate a request with a single one-sided operation, as well as (b) a failure detection mechanism that does not incur false positives due to common network delays—a property that permits Mu to use aggressively small timeout values.

Abstract

Consensus-based replicated systems are complex, monolithic, and difficult to upgrade once deployed. As a result, deployed systems do not benefit from innovative research, and new consensus protocols rarely reach production. We propose virtualizing consensus by virtualizing the shared log API, allowing services to change consensus protocols without downtime. Virtualization splits the logic of consensus into the VirtualLog, a generic and reusable reconfiguration layer; and pluggable ordering protocols called Loglets. Loglets are simple, since they do not need to support reconfiguration or leader election; diverse, consisting of different protocols, codebases, and even deployment modes; and composable, via RAID-like stacking and striping. We describe a production database called Delos¹ which leverages virtual consensus for rapid, incremental development and deployment. Delos reached production within 8 months, and 4 months later upgraded its consensus protocol without downtime for a 10X latency improvement. Delos can dynamically change its performance properties by changing consensus protocols: we can scale throughput by up to 10X by switching to a disaggregated Loglet, and double the failure threshold of an instance without sacrificing throughput via a striped Loglet.

1 Introduction

The last decade has seen significant research advances in faster and more flexible consensus protocols. Unfortunately, systems that use consensus to replicate state are monolithic, complex, and difficult to evolve. As a result, deployed systems rarely benefit from new research ideas (e.g., ZooKeeper [20] still runs a decade-old protocol [22]); in turn, such ideas only have real-world impact when entire new production systems and applications are built from scratch around them (e.g., VMware's CorfuDB [1] uses sharded acceptors [7, 16]; Facebook's LogDevice [3] implements flexible quorums [19];

etcd [2] runs on Raft [39]). Contrast this state of affairs with other areas such as OSES and networks, where modular design and clean layering allow plug-and-play adoption of new mechanisms and incremental improvement of existing ones: for example, a new type of SSD, a new filesystem layout, or a new key-value store like RocksDB can each be deployed with no modification to the layers above or below it.

Recently, the shared log has gained traction as an API for consensus in research [7–9, 16, 37] and industry [1, 3, 23, 47]. Applications can replicate state via this API by appending updates to the shared log, checking its tail, and reading back updates from it. The consensus protocol is hidden behind the shared log API, allowing applications to bind to any implementation at deployment time.

Unfortunately, an API on its own is not sufficient to enable incremental evolution. First, new implementations of the shared log are *difficult to deploy and operate*: no support exists for upgrading and migrating applications to different implementations without downtime, which is untenable for highly available services. Second, new implementations are *difficult to develop*: the consensus protocol implementing the shared log is itself a complex distributed system containing a data plane (for ordering and storing commands durably) and a control plane (for reconfiguring leadership, roles, parameters, and membership). Existing protocols such as Raft aggressively combine both planes into a single protocol; in doing so, they give up the ability to incrementally change the data plane (i.e., the ordering mechanism) without reimplementing the entire control plane. As a result of these two limitations, systems have to be written and deployed from scratch around new consensus protocols (e.g., ZooKeeper cannot be upgraded to run over Raft [39] or CORFU [7]); and protocols have to be rewritten around new ordering mechanisms (e.g., Raft cannot be changed easily to support sharded acceptors).

In this paper, we virtualize consensus by virtualizing the shared log API. We propose the novel abstraction of a virtualized shared log (or *VirtualLog*). The VirtualLog exposes a conventional shared log API; applications above it are oblivious to its virtualized nature. Under the hood, the VirtualLog

¹Delos is an island in the Cyclades, a few hundred miles from Paxos and Corfu.

Figure 1: *Virtual consensus: servers replicate state via a VirtualLog, which is mapped to underlying Loglets.*

chains multiple shared log instances (called *Loglets*) into a single shared log. Different Loglets in a VirtualLog can be instances of the same ordering protocol with different parameters, leadership, or membership (e.g., different instances of MultiPaxos [45]); they can be entirely distinct log implementations (e.g., Raft [39], LogDevice [3], Scallog [16], or CORFU [7]); or they can be simple log shims over external storage systems (e.g., ZooKeeper [20] or HDFS [43]). Virtualization enables *heterogeneous reconfiguration*: a single VirtualLog can span different types of Loglets and dynamically switch between them.

We implemented virtual consensus in Delos, a database that stores control plane state for Facebook. Delos has been in production for over 18 months and currently processes over 1.8 billion transactions per day across all our deployments. One of its use cases is Twine’s Resource Broker [44], which stores metadata for the fleet of servers in Facebook; each Delos deployment runs on 5 to 9 machines and manages server reservations for a fraction of the fleet. Internally, Delos is a shared log database [7, 8, 33]; it replicates state across servers by appending and playing back commands on the VirtualLog. Delos supports multiple application-facing APIs; we have a Table API in production, while a second ZooKeeper API is under development.

Virtual consensus in Delos *simplified the deployment and operation* of consensus implementations. Virtualization slashed time to deployment since we had the ability to deploy the system rapidly with an initial Loglet implementation, and later upgrade it without downtime. We reached production within eight months with a simple Loglet implemented as a shim over ZooKeeper (ZKLoglet); later, we obtained a 10X improvement in end-to-end latency in production by migrating online to a new, custom-built Loglet implementation (NativeLoglet). We also enabled seemingly infinite capacity for the VirtualLog by migrating older segments to a Loglet layered on cold storage (BackupLoglet); in turn, this allowed

Delos to provide operators with a point-in-time restore capability. Loglets can be converged (i.e., collocated on the same machines as the database) or disaggregated (i.e., running on an entirely different set of machines), allowing operators to switch the Delos deployment mode on the fly to obtain different performance and fault-tolerance properties.

Virtual consensus also *simplifies the development* of new consensus implementations. Virtualization splits the complex functionality of consensus into separate layers: a control plane (the VirtualLog) that provides a generic reconfiguration capability; and a data plane (the Loglet) that provides critical-path ordering. While the VirtualLog’s reconfiguration mechanism can be used solely for migrating between entirely different Loglet implementations, it can also switch between different instances of the same Loglet protocol with changes to leadership, roles, parameters, and membership. As a result, the Loglet itself can be a statically configured protocol, without any internal support for reconfiguration. In fact, the Loglet does not even have to implement fault-tolerant consensus (i.e., be highly available for appends via leader election), as long as it provides a fault-tolerant *seal* command, which is theoretically weaker and practically simpler to implement. When a Loglet fails for appends, the VirtualLog seals it and switches to a different Loglet, providing leader election and reconfiguration as a separate, reusable layer that can work with any underlying Loglet.

Accordingly, new Loglets are simple to design and implement since they are not required to implement fault-tolerant consensus or reconfiguration. To demonstrate this point, we describe the Delos NativeLoglet, which uses a primary-driven protocol that is unavailable for appends if the primary fails, but can support seals as long as a quorum is alive. New Loglets are also easy to construct via RAID-like composition; for example, we describe StripedLoglet, a thin shim layer that stitches together multiple Loglets to enable behavior equivalent to rotating sequencers [35] and sharded acceptors [7, 16].

Virtual consensus has some limitations. The reusability of VirtualLog-driven reconfiguration comes with a latency hit for certain types of reconfigurations such as planned leader changes. Loglets can optimize for specific cases by relying on their own in-band reconfiguration instead of the VirtualLog. A second limitation relates to generality: since we virtualize a specific API for consensus that captures a total order of commands, we do not currently support protocols that construct partial orders based on operation commutativity [26, 36]. In future work, we plan to extend virtual consensus to partially ordered shared logs [33].

We are the first to propose a virtualized shared log composed from heterogeneous log implementations. Prior work composes a logical shared log directly from storage servers [7, 9, 16, 47]; or virtualizes in the opposite direction, multiplexing homogenous streams over a single shared log [8, 48]. Delos is the first replicated database that can switch its consensus implementation on the fly to different

protocols, deployment modes, or codebases. While the theory of consensus has always allowed learners and acceptors to be disaggregated, Delos is also the first production system that can switch between converged and disaggregated acceptors.

In this paper, we make the following contributions:

- We propose virtualizing consensus via the novel VirtualLog and Loglet abstractions; and describe Delos, a storage system that implements these abstractions.
- Using production data, we show Delos upgrading to NativeLoglet without downtime for a 10X latency improvement.
- Using experiments, we show that Delos can: A) switch to a disaggregated Loglet for a 10X improvement in throughput under a 15ms p99 SLA; B) double its failure threshold without lowering throughput via a Striped-Loglet that rotates sequencers. Further, we show that StripedLoglet can support over a million 1KB appends/s on a log-only workload by sharding acceptors.

2 The Path to Virtual Consensus

Virtualization for faster deployment: In 2017, Facebook needed a table store for its core control plane services with strong guarantees on durability, consistency, and availability. Two practical imperatives drove the design and development of this system: fast deployment (it had to reach production within 6-9 months) and incremental evolution (it had to support better performance over time).

At the time, Facebook already operated four different storage systems: a ZooKeeper service; a shared log service based on LogDevice [3]; a key-value service called ZippyDB [5]; and a replicated MySQL service [13]. None of these systems fit the exact use case, either due to a mismatch in API (e.g., ZooKeeper does not provide a table API) or fault-tolerance guarantees (e.g., the MySQL service provided inadequate availability).

Further, these systems could not be easily modified to provide the required API or guarantees. Each of them was a monolith: the database API could not be easily changed, nor could the underlying consensus protocol be re-used. In some systems, no abstraction boundary existed between the database and the consensus protocol. In other systems, an abstraction boundary did exist in the form of a shared log API, allowing the underlying consensus protocol to be reused; however, no support existed to migrate from one implementation of the abstraction to another.

Building yet another monolithic system from scratch – including a new consensus implementation – was not feasible since we had to hit deployment within 6-9 months. Layering the system over an existing shared log such as LogDevice would allow us to reach production quickly, but also tie us for

perpetuity to the fault-tolerance and performance properties of that consensus implementation.

Our solution was to virtualize consensus. In the remainder of this paper, we describe how virtual consensus allowed us to reach production quickly with an existing implementation of consensus, and then migrate without downtime to new implementations.

Virtualization for faster development: Beyond fast initial deployment and online migration, virtualization also enabled faster development of new consensus implementations. On its own, the shared log abstraction simplifies consensus-based systems, separating applications from the logic of consensus via a data-centric API. Virtualizing the shared log further splits the consensus protocol into two layers: a control plane, which includes the logic for reconfiguration, and a data plane, which orders commands on the critical path.

In practice, such separation allowed us to incrementally improve the system by re-implementing just the data plane of the consensus protocol via new Loglets, while reusing the VirtualLog control plane for features such as leader election and membership changes. In the process, we completely changed the operational characteristics and performance of the system, as we describe later.

Importantly, such a separation also enables diversity in the data plane. The last few years have seen a number of consensus protocols with novel ordering mechanisms [3, 7, 14–16, 22, 24, 31, 35, 37, 39, 42], providing vastly different trade-offs between performance and fault-tolerance. By making it easier to implement such protocols and deploy them within running systems, virtualization lowers the barrier to innovation.

3 Abstractions for Virtual Consensus

In this paper, we propose virtualizing consensus by virtualizing the shared log abstraction. We have three design goals for virtualization. First, virtualization should be *transparent to applications*, which should be unmodified and oblivious to the virtualized nature of the log. Second, virtualization should allow underlying logs to be *simple and diverse*, lowering the barrier to new log implementations. Third, virtualization should allow for *migration* between implementations without downtime. We obtain these properties via two core abstractions.

In virtual consensus, the application operates above a VirtualLog, which stitches together multiple independent Loglets. The VirtualLog and Loglets expose a conventional shared log API (see Figure 2). Applications can append an entry, receiving back a log position; call `checkTail` to obtain the first unwritten position; call `readNext` to read the first entry in the passed-in range; and call `prefixTrim` to indicate that a prefix of the log can be trimmed. Virtualization requires two additions to this basic API: a `seal` command, which ensures that any new appends fail; and an augmented `checkTail` response

```

class ILoglet {
    logpos_t append(Entry payload);
    pair<logpos_t, bool> checkTail();
    Entry readNext(logpos_t min, logpos_t
        max);
    logpos_t prefixTrim(logpos_t trimpos);
    void seal();
}
class IVirtualLog : public ILoglet {
    bool reconfigExtend(LogCfg newcfg);
    bool reconfigTruncate();
    bool reconfigModify(LogCfg newcfg);
}

```

Figure 2: Loglet and VirtualLog APIs.

that indicates via a boolean whether the log is sealed. In addition, the VirtualLog also implements extra reconfiguration APIs to add and remove Loglets.

The VirtualLog is the only required source of fault-tolerant consensus in the system, providing a catch-all mechanism for any type of reconfiguration. The Loglet does not have to support fault-tolerant consensus, instead acting as a pluggable data plane for failure-free ordering. Existing systems typically struggle to implement monolithic consensus protocols that are simple, fast, and fault-tolerant. In virtual consensus, we divide and conquer: consensus in the VirtualLog is simple and fault-tolerant (but not necessarily fast, since it is invoked only on reconfigurations), while consensus in the Loglet is simple and fast (but not necessarily fault-tolerant). We now describe these abstractions and their interaction in detail.

3.1 The VirtualLog abstraction

The VirtualLog implements a logical shared log by chaining a collection of underlying Loglets. In this section, we use the term ‘client’ to refer to an application process that accesses the VirtualLog. Clients accessing the VirtualLog see a shared, append-only virtual address space that is strongly consistent (i.e., linearizable [18]), failure-atomic, and highly available. Internally, this address space is mapped to the individual address spaces of different Loglets in a chain. Operations to the VirtualLog are translated to operations on underlying Loglets based on this chain-structured mapping.

The simplest possible VirtualLog is a trivial singleton chain: $[0, \infty)$ of the VirtualLog is mapped to $[0, \infty)$ of a single Loglet. In this case, commands to the VirtualLog are passed through unmodified to the underlying Loglet. A more typical chain consists of multiple Loglets, mapping different segments of the virtual address space to each log: for example, $[0, 100)$ is mapped to $[0, 100)$ of Loglet A; $[100, 150)$ is mapped to $[0, 50)$ of Loglet B; $[150, \infty)$ to $[0, \infty)$ of C. We use the follow-

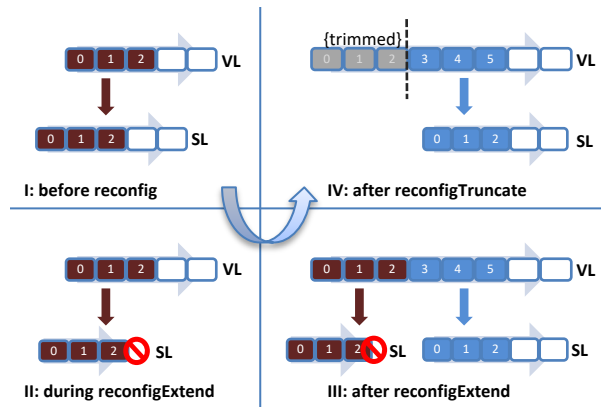

Figure 3: The VirtualLog reconfigures from a single Loglet (I) by first sealing the Loglet (II) and installing a new Loglet (III). Later, the old Loglet is removed (IV).

ing notation for such a chain: $[0 \xrightarrow{A} 100 \xrightarrow{B} 150 \xrightarrow{C} \infty]$.

Any append and checkTail commands on a VirtualLog are directed to the last Loglet in the chain, while readNext commands on a range are routed to the Loglet storing that range. In the process, log positions are translated from the virtual address space to each Loglet’s individual address space (for example, in the chain described above, if an append that is routed to Loglet C returns position 10, we map it to position 160 on the VirtualLog). Log positions can be contiguous (i.e., every position has an entry) or sparse (i.e., positions can be left unoccupied), depending on the underlying Loglet. Importantly, only the last log in the chain is appendable (we call this the active segment); the other logs are sealed and return errors on appends (we call these sealed segments).

The VirtualLog can be reconfigured to a new chain via its API (see Figure 2). The reconfigExtend call changes the active segment of the VirtualLog so that new appends are directed to an entirely different Loglet. Reconfigurations can also modify sealed segments via the reconfigModify call (e.g., to replace failed servers within a sealed Loglet). The reconfigTruncate call is used to remove the first sealed segment from the chain (e.g., when the VirtualLog’s address space is trimmed).

3.2 VirtualLog design

The VirtualLog is composed of two distinct components: a client-side layer exposing the shared log API, which routes operations to underlying Loglets based on the chain-structured mapping; and a logically centralized metadata component (MetaStore) that durably stores the chain. Each client maintains a local (potentially stale) cached copy of the chain.

The MetaStore component has a simple API: it is a single versioned register supporting a conditional write. Reading the MetaStore returns a value with an attached version. Writing

to it requires supplying a new value and an expected existing version.

The primary technical challenge for the VirtualLog is providing clients with a shared, strongly consistent, and highly available virtual address space. In steady-state, when the chain remains unchanged, this task is trivial: the client-side layer can use its locally cached copy of the chain to route operations. However, the chain can be changed via the VirtualLog reconfiguration APIs shown in Figure 2.

Any client can initiate a reconfiguration, or complete a reconfiguration started by some other client. Reconfiguration involves three steps: *sealing* the old chain, *installing* the new chain on the MetaStore, and *fetching* the new chain from the MetaStore. The following reconfiguration protocol is expressed entirely in the form of data-centric operations against the Loglet and MetaStore; it assumes nothing about the internal implementation of either component.

Step 1: Sealing the current chain by sealing its last Loglet: The first step of a reconfiguration involves sealing the current chain (C_i) to stop new appends from succeeding within it. To seal the current chain, the reconfiguring client simply calls `seal` on the active segment, since this is the only segment that receives appends, and all other segments are already sealed. Seals on a Loglet are idempotent; accordingly, multiple clients can concurrently seal the current chain. Once the current chain is sealed by the reconfiguring client, any subsequent `append` on the current chain by a client returns an error. After sealing the active segment, the client calls `checkTail` to retrieve its tail; this determines the start of the new active segment.

Step 2: Installing the new chain in the MetaStore: Once the old chain C_i is sealed, the reconfiguring client writes a new chain C_{i+1} to the MetaStore. The MetaStore is simply a versioned register supporting a conditional write; accordingly, it only accepts the new chain C_{i+1} if the existing chain is C_i . In effect, multiple reconfiguring clients – after running step 1 idempotently – can race to install the new chain in the MetaStore, with at most one guaranteed to win. The chain is stored as a list of segments with start/stop positions, each with an opaque Loglet-specific configuration.

Step 3: Fetching the new chain from the MetaStore: In the final step, the reconfiguring client fetches the latest chain from the MetaStore. In the common case, this step can be omitted if the reconfiguring client succeeded in installing its candidate chain in Step 2. Alternatively, if the write in Step 2 failed, some other client may have won the race and installed a different chain, which we have to fetch.

Concurrency: After a client seals a chain in Step 1, it is possible that other clients continue operating within it. An `append` to the VirtualLog using the sealed chain will be routed to its last Loglet, which is now sealed in the new chain. As a result, a client issuing appends in the old chain will obtain an error code indicating that the Loglet is sealed; it will then fetch the latest chain from the MetaStore and retry.

A `checkTail` to the VirtualLog using the sealed chain also gets routed to the last Loglet in the chain. In response, the Loglet returns not just its tail position, but also a bit indicating whether or not it is sealed. If the Loglet has been sealed, then the client knows that it is operating on a stale chain, which means in turn that the computed tail is likely to not be the true tail of the VirtualLog. In this case, it fetches the latest chain from the MetaStore and retries.

Failure Atomicity: When a client encounters a sealed chain, it is possible that it does not find a newer chain in the MetaStore. This can happen if the reconfiguring client (which sealed the chain) either failed or got delayed after the seal step but before installing the new chain. In this case, after a time-out period, the client ‘rolls forward’ the reconfiguration by installing its own new chain. Note that the client completing the reconfiguration does not know the original intention of the failed client (e.g., if it was reconfiguring to a different Loglet type); hence, it creates a default new chain by cloning the configuration of the previous active segment.

Reconfiguration Policy: The protocol above provides a generic mechanism for reconfiguration. However, it has to be invoked based on some policy. There are three primary drivers of reconfiguration. First, planned reconfigurations (e.g., upgrading to a faster Loglet) are driven via a command line tool by operators. Second, the VirtualLog calls `reconfigTruncate` on itself when it trims the entirety of its first sealed Loglet while servicing a `prefixTrim`. For example, if the application calls `prefixTrim(100)` on chain $[0 \xrightarrow{A} 100 \xrightarrow{B} \infty]$; the VirtualLog trims all of A and then reconfigures to chain $[100 \xrightarrow{B} \infty]$. Third, individual Loglets that do not implement their own leader election or reconfiguration are responsible for detecting failures and requesting a `reconfigExtend` on the VirtualLog, as we describe later.

A subtle point is that an old chain only has to be sealed if it conflicts with a newer chain: i.e., the new chain remaps some unwritten virtual address to a different Loglet. Reconfigurations for sealed segments (e.g., to rebuild failed servers in a sealed Loglet, or to copy and remap a sealed segment to a different Loglet) do not change the locations of unwritten virtual addresses. As a result, they do not necessarily require the old chain to be sealed first before the new chain is installed; different clients can concurrently operate in the old and new chains. Similarly, truncation (i.e., removing the first segment) does not require the old chain to be sealed; if a client with the old chain tries to access an address on a truncated Loglet, it may succeed or receive an error saying the entry has been deleted. In practice, this means rebuild and GC activity on sealed segments does not interfere with appends at the tail of the VirtualLog.

3.3 The VirtualLog MetaStore

As described above, the VirtualLog stores a mapping – its chain of constituent Loglets – in a MetaStore: a single ver-

sioned register supporting a conditional write predicated on the current version. We now discuss the requirements and design space for this component.

The VirtualLog MetaStore is a necessary and sufficient source of fault-tolerant consensus in our architecture; as we describe later, Loglets are not required to implement consensus. The MetaStore has to be highly available for writes; accordingly, it requires a fault-tolerant consensus protocol like Paxos. Since the VirtualLog (and its MetaStore) is a separate, reusable layer, we need to implement this fault-tolerant consensus protocol only once. Further, the MetaStore is not required to be particularly fast, since it is accessed by the VirtualLog only during reconfigurations.

Why does the VirtualLog require its own MetaStore? Existing reconfigurable systems often store similar information (e.g., the set of servers in the next configuration) inline with the same total order as other commands (within the last configuration [34] or a combination of the old and new configurations [39]). In this case, the steps of sealing the old chain and writing the membership of the new chain can be done in a single combined operation. In the VirtualLog, this would be equivalent to storing the identity of the next Loglet within the current active Loglet while sealing it. However, such a design requires the Loglet itself to be highly available for writes (i.e., implement fault-tolerant consensus), since reconfiguring to a new Loglet would require a new entry to be written to the current Loglet. With a separate MetaStore, we eliminate the requirement of fault-tolerant consensus for each Loglet. Since one of our design goals is to make Loglets simple and diverse, we choose to use a separate MetaStore.

Using a separate MetaStore means the common-case latency of a reconfiguration consists of a `seal`, a `checkTail`, and a write to the MetaStore. In our current setting (control plane applications running within a single data center), reconfiguration latencies of 10s of ms are tenable. If reconfiguration is driven by failure, the latency of failure detection is typically multiple seconds in any case, to avoid false positives [30]. In the future, when we run across regions, it may be important to optimize for planned reconfiguration (e.g., replacing servers); since the Loglet is still available in this case, we can potentially reconfigure by storing inline commands within the Loglet itself, borrowing existing techniques such as α -windows [25, 34].

3.4 The Loglet abstraction

The Loglet is the data plane abstraction in virtual consensus: a shared log designed to operate as a segment of the VirtualLog. The requirements for a Loglet are minimal: it provides totally ordered, durable storage via the shared log API. Significantly, the Loglet can operate within a static configuration; it does not have to provide support for role or membership changes. It does not have to support leader election, either; i.e., it is not required to provide high availability for `append`

calls. Instead, the Loglet provides a highly available `seal` command that prevents new appends from being successfully acknowledged. The VirtualLog uses such a sealing capability to support highly available `append` calls via reconfiguration, as described earlier in this section.

A `seal` bit does not require fault-tolerant consensus. Compared to similar data types that are equivalent to consensus, it differs from a write-once register [42], since only one ‘value’ can be proposed (i.e., the bit can be set); and a sticky bit [40], since it has only two states (undefined and set) rather than three. It can be implemented via a fault-tolerant atomic register that stores arbitrary values [6, 11], which in turn is weaker than consensus and not subject to the FLP impossibility result [17]. As we describe later, a `seal` is also much simpler to implement than a highly available `append`.

In addition to supporting `seal`, the Loglet provides an augmented `checkTail` to return its sealed status along with the current tail (i.e., `checkTail` returns a *(tailpos, sealbit)* tuple rather than a single tail position). To lower the burden of implementing this extra call on each Loglet, it is designed to have weak semantics: the tail position and seal status do not need to be checked atomically. Instead, the `checkTail` call is equivalent to a conventional `checkTail` and a `checkSeal` executed in parallel, combined in a single call for efficiency.

In similar vein, a successful `seal` call ensures that any new `append` call will not be successfully acknowledged to the appending client; however, these failed appends can become durable and be reflected by future `checkTail` calls on the Loglet due to specific failure scenarios. As a result, calling `checkTail` on a sealed log can return increasing values for the tail position even after the log is successfully sealed. These ‘zombie’ appends on a sealed log do not appear on the VirtualLog’s address space, which maps to fixed-size segments of the Loglet’s address space (i.e., if the VirtualLog chain is $[0 \xrightarrow{A} 100 \xrightarrow{B} \infty]$, appends on log A can become durable beyond 100 without any impact on the VirtualLog). These semantics are sufficient to implement a linearizable VirtualLog: all we need is that any `append` on a sealed log throws an exception, and that any `checkTail` returns the seal status correctly.

The Loglet API provides a common denominator interface for different log implementations. Such implementations may provide availability for appends via internal leader election protocols; they may even support their own reconfiguration protocols for adding and removing storage servers. In such cases, the VirtualLog can be used to reconfigure across different Loglet types, while each Loglet can perform its own leader election and membership changes. To draw an analogy with storage stacks, Loglets can be functionally simple (e.g., like hard disks) or rich (e.g., like SSDs).

The log positions returned by a Loglet can be contiguous or sparse, depending on its internal implementation. Loglets that implement their own leader election or reconfiguration protocols typically expose sparse address spaces, since the log

Figure 4: *Delos design: multiple APIs can run over a Core platform, which in turn can switch dynamically between multiple Loglet implementations.*

position often embeds some notion of a membership epoch.

In the case where the Loglet operates within a static configuration and relies on the VirtualLog for any form of reconfiguration, it reacts to failures by invoking `reconfigExtend` on the VirtualLog, which seals it and switches to a different Loglet. In this case, each Loglet is responsible for its own failure detection, and for supplying a new Loglet configuration minus the failed servers. In other words, while the VirtualLog provides the mechanism for reconfiguration, Loglets are partially responsible for the policy of reconfiguration.

4 Delos: Design and Implementation

Delos is a replicated storage system for control plane services. The design of Delos is driven by a number of requirements unique to control plane services: low dependencies on other services; strong guarantees for durability, availability, and consistency; and rich and flexible storage APIs. Delos is a fully replicated ACID database providing strict serializability. It does not implement transparent sharding or multi-shard transactions, but can be layered under other systems that provide these capabilities. Delos occupies a similar role in the Facebook stack to Google’s Chubby [12], or the open-source etcd [2] and ZooKeeper [20].

The Delos database is similar to Tango [8]. Each Delos server maintains a local copy of state in RocksDB and keeps this state synchronized via state machine replication (SMR) over the VirtualLog. When a server receives a read-write transaction, it serializes and appends it to the VirtualLog without executing it. The server then synchronizes with the VirtualLog; when it encounters a transaction in the log (whether appended by itself or other servers), it executes the operation within a single thread as a failure-atomic transaction on its local RocksDB. The transaction returns when the appending server encounters it in the VirtualLog and applies it to the

local RocksDB store. To perform a read-only transaction, the server first checks the current tail of the VirtualLog (obtaining a linearization position); it then synchronizes its local state with the VirtualLog until that position. The read-only transaction is then executed on the local RocksDB snapshot. For efficiency, Delos borrows a technique from Tango, queuing multiple read-only transactions behind a single outstanding synchronization with the VirtualLog.

As Figure 4 shows, the logic described above is separated into three layers on each Delos server: an API-specific wrapper at the top; a common Core consisting of a runtime that exposes an SMR interface, which in turn interacts with the VirtualLog; and individual Loglets under the VirtualLog. This layered design provides extensibility in two dimensions. First, Delos can support multiple Loglets under the VirtualLog, which is the focus of this paper. Second, Delos can support multiple application-facing APIs on a single platform. Each API wrapper is a thin layer of code that interacts with the Delos runtime and provides serialization logic against RocksDB. We support a Table API in production, with support for transactions, range queries, and secondary indices; we are currently deploying a second API identical to ZooKeeper. The ability to support multiple APIs on a common base is not novel: most state machine replication libraries treat the application as a black box. However, Delos provides a larger subset of application-agnostic functionality within the common Core, including local durable storage, backups, and state transfer when new servers join.

4.1 The Delos VirtualLog

In Delos, the VirtualLog is implemented via a combination of a client-side library and a MetaStore implementation. The library code implements the protocol described in Section 3.2, interacting with underlying Loglet implementations and the MetaStore. Initially, Delos went to production with the MetaStore residing on an external ZooKeeper service as a single key/value pair. Later, to remove this external dependency, we implemented an embedded MetaStore that runs on the same set of Delos servers as the database layer and VirtualLog library code.

To implement this embedded MetaStore, we used Lamport’s construction of a replicated state machine from the original Paxos paper [25], which uses a sequence of independent Paxos instances. Each such instance is a simple, unoptimized implementation of canonical single-slot Paxos, incurring two round-trips to a quorum for both writes and reads. As in Lamport’s description, each Paxos instance stores the membership of the next instance. We further simplify the protocol by disallowing pipelined writes at each proposer, and removing liveness optimizations such as leader election across multiple slots.

Such a protocol has inadequate latency and throughput to be used in the critical path of ordering commands, which is why

Loglet	Consensus	Deployment	Prod	Use
ZK	Yes	Disagg	Yes	Bootstrap
Native	No	Conv/Disagg	Yes	Primary
Backup	Yes	Disagg	Yes	Backup
LogDevice	Yes	Disagg	No	Perf
Striped	No	Conv/Disagg	No	Perf

Figure 5: Different Loglet implementations in Delos.

so many (complex) variants of Multi-Paxos exist. However, it is more than sufficient for a control plane protocol that is invoked only for reconfigurations.

4.2 The Delos Loglet(s)

Loglets can be converged, running on the Delos database servers; or disaggregated, as shims on the Delos servers accessing an external service. Each deployment model has its benefits: a converged log allows Delos to operate without a critical path service dependency, and without incurring the extra latency of accessing an external service. Disaggregation enables higher throughput by placing the log on a storage tier that can be independently scaled and I/O-isolated from the database servers. Delos currently supports three disaggregated Loglets (see Figure 5): ZKLoglet stores log entries on a ZooKeeper namespace; LogDeviceLoglet is a pass-through wrapper for a LogDevice service; BackupLoglet layers over an HDFS-like filesystem service used for cold storage. All three backing systems – ZooKeeper, LogDevice, and the HDFS-like filesystem – internally implement fault-tolerant consensus, including leader election and reconfiguration; Delos uses the VirtualLog solely to switch to/from them.

4.2.1 Loglets sans consensus: NativeLoglet

We argued earlier that Loglets can be simple since they do not require fault-tolerant consensus (i.e., highly available appends) or any form of reconfiguration. We now describe the NativeLoglet, which illustrates this point. A NativeLoglet can be either converged or disaggregated; we describe its converged form, which is how we use it in production.

Each Delos server – in addition to running the materialization logic and the VirtualLog code – runs a NativeLoglet client and a NativeLoglet server (or LogServer). One of the Delos servers also runs a sequencer component. The NativeLoglet is available for `seal` and `checkTail` as long as a majority of LogServers are alive; and for `append` if the sequencer is also alive. Each LogServer stores a local on-disk log, along with a seal bit; once the seal bit is set, the LogServer rejects new appends to its local log. The local log stores commands in a strictly ascending order that can have gaps (i.e., it may not store every command).

We first define some terms before describing the protocol. A command is *locally committed* on a particular LogServer after it has been written and synced to its local log. The *local tail* for a particular LogServer is the first unwritten position in its local log. A command is *globally committed* once it is locally committed on a majority of LogServers and all previous commands have been globally committed. The *global tail* of the NativeLoglet is the first globally uncommitted log position. The NativeLoglet does not have gaps; i.e., every position from 0 up to the global tail stores a globally committed command. Each component (i.e., LogServers, clients, and the sequencer) maintains a *knownTail* variable: the global tail it currently knows about, which can trail the actual global tail. Components piggyback *knownTail* on the messages they exchange, updating their local value if they see a higher one.

append: To append commands to the NativeLoglet, Delos servers send requests to the sequencer. The sequencer assigns a position to each command and forwards the request to all LogServers. It considers the append globally committed (and acknowledges to the client) once it receives successful responses from a majority of unsealed LogServers. If a majority of LogServers report that they have been sealed, an error is returned indicating that the NativeLoglet is sealed. In all other cases where a majority of LogServers respond negatively or fail to respond before a timeout, the sequencer retries the append. Retries are idempotent (i.e., the same command is written to the same position), and the sequencer continues to retry until the append succeeds or the NativeLoglet is sealed.

Each LogServer locally commits a particular log position n only after the previous position $n - 1$ has either (1) been locally committed on the same server, or (2) has been globally committed on a majority of servers (i.e., $knownTail > n - 1$). The sequencer maintains an outgoing queue of appends for each LogServer, and omits sending a command to a particular LogServer if it knows the command has already been globally committed. As a result, slow LogServers do not block appends from completing on other LogServers and a trailing LogServer can catch up more easily because it is allowed to omit storing commands that are already globally committed.

seal: Any client can seal the NativeLoglet by contacting each LogServer to set its seal bit. If the seal completes successfully – i.e., a majority of LogServers respond – future appends are guaranteed to return an error code indicating the NativeLoglet is sealed. Note that a successful seal operation can leave different LogServers with different local tails.

checkTail: This call returns both the current global tail of the NativeLoglet, as well as its current seal status. Any client can issue a `checkTail` by sending a command to all the LogServers and waiting for a majority to respond. Once a majority responds, the `checkTail` call follows a simple 5-state state machine, as described in Figure 6. For ease of exposition, we assume that no more than a majority responds; if this is not true, the protocol below can work trivially by discarding the extra responses, though in practice we use the additional infor-

Figure 6: *NativeLoglet checkTail state machine.*

mation for better performance. Three outcomes are possible for the returned seal bits:

1. *all-sealed*: In the case where all responding LogServers are sealed and they all return the same local tail X , the return value is (X, true) . However, it is possible that the LogServers can have different local tails (e.g., if a seal arrives while an append is ongoing). In this case, the client ‘repairs’ the responding LogServers to the maximum returned position X_{\max} , copying over entries from the LogServers that have them (and bypassing the seal bit). It then returns X_{\max} to the application. Note that repair is safe: the single sequencer ensures that there can never be different entries for the same position on different LogServers. This repair activity can result in the ‘zombie’ appends described in Section 3.4, where appends on a sealed Loglet are not acknowledged but can complete later due to repairs.

2. *some-sealed*: In the case where the responding LogServers have a mix of sealed and unsealed status bits, the client issues a `seal` first and then reissues the `checkTail`. In the absence of an adversarial failure pattern (e.g., where the seal continually lands on a different majority), the subsequent `checkTail` should return the *all-sealed* case above where all responding LogServers are sealed.

3. *none-sealed*: In the case where none of the responding LogServers are sealed, the client picks the maximum position X_{\max} and then waits for its own *knownTail* to reach this position. While waiting, if the client discovers that some LogServer is sealed, the `checkTail` is in the *some-sealed* state described above, and proceeds accordingly. If the sequencer fails, the client’s *knownTail* may never reach X_{\max} ; in this case, the Loglet will eventually be sealed, putting the client in the *some-sealed* or *all-sealed* state.

The latency of the `checkTail` in the *none-sealed* case depends on how quickly the client’s *knownTail* is updated, along with its knowledge of the seal status of a majority of LogServers. Clients quickly and efficiently discover this information via an extra API exposed by each LogServer, which allows them to ask for notification when the local tail reaches a particular position or the LogServer is sealed.

readNext: Loglet semantics dictate that `readNext` behavior is defined only for log positions before the return value of a

previous `checkTail` call from the same client. As a result, a `readNext` call translates to a read on a particular log position that is already known to exist. This simplifies the `readNext` implementation: the client first checks the locally collocated LogServer to find the entry. If it can’t find the entry locally, it issues a read to some other LogServer. Note that a quorum is not required for reads, since we already know that the entry has been committed; we merely have to locate a copy.

To reiterate, the NativeLoglet does not implement fault-tolerant consensus: it becomes unavailable for appends if the sequencer fails. As a result, the `append` path has no complex leader election logic. Instead, the NativeLoglet implements a highly available `seal`, which is a trivial operation that sets a bit on a quorum of servers. The `checkTail` call follows a compact state machine for determining the seal status and global tail of the NativeLoglet. Practically, we found this protocol much easier to implement than fault-tolerant consensus: it took just under 4 months to implement and deploy a production-quality NativeLoglet.

When the sequencer or one of the LogServers fails, the NativeLoglet is responsible for detecting this failure and invoking reconfiguration on the VirtualLog (which in turn seals it and switches to a new NativeLoglet). In our implementation, we use a combination of in-band detection (e.g., the sequencer detecting that it has rebooted, or that other servers are persistently down) and out-of-band signals (via a gossip-based failure detector, as well as information from the container manager) to trigger reconfiguration. In other words, the VirtualLog provides the mechanism of reconfiguration / leader election, while the NativeLoglet handles the policy by selecting the LogServers and sequencer of the new NativeLoglet instance.

4.2.2 Loglets via composition: StripedLoglet

The StripedLoglet stripes a logical address space across multiple underlying Loglets. The mapping between address spaces is a simple and deterministic striping: logical position L_0 maps to position A_0 on stripe A; L_1 maps to position B_0 ; L_2 to C_0 ; L_3 to A_1 ; and so on (see Figure 7).

Incoming `append` calls to the StripedLoglet are routed to individual stripe Loglets in round-robin order. This routing is done independently at each StripedLoglet client (i.e., the Delos database servers). When the `append` on an individual Loglet returns with a stripe-specific position (e.g., A_1), we map it back to a logical position (e.g., L_3). However, we do not acknowledge the `append` to the StripedLoglet client immediately; instead, we wait until all prior logical positions have been filled, across all stripes. This ensures linearizability for the StripedLoglet: if an `append` starts after another `append` completes, it obtains a greater logical position. For example, in Figure 7, an `append` is routed to stripe B at position B_2 or L_7 ; but it is not acknowledged or reflected by `checkTail` until L_6 appears on stripe A at position A_2 .

Figure 7: The StripedLoglet stripes over underlying Loglets. Loglets can be disjoint (sharded acceptors) or have overlapping membership but different sequencers (rotating sequencer).

A `checkTail` call fans out to all stripes and returns the first unfilled logical position, while `readNext` calls are directed to the corresponding stripe. For this protocol to work, the StripedLoglet requires the stripe Loglets to have contiguous log positions. While the NativeLoglet provides this property, LogDeviceLoglet does not: LogDevice embeds an epoch number (generated by its own internal reconfiguration mechanism) within the log position, so that positions are typically contiguous but can skip forward if an internal reconfiguration takes place.

We found composition to be a simple and effective way to create protocols with new properties. The StripedLoglet is a shim layer with only around 300 lines of code and consists entirely of invocations on the underlying Loglets; yet it provides a versatile building block for scaling throughput. We experimented with two uses of it (shown in Figure 7):

Rotating sequencer: A StripedLoglet can be composed from NativeLoglets with identical LogServers but different sequencers. For instance, a 9-node NativeLoglet will bottleneck on the single sequencer, which has to transmit each entry 8 times. Instead, a StripedLoglet can be layered over two NativeLoglet stripes, each of which uses the same LogServers but a different sequencer.

Sharded acceptors: A StripedLoglet can be layered over multiple disaggregated Loglets, achieving a linear scaling of throughput similar to CORFU [7] or Scalog [16], albeit via a design that doesn’t require a centralized sequencer or separate ordering layer. StripedLoglet also differs by relying on virtualization: it implements a Loglet API over other Loglets. As a result, StripedLoglet can scale any existing Loglet while inheriting its fault-tolerance properties (i.e., the StripedLoglet fails if any of its stripes fail).

Note that the StripedLoglet code is identical for both these use cases: what changes is the composition of the individual

Loglets. These Loglets can have different memberships (and even entirely different Loglet implementations) in the sharded acceptor case; or identical membership (and the same Loglet implementation) but different sequencers in the rotating sequencer case.

From the viewpoint of the VirtualLog, the StripedLoglet is like any other Loglet; it has to be sealed as a whole (i.e., every stripe has to be sealed) even if only one of its stripes needs to be changed via the VirtualLog reconfiguration mechanism. In the future, we plan to explore schemes for selectively sealing and replacing a single stripe.

5 Evaluation

We use two hardware setups for evaluating Delos. The first is the *production* hardware that most of our instances run on, which consists of 5 servers with shared boot SSDs. Since Delos has to run in a variety of data centers, we cannot assume specific or dedicated storage hardware. The second is *benchmark* hardware with dedicated NVMe SSDs. In both setups, we run within Twine [44] containers, and have production-grade debug logging and monitoring enabled.

We show numbers for two workloads. The first is real production traffic. For a representative deployment, the workload consists of 425 queries/sec and 150 puts/sec on the Delos Table API. Write size has a median of 500 bytes and a max of 150KB. Each deployment stores between 1GB and 10GB. In production, Delos takes local snapshots every 10 minutes and ships them to a backup service every 20 minutes.

The second workload is a synthetic one consisting of single-key puts and gets. The value consists of a single 1KB blob. The keys are chosen from an address space of 10M keys; we select keys randomly with a uniform distribution and generate random values, since this provides a lower bound for performance by reducing caching and compression opportunities, respectively. We pre-write the database before each run with 10GB; this matches our production data sizes.

Delos runs with two Loglets in production: ZKLoglet and NativeLoglet. In our experiments, we additionally use LogDeviceLoglet (or LDLoglet) and StripedLoglet. The external ZooKeeper service used by ZKLoglet lives on a set of 5 servers similar to our production hardware, running on shared boot SSDs and collocated with other jobs. LDLoglet uses a LogDevice service deployed on a set of 5 servers similar to our benchmark hardware, with dedicated NVMe SSDs.

In all the graphs, we report 99th percentile latency over 1-minute windows. We assume a p99 SLA of 15ms, which matches our production requirements.

5.1 The Benefit of Virtualization

Virtual consensus allowed Delos to upgrade its consensus protocol in production without downtime. In Figure 8, we show the actual switch-over happening from ZKLoglet to

Figure 8: Production upgrade from ZKLoglet to NativeLoglet (log-scale y-axis).

a converged NativeLoglet for the first time on a Delos production instance on April 2nd 2019. Switching to a different log implementation provides substantially lower latency for a production workload. The graph shows p99 latencies for four categories of Table operations: we see 10X improvements for multi-gets and indexed queries, and a 5X improvement for multi-puts. Additionally, the switch-over happens without downtime: p99 latency spikes for indexed queries during reconfiguration, but otherwise service availability is not disrupted. The latency improvement is largely due to the unoptimized nature of our ZKLoglet implementation, which simply writes a new sequential ZooKeeper key on each append.

Interestingly, the graph shows two reconfigurations: the first is a `reconfigExtend` that seals the ZKLoglet and switches the active segment to a NativeLoglet, causing the visible shift in performance; the second, which happens a few minutes later, is a `reconfigTruncate` that removes the old ZKLoglet segment from the VirtualLog, but does not require a seal (as described in Section 3.2) and hence does not cause any disruption. The hourly spikes in multi-puts are due to periodic large writes from the application.

Delos can scale throughput by running over a disaggregated Loglet. In Figure 9, we plot throughput on the x-axis and p99 latency on the y-axis, for the synthetic workload with 90% gets and 10% puts. We compare the converged NativeLoglet vs. the disaggregated LDLoglet. In the top two graphs, the Delos database runs on production HW with shared SSDs; la-

Figure 9: Delos can scale throughput between 10X (top) and 33% (bottom) for different HW types with a disaggregated LDLoglet instead of a converged NativeLoglet.

tency with NativeLoglet starts rising at 15K ops/s for puts due to contention between the Loglet and the database. With a disaggregated LDLoglet running on 5 other machines, throughput scales 10X higher at 150K ops/s without breaching 15ms p99 latency for either puts or gets. This 10X improvement is partly due to more HW (twice the machines); better HW for the log (LDLoglet runs over dedicated NVMe SSDs); and less I/O contention (the database and log are on different machines).

In the bottom two graphs, Delos runs on benchmark HW with dedicated SSDs; the performance hit for the converged NativeLoglet is less stark due to more IOPS to share between the log and database, with latency rising for both puts and gets at around 139K ops/s. The disaggregated LDLoglet provides 33% higher throughput at 190k ops/s. For both types of HW, disaggregation allows the shared log to utilize a separate, dedicated set of resources. We get similar results running against a disaggregated NativeLoglet instead of LDLoglet, but wanted to highlight Delos' ability to run over different consensus implementations.

Delos can switch dynamically between converged and disaggregated modes without downtime. Figure 10 (Left) demonstrates the ability of Delos to change dynamically between converged and disaggregated modes, and the utility of doing so in order to handle workload shifts. In this experiment, we run the synthetic workload on the high-contention production HW. We want to maintain a 15ms p99 latency SLA.

Figure 10: *Left:* Delos can dynamically switch from converged (NativeLoglet) to disaggregated (LDLoglet) logging to handle workload shifts (log-scale y-axis). *Middle:* StripedLoglet (rotating sequencer) alleviates the sequencer bottleneck as Delos scales. *Right:* StripedLoglet (sharded acceptors) scales to 1M+ appends/s for a log-only workload.

For the first 180 secs, we run a constant, low workload of 100 puts/sec; after that, we increase the workload to 2500 puts/sec. Delos initially runs over the NativeLoglet, which meets the 15ms SLA for the low workload. But when the workload switches, Delos+NativeLoglet is no longer able to keep up due to I/O contention for the SSDs, with p99 latency degrading to over a second. At around 530 secs, we reconfigure to use LDLoglet; this reduces I/O pressure on the local SSDs, allowing p99 latencies to drop back to under 15ms (after a 60-second lag due to the 1-minute sliding window).

If a disaggregated log provides better throughput and lower latency, why not always use one? First, disaggregation is inefficient from a resource standpoint for low workloads, using 10 machines compared to 5 with a converged log. Second, converged Delos does not depend on any external service in the critical path, which is important for some control plane applications.

New protocols with useful properties can be implemented via Loglet composition. In the NativeLoglet, all appends are routed via the sequencer node. For a 100% 1KB put workload on a 5-node cluster, Delos is bottlenecked by the IOPS of the NativeLoglet LogServers. However, when we run Delos over 9 LogServers for higher fault-tolerance, the bottleneck shifts to the NativeLoglet sequencer, which now has to send out each entry 8 times. If we instead use a StripedLoglet over 2 NativeLoglets (each with the same set of LogServers but different sequencers), we rotate the sequencing load across two servers. As Figure 10 (Middle) shows, Delos+StripedLoglet runs 25% faster than Delos+NativeLoglet with 9 nodes on the benchmark HW.

We also ran log-only experiments with StripedLoglet in Figure 10 (Right). We created a StripedLoglet over multiple 3-node NativeLoglets, and appended 1KB payloads from 20 VirtualLog clients. We see linear scaling of throughput as we go from 1 stripe (3 LogServers) to 30 stripes (i.e., 90 LogServers); beyond that, our clients became the bottleneck. The LogServers run on shared NVMe SSDs, which provide 30K IOPS with a p99 of 75ms; we report the maxi-

mum throughput for each configuration with a p99 latency of under 75ms. We obtained similar results with 4KB payloads (750K appends/s with 30 shards); this is the highest reported single-log throughput in a non-emulated experiment, exceeding CORFU (570K/s) and Scalog (255K/s). Delos cannot leverage such a high-throughput log, since it bottlenecks on log playback; we plan to explore selective playback [8], as well as compare against Scalog’s higher emulated numbers.

5.2 The Cost of Virtualization

Virtualization is inexpensive in terms of critical path latency. In most cases, the VirtualLog acts as a simple pass-through layer. Figure 11 (Left) shows the p99 latency of VirtualLog and NativeLoglet operations; this data is measured over a one-hour time period on a production cluster running over the NativeLoglet. For `append` and `checkTail`, virtualization adds 100-150 μ seconds to p99 latency; this is largely due to the overhead of an asynchronous Future-based API. In contrast, `readNext` is a synchronous pass-through call and adds only a few μ seconds.

Reconfigurations occur within 10s of ms. In Figure 11 (Middle), we show a histogram of all reconfigurations in a 1-month period on our production clusters. Since `reconfigTruncate` does not call `seal`, it has lower latency than `reconfigExtend`. For our applications, reconfiguration latencies of 10s of ms are tenable. The vast majority of these reconfigurations are triggered by 1) continuous deployment of software upgrades; and 2) machine preemptions for hardware maintenance, kernel upgrades, etc. Actual failures constitute a small percentage of the reconfigurations. In practice, clusters see a few reconfigurations per day; for example, one of our production clusters was reconfigured 98 times in the 1-month period.

Virtualization does not affect peak throughput. We performed an apples-to-apples comparison of Delos to ZooKeeper on our benchmark HW. We translate puts into `SetData` commands and gets into `GetData` commands on the

Figure 11: *Left:* virtualization overhead is low in production: 6 μ s for readNext and 100 to 150 μ s for append / checkTail p99. *Middle:* reconfigurations take tens of ms in production. *Right:* Delos+NativeLoglet matches ZooKeeper performance.

ZooKeeper API. Since ZooKeeper does not support more than a few GB of data, we ran with a 1GB database. Figure 11 (Right) shows that ZooKeeper can provide over 30K puts/sec before p99 latency degrades beyond 15ms. In contrast, Delos+NativeLoglet manages around 26K puts/sec. The primary reason for the performance difference is that ZooKeeper stores its materialized state in memory while Delos uses RocksDB. We also ran a version of Delos where the materialized state lives in memory; this prototype hit 40K puts/sec. While storing state in RocksDB causes a performance hit at small sizes, it enables us to scale; the Delos+NativeLoglet curve for a 100 GB database (not shown in the graph) is nearly identical to the 1GB case. These results show that Delos performance is comparable to unvirtualized systems.

6 Discussion

Virtual consensus provided a number of ancillary benefits for the operation of Delos.

Fate-sharing... but only when my fate is good: In production, Delos typically runs as a converged database with no external dependencies, where all logic and state (including the database and the log) resides on a set of 5 machines. However, the database / learner layer is simultaneously more fragile than the log / acceptor layer (since it is updated frequently to add features) and requires lower fault-tolerance (only one learner needs to survive, compared to a quorum of acceptors). If two converged replicas crash out of five, another failure can cause unavailability and data loss for the log. In this situation (which was not uncommon), we found it valuable to reconfigure the system to a disaggregated log, temporarily decoupling the fate of the database and the log. Once the database was restored to five replicas, we reconfigured back. This style of temporary decoupling also proved valuable when we discovered latent bugs in the NativeLoglet; we reconfigured to ZKLoglet, rolled out hotfixes, and then reconfigured back. Currently, switching between converged and disaggregated logs is a manual operation driven by operators; in the future,

we may explore automated switching.

Consensus is forever... until it's not: Deletion of arbitrary entries is typically quite difficult in conventional consensus protocols. However, with virtual consensus, we can delete an entry simply by changing the metadata of the VirtualLog. Similarly, altering written entries is possible via remapping. We found this kind of surgical editing capability useful when faced with site-wide outages: on one occasion, a “poison” entry caused hangs on all learners processing the log.

ZooKeeper over Delos... over ZooKeeper: Virtualization often enables interesting and practically useful layerings; for example, it is routine in storage stacks to run a filesystem over a virtual block device that in turn is stored on a different instance of the same filesystem. Virtual consensus brings similar flexibility to replicated databases: in our current stack, we have the ability to run our experimental ZooKeeper API over the VirtualLog, which in turn can run over the ZooKeeper-based ZKLoglet.

7 Related Work

Virtual consensus builds upon a large body of work in fault-tolerant distributed systems. Most approaches to reconfigurable replication (including Viewstamped Replication [32, 38], ZAB [22], Raft [39], Vertical Paxos [27], and SMART [34]) use protocols for leader election and reconfiguration that are tightly intertwined with the ordering protocol. Virtual Synchrony [10, 46] is an exception: it uses a unified view change protocol for leader election and reconfiguration that sits above the ordering mechanism used within each view. This unified approach is also found in more recent systems such as Derecho [21] and CORFU [7]. Reconfiguration has been explored as a layer above a generic state machine by Stoppable Paxos [28, 29]; unlike Loglets, the underlying state machine has to implement fault-tolerant consensus.

Virtual consensus borrows many ideas from this literature, combines them, and applies them to a production system: for example, unified leader election and reconfiguration (Vir-

tual Synchrony); a segmented total order with potentially disjoint configurations (SMART); an external auxiliary (Vertical Paxos); and a generic ordering abstraction (Stoppable Paxos). However, virtual consensus also differs from all this prior work in several important aspects. First, we target and demonstrate diversity in the ordering layer (e.g., deploying new layers, switching to disaggregated mode, etc.). Second, the ordering layer is only required to provide a highly available seal, which is weaker than fault-tolerant consensus and easier to implement. Finally, virtual consensus applies and extends these ideas to shared logs, which pose unique opportunities (e.g., data-centric APIs that hide complexity) and challenges (e.g., application-driven trims and explicit reads).

To assess the generality of the Loglet abstraction, we did an informal survey of recent replication protocols. The majority of these protocols either directly expose a log API [3, 7, 16, 37, 42] or can be wrapped as a Loglet [14, 15, 22, 24, 31, 35, 39]. Virtualization gives us the ability to easily experiment with these protocols under Delos and deploy them to production. Other work – such as protocols that exploit speculation [41] or commutativity [4, 26, 36] – does not currently fit under the Loglet API.

Virtual consensus is based on the shared log approach for building replicated systems; we leverage the existence of the shared log API as a boundary between the database and consensus mechanism. Shared logs were first introduced by CORFU [7] and Hyder [9] as an API for consensus. Subsequently, CorfuDB [1] was the first production database to be deployed over a shared log API. Along similar lines, systems such as Kafka [23] and LogDevice [3] have become popular in industry, exposing large numbers of individual, independently ordered logs. In contrast, research has largely focused on scaling a single log, either via faster ordering protocols [16] or different forms of selective playback [8, 48]. Rather than build a faster shared log or a more scalable database above it, virtual consensus seeks to make such systems simpler to build and deploy as they become commonplace in industry.

8 Conclusion

Virtual consensus enables faster deployment and development of replicated systems. Reconfiguration and leader election is encapsulated in a control plane (the VirtualLog) that can be reused across any data plane (Loglets). Delos is the first system that supports heterogeneous reconfiguration, allowing changes to not just the leader or the set of servers in the system, but also the protocol, codebase, and deployment model of the consensus subsystem. As a result, new systems can be developed and deployed rapidly (e.g., Delos hit production within 8 months by leveraging an external service for its Loglet); and upgraded without downtime to provide significantly different performance and fault-tolerance properties (e.g., we hot-swapped Loglets in production for a 10X latency reduction).

Acknowledgments

We would like to thank our shepherd, Jay Lorch, and the anonymous OSDI reviewers. Many people contributed to the Delos project, including Adrian Hamza, Mark Celani, Andy Newell, Artemiy Kolesnikov, Ali Zaveri, Ben Reed, Denis Samoylov, Grace Ko, Ivailo Nedelchev, Mingzhe Hao, Maxim Khutornenko, Peter Schuller, Suyog Mapara, Rajeev Nagar, Russ Arun, Soner Terek, Terence Feng, and Vidhyashankar Venkataraman. Abstract

The specific order of commands agreed upon when running state machine replication (SMR) is immaterial to fault-tolerance: all that is required is for all correct deterministic replicas to follow it. In the permissioned blockchains that rely on Byzantine fault tolerant (BFT) SMR, however, nodes have a stake in the specific sequence that ledger records, as well as in preventing other parties from manipulating the sequencing to their advantage. The traditional specification of SMR correctness, however, has no language to express these concerns. This paper introduces *Byzantine ordered consensus*, a new primitive that augments the correctness specification of BFT SMR to include specific guarantees on the total orders it produces; and a new architecture for BFT SMR that, by factoring out ordering from consensus, can enforce these guarantees and prevent Byzantine nodes from controlling ordering decisions (a Byzantine oligarchy). These contributions are instantiated in Pompē,¹ a BFT SMR protocol that is guaranteed to order commands in a way that respects a natural extension of linearizability.

1 Introduction

This paper aims to add a new dimension to state machine replication (SMR) [62], a fundamental building block in fault-tolerant distributed computing, by introducing a way to express, reason about, and enforce specific properties about how the SMR protocol *orders* the commands it receives.

SMR coordinates a set of replicas of a deterministic service so that, collectively, they implement the abstraction of a single, correct server. In particular, the protocol sequences client-issued requests to produce a total order, which correct replicas then follow when processing the requests. As long as the system includes sufficiently many correct replicas, voting on replica outputs guarantees that clients of the replicated service can recognize and accept only output values that would have been generated by a correct server.

SMR totally orders client requests by running an instance of consensus for each position in the request sequence. The only requirement on the sequence agreed upon is that it eventually contains all requests from correct clients. Indeed, if all SMR is used for is fault-tolerance, no further legislation is necessary: the specific sequence of states that correct replicas traverse is immaterial.

Not so, however, when SMR is used (typically, in a Byzantine fault tolerant (BFT) configuration) across multiple administrative domains to support a blockchain. Consider, for instance, permissioned blockchains like Libra [3], CCF [60], or HyperLedger Fabric [6]: the specific order of transactions held by their ledger can have significant financial implications [24, 47]. The nodes running these protocols are not just interested in converging on an agreed-upon ledger: they have a real stake in the specific sequence that ledger records, as well as in preventing other parties from manipulating the sequencing to their advantage.

The traditional specification of correctness for (BFT) SMR, however, has no language for addressing such concerns; because it attaches no significance to the sequence it produces, it is intrinsically incapable of characterizing what makes a total order “right” or “wrong”.

Our aim in this paper is to introduce a framework for expressing and enforcing such distinctions. A key challenge is that the lack of expressiveness in the correctness specification of SMR has deep architectural roots. Specifically, in standard leader-based SMR [16, 43], the ordering of a command is hardcoded in the protocol that adds the command to the ledger: the leader runs concurrently a set of consensus instances, each dedicated to filling a specific ledger position with a command of its choosing.

Thus, we pursue a two-pronged approach: for expressiveness, we expand the correctness specification of the BFT SMR primitive; for enforcement, we articulate a new architecture for BFT replication that makes it possible to implement in practice our newly-introduced correctness requirements.

Our first contribution is to introduce *Byzantine ordered consensus*, a new primitive that augments the correctness specification of BFT SMR to include the enforcement of specific guarantees on the total orders it produces. The new specification allows the nodes that implement a replicated state machine to associate an *ordering indicator* to the commands they ultimately agree upon. Through these indicators, nodes can express how they would like commands to be ordered with respect to one another. The correctness conditions for Byzantine ordered consensus specify, given a set of input $\langle \text{ordering indicator}, \text{command} \rangle$ pairs, the set of allowable total orders for the commands.

To identify meaningful correctness conditions in the presence of Byzantine nodes, we draw inspiration from classic work in social choice theory [7, 9, 11] and explore the limits of what *can* be guaranteed in the presence of Byzantine

¹The urban ritual of the pompē (πομπή, or *procession*) was central to civic and religious life in the Byzantine empire.

nodes. In particular, we ask: is it possible to prevent Byzantine nodes from dictating the ordering of commands? And, at the other end of the spectrum, is it possible to completely prevent Byzantine nodes from wielding influence on that order? We find that, while eliminating Byzantine influence is provably impossible, new mechanisms can prevent the establishment of a Byzantine oligarchy.

Simply expressing these correctness conditions, however, is not enough: we need the means to enforce them. Our second main contribution is to introduce a new general architecture for BFT protocols that *factors ordering out of consensus*: it cleanly separates the process of establishing the relative order of commands from the consensus step necessary to add those ordered commands to the ledger. This separation completely eliminates the leader's ability to control a command's position in the ledger; at the same time, it retains the simplicity and efficiency of having a leader in charge of the consensus step.

Finally, we design, implement, and evaluate Pompē, a BFT SMR protocol based on Byzantine ordered consensus that enforces *ordering linearizability*, a new correctness condition that prevents a Byzantine oligarchy and offers correct nodes a meaningful guarantee about the order ultimately recorded in the ledger. Informally, it ensures that if the *lowest* timestamp that any correct node assigns to command c_2 is larger than the *highest* timestamp that any correct node assigns to c_1 , then c_1 will precede c_2 in the ledger.

We implement Pompē by extending prior state-of-the-art BFT implementations [1, 2]. Our experimental evaluation demonstrates that while Pompē incurs higher latencies than its baselines, Pompē can achieve higher throughput at competitive latencies by batching commands in both the ordering step and the consensus step. For example, with $n = 4$ nodes in a single datacenter, a version of Pompē that extends ordering linearizability to HotStuff [2, 67] achieves a throughput of approximately 360,000 commands/s at a latency of about 53 ms, which corresponds to 40% higher throughput and 6% higher latency than HotStuff. Additionally, since in Pompē nodes can order multiple commands in parallel, we find that, if the computing resources assigned to each node are scaled up proportionally with the number of nodes, Pompē can sustain its high throughput in settings with 100 nodes distributed over three geo-distributed datacenters.

2 Background and motivation

The increasing popularity of blockchains as a platform for co-operation and data sharing among mutually distrustful parties has brought about a renewed interest in Byzantine fault tolerance (BFT). In particular, permissioned blockchains, which promise a platform for executing commands without trusting a centralized authority, have adopted as their core the standard BFT SMR architecture [62]. Transitioning BFT to this new application domain has introduced some new challenges. One that has received much attention is scalability. Traditional BFT SMR protocols have typically targeted deployments in-

volving a number of nodes in the single digits, while some permissioned blockchains envision running BFT at scales that are two orders of magnitude or larger. A new breed of BFT SMR protocols have raised to this challenge, finding clever ways to pipeline requests and streamline the communication required to achieve consensus [10, 31, 50, 54, 68].

In this paper we address a different challenge that emerges when applying BFT SMR in a blockchain context, one fundamental enough to bring into question whether this primitive is sufficiently expressive to serve as the basis for this new class of applications.

Consider the correctness specification of SMR: it requires all correct nodes replicating a service to traverse the same set of states and produce the same outputs. If replicas are deterministic, an expedient way to satisfy this requirement is to ensuring that all correct replicas process the same sequence of inputs: identical inputs translate into identical states and outputs. As long as these inputs are valid client commands, the correctness specification assigns no semantic meaning to the particular order in which they are executed by the replicas: that order is simply a syntactic mechanism used to achieve the desired safety property.

In blockchains, however, the specific order adopted by the underlying SMR protocol tends to have rich semantic implications, which often translate into substantially different financial rewards for the parties involved. Allowing some users to front-run their commands ahead of others clearly gives them an unfair advantage in applications such as auctions and exchanges [47, 57]; indeed, a recent paper [24] details how bots have reaped from unsuspecting parties profits in excess of \$6M by replicating, within the Ethereum network, transaction manipulation strategies already notorious in traditional exchanges [47]. Yet, order manipulation (including censorship, selective inclusion, command reordering, and command injection) does not, per se, violate the specification of SMR, the technology at the core of projects like Libra [3].

Unfortunately, adding the “BFT” qualifier to SMR does not help address these concerns: all it does is to ensure that the standard SMR specification continues to hold even if some nodes are Byzantine. The crux, rather, is that the correctness expectations of blockchain users do not stop at requiring all ledgers to hold the same total order: *which order* matters.

A symptom of the discomfort caused by this semantic gap is the growing focus on curbing the discretion of the single node that, in Paxos-like BFT SMR, leads the consensus decisions: if Byzantine, this *leader* node can single-handedly control the ledger's order. Proposed solutions include rotating leaders [13, 21, 68]; holding leaders accountable for their actions [33, 35]; or developing outright “leaderless” protocols that give no node a special role in the execution of consensus [23, 44, 54]. These efforts are a step in the right direction, but they also, arguably, miss the point. While it is clear enough that leaving a single leader in full control of the ledger's order is undesirable, they fiddle with a low-level mechanism with-

out offering a way to express the correctness guarantees that such mechanisms, whatever they may be, should enforce. Recent work on order-fairness [38], concurrent with ours, takes a further step forward by adding to consistency and liveness the additional requirement of *transactional order-fairness*; however, it offers neither a general framework for synthesizing desirable ordering guarantees from the ordering preferences of individual nodes, nor tries to precisely characterize the degree to which Byzantine nodes can affect ordering.

This paper argues that the correct approach to bridge the current semantic gap is instead to start from first principles. Thus, we introduce a new primitive, *Byzantine ordered consensus*, that expands the correctness specifications of BFT SMR so it can express specific correctness guarantees about the total orders it produces. Inspired by classic work in social choice theory [7, 9, 11], Byzantine ordered consensus lets participating nodes not only propose commands, but also indicate how they prefer to see them ordered. Essentially, Byzantine ordered consensus makes it possible to specify which total orders a correct BFT SMR is allowed to produce, given the nodes' ordering preferences. For example, assuming that nodes use as their ordering preference the time they first see a command, we show that it is possible to require total orders that satisfy a natural generalization of linearizability: *ordering linearizability*, which ensures that, if the highest timestamp from all correct nodes for command c_1 is lower than the lowest timestamp from all correct nodes for c_2 , c_1 is ordered before c_2 .

The design space for ordering properties that we explore is delimited by two overarching concerns. On the one hand, we want to curb as much as possible the clout of Byzantine nodes; on the other hand, we want to ensure that the preferences of correct nodes will carry weight in the final ordering.

These goals can sometimes align; in particular, when it comes to preventing Byzantine nodes from solely controlling the ledger's final ordering. As we noted above, the standard approach to BFT SMR allows a Byzantine leader to alone dictate which command commits in which consensus instance, independent of what other nodes prefer. We aim for, and define, guarantees (such as ordering linearizability) that prevent such Byzantine dictatorships. Indeed, we show that it is possible to rule out a Byzantine oligarchy, in which Byzantine nodes are jointly able to determine the ordering decisions, regardless of the correct nodes' ordering preferences.

Sometimes, however, we find these goals fundamentally at odds with one another: in particular, we find that ensuring that each correct node has a saying in the final order makes it impossible, in general, to completely prevent Byzantine nodes from influencing the final order. This is the price, if you wish, of operating in a Byzantine democracy.

3 Byzantine ordered consensus

Byzantine ordered consensus generalizes BFT SMR to expose the ordering aspect explicitly, but preserves the same system

model, which consists of a distributed system of n nodes (with at most f Byzantine faults) that act as clients as well as servers: they both propose commands and execute them. This model simplifies our presentation without any loss of generality; we discuss how it relates to different real-world deployment scenarios in Section 8.

Ordering indicators. As in standard BFT SMR, nodes in Byzantine ordered consensus propose commands as inputs and output a consistent totally-ordered ledger. Unlike standard BFT SMR, each node associates a proposed command c with an *ordering indicator* o , which is metadata indicating the node's ordering preference for c , so proposals are of the form $\langle o, c \rangle$. Let \mathcal{O} denote the set of ordering indicators; we define an *order-before relation* \prec_o on $\mathcal{O} \times \mathcal{O}$ as follows: For any pair of proposals $\langle o_1, c_1 \rangle$ and $\langle o_2, c_2 \rangle$, where $o_1, o_2 \in \mathcal{O}$, $o_1 \prec_o o_2$ indicates a preference to order c_1 before c_2 .

Examples of ordering indicators include timestamps, sequence numbers, and dependency sets or graphs. For timestamps (or sequence numbers), the order-before relation \prec_o can simply be the $<$ relation on timestamps (or sequence numbers), while for dependency sets/graphs, \prec_o can be the subset/subgraph relation on dependency sets or graphs.

Profiles, executions, and traces. We refer to a set of $\langle o, c \rangle$ proposals as a *profile*. Let \mathcal{P}^i and \mathcal{P}^C denote, respectively, the set of proposals from node i and the set of proposals from all correct nodes. Given a command c , we say that $c \in \mathcal{P}^C$ if and only if there exists a correct node i and an ordering indicator o , such that $\langle o, c \rangle \in \mathcal{P}^i$.

In an *execution*, correct nodes follow their prescribed protocol and input their proposals from \mathcal{P}^C , whereas Byzantine nodes and the network are under the control of an adversary. For a given profile, an execution can produce different *traces*; each trace captures a single deterministic run of the protocol, recording the behavior of all nodes (both correct and Byzantine) as well as of the adversarial network. Although all traces of an execution take as input the same \mathcal{P}^C , the content of the ledger on which correct nodes agree may be different for different traces, because of the actions of Byzantine nodes or the behavior of the network. But what is the degree to which Byzantine nodes can exert their influence on a given protocol? And what is the price to curb it?

The politics of Byzantium. A minimum guarantee that any protocol should offer is to make it impossible for Byzantine nodes to dictate the ordering of the ledger's entries. It is out of concern for ensuring this guarantee that recent work in BFT SMR has focused on limiting the leader node's discretion in making ordering decision. The formal structure offered by Byzantine ordered consensus allows us to move past the inadequacies of the current mechanisms used to drive consensus and focus instead on a precise characterization of what any such mechanism should guarantee. In particular, we capture the intuition that Byzantine nodes can dictate the ordering decisions through the notion of Byzantine oligarchy.

Byzantine Oligarchy. A protocol execution is subject to a *Byzantine oligarchy* if and only if, for all profiles of correct nodes \mathcal{P}^C , for all pairs of commands c_1 and c_2 in \mathcal{P}^C , there exists a trace for \mathcal{P}^C that results in c_1 before c_2 in the ledgers of correct nodes and another trace for \mathcal{P}^C that results in c_2 before c_1 in the ledgers of correct nodes.

Intuitively, this definition conveys that, in a Byzantine oligarchy, the actions of Byzantine nodes can determine the ordering of any two commands c_1 and c_2 , regardless of the ordering indicators from correct nodes.

Can we do more, and completely eliminate any influence of Byzantine nodes over the ledger's final ordering? The framework offered by Byzantine ordered consensus allows us to prove that this target can be achieved only at the price of denying *correct* nodes a voice in the ordering decision. The intuition is simple: since in general it is impossible to distinguish a priori between correct and Byzantine nodes, a policy that enfranchises the first group necessarily also gives some influence to the second.

To formalize this intuition, we introduce two new notions. First, we express what it means for a protocol to allow the ordering preferences of its nodes to influence the ledgers' final total order. Note that, if a node can influence the outcome, then there will be some circumstances in which the node's preferences will actually *determine* the outcome. The second notion we introduce characterizes the impact of according such influence to a Byzantine node.

Free Will. We say that a protocol respects the nodes' *free will* if and only if (i) for all profiles of correct nodes \mathcal{P}^C , there exists a trace for \mathcal{P}^C , such that all commands in \mathcal{P}^C appear in the ledgers of correct nodes in the trace and (ii) there exist two profiles \mathcal{P}_A and \mathcal{P}_B , such that, for all commands c_1 and c_2 that appear in both profiles, there exists a trace for \mathcal{P}_A that results in c_1 before c_2 in the ledgers of correct nodes and there exists a trace for \mathcal{P}_B that results in c_2 before c_1 in the ledgers of correct nodes.

Free will rules out (i) arbitrarily denying proposed commands and (ii) trivial and predetermined ordering mechanisms (e.g., ordering commands by their hash values).

Byzantine Democracy. We say that a protocol upholds *Byzantine democracy* if and only if there exists a profile of correct nodes \mathcal{P}^C , such that for all pairs of commands c_1 and c_2 in \mathcal{P}^C , there exists a trace for \mathcal{P}^C that results in c_1 before c_2 in the ledgers of correct nodes and another trace for \mathcal{P}^C that results in c_2 before c_1 in the ledgers of correct nodes.

Unlike a Byzantine oligarchy, a Byzantine democracy gives Byzantine nodes sway over the final ledger only for *some* profiles of correct nodes, rather than all of them.

We are now ready to formulate a theorem that places fundamental limits to the degree to which it is possible to curb the influence of Byzantine nodes.

Theorem 3.1. *Free will \implies Byzantine democracy.*

Proof. Consider the following $n + 1$ profiles, where $\mathcal{P}_{\#1} =$

\mathcal{P}_A and $\mathcal{P}_{\#n+1} = \mathcal{P}_B$ and every node proposes the same commands (though, possibly, with different ordering preferences) in \mathcal{P}_A and \mathcal{P}_B .

$$\begin{aligned}\mathcal{P}_A &= \mathcal{P}_{\#1} = \mathcal{P}_A^1 \cup \mathcal{P}_A^2 \cup \dots \cup \mathcal{P}_A^{n-1} \cup \mathcal{P}_A^n \\ \mathcal{P}_{\#2} &= \mathcal{P}_B^1 \cup \mathcal{P}_A^2 \cup \dots \cup \mathcal{P}_A^{n-1} \cup \mathcal{P}_A^n \\ \mathcal{P}_{\#3} &= \mathcal{P}_B^1 \cup \mathcal{P}_B^2 \cup \dots \cup \mathcal{P}_A^{n-1} \cup \mathcal{P}_A^n \\ &\dots \\ \mathcal{P}_{\#n} &= \mathcal{P}_B^1 \cup \mathcal{P}_B^2 \cup \dots \cup \mathcal{P}_B^{n-1} \cup \mathcal{P}_A^n \\ \mathcal{P}_B &= \mathcal{P}_{\#n+1} = \mathcal{P}_B^1 \cup \mathcal{P}_B^2 \cup \dots \cup \mathcal{P}_B^{n-1} \cup \mathcal{P}_B^n\end{aligned}$$

In profile $\mathcal{P}_{\#i}$, the proposals of the first $i - 1$ nodes are the same as in \mathcal{P}_B ; those of the other $n - i + 1$ nodes are the same as in \mathcal{P}_A . Because free will (condition (ii)) holds, there is a trace for $\mathcal{P}_{\#1}$ for which the ledgers of correct nodes order c_1 before c_2 , and a trace for $\mathcal{P}_{\#n+1}$ where instead they appear in the opposite order. And, also because free will (condition (i)) holds, for each index k , there exists a trace for $\mathcal{P}_{\#k}$, such that c_1 and c_2 appear in the final ledgers. Then, there must exist some index i for which the relative order of c_1 and c_2 switches when going from $\mathcal{P}_{\#i}$ to $\mathcal{P}_{\#i+1}$. Consider the smallest such i . $\mathcal{P}_{\#i}$ and $\mathcal{P}_{\#i+1}$ only differ in what node i proposes: in $\mathcal{P}_{\#i}$ node i 's proposals come from \mathcal{P}_A ; in $\mathcal{P}_{\#i+1}$, they come from \mathcal{P}_B . Hence, by choosing whether to \mathcal{P}_A^i or \mathcal{P}_B^i , node i determines the relative order of c_1 and c_2 .

If i is Byzantine, then Byzantine democracy holds for the following correct profile:

$$\mathcal{P}^C = \mathcal{P}_B^1 \cup \dots \cup \mathcal{P}_B^{i-1} \cup \mathcal{P}_A^{i+1} \dots \cup \mathcal{P}_A^n \quad \square$$

The definition of Byzantine democracy makes clear that there exist some profiles that allow Byzantine nodes to control ordering decisions. A natural question then is: can we design protocols that, by construction, enforce guarantees that specify profiles on which Byzantine nodes can have no influence? And what would such properties look like? We address the second question next, leaving the answer to the first to Section 4.

Ordering properties. Since under standard BFT assumptions (Section 4) correct nodes are more than two thirds of the total (a supermajority!), the profiles less likely to be influenced by Byzantine nodes are intuitively those in which the voting preferences of correct nodes are aligned. We examine two natural ordering properties that one might want to see holding in such profiles; other definitions are possible.

The first requires that, if the ordering indicators of correct nodes are unanimous on how to relatively order two commands, their preference should be reflected in the final ledger.

Ordering unanimity: For all profiles of correct nodes \mathcal{P}^C , for all commands c_1 and c_2 that appear in \mathcal{P}^C and in the

ledgers of correct nodes, if, for every correct node i , $\langle o_1, c_1 \rangle \in \mathcal{P}^i \wedge \langle o_2, c_2 \rangle \in \mathcal{P}^i \Rightarrow o_1 \prec_o o_2$, and there exists at least one correct node j , such that $\langle o_1, c_1 \rangle \in \mathcal{P}^j \wedge \langle o_2, c_2 \rangle \in \mathcal{P}^j$ holds, then c_1 must precede c_2 in the ledgers of correct nodes.

The second ordering property is inspired by linearizability [36], which orders a command c_1 before a command c_2 if the first ends before the second starts.

Ordering linearizability: For all profiles of correct nodes \mathcal{P}^C , for all commands c_1 and c_2 in \mathcal{P}^C and in the ledgers of correct nodes, let $O_1 = \{o_1 | \langle o_1, c_1 \rangle \in \mathcal{P}^C\}$ and $O_2 = \{o_2 | \langle o_2, c_2 \rangle \in \mathcal{P}^C\}$, if $o_1 \prec_o o_2$ holds for all $o_1 \in O_1$ and $o_2 \in O_2$, then c_1 must precede c_2 in the ledgers of correct nodes.

Informally, the “lowest” and “highest” ordering indicators in O_1 (or O_2) indicate when c_1 (or c_2) start and end in the collective perception of correct nodes. Hence, by analogy with linearizability, if all ordering indicators in O_1 are lower than those in O_2 , then c_1 is to be ordered before c_2 .

Unfortunately, even when correct nodes are unanimous, their wishes are not guaranteed to come true. The issue again arises from the tension between the desire of giving a voice to every correct node and the inability to distinguish a priori between correct and Byzantine nodes.

Theorem 3.2. *No protocol can uphold both free will and ordering unanimity.*

Proof (sketch). Consider the four-node profile ($f = 1$) in Figure 1. It is an example of what classic social choice theory calls a Condorcet cycle [11, 22]: for any two commands c_i and c_{i+1} (modulo 4), three nodes prefer the first before the second; the fourth begs to differ.

$$\begin{aligned}\mathcal{P}^1 &= \{\langle 1, c_1 \rangle, \langle 2, c_2 \rangle, \langle 3, c_3 \rangle, \langle 4, c_4 \rangle\} \\ \mathcal{P}^2 &= \{\langle 1, c_2 \rangle, \langle 2, c_3 \rangle, \langle 3, c_4 \rangle, \langle 4, c_1 \rangle\} \\ \mathcal{P}^3 &= \{\langle 1, c_3 \rangle, \langle 2, c_4 \rangle, \langle 3, c_1 \rangle, \langle 4, c_2 \rangle\} \\ \mathcal{P}^4 &= \{\langle 1, c_4 \rangle, \langle 2, c_1 \rangle, \langle 3, c_2 \rangle, \langle 4, c_3 \rangle\}\end{aligned}$$

FIGURE 1—A Condorcet cycle

Since any single node may be Byzantine, the requirement of ordering unanimity applies to all ordering preferences endorsed by at least three nodes—but in this example they form a *cycle*, and thus cannot be all satisfied. \square

Like ordering unanimity, ordering linearizability also promises to respect the collective preferences of correct nodes; fortunately, unlike the former property, it *is* achievable. What allows ordering linearizability to escape the Condorcet cycle trap is a simple insight: it expresses ordering preferences in terms of real-time *happened before*, a relation that is inherently acyclical. Indeed, as we show next, it is not only achievable, but can be efficiently implemented.

4 Pompē

Pompē is a new protocol explicitly designed for Byzantine ordered consensus that preserves the same interface as a stan-

dard BFT protocol: clients propose commands and correct nodes reach consensus on a sequence of committed commands. In addition to satisfying the standard safety and liveness properties of BFT SMR, Pompē introduces an ordering phase for Byzantine ordered consensus and prevents Byzantine oligarchies by enforcing ordering linearizability.

A new architecture. Pompē’s two-phase architecture is designed to mirror the decoupling of ordering from consensus made possible by the ordered consensus primitive. First, an *ordering phase* decides the total ordering of commands, “locking” the relative position among the commands proposed in this phase in a way that Byzantine nodes cannot alter; then, a *consensus phase* allows all correct nodes to agree on a stable prefix of the final sequence, following the total ordering decisions in the ordering phase, and to record it in the ledger. We refer to commands in the ledgers of correct nodes as *stable commands*. Note that, since the total order of commands that have completed the ordering phase cannot be changed during the consensus phase, it is again safe to put a single leader node in charge of finalizing consensus. Thus, Pompē can retain the performance benefits of leader-based BFT SMR without fears of enabling a Byzantine oligarchy.

System model. As in prior works in the BFT SMR literature, we consider a distributed system with a set of $n = 3f + 1$ nodes, where up to f nodes can be *Byzantine* (i.e., deviate arbitrarily from their prescribed protocol) and the rest are *correct*. We assume the existence of standard cryptographic primitives (unforgeable digital signatures and collision-resistant hash functions) and that cryptographic hardness assumptions necessary to realize these primitives hold. Furthermore, we assume that each node holds a private key to digitally sign messages, and that each node knows the public keys of other nodes in the system. We consider an adversarial network that can drop, reorder, or delay messages. However, for liveness properties, we assume that the network satisfies a weak form of synchrony [16, 27, 28]. Finally, we assume that each node has access to a timer, which produces monotonically increasing timestamps each time it is queried.

4.1 Protocol description

We now describe how Pompē instantiates each of the phases in our new architecture. Throughout the protocol, we assume that correct recipients of messages that are not well-formed (e.g., because they carry an incorrect signature) will drop them: we omit these actions in the interest of brevity.

(1) Ordering phase. Pompē uses timestamps as ordering indicators. To “lock” a position for a command in a total order, Pompē proceeds in two steps.

In the first step, a node N_i with a command c collects signed timestamps on c from a quorum of $2f + 1$ nodes. The median timestamp in the set of $2f + 1$ signed timestamps is the *assigned timestamp* for c , and it determines the position of c in the total order. Because there are at most f Byzantine

nodes, by picking the median value, the assigned timestamp is both upper- and lower-bounded by timestamps from correct nodes. This is the key observation that allows the protocol to achieve ordering linearizability.

To lock this position in the total order for c , in the second step N_i broadcasts c along with its assigned timestamp and waits for it to be accepted by a quorum $2f + 1$ nodes (we explain below what it means for a command to be accepted). If a command c is accepted by a quorum of $2f + 1$ nodes, c is not only guaranteed to be included in the totally-ordered ledgers of correct nodes, but also that its position in the ledgers is determined by the assigned timestamp of c . We refer to such commands as *sequenced*.

Local state. Each node maintains the following local data structures: (1) `localAcceptThresholdTS`, an integer, initialized to 0, that tracks what N_i believes to be, currently, the latest possible timestamp of any stable command in the ledger; (2) `localSequencedSet`, a set, initially empty, that tracks all commands that the node has accepted; (3) `highTS`, an n -sized vector of integers where `highTS[i]`, initialized to 0, stores the highest timestamp received from node N_i ; and (4) `highTSMs`, an n -sized vector of messages where `highTSMs[i]`, initialized to *null*, stores the message signed by node N_i that carried the value currently stored in `highTS[i]`.

To complete our discussion of each node's local state, we first need to introduce a simple protocol that nodes use to update their timers.

The protocol. Let \mathcal{T} be the $(f + 1)^{\text{th}}$ highest timestamp in `highTS`. Because at most f nodes are Byzantine, \mathcal{T} is upper-bounded by a timestamp from a correct node. Let each node reset its timer to \mathcal{T} whenever \mathcal{T} is higher than the current value of the local timer. Periodically, each node broadcasts its current value of \mathcal{T} in a Sync message to indicate that all correct nodes can now set their timer to be \mathcal{T} or higher. To prove to its recipients that the \mathcal{T} value is valid, the Sync message also includes the sender's `highTSMs` vector. \square

We are now ready to define two additional data structures: (4) `globalSyncTS` stores the highest \mathcal{T} received so far in a Sync message; and (5) `localSyncTS` stores instead the node's local timestamp at the time it received that Sync message.

Actions. Each node N_i with a command c executes the following two steps to lock a position for c in a total ordering of commands:

1. N_i broadcasts $\langle \text{RequestTS}, c \rangle_{\sigma_{N_i}}$ and waits for responses from $2f + 1$ nodes, where σ_{N_i} is a signature on the payload using N_i 's private key.
 - A node N_j responds with $\langle \text{ResponseTS}, c, ts \rangle_{\sigma_{N_j}}$, where ts is a timestamp from N_j 's local timer.
2. N_i broadcasts $\langle \text{Sequence}, c, T \rangle_{\sigma_{N_i}}$, where T is a set of $2f + 1$ responses received in the first step, and waits for responses from a quorum of $2f + 1$ nodes.
 - A node N_j *accepts* the broadcast message and adds

it to its `localSequencedSet` if the assigned timestamp of c is higher than `localAcceptThresholdTS`. If so, N_j responds with $\langle \text{SequenceResponse}, \text{ack}, h \rangle_{\sigma_{N_j}}$; otherwise, it responds with $\langle \text{SequenceResponse}, \text{nack}, h \rangle_{\sigma_{N_j}}$, where h is the cryptographic hash of the Sequence message.

The second step above is crucial to establish stable prefixes in the sequence of commands. Intuitively, it requires every correct node N_j to refuse sequencing commands if their timestamp may be lower than that of a stable command. Note that, during sufficiently long periods of synchrony (which are necessary for liveness), nodes can get their commands sequenced in just two round-trips—a lower latency than recent BFT protocols [18, 68]. However, sequenced commands are not yet suitable for execution until they become stable: only then they are guaranteed that commands with lower timestamps will not be sequenced.

Nodes *can* execute commands speculatively in their `localSequencedSet`, but they must wait for the consensus phase to finish before externalizing output and be ready to perform selective reexecution if their speculation is incorrect.

(2) Consensus phase. The principal goal of the consensus phase is to ensure that all correct nodes agree that a certain prefix of the total order constructed in the previous phase is now stable, meaning that the prefix is forever immutable.

To accomplish this, Pompē employs any standard leader-based BFT SMR protocol (e.g., [16, 31, 68]) that offers a primitive to agree on a value for each slot in a sequence of consensus slots. We generically refer to this protocol as Consensus. For simplicity, we assume that each consensus slot is associated with non-overlapping time intervals $[ts, ts')$ such that $ts' > ts$, and that for the first consensus slot $ts = 0$. We further assume that the mapping from consensus slot numbers to time intervals is common knowledge. In practice, this can be implemented by making the interval of the first consensus slot as $[0, \tau)$, where τ is the system initialization time, and then assigning each subsequent consensus slot a fixed window of time (e.g., $[ts, ts + 100 \text{ ms})$). Note that this does not mean that nodes must agree on a value during these time intervals.

For liveness, Pompē relies on a bound Δ on the sum of two terms: the maximum difference Δ_1 between the values returned, at any time, by local timers of correct processes, which in turn depends on the time it takes for a Sync to travel from one node to another and be processed at the recipient; and the maximum time Δ_2 needed by a correct node to execute the ordering phase (we assume that these bounds include additional slack to account for clock drifts across nodes). Pompē's safety properties hold even when Δ does not hold, but, during sufficiently long periods of synchrony (which is necessary for liveness), we assume that the bound holds for proving liveness (Section 4.2).

Local state. The local state of each node is a totally-ordered ledger, initially empty.

Actions. Suppose that consensus slot k maps to time inter-

val $[ts, ts')$, meaning that all commands with assigned timestamp in this interval are expected to be included in this slot. If node N_i wishes to serve as a leader in reaching consensus on a value for slot k using Consensus, it proceeds as follows.

1. N_i broadcasts $\langle \text{Collect}, k \rangle_{\sigma_{N_i}}$, and waits for responses from $2f + 1$ nodes.
 - Node N_j waits until two conditions hold. First, the value of N_j 's `globalSyncTS` is higher than ts' , meaning that some node sent N_j a Sync message with $\mathcal{T} \geq ts'$. Second, since that Sync message was received, a time interval of at least Δ has elapsed on N_j 's timer (i.e., N_j 's timer reads at least `localSyncTS` + Δ). Note that, during sufficiently long periods of synchrony, these delays give all correct nodes enough time to sequence all their commands with assigned timestamps lower than ts' before N_j advances its `localAcceptThresholdTS` to ts' . In more detail, after Δ_1 , all correct nodes should have received and processed a Sync message with $\mathcal{T} \geq ts'$ to set their local timer to be at least \mathcal{T} , so after this point, any new command entering the ordering phase will not have an assigned timestamp lower than ts' . After an additional Δ_2 , any command with an assigned timestamp lower than ts' must have completed the ordering phase.
 - N_j updates its `localAcceptThresholdTS` $\leftarrow \max(ts', \text{localAcceptThresholdTS})$.
 - N_j responds with $\langle \text{CollectResponse}, k, \mathcal{S} \rangle_{\sigma_{N_j}}$, where \mathcal{S} is the set of messages in the `localSequencedSet` of N_j with assigned timestamps in the interval $[ts, ts')$.
2. N_i runs Consensus to agree on value \mathcal{U} for consensus slot k , where \mathcal{U} is the union of `CollectResponse` messages from $2f + 1$ nodes for consensus slot k .

Constructing a totally-ordered ledger. Once a prefix of consensus slots are agreed upon, nodes can construct a totally-ordered prefix of the ledger by sorting commands in each slot (of the prefix) by their assigned timestamps, breaking ties by their cryptographic hashes. When a node adds a proposal to its totally ordered ledger, it can execute them in the order specified by the ledger.

4.2 Proofs of safety and liveness

This section proves that Pompē satisfies ordering linearizability and a strengthened version of liveness in addition to standard safety properties.

Theorem 4.1 (Consistency). *For every pair of correct nodes N_i and N_j with local ledgers \mathcal{L}_i and \mathcal{L}_j , the following holds: $\mathcal{L}_i[k] = \mathcal{L}_j[k] \forall k :: 0 \leq k \leq \min(\text{len}(\mathcal{L}_i), \text{len}(\mathcal{L}_j))$, where $\text{len}(\cdot)$ computes the number of entries in a ledger.*

Proof. By the safety properties of BFT SMR, every pair of correct nodes agrees on the same value for each consensus slot. Furthermore, the transformation from values in consensus slots to a totally-ordered ledger is deterministic. Together,

these observations imply the desired result. \square

Theorem 4.2 (Validity). *If a correct node appends a command c to its local totally-ordered ledger, then at least one node in the system proposed c in the ordering phase.*

Proof. Each command in the ledger of a correct node is constructed from a valid value agreed upon in one of the consensus slots. Furthermore, for a given consensus slot k with assigned time interval $[ts, ts')$, by our construction, a valid value is a set of `CollectResponse` messages for slot k from at least $2f + 1$ nodes, where each `CollectResponse` contains commands with timestamps in the interval $[ts, ts')$. Additionally, for a command to have an assigned timestamp, it must have been proposed in the first step of the ordering phase. Together, these observations imply the statement of the theorem. \square

Lemma 4.1. *The assigned timestamp of a command is bounded by timestamps provided by correct nodes.*

Proof. By assumption, there are at most f Byzantine nodes. Thus, at least $f + 1$ (out of $2f + 1$) timestamps provided in the ordering phase for a given command are from correct nodes. Furthermore, the assigned timestamp of a command discards f lowest and f highest timestamps in the $2f + 1$ `ResponseTS` messages, thus the assigned timestamp of a command is bounded by timestamps provided by correct nodes. \square

Theorem 4.3 (Ordering linearizability). *If the highest timestamp provided by any correct node for a command c_1 is lower than the lowest timestamp provided by any correct node for another command c_2 and if both c_1 and c_2 are committed, then c_1 will appear before c_2 in the totally-ordered ledgers constructed by correct nodes.*

Proof. By Lemma 4.1, the assigned timestamp of a command is bounded by timestamps provided by correct nodes. As a result of this and the pre-condition in the statement of the theorem, the assigned timestamp of c_1 will be smaller than the assigned timestamp of c_2 . Thus, if both c_1 and c_2 are committed, c_1 will appear before c_2 in the totally-ordered ledgers of correct nodes because nodes sort commands by their assigned timestamps. \square

Lemma 4.2. *During sufficiently long periods of synchrony, a correct node can get its command (along with its assigned timestamp) added to `localSequencedSet` of at least $2f + 1$ nodes.*

Proof (sketch). Suppose a correct node executes the first step of the ordering phase for its command c and obtains an assigned timestamp of ts . During sufficiently long periods of synchrony, by the choice of Δ , a Sequence message that includes c will reach $2f + 1$ correct nodes and be added to their `localSequencedSet` before they advance their `localAcceptThresholdTS` past ts , which implies the statement of the lemma. \square

Lemma 4.3. *If a command c with assigned timestamp ts is added to `localSequencedSet` of at least $2f + 1$ nodes, then c will eventually be included in the value committed by a unique consensus slot whose time interval includes ts .*

Proof (sketch). Let k denote the consensus slot whose time interval includes ts . When a leader broadcasts `Collect` for consensus slot k , the local timers on correct nodes will eventually meet the condition required to send `CollectResponse` messages. Since c appears in the `localSequencedSet` of at least $2f + 1$ nodes, and, by assumption, since at most f of them are Byzantine, at least $f + 1$ nodes will include c in their `CollectResponse` for consensus slot k . Denote these $f + 1$ nodes with \mathcal{C} .

Since Pompē’s use of BFT SMR requires proposals that are constructed by taking a union of $2f + 1$ `CollectResponse` messages, a leader must include at least one message from nodes in \mathcal{C} . Thus, c must be included to construct a valid proposal for consensus slot k . These combined with the liveness property of the employed BFT SMR protocol (which ensures that a valid value will eventually be chosen for each consensus slot) implies the desired result. \square

Theorem 4.4 (Strong liveness). *During sufficiently long periods of synchrony, a correct node can get an assigned timestamp for its command c such that c will eventually be included in the total order constructed by correct nodes at a position determined by the assigned timestamp of c .*

Proof. During sufficiently long periods of synchrony, by Lemmas 4.2 and 4.3, c will eventually be included in the value committed by a unique consensus slot whose time interval includes the assigned timestamp of c . Since the algorithm to construct a total ordering of commands from values committed by consensus slots sorts commands by their assigned timestamps, the position of c is determined by the assigned timestamp of c . \square

4.3 Byzantine influence in Pompē

Pompē greatly diminishes the leverage of Byzantine nodes. Once a command is sequenced, Byzantine nodes can neither censor it nor affect its position in the totally-ordered ledgers of correct nodes. Furthermore, they cannot violate ordering linearizability. Nonetheless, as we saw in Sections 2 and 3, in a Byzantine democracy, it is impossible to completely eliminate the influence of Byzantine nodes, and Pompē is not immune from it.

Byzantine democracy in action. Consider the following execution of Pompē, where $n = 4$ and $f \leq 1$. There are two commands, c_1 and c_2 , that in the ordering phase obtained the following timestamps from a quorum of $2f + 1$ nodes.

	N_1	N_2	N_3
c_1	0	3	3
c_2	1	4	2

Assume, without loss of generality, that N_3 is Byzantine, and that the remaining nodes are correct. The timestamps make clear that correct nodes prefer to order c_1 before c_2 . However, since the median timestamp of c_1 is higher than the median timestamp of c_2 , it is c_2 that will be ordered before c_1 . On a positive note, we observe that, in the normal case where the timers on correct nodes are sufficiently synchronized and network delays are small, this window of vulnerability to Byzantine manipulation is small.

Early stopping and deferred selective inclusion. Pompē cannot prevent a Byzantine node from obtaining an assigned timestamp for its command, but not proceeding with the rest of the ordering phase, as this misbehavior is indistinguishable from what may result from a network failure. This ambiguity allows a Byzantine node (possibly with the aid of a Byzantine leader) to decide later, during the consensus phase, whether or not to include its timestamped-but-not-yet-sequenced command in the ledger.

Preventing or reliably detecting this type of misbehavior is impossible, but mechanisms to mitigate the risks and raise suspicion do exist. One possibility is for each node to employ an append-only linear hash chain to record the timestamps it assigns to other nodes’ commands. Nodes exchange those hash chains and refer to the corresponding hash value (in the hash chain) in each `ResponseTS` message. Such hash chains constrain the ability for Byzantine nodes to assign timestamps abnormally (e.g., out of order), and allow after-the-fact auditing (which could be used to expose nodes that routinely timestamp their commands, but do not always sequence those commands). In addition, a correct node N_i can piggyback the tail of a hash chain of all previously timestamped commands of N_j whenever N_j requests a timestamp; this makes it hard for a Byzantine N_j to blame on the network when silently dropping an earlier timestamped command. An alternative mechanism is for correct nodes to hide their commands using a threshold encryption scheme until those commands are totally ordered. This additional step prevents Byzantine nodes from observing the contents of other timestamped commands before deciding whether to drop their timestamped commands.

5 Implementation

We implement two variants of Pompē, where the artifacts differ in the specific BFT protocol they employ for the consensus phase. Specifically, we extend two prior state-of-the-art leader-based BFT protocols: SBFT [31] and HotStuff [68]. SBFT implements a variant of PBFT [16] that includes many optimizations for scalability. HotStuff uses a rotating leader paradigm while incurring low network costs and serves as the foundation of the Libra blockchain [3]. For SBFT, we use its implementation in VMware’s Concord [1], and for HotStuff, we use the authors’ implementation [2].

	base	extensions
Concord [1]	22,141	1122
HotStuff [68]	4,983	900

FIGURE 2—Number of lines of C++ code in Pompē, which we build atop a base BFT library with a set of extensions.

Ease of implementation. Implementing Pompē atop an existing consensus protocol involves modest system effort. Figure 2 reports the numbers of lines of code we add to the base BFT protocol implementations. These extensions primarily focus on implementing the two steps of the ordering phase in our new architecture. Specifically, we implement four new message types, as described in Section 4. We then implement message handlers to sign and verify timestamps and to manage data structures for `localSequencedSet` and `localAcceptThresholdTS`. Additionally, we modify the leader logic so that, for each time interval, a leader starts a consensus phase after assembling a proposal by collecting responses from a quorum of $2f + 1$ nodes, as described in Section 4. The rest of the consensus protocol is unmodified: the leader of an instance runs the original consensus protocol for a slot with a proposal assembled as described above. Within each slot, commands are ordered by their assigned timestamps.

Optimizations. In Pompē’s consensus phase, the `CollectResponse` message used for consensus slot k contains all commands in a node’s `localSequencedSet` whose assigned timestamp falls within the time interval associated with k . This can lead to large message sizes. However, when the network is synchronous and correct nodes respond in a timely manner, `CollectResponse` messages will contain the same set of commands. Therefore, we optimize Pompē by having `CollectResponse` messages sent to the leader carry only a hash of the set commands in the sender’s `localSequencedSet`. The leader compares the hash of its own `localSequencedSet` with the hashes carried in the `CollectResponse` messages received from $2f$ other nodes. If the hashes match, then the leader proceeds to reach consensus for slot k on the commands from its `localSequencedSet`, using the $2f + 1$ signed hash values (those received from the other nodes as well as its own) as proof that $2f + 1$ nodes reported the same set of commands. Otherwise, the leader requests a new set of `CollectResponse` messages, this time including the actual set of commands. We enable this optimization by default.

6 Experimental evaluation

This section experimentally evaluates Pompē. We ask two main questions: (1) How does the performance of Pompē compare with that of state-of-the-art BFT protocols? (or, what is the price of transitioning from a Byzantine oligarchy to a Byzantine democracy that enforces Byzantine-tolerant ordering guarantees?) and (2) What is the impact of separating ordering from consensus on end-to-end performance? Figure 3 provides a summary of our findings.

Figure 3 provides a summary of our findings.

We choose as baselines two prior state-of-the-art BFT protocol implementations: Concord [1, 31] and HotStuff [2, 68]. Both are leader-based (and hence subject to Byzantine oligarchy) and hardcode ordering decisions within consensus. As described in Section 5, we implement two variants of Pompē, both upholding ordering linearizability (and hence free of Byzantine oligarchy), by augmenting those two BFT protocols. We refer to Pompē that extends HotStuff as *Pompē-HS*, and to Pompē that extends Concord as *Pompē-C*.

Methodology, testbed, and metrics. We run our experiments on 100 Standard D16s_v3 (16 vcpus, 64 GB memory) VMs on the Azure cloud platform spanning three datacenters, each running Ubuntu Linux 18.04: 34 in West US, 33 in South-East Asia, and 33 in North Europe. We run single-datacenter experiments using VMs in the West US.

We report results only for failure-free executions, as failures do not alter how Pompē performs relative to its baselines.

Our workload is generated by clients that submit their commands in a closed loop, i.e., they wait to receive a response to their currently outstanding command before submitting the next one. To run experiments with different loads, we vary the number of clients. For HotStuff and Pompē-HS, as in prior work [67], we run experiments where commands are random, 32-bytes-long values.²

Similarly, for Concord and Pompē-C, as in prior work [31], we use a benchmark that writes a random value to a randomly-selected key in a key-value store.

Our principal performance metrics are client-perceived latency (measured in ms) and throughput (in commands/second). To measure latency, each client records the latency of each command using its local clock, and our scripts aggregate latencies across clients and across commands. For throughput, we compute the total number of commands processed by the system and divide it by the duration of the experiment. To measure the peak throughput of a given system, we increase the number of clients until saturation.

Since Pompē separates ordering from consensus, clients in Pompē receive two responses, one for confirming the relative position of the command in the totally-ordered ledger (when a command is sequenced; see Section 4 for details), and another for the execution result of the command. Therefore, we report two types of latency for Pompē, which we refer to as *ordering latency* and *consensus latency*. Since our baselines hardcode ordering decisions within consensus, both ordering and consensus complete at the same time, so, for baselines, we report a single type of latency.

6.1 End-to-end performance: Throughput and latency

We begin by measuring the performance of Pompē and its baselines in a four-node configuration (we report results for

²The HotStuff implementation reaches consensus not on actual commands, but on their 32-byte-long cryptographic hashes; clients communicate the actual commands to the replica nodes outside of the consensus protocol.

Pompē incurs higher latency than its baselines, but by batching in both phases, Pompē achieves higher throughput at competitive latencies	\$6.1, 6.2
Pompē's throughput degrades when n increases, but Pompē can scale up each node for higher throughput	\$6.3
Pompē incurs modest network overheads over its baselines	\$6.4

FIGURE 3—Summary of evaluation results.

FIGURE 4—Peak throughput and median latency for Pompē and its baselines in a single datacenter with $n = 4$ nodes. Pompē's leader starts the consensus phase every 50 ms with $\Delta = 10$ ms. Pompē's *ordering latency* is denoted with “o”, its *consensus latency* with “c”.

larger system sizes in the next subsection). We run clients on a separate set of virtual machines so that clients and nodes do not contend for computing resources.

A note about batching. Batching is a standard technique in SMR protocols to increase throughput at the cost of higher latency by amortizing the cost of running consensus across all the commands in a batch. Both Pompē and its baselines can take advantage of it, and we report experiments for different batch sizes. However, Pompē's separation of ordering from consensus has two significant implications for batching.

First, it eliminates the unintended leverage that Byzantine nodes can gain through batching even in BFT SMR protocols that rotate leaders out of concern for “fairness”. The larger the batch, the larger the number of commands whose ordering is left to the unchecked discretion of the current leader: throughput gains thus come at the cost of expanding opportunities for Byzantine oligarchy. Pompē removes these concerns: its ordering guarantee (e.g., ordering linearizability) is unaffected by either the existence of batches or by their sizes.

Second, separating order and consensus affects the trade-off between latency and throughput that comes with batching. When Pompē's baselines do not batch commands, they achieve lower latency *and* lower peak throughput than Pompē. Latency is higher under Pompē because a leader in Pompē must wait for a fixed time window before initiating a proposal; peak throughput is higher because Pompē implicitly batches commands whose timestamps fall within a time window during consensus. However, when the baselines batch commands to match Pompē's latencies, they achieve significantly higher peak throughput than Pompē. Pompē's peak throughput is lower because nodes must produce and validate signed timestamps during the ordering phase, which causes nodes to saturate earlier.

	throughput (cmds/s)	median latency (ms)
HotStuff ($\beta_c = 800$)	6,160	915.8
Pompē-HS ($\beta_o = 200$)	315,753	259.7 (o), 1518.1 (c)
Concord ($\beta_c = 800$)	1,461	616
Pompē-C ($\beta_o = 200$)	172,774	325 (o), 1415 (c)

FIGURE 5—Peak throughput and median latency for Pompē and its baselines with $n = 4$ nodes spanning three geo-distributed datacenters. Batch sizes are as in the single datacenter experiments in a single datacenter. Pompē's leader starts the consensus phase every 500 ms with $\Delta = 400$ ms.

Fortunately, the separation gives Pompē an additional batching opportunity: each node can execute the ordering phase once to assign a single timestamp to an ordered sequence of its own commands (or of commands from clients that belong to the same organization as the node). Such batching does not affect Pompē's ordering properties (e.g., ordering linearizability) because each batch contains commands from a single node. The throughput boost that comes from this additional source of batching can more than make up for Pompē's lost ground, but raises the question of how to fairly compare the Pompē variants to their baselines.

We balance these different considerations in our experiments as follows: if, in a configuration with n nodes, the baseline's consensus protocol uses a batch size $\beta_c = S(> 1)$, then we allow each node in corresponding variant of Pompē to use batches of size $\beta_o = S/n$ during its ordering phase.

Performance results. Figure 4 shows peak throughput and median latency at peak throughput for Pompē and its baselines, for different batch sizes. Since Pompē-C and Pompē-HS perform similarly compared with their respective baselines, so we focus only on Pompē-HS.

Performance without batching. When $\beta_o = 1$, Pompē-HS's median ordering latency is 28% of the median latency of HotStuff with $\beta_c = 1$, while its peak throughput is about 3.5 \times higher than HotStuff's. The lower ordering latency is due to Pompē's ordering phase, which incurs only two RTTs compared to the four RTTs required by HotStuff; the higher throughput, perhaps surprisingly given that $\beta_o = 1$, is instead due to batching. In Pompē-HS, setting $\beta_o = 1$ means that nodes do not batch in the *ordering phase*; however, since Pompē-HS does not start consensus until a time window has elapsed, it can still collect commands from multiple clients: for a 50 ms time window, we observed an effective batch size of 82 commands. Unsurprisingly, the flip side of this higher throughput is significantly higher consensus latency. Pompē-HS starts the consensus phase every 50 ms; with $\Delta = 10$ ms,

FIGURE 6—Latency vs. throughput for HotStuff and Pompē-HS in a geo-distributed deployment. The left and right graphs show respectively the maximum ordering latency and consensus latency experienced by different percentiles of the fastest commands. The experimental setup is the same as in Figure 5. Pompē-HS achieves higher throughput at the cost of higher consensus latency, even as its low ordering latency lets nodes know quickly when their commands are guaranteed to appear in the ledger.

every client waits on average 35 ms for the next consensus phase, ultimately leading to a consensus latency of 47.7 ms.

Performance with batching. We fix the batch size for HotStuff to $\beta_c = 800$ commands, and accordingly set the ordering-phase batch size of each of the four nodes in Pompē-HS to $\beta_o = 200$. Unsurprisingly, the throughput increases significantly for both Pompē-HS and HotStuff, respectively by $220\times$ and $535\times$ over the values we measured for Pompē-HS ($\beta_o = 1$) and HotStuff ($\beta_c = 1$): both systems are CPU-bound, and batching allows them to amortize the cost of cryptographic operations across all commands in a batch. In absolute terms, we find that Pompē-HS achieves $1.4\times$ the throughput of HotStuff; as discussed earlier, the reason is the additional batching effect due to the 50 ms interval that in Pompē-HS separates successive invocations of consensus.

6.2 Performance with a geo-distributed setup

We consider next a geo-distributed setup, where $n = 4$ nodes are deployed in three separate datacenters, with one datacenter running two nodes. We use the same batch size as in the single datacenter setup (i.e., $\beta_c = 800$ for baselines and $\beta_o = 200$ for each node’s ordering phase for the corresponding Pompē variants).

Peak throughput. Figure 5 shows our results. For HotStuff, geo-replication causes throughput to drop dramatically, to only 2.4% of its value for the same configuration in a single datacenter. For geo-distributed Pompē-HS instead the loss is much more contained: throughput is at 87.3% of its single-datacenter value. Two main factors explain these results. First, as in the single-datacenter case, Pompē-HS can take advantage of effective batching, now with a time interval between successive proposal of 500 ms and $\Delta = 400$ ms; second, HotStuff is hampered by its use of rotating leaders, as a new leader does not propose a new batch until after collecting enough votes for the previous leader’s batch: in a geo-distributed setting, this delay can become significant and negatively affect throughput.

Latency. Figure 6 shows the maximum ordering and consensus latencies experienced by the fastest 50%, 90%, and 99% of commands. The key take-away is that Pompē-HS achieves

higher throughput at the cost of higher consensus latencies. As expected, in Pompē-HS both types of latency stay stable until system saturation. HotStuff’s latency drops at the beginning because, with more clients, it fills up a batch more quickly while also increasing the throughput. Furthermore, the ordering latency is lower than the median consensus latency (since the latter adds more communication rounds to the former) meaning that nodes can get early notification for when their commands are guaranteed to appear in the ledger.

6.3 Scalability

To understand how well Pompē scales to a larger number of nodes, we experiment with increasing values of n . We vary the number of nodes in an experiment from 4 to 100. Our results for Pompē-C (in comparison with its baseline Concord) are qualitatively similar to our results for Pompē-HS (in comparison with HotStuff), so we focus on Pompē-HS.

HotStuff uses the same batch size as before (i.e., $\beta_c = 800$). For Pompē-HS, we experiment with three configurations.

1. Light: We set $\beta_o = 800/n$ and allocate a single VM to each node regardless of n .
2. Scale-up: We set $\beta_o = 800/n$ and, as n increases, so does proportionally the number of VMs associated with each node to equal $\lfloor n/4 \rfloor$. So, for example, for $n = 4$, we use one VM per node; but when $n = 10$, each node uses two.
3. Fixed batch: We set $\beta_o = 200$ regardless of n .

Figures 7 and 8 depict throughput and latency achieved by Pompē and its baselines for different values of n .

Throughput. HotStuff scales well as n grows, whereas throughput quickly degrades under Pompē-HS (light). This is because batch sizes under Pompē-HS (light) are inversely proportional to n , so throughput degrades as n increases. This is confirmed by the scaling behavior of Pompē-HS (fixed batch) where $\beta_o = 200$ regardless of n . Of course, using a fixed β_o regardless of n may not be desirable.

Fortunately, we find that Pompē-HS (scale-up) can achieve a behavior similar to Pompē-HS (fixed batch) without having to use a fixed β_o . In Pompē-HS (scale up), each node uses multiple VMs to run the ordering phase, thereby avoiding

FIGURE 7—Peak throughput and median latency of different configurations of Pompē-HS and of HotStuff as a function of the number of nodes (n) in a geo-distributed deployment. The light blue cross at $n = 31$ depicts the performance of Pompē-HS (scale up) with 3 VMs per node; the blue square above it shows the *predicted* throughput when each node is assigned $\lceil 31/4 \rceil = 7$ VMs. The prediction is based on benchmarks showing that the ordering phase scales near linearly as more VMs are assigned to each node. The blue squares connected by a dotted line at $n = 61$ and $n = 100$ are similarly predicted rather than measured.

the throughput degradation experienced by Pompē-HS (light). Our testbed has 100 nodes, so we could only run Pompē-HS (scale-up) for $n \in \{4, 10, 16\}$. For higher values of n , we predict the throughput of Pompē-HS (scale-up) using experimental results from smaller-scale experiments and additional benchmarks that we used to validate that the ordering phase achieves a near-linear scaling as each node gets more VMs.

Latency. For both Pompē-HS and HotStuff, latency stays relatively stable when the system scales out. This is because latency is dominated by network communication in a geo-distributed deployment.

6.4 Network overhead

Compared to its baselines, Pompē incurs higher network costs to attach timestamps with each command and for executing a separate ordering phase. To understand the increased network costs, we use $n = 4$ and experiment with both Pompē and its baselines. We experiment with Pompē-HS ($\beta_o = 1$) and HotStuff ($\beta_c = 1$), and record the total number of bytes sent by each node during the experiment. We find that Pompē-HS incurs about 18% higher network costs compared to HotStuff, which, we believe, is a tolerable price for the stronger ordering properties ensured by Pompē.

7 Related work

Leader-based BFT protocols. There is a long line of work on practical Byzantine consensus protocols [10, 17, 20, 31, 34, 41, 42, 49–52, 59, 65, 66], starting with the seminal work of PBFT [16]. These works focus on improving performance, round complexity, fault models, etc. Some works also focus on using trusted hardware to improve fault thresholds [10, 19, 37, 46]. However, all of them employ a special leader node to orchestrate both ordering and consensus, so they suffer from both Byzantine dictatorship and Byzantine oligarchy.

There are some works that defend against faulty leaders, but they focus only on preventing faulty leaders from affecting the system’s performance or defenses for a restricted class of attacks. For example, Aardvark [21] employs periodic leader changes to prevent a faulty leader from exercising full control

over the system’s performance. It achieves this by having correct nodes set an expectation on minimal acceptable throughput that a leader must ensure and trigger a leader election in case the current leader fails to meet its expectation. While Aardvark [21] focuses on achieving acceptable performance in the presence of faulty leaders, Prime [5] targets a different performance property: any transaction known to a correct node is executed in a timely manner. The Prime Ordering protocol consists of a pre-ordering phase and a global ordering phase. Unlike Pompē’s ordering phase, the pre-ordering phase imposes only a partial order, rather than a timestamp-based global ordering in Pompē.

Instead of monitoring leaders to detect (or prevent) certain attack vectors, Pompē separates ordering from consensus, which completely eliminates a leader’s power in selecting which transactions to propose and in what order. More generally, our work provides the first systematic study of properties desirable when employing BFT protocols for systems that span multiple administrative domains, proves what are impossible, and designs mechanisms to realize desirable properties that are achievable.

Rotating leaders. BART [4] enables cooperative services to tolerate both Byzantine faults and rational (selfish) behavior under the new BAR (Byzantine, altruistic, and rational) model. The consideration of rational behavior leads to an RSM design with rotating leaders, which has now become a standard practice for blockchains based on BFT [3, 18, 68]. However, the rotating leader paradigm still suffers from Byzantine dictatorship because a Byzantine node can still dictate ordering when it is in the leadership role, whereas Pompē achieves stronger properties by separating ordering from consensus.

Leaderless BFT protocols. Recognizing the implications of relying on a special leader, Lamport offers a leaderless Byzantine Paxos protocol [44]. Unfortunately, it relies on a synchronous consensus protocol to instantiate a “virtual” leader, which requires at least $f + 1$ rounds, where f is the maximum number of faulty nodes in the system and the duration of each round must be set to an acceptable round trip delays. When the number of nodes is high or when nodes

FIGURE 8—Scalability of Pompē-C and Concord in a geo-distributed deployment. Peak throughput and median latency with varying number of nodes (n). We use $\beta_c = 800$ for the baseline; see the text for different configurations of Pompē.

are geo-distributed, this protocol adds unacceptable latencies. Democratic Byzantine Fault Tolerance (DBFT) [23] is another leaderless Byzantine consensus protocol, which builds on Psync, a binary Byzantine consensus algorithm. As in Lamport’s leaderless protocol [44], Psync terminates in $O(f)$ message delays, where f is the number of Byzantine faulty nodes, even though DBFT relies on a weak coordinator for a fast path through optimistic execution.

EPaxos [55] is a Paxos [43] variant in which proposed transactions are ordered without relying on a single leader. But EPaxos ensures safety and liveness only in a crash fault model, and it is unclear how to ensure those properties in a Byzantine fault model, which is our target setting.

Building on the work of Cachin et al. [14, 15], HoneybadgerBFT [54] and BEAT [26] propose leaderless protocols that preserve liveness even in asynchronous and adversarial network conditions. To achieve these properties, they rely on randomized agreement protocols, which bring significant complexity and costs. Unfortunately, these works do not defend against the formation of a Byzantine oligarchy nor do they satisfy ordering linearizability.

Censorship-resistance. HoneybadgerBFT [54] and Helix [8] run consensus on transactions encrypted with a threshold encryption scheme to prevent malicious nodes from censoring transactions, but faulty nodes can always filter transactions based on metadata, a point made by Herlihy and Moir [35]. In contrast, Pompē’s separation of ordering from consensus offers a simple mechanism to prevent censorship: once a correct node executes the ordering phase, the transaction is not only guaranteed to be included in the ledgers of correct nodes, it will also be included in a position determined by the assigned timestamp of the transaction.

Accountability and proofs. Herlihy and Moir [35] propose several mechanisms to hold participants accountable in a consortium blockchain. These techniques extend and generalize prior work on accountability [32, 33] and untrusted storage [48, 53]. Similarly, nodes can produce succinct (zero-knowledge) proofs of their correct operation, which other nodes can efficiently verify [12, 58, 63, 64]. Recent work [45, 56] employs such proofs to reduce CPU and network costs in large-scale replicated systems (e.g., blockchains). Unfortunately, such proofs do not prevent a

Byzantine leader node from deciding which commands to propose and in what order.

Order fairness. Recent work by Kelkar et al. [38] also recognizes the need to introduce a new ordering property for BFT, which they characterize as order fairness. Their work shows that a natural definition of Receive-Order-Fairness, which states that the total order of commands in the consensus output must follow the actual receiving order of at least a γ -fraction of all nodes (if they agree), is impossible to achieve, due to the Condorcet paradox. They relax Receive-Order-Fairness and define Block-Order-Fairness, where ordering constraints apply only to *blocks* of commands.

Starting from a similar motivation, our work takes a different direction, with both theoretical and practical implications.

First, rather than trying to characterize the fairness of a particular ordering, we introduce the notions of Byzantine oligarchy and Byzantine democracy to focus on the degree to which it is possible (and impossible) to curtail the influence of Byzantine nodes in determining any given order of commands. Thus, while Kelkar et al. observe that protocols that order commands using timestamps from a quorum of nodes are not suitable for ensuring fairness (as they suffer from the type of manipulations described in Section 4.3), we are able to prove (see Theorem 3.1) that *any* protocol is subject to these types of manipulations in a Byzantine democracy, as long as we uphold free will.

Further, we choose to express our ordering properties as a function of the preferences of correct nodes, rather than some γ -fraction of all the nodes (some of which could be Byzantine); we believe this choice was instrumental in deriving clean definitions for ordering unanimity and ordering linearizability.

Our different design choices have also significant practical consequences. While Pompē can use any existing BFT protocol in its consensus phase, Kelkar et al. design a compiler to automatically convert a standard consensus protocol into one that satisfies order fairness. However, protocols output by this compiler require more resources than a standard BFT protocol for the same level of fault tolerance; for example, in the same setting as in standard BFT (leader-based, partial synchrony network model) with γ set to 1 (their best case), these protocols require at least $4f + 1$ nodes to tolerate f Byzan-

tine failures, rather than the $3f + 1$ nodes needed by Pompē. Further, the practicality of these compiler-produced protocols is unclear, since to date they appear to have been neither implemented nor evaluated, whereas Pompē is competitive with state-of-the-art BFT protocol implementations.

Permissionless blockchains. A trend in the blockchain community is to avoid energy-intensive proof-of-work mechanism. This has led to permissionless blockchains that employ a BFT protocol among a set of nodes chosen based on different mechanisms (e.g., verifiable random functions, financial stake, etc.) to agree on a value [25, 30, 39, 40]. Pompē can be used as a building block in some of these blockchains.

Social choice theory. Social choice theory studies desirable properties in the context of elections. A seminal work in this area is by Kenneth Arrow [7], who won the Nobel Prize in Economics Sciences in 1972 for this work. Arrow’s work defines properties such as *non-dictatorship* and *unanimity*, which inspired our definitions of Byzantine oligarchy and ordering unanimity. Following Arrow’s work, Gibbard and Satterthwaite defined the *manipulation* property and proved that any voting rule is either dictatorial or manipulable [29, 61]. This property inspired our definition of Byzantine democracy. Finally, in the past two decades, computer scientists became interested in social choice theory, leading to the creation of the field of computational social choice [11].

8 Discussion

Deployment models. Section 4 describes our protocol in a simplified deployment model centered on nodes, without explicitly mentioning clients, for ease of exposition. This is a reasonable model in the context of our target application of permissioned blockchains, where each node is owned and operated by a separate organization: we can expect clients that belong to an organization to submit their transactions to a node owned by the same organization (so the incentives of clients and nodes are aligned). This deployment model also increases the opportunity for batching in the ordering phase at each node on behalf of all clients in the same organization.

Nevertheless, other deployment models are possible (e.g., those involving clients explicitly without associating them with trusted organizational nodes). Pompē’s separation of ordering from consensus makes the following possible: each client executes the ordering phase with nodes for its commands and nodes execute the consensus phase. The protocol does have to account for the revised client/node communication pattern in the calculation of the delay (previously, Δ) in the consensus phase to ensure liveness, as well as handling duplicate requests from clients to different nodes to ensure that one of the nodes is correct and will accept the request.

Powerful network adversaries. Our network model assumes partial synchrony (as do prior BFT protocols). This does not eliminate a network-level adversary from affecting the assigned timestamps of commands. For example, a

powerful adversary that controls the entire network connecting honest nodes can selectively reorder or delay messages among honest nodes to bias timestamps assigned to commands. Unfortunately, it appears impossible to completely curb the influence of such powerful network adversaries.

Another commonly adopted network-adversary model [51] assumes that an adversary cannot influence the network connecting correct nodes. In this model, an adversary does not gain additional power in biasing the assigned timestamps beyond what Byzantine nodes could already do.

Command dependencies or replay protection. As in prior BFT protocols, Pompē does not consider dependencies among different commands, nor does it prevent the same command from appearing multiple times in the total order. However, one can embed additional metadata inside commands (e.g., nonces, explicit dependencies, etc.), which correct nodes can use at the time of execution (i.e., after Pompē’s consensus phase outputs a total order) to enforce dependencies among commands or to defend against replay attacks.

9 Concluding remarks

Pompē is a new, practical, and surprisingly simple BFT protocol that demonstrates an ideal world of Byzantine democracy, where free will is respected, under the “constitution” of ordering linearizability, and is not subject to Byzantine oligarchy. And this ideal world has been shown to operate competitively against the traditional world with Byzantine dictatorship.

Pompē’s source code along with instructions to reproduce our experimental results will be available from: <https://github.com/pompe-org>.

Acknowledgments

We thank Frans Kaashoek (our shepherd) and the anonymous OSDI reviewers for their thorough and insightful comments. Trevor Eberl, Jim Jernigan, and Kris Zentner offered timely help with setting up a large-scale cluster on Azure. The initial steps towards a theory of Byzantine ordered consensus benefited from early conversations with Florian Suri-Payer and Mahimna Kelkar, and the help of Mao-fan Yin was invaluable in making it possible to use HotStuff as one of our baselines. This work was supported in part by NSF grants CSR-17620155 and CNS-CORE 2008667.

From Global to Local Quiescence: Wait-Free Code Patching of Multi-Threaded Processes

Abstract

Live patching has become a common technique to keep long-running system services secure and up-to-date without causing downtimes during patch application. However, to safely apply a patch, existing live-update methods require the entire process to enter a state of quiescence, which can be highly disruptive for multi-threaded programs: Having to halt all threads (e.g., at a global barrier) for patching not only hampers quality of service, but can also be tremendously difficult to implement correctly without causing deadlocks or other synchronization issues.

In this paper, we present WFPATCH, a wait-free approach to inject code changes into running multi-threaded programs. Instead of having to stop the world before applying a patch, WFPATCH can gradually apply it to each thread individually at a local point of quiescence, while all other threads can make uninterrupted progress.

We have implemented WFPATCH as a kernel service and user-space library for Linux 5.1 and evaluated it with OpenLDAP, Apache, Memcached, Samba, Node.js, and MariaDB on Debian 10 (“buster”). In total, we successfully applied 33 different binary patches into running programs while they were actively servicing requests; 15 patches had a CVE number or were other critical updates. Applying a patch with WFPATCH did not lead to any noticeable increase in request latencies – even under high load – while applying the same patch after reaching global quiescence increases tail latencies by a factor of up to $41\times$ for MariaDB.

1 Introduction

The internet has become a hostile place for always-online systems: Whenever a new vulnerability is disclosed, the respective fixes need to be applied as quickly as possible to prevent the danger of a successful attack. However, it is not viable for all systems to just restart them whenever a patch becomes available, as the update-induced downtimes become too expensive. The prime example for this are operating-system

updates, where rebooting can take minutes. However, we increasingly see similar issues with system services at the application level: For example, if we want to update and restart an in-memory database, like SAP HANA or, at smaller scale, an instance of *Memcached* [11] or *Redis* [32], we either have to persist and reload their large volatile state or we will provoke a warm-up phase with decreased performance [26]. With the advent of nonvolatile memory [24], these issues will become even more widespread as process lifetimes increase [19] and eventually even span OS reboots [35]. In general, downtimes pose a threat to the service-level agreement as they provoke request rerouting and increase the long-tail latency.

A possible solution to the update–restart problem is dynamic software updating through live patching, where the patch is directly applied, in binary form, into the address space of the running process. However, live patching can also cause unacceptable service disruptions, as it commonly requires the entire process to become quiescent: Before applying the patch, we have to ensure that a safe state is reached (e.g., no call frame of the patched function f exists on any call stack during patching), which usually involves a global barrier over all threads – with long and potentially unbounded blocking time. In programs with inter-thread dependencies it is, moreover, tremendously difficult to implement such a barrier without risking deadlocks. To circumvent this, some approaches (such as UpStart [22]) also allow patching active functions, which involves expensive state transformation during patch application. Others (like KSplice [3]) probe actively until the system is in a safe state, which, however, is unbounded and may never be reached. Moreover, even in these cases it is necessary to halt all threads during the patch application. DynAMOS [23] and kGraft [29] avoid this at the cost of additional indirection handlers, but are currently restricted to the kernel itself as they rely on supervisor mechanisms. So, while disruption-free OS live patching is already available, live patching of multi-threaded user-space servers with potentially hundreds of threads is still an unsolved problem.

In a Nutshell We present WFPATCH, a wait-free live patching mechanism for multi-threaded programs. The fundamen-

tal difference of WFPATCH is that we do not depend on a safe state of *global quiescence* (which may never be reached) before applying a patch to the whole process, but instead can gradually apply it to each thread at a thread-specific point of *local quiescence*. Thereby, (1) no thread is ever halted, (2) a single hanging thread cannot delay or even prevent patching of all other threads, and (3) the implementation is simplified as quiescence becomes a (composable) property of the individual thread instead of their full orchestration. Technically, we install the patch in the background into an additional *address space* (AS). This AS remains in the same process and shares all memory except for the regions affected by the patch – which then is applied by switching a thread’s AS.

A current limitation of WFPATCH is that we can only patch read-only regions (.text and .rodata). In particular, we cannot apply patches that change the layout of data structures or global variables. However, WFPATCH is intended for hot patching and not for arbitrary software updates and the vast majority of software fixes are .text-only: In our evaluation with OpenLDAP, Apache, Memcached, Samba, Node.js, and MariaDB, this holds for 90 out of 104 patches (87%). For CVE mitigations and other critical issues, it holds for 36 out of 41 patches (88%).

This paper makes the following contributions:

- We analyze the qualitative and quantitative aspects of global quiescence for hot patching and suggest local quiescence as an alternative (Section 2, Section 4).
- We present the WFPATCH wait-free code-injection approach for multi-threaded applications and its implementation for Linux (Section 3).
- We demonstrate and evaluate the applicability of WFPATCH with six multi-threaded server programs (OpenLDAP, Apache, Memcached, Samba, Node.js, and MariaDB), to which we apply patches under heavy load (Section 4).

The patching procedure itself is out of scope for this paper, specifically, how binary patches are generated and what kind of transformations take place when applying them to an AS. Without loss of generality, we used a slightly modified version of Kpatch [30] to generate the binary patches for this paper. However, WFPATCH is mostly transparent in this regard and could be combined with any patch generation framework. We discuss its general applicability, the soundness and limitations and other properties of WFPATCH in Section 5 and related work in Section 6 before we conclude the paper in Section 7.

2 Problem Analysis: Quiescence

Most live-patching methods require the whole system to be in a safe state before the binary patch gets applied. Thereby, situations are avoided where the process still holds a reference to memory that is modified by the update. For example, for a

Figure 1: Problems of Global Quiescence. As all threads have to synchronize at the global-quiescence barrier, problems in individual threads can prolong the transition phase: (1) Long-running computations introduce bounded delays, (2) I/O wait leads to (potentially) unbounded barrier-wait times, and (3) inter-thread dependencies force a specific arrival order to avoid deadlocks.

patch that replaces a function f , the system is in a safe state if no call frame for f exists on the execution stack (denoted as *activation safety* in the literature [16]). Otherwise, it could happen that a child of f returns to a now-altered code segment and provokes a crash. While defining and reaching safe states is relatively easy for single-threaded programs, it is much harder for multi-threaded programs, like operating systems or network services.

In general, a safe state of a running process is a predicate Ψ_{proc} over its dynamic state S . For a multi-threaded process, we can decompose this predicate into multiple predicates, one per thread ($\text{th1}, \text{th2}, \dots$), and the whole process is patchable iff all of its threads are patchable at the same time:

$$\Psi_{\text{proc}}(S) \Leftrightarrow \Psi_{\text{th1}}(S) \wedge \Psi_{\text{th2}}(S) \dots$$

One possibility to bring a process into the safe state is to use *global quiescence* and insert *quiescence points* into the control flow: When a thread visits a quiescence point its Ψ_{thN} is true and we let the thread block at a barrier to keep the thread in this patchable state. One after another, all threads visit a quiescence point, get blocked at the barrier, and we eventually reach Ψ_{proc} after all threads have arrived. In this stopped world, we can apply all kinds of code patching and object translations [17, 15] as we have a consistent view on the memory.

However, *global quiescence* is problematic as it can take – depending on the system’s complexity – a long or even *unbounded* amount of time to reach. Furthermore, eager blocking at quiescence points can result in deadlocks: If the progress of thread A depends on the progress of thread B, thread B must pass by its quiescence points until thread A has reached $\Psi_A(S)$. Even worse, in an arbitrary program, it is possible that $\Psi_C(S)$ and $\Psi_D(S)$ contradict each other such

that $\Psi_{\text{proc}}(S)$ can never be reached. Therefore, programmers need an in-depth understanding of the system to apply global quiescence without introducing deadlocks, and they must take special precautions to ensure that it is reachable eventually.

Figure 1 illustrates these problems. For example, if any thread in the system is performing a long-running computation when the patch request arrives, that is, *Problem 1*, the others will reach the barrier, which is now activated, one by one and stop doing useful work. During this transition-period clients will notice significant delays in response times and requests will queue-up or even time out. We have seen this problem in most of the systems that we examined. For example, Node.js threads perform long-running just-in-time compilation of Javascript code.

Similarly, in *Problem 2*, a thread is waiting on an IO operation. During this potentially unbounded period, other threads will reach the barrier. Again, the overall progress rate deteriorates before it becomes zero during the patching itself. This happens, for instance, when the Apache web server is transferring huge files to a client or executing a long-running PHP script. In an extreme case, the system could even have a thread that is waiting for interactive user input that never comes. Both problems are hard to avoid without changing the complete software structure by the programmer who has to insert quiescence points. Sometimes I/O operations can be quiescence points, but this is application-specific; for example, an I/O operation deep in the call stack or with locks held would be no suitable point for quiescence.

Problem 3 is more subtle and related to inter-thread dependencies. In MariaDB, for instance, worker threads perform database transactions and, thus, have to be synchronized. If a thread that is holding a lock reaches the barrier and blocks, a deadlock will occur if another thread tries to acquire that lock. In this case, the second thread would block and never reach the barrier to free the lock-holding thread. Therefore, a lock-holding thread must not enter the barrier, although its $\Psi_{\text{thN}}(S)$ is true, to avoid the cyclic-wait situation between barrier and lock. More generally speaking, applying global quiescence correctly requires full knowledge about *all* inter-thread dependencies where one thread's progress depends on another thread's progress.

In this paper, we mitigate the aforementioned problems by proposing the concept of local quiescence. Our main contribution is the concept of address-space generations, that is, slightly differing views of an AS that can be assigned on a per-thread basis. This makes it possible to prepare a patch in the background in a new AS and to migrate threads one-by-one to the patched universe. A global barrier is not needed. The approach is “wait-free” in the sense that a thread that has reached a quiescence point ($\Psi_{\text{thN}}(S)$ is true) can be patched immediately. Sections 4.2 and 5 discuss how this approach and its limitations apply to widely-used software projects.

Figure 2 illustrates the difference between the normal “global quiescence” approach (upper half) and the proposed

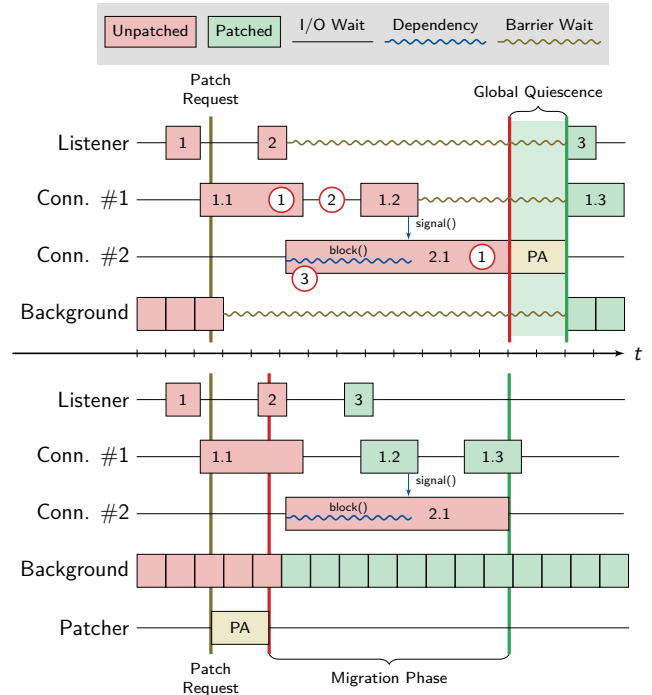

Figure 2: Live Patching a Multi-Threaded Server with Global (upper half) vs. Local (lower half) Quiescence. The global quiescence approach suffers from Problem 1–3 (see Figure 1) while the threads with the local quiescence model can be migrated to the patched state individually.

“local quiescence” (lower half). The scenario is a database server with a “Listener” thread for accepting connections, connection threads (“Conn. #1 and #2”) for each client connection, and a “Background” thread for cleanup activities. The patch request comes in asynchronously while the listener is accepting the second connection. At this point in time “Conn. #1” has already started a transaction and is holding a lock. In the upper half (global quiescence) we find all three problems again. For example, the computation time of 1.1 and 2.1 as well as the I/O wait between 1.1 and 1.2 delay the patch application. During this period, the listener does not accept any new connections (request 3) and the background thread is blocked. Furthermore, the programmer must make sure that “Conn. #1” does not block at the barrier before executing 1.2 and releasing the transaction lock, as this would lead the whole system into a deadlock. With local quiescence, each thread can be migrated to the patched program version individually. Thus, no artificial delays are introduced and the quality of service is unaffected. For all but one thread the patch is applied earlier than in the global quiescence case. These seconds might be crucial in the case of an active security attack. Furthermore, deadlocks cannot occur as long as the patched version of the code releases the transaction lock.

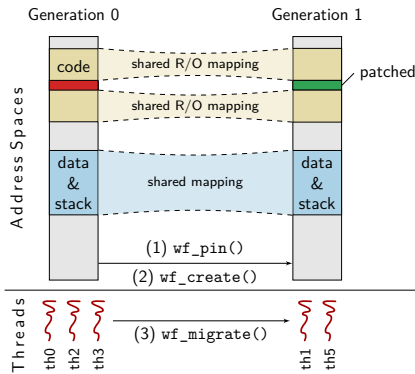

Figure 3: Process during the Wait-Free Patching

3 The WFPATCH Approach

Most previous live-patching mechanisms require a global safe state before applying the changes to the *address space* (AS) of the process. With our approach (see Figure 3), we reverse and weaken this precondition with the help of the OS and a user-space library: Instead of modifying the currently-used AS, we create a (shallow) clone AS inside the same process, apply the modifications there in the background, and migrate one thread at a time to the new AS, whenever they reach a local quiescence point, where their Ψ_{thN} becomes true. In the migration phase, we require no barrier synchronization and all threads make continuous progress. After the migration is complete, we can safely drop the old AS.

While both AS generations exist, we synchronize memory changes efficiently by sharing all unmodified mappings between old AS (Generation 0) and the new AS (Generation 1): We duplicate the *memory-management unit* (MMU) configuration but reference the same physical pages. Thereby, all memory writes are instantaneously visible in both ASs and even atomic instructions work as expected. Only for patch-affected pages, we untie the sharing lazily with existing *copy on write* (COW) mechanisms.

3.1 System Interface

As WFPATCH requires a kernel extension for handling multiple AS generations per process, we introduce four new system calls: `wf_create()`, `wf_delete()`, `wf_pin()`, and `wf_migrate()`. By the integration into the kernel, we are able to modify the AS without halting the whole process.

With `wf_create()`, the kernel instantiates a new AS generation which is a clone of the process’s current AS. Any thread, even from a signal handler, can invoke `wf_create()`. AS generations are identified by a numeric ID and can be deleted with the `wf_delete()` system call. We keep AS generations in sync and changes to the AS are equally performed on all generations.

With `wf_pin()`, we can configure, in advance, memory regions that are not shared between AS generations. Within pinned regions, memory writes and page-protection changes will only affect the AS generation of the current thread. Thereby, we are able to have AS generations that differ only in patched pages.

On creation, new AS generations host no threads, but individual threads migrate explicitly by calling `wf_migrate(AS)`. On migration, the kernel modifies the *thread control block* (TCB) to use the patched AS, and the thread continues immediately once the system-call returns. For live patching, threads invoke `wf_migrate()`, via our user-space library, at their local-quiescence points.

3.2 Implementation for Linux

We implemented the WFPATCH kernel extension as a patch with 2000 (added or changed) lines for Linux 5.1. We tested and evaluated WFPATCH on the AMD64 architecture but it should work on every MMU-capable architecture supported by Linux. The basic idea is to clone address spaces in a fork-like manner and rely mostly on the page-sharing mechanism to keep clones lightweight and efficient. In contrast to fork, we do not apply COW, and we synchronize mapping changes between the generations.

The Linux virtual-memory subsystem manages ASs in two layers: The lower layer is hardware dependent and consists of page directories and tables, which have on AMD64 up to 5 (sparsely-populated) indirection levels. On top of this, *virtual memory allocations* (VMAs) group together the non-connected pages into continuous ranges. VMAs contain information for the page-fault handler (e.g. file backing), swapping, and access control. Together, page directories and the list of VMAs, are kept in the *memory map* (MM), which is attached to a *thread control block* (TCB).

While Linux normally has a one-to-one relation between MM and process, we discard this convention and let threads in the same process have different MMs, which are *siblings* of each other. Each AS generation has its own distinct MM, which we keep synchronized with its siblings.

Besides adding a list of all existing siblings to the process, we extended each MM to include a reference to a *master MM*. We use this master MM, which is the process’s initial MM and its very first generation, to keep track of all shared memory pages. Furthermore, we use the master MM as a fallback for lazily-instantiated page ranges. Therefore, the master persists until the process exits. It cannot be deleted before, even if no thread currently executes in this generation.

When the user calls `wf_pin()` on a memory region, we mark underlying VMAs as non-shared between generations. We allow pinning only on the granularity of whole VMAs and before the first call to `wf_create()`, when the master MM is the only MM in the process.

On `wf_create()`, we duplicate the calling thread’s MM

similar to the `fork()` system call when it creates a new child process: For each VMA of the MM, we copy it and its associated page directories to the newly created sibling MM, while all user-pages are physically shared between generations. While `fork()` marks all user pages as COW, we use COW only for pinned VMAs, while most VMAs behave as shared memory regions, which results in the automatic synchronization of user data between generations. By using Linux's COW mechanism for the pinned regions, we are able to lazily duplicate only those physical pages that are actually modified by the patch. After duplication, we select a new generation ID and insert the MM into the process's sibling list.

When a thread calls `wf_migrate()`, we modify its TCB to point to the respective sibling MM. When the thread returns from the system call, it automatically continues its execution in the selected AS generation. Furthermore, each thread that inhabits a generation increases the reference count of the generation by one. Thereby, we ensure that a generation keeps existing as long as threads execute in this address space, even after the user has instructed us to remove the generation (by calling `wf_delete()`). Only after the last thread leaves a deleted generation, we remove the MM and its page directories.

While the system call interface of WFPATCH is straightforward to implement, its integration with other system calls and the page fault handler requires special attention: As some system calls (e.g., `mmap()`, `mprotect()`, or `munmap()`), change a process's AS, we modified these system calls to apply their effects, as long as they touch shared VMAs, not only to the currently active MM but also to all siblings. However, modifying the protection bits for regions in pinned mappings (via `mprotect()`) affects the current MM only.

We also had to modify the page-fault handler, as Linux allows VMAs and the underlying page directory to become out of sync. For example, within a newly-created anonymous VMA, no pages are mapped in the page directory, but they are lazily allocated and mapped by the page-fault handler. By having multiple sibling MMs, we have to make such lazy page loads visible in all generations, when they happen in a shared VMA. We accomplish this by updating not only the current page directory, but also the page directory of the master MM. Upon page faults, we first search the master MM for lazily loaded pages, before allocating a new page.

In order to avoid race conditions between concurrent system calls that modify a process's AS, we use the master MM as a read-write lock that protects all siblings at once. Normally, the MM linked in the TCB is used for this synchronization, but this is insufficient for WFPATCH to synchronize concurrent accesses. Therefore, we decided to use the master MM as a locking proxy and automatically replaced all MM locks with equivalent lock calls to the master MM by using a Coccinelle [27, 28] script. This replacement alone is responsible for 700 of the 2000 lines of changed source code. For

processes that do not have multiple generations, this locking strategy imposes no further overhead as the initial MM is the master MM.

In case a process with multiple AS generations invokes `fork()`, we clone solely the calling thread's currently active generation and make it the only generation in the AS of the child process. This is sufficient, as `fork()` only copies the currently active thread to the newly created process. In order to maintain COW semantics between the forked AS and all generations of the original AS, we have to mark the appropriate page-table entries of all generations as COW pages (i.e. set the read-only flag) – not only the entries of the two directly involved MMs, as we normally would do. This poses a small overhead when forking processes with multiple generations.

When a COW page gets resolved in an AS with multiple generations, we must ensure that the newly copied page replaces the old shared page in all generations, not just in the current one. Therefore, the page fault handler removes the corresponding page-table entry in all generations and maps the new page into the master MM. The master MM fallback mechanism will fill the siblings' page-table entries again (with the copied page) in case of a page fault.

As the AS generations are technically distinct MMs, the migration of a thread to a new AS generation is treated like a context switch between processes. Each generation gets its own *address-space identifier (ASID)* on the processor. Thus, there is no need for a TLB shutdown on AS migrations. Of course, a TLB shutdown (for all generations) is still necessary if access rights become more restricted.

While our kernel extension is a robust prototype, several features are still missing (e.g., `userfaultfd`, a mechanism to handle page faults in user space) and some are not extensively tested (e.g., swapping, NUMA memory migration, memory compaction). However, for none of these features, we see any fundamental problem that would conflict with our approach or cause a significant deterioration in the performance of the overall system after adding full support.

3.3 User-Space Library

Our proposed system interface (see Section 3.1) allows a process to create new AS generations, to migrate individual threads, and to delete old generations. In order to utilize this system-call interface for live patching with local quiescence, we built a user-space library around this system-call interface. In the following, we will describe its API as well as its usage in a multi-threaded server with one thread per connection (see Figure 4).

At start, the user initializes and configures our library with `wf_init()`: With `track_threads`, she promises to signal the birth and death of threads such that our library can keep track of all currently active threads and delete old AS generations after the last thread has migrated away. Alternatively, the user can configure a callback that returns the current number

```

int main(void) {
    wf_config_t config = {
        .track_threads = 1,
        .on_migration_start=&f,
    };
    wf_init(config);
    wf_thread_birth();
    signal(RTMIN, sigpatch);
    ...
    while (true) {
        int c = accept();
        spawn_worker(c);
        wf_quiescence();
    }
}

void worker(int fd) {
    wf_thread_birth();
    while (!done) {
        x = read(fd);
        work(x);
        wf_quiescence();
    }
    wf_thread_death();
}

void sigpatch(int) {
    char *p;
    p = find_patch();
    wf_load_patch(p);
}

```

Figure 4: Usage of our User-Space Library

of threads. Furthermore, the user can install other callbacks that we invoke at certain points of the migration cycle. In the example, we invoke `f()` when the new AS is ready for migration and, thereby, give the user the possibility to trigger blocked threads in order to speed up the migration phase. With the initialization, the library starts the patcher thread, which pins the text segment, creates new AS generations, and orchestrates the migration phase.

As initiation of live updates and the location of patch files is application specific, we leave this to the user application and only provide a library interface to start the patching application (`wf_load_patch()`). This function instructs the patcher thread to load a binary patch from the file system and apply it in a new AS generation. In our current implementation, `wf_load_patch()` supports ELF-format patches created by Kpatch [30]. These patches are loaded, relocated, and all contained functions are installed in the cloned text segment via unconditional jumps at the original symbol addresses. Furthermore, all references within the patch to unmodified functions, global variables, and shared-library functions are resolved dynamically. Afterwards, the patcher marks the new AS as ready for migration and sleeps until all thread have migrated.

At the thread-local quiescence points, the user has to call `wf_quiescence()` periodically, which checks if a new AS generation is available and ready for migration. If so, the library calls `wf_migrate()` in the context of the current thread and increases the number of migrated threads. After all threads have migrated, the patcher thread is woken, deletes the old AS generation and ends the migration phase.

4 Evaluation

We evaluate WFPATCH with six production-quality infrastructure services on a Linux 5.1 kernel running the Debian 10 Linux distribution (codename “buster”, released on 2019-07-10). Table 1 provides a brief overview of the respective Debian packages for OpenLDAP, Apache HTTPD, Memcached, Samba, Node.js, and MariaDB. We use the initial Debian 10

packages and prepare the server executables for dynamic patching with global and local quiescence (Section 4.1). Our goal is to apply all patches published by the Debian maintainers until 2020-05-09 for these binaries with our approach (Section 4.2). This situation mimics a system administrator who maintains a long-running server running one of these services.

For quantitative evaluation, we measure and compare the service latency while applying a binary patch with global and local quiescence (Section 4.3), respectively, as well as the memory and run-time overheads caused by WFPATCH (Section 4.4).

4.1 Implementation of Quiescence

As outlined in Section 2, implementing global quiescence in a complex multi-threaded program can be a difficult undertaking causing three problems in general: Long-running computations (Problem 1) and waiting for I/O (Problem 2) prolong the transition period, which results in deteriorating service quality, while inter-thread dependencies necessitate stopping the threads in an application-specific order to avoid deadlocks (Problem 3). In the following, we describe how we encountered these three problems in our evaluation targets and how they manifest in their structure and fundamental design decisions. Besides the steps we had to take in order to achieve global quiescence, we also describe how we can reach local quiescence for each of the projects we evaluated.

OpenLDAP The OpenLDAP server (`slapd`) uses a listener thread that accepts new connections and dispatches requests as work packages to a thread pool of variable, but limited size (≤ 16 threads). Each work package is processed by a single worker thread, which alternates between computation and blocking I/O until the request is answered.

For global quiescence, we submit a special task to the thread pool. The executing worker pauses all other workers with the built-in pause-pool API, which can only be called from a worker context, and visits a quiescence point on behalf all worker threads. Since the listener thread waits indefinitely for new connections, we need to introduce an artificial timeout (1 second) to provoke quiescence points periodically. For *local* quiescence, we only introduce a quiescence point before the listener waits for a new connection and after a worker thread completes a task.

As worker threads execute client requests as a single task without visiting a quiescence point, complex requests (problem 1), slow client connections (problem 2), and large result sets (problem 2) prolong the barrier-wait time.

Apache The default configuration of the Apache web server (`httpd`) uses the built-in multi-processing module `event`, which implements one dedicated listener thread and a configurable number of worker threads (default: 25). That listener thread handles all new connections, all idle network sockets, and all network sockets whose write buffers are full to

avoid blocking of the worker threads. In its main loop, the listener thread periodically checks for activity on the listening, idle, and full network sockets by using the Linux system call `epoll()` with a timeout of up to 30 seconds, which can cause Problem 2. Once a network socket becomes active, the listener thread unblocks the next free worker thread to serve that socket.

We introduce one quiescence point into each main loop of the listener and worker threads. For global quiescence, however, we have to make sure that the listener thread enters global quiescence after all worker threads have done. Otherwise, some worker threads may block indefinitely because the listener thread cannot unblock them anymore (Problem 3). When returning from global quiescence, the listener's timeout queue needs to be fixed manually to account for the elapsed time spent in global quiescence.

Implementing *local* quiescence in Apache is straightforward by just introducing the same quiescence points without bothering about deadlocks nor timeouts.

Memcached Memcached is event-driven and uses 10 threads in the default configuration: Four worker threads wait for network requests and the completion of asynchronous I/O tasks. One listener thread accepts new connections and wakes up at least every second to update a timestamp variable. Both the workers and the listener use `libevent` to orchestrate event processing. Furthermore, three background threads wait on a condition variable, while two other threads use `sleep()` to wake up periodically with a maximal period of one second.

For global quiescence, we use a built-in notify mechanism to wake up the all workers immediately, even if they are blocking in `libevent`. For the listener thread, we have to use `event_base_loopbreak()` to interrupt the event-processing loop. Unfortunately, this only sets a flag that the listener checks within the aforementioned one-second period. Furthermore, we have to signal the three condition variables to wake up the associated maintenance threads, as they would block indefinitely otherwise. The two sleeping threads will, eventually, reach the quiescence point, but waking them is not necessary to avoid deadlocks. For *local* quiescence, we use the same quiescence points and the same wake-up strategy as for global quiescence.

While the main operation of Memcached is event-driven and, therefore, the threads do not block on I/O operations, the periodic maintenance threads and the listener thread provoke barrier-wait times of up to one second (Problem 2).

Samba For live patching, Samba's `smbd` was especially challenging as it uses a combination of process-based and thread-based parallelization. For each connection, which can live for hours and days if established by a client mount, the process is forked and uses internally a thread pool to parallelize requests. This thread pool shrinks and grows dynamically with the request load, while idling worker threads retire only after a given timeout (1 second). Technically, these workers wait on a condition variable with a one-second timeout and are

woken when a listener thread enqueues a received request. In order to issue a patch request, the system administrator has to inform all processes to initiate the patching process.

For global quiescence, we have to signal each worker's condition variable. A woken worker checks whether the barrier is active and visits a quiescence point instead of retiring early as an idle worker. For local quiescence, we just inserted quiescence points after the condition wait and after a received network request.

As each request is limited in size, `smbd` only suffers from problem 2 when workers wait for a send operation to complete. However, as the thread pool dynamically grows to up to 100 threads under heavy load, the overall barrier-wait peaks when the server is most intensely used.

Node.js For asynchronous I/O operations, Node.js spawns one thread that executes a `libuv` loop. For computation, Node.js uses one work queue for immediate tasks executed by a variable number (n) of worker threads, and a second queue for delayed tasks, which is serviced by a dedicated thread. Each worker executes tasks sequentially and offloads I/O to the `libuv` thread.

For binary patching, we introduce quiescence points in the I/O thread and after a worker completes a task. For global quiescence, we submit n empty tasks to the immediate work queue and one task to the delayed work queue. For the `libuv` thread, we had to manually signal a semaphore to prevent deadlocks (problem 3). For *local* quiescence, we only submit one task to the delayed work queue and use the same quiescence points otherwise.

As all computation, including the just-in-time compilation, is dispatched via work queues, a long job (problem 1) will increase the barrier-wait time even though the Javascript execution model is inherently event-driven.

MariaDB MariaDB's `mysqld` supports two thread models: one thread per connection, which is the default, or a pool of worker threads. In both cases, a separate listener thread accepts new connections and passes them to connection or worker threads, and a total of 30 helper threads handle off-loaded I/O and housekeeping. We implemented patching support for both thread models.

Judging from its public bug tracker, SQL query evaluation appears to be MariaDB's most error-prone component. We therefore limit the global barrier to threads parsing or executing SQL statements and do not add quiescence points to listener or helper threads. Even so, our global quiescence implementation faces all the three challenges outlined in Section 2.

Slow queries, such as complex `SELECT` or large `INSERT` statements, increase the barrier-wait time as threads perform the computation (problem 1) without visiting a quiescence point. Depending on the query and the size of the database, this can lead to excessive wait times.

In both threading variants, idle threads are cached in anticipation of new work before being retired. In one thread

per connection mode, the hard-coded timeout is five minutes; for the thread pool, it defaults to one minute (problem 2). As barrier-wait times of over a minute are unrealistic for any global-quiescence integration, we utilize preexisting functions to wake up all cached threads for patching. We introduce a new global patch variable to distinguish between a wake up due to a new connection, server shutdown, or patching in one thread per connection mode.

MariaDB supports *SQL transactions*, which are an atomic group of SQL statements whose effects are only visible to other connections after the transaction has completed. As MariaDB serializes transactions which access the same data via locks, threads encounter request- and database-induced dependencies (problem 3). If a thread reaches the barrier while holding a transaction lock, other threads that try to get this lock before their next visit at a quiescence point will deadlock. In one thread per connection mode, we handle this by skipping the barrier if the connection holds a transaction lock. For the thread pool, this does not suffice: as each thread handles several connections, waiting on the barrier is forbidden as long as any open transaction is present.

For *local* quiescence, visiting a quiescence point is possible regardless of the transaction state. Apart from that, we use the same quiescence points and wake-up strategies as for global quiescence.

Global vs. Local Quiescence Summarized, we encountered Problem 1 in three projects (OpenLDAP, Node.js, MariaDB), Problem 2 in four projects (OpenLDAP, Memcached, Samba, MariaDB), and Problem 3 in four projects (OpenLDAP, Apache, Node.js, and MariaDB). While Problem 1 and 2 in combination with global quiescence only affect service quality, Problem 3 forced us to introduce different application-specific dead-lock avoidance techniques into our benchmarks. Thereby, we repeatedly experienced set-backs and spurious deadlocks while navigating the often complex web of existing inter-thread dependencies – achieving global quiescence was the hardest part of our evaluation! In contrast, incorporating WEPATCH was straightforward as we only had to identify the local-quiescence points before patch application could start.

4.2 Binary Patch Generation

To demonstrate the applicability of live patching in running user-space programs, we created a set of binary patches for the aforementioned six network services (see Table 1). For each project, we use the current version that is shipped with Debian 10.0 as a baseline against which we apply patches. In Debian, it is common to select one version of a project for a specific Debian release and have the maintainer backport critical patches onto that version.

For five projects (except MariaDB), we systematically inspected the Debian source package for maintainer-prepared patches that touch the source code of the network service.

Debian patches reflect critical updates that an expert on the service selected for this specific version. Therefore, we consider these patches as a good candidate set for live patches that a system administrator wants to apply. We also review the subset of patches with a CVE entry to get statistics of highly-critical security updates.

For MariaDB, the source package contains no patches: Debian follows MariaDB releases instead of backporting individual patches. Therefore, we processed all commits in the 10.3 branch of the MariaDB repository, starting with the 10.3.15 release shipped with Debian 10.0. Each set of commits that references a single bug tracker entry classified as *Bug* with a severity of at least *Major* related to `mysqld` is a source patch. As the bug tracker does not reference CVE numbers, we use patches with a severity of at least *Critical* instead.

From these source-code patches, we manually select those which only influence the `.text` segment and do not alter data structures or global variables, as such patches are currently out of scope for our mechanism. In Table 1, we see that most patches that are hand-selected by a maintainer are text-only patches; for CVE patches, the correlation is even higher. For MariaDB, where we have a large set of critical patches, 91 percent of the patches exclusively modify the program logic. We therefore conclude that a mechanism which supports live patching with a restriction to code-only changes is nevertheless a useful contribution for keeping running services up to date.

As patch generation, in contrast to patch application, is not among our intended contributions, we use the Kpatch toolchain, which was developed for live-updating the Linux kernel, to prepare binary patches from source code changes. Unfortunately, due to shortcomings in Kpatch, we could not create binary patches for all text-only changes. Especially MariaDB and Node.js, which are implemented in C++, show a low success rate. In the lower half of Table 1 we summarize, over all generated binary patches, the average number of changed object files, modified function bodies, and the size of each patch text segment.

We verified our mechanism by applying each patch into the corresponding service while processing requests. We successfully applied all binary patches generated by Kpatch with our user-space library using thread migration at local quiescence points.

In total, we successfully applied 33 different binary patches including 15 CVE-relevant patches. For OpenLDAP, Apache, and Samba, we were able to apply all generated patches sequentially into the running process. This was not possible for MariaDB because the patches are not applicable to a common base version due to the amount of patches that we could not generate with Kpatch. Making the patches applicable sequentially in MariaDB would have meant to backport them to the initial version, like the Debian maintainers did for the other projects.

		OpenLDAP (slapd)	Apache (httpd)	Memcached	Samba (smbd)	MariaDB* (mysql)	Node.js

All Patches (CVE)	[#]	13 (2)	10 (10)	1 (1)	2 (2)	74 (26)	4 (0)
.text Only (CVE)	[#]	9 (2)	7 (7)	1 (1)	2 (2)	67 (24)	4 (0)
kpatch'able (CVE)	[#]	9 (2)	7 (7)	1 (1)	2 (2)	16 (5)	0 (0)
∅Mod. Files	[#]	1.11	1.71	1	1	1.19	–
∅Mod. Functions	[#]	3.67	13.71	1	5.5	2.94	–
∅Patch Size	[KiB]	13.02	56.94	43.91	9.23	15	–

* For MariaDB, no Debian patches were available and MariaDB maintainers do not relate bugs to CVEs. We instead took patches with severity \geq *Major* from the project's bug tracker as base; numbers in brackets denote patches with severity \geq *Critical*.

Table 1: Evaluation projects and patches (of which CVE-related) since Debian 10.0 release

4.3 Request Latencies

In order to quantify the service quality benefits of local quiescence and incremental thread migration over the barrier method, we perform an end-to-end test for our selected projects. For each project, we define a benchmark scenario and measure the end-to-end request latencies encountered on the client side, while we (a) generate new AS generations and migrate threads, or (b) stop all threads at a global barrier. For this, we extended our user-space library to also support global-quiescence states via the barrier method. We periodically send patch requests to the same process and skip the actual text-segment modification in these tests, while still inducing barrier-wait times on the one side and AS-creation overheads on the other side. Thereby, we achieve a high coverage of different program states at patch-request time, while keeping the comparison fair.

All experiments are conducted on a two machine setup. The server process runs on a 48-core (96 hardware threads) Intel Xeon Gold 6252 machine clocked at 2.10 GHz with 374 GiB of main memory. The clients execute on a 4-core Intel Core i5-6400 machine running at 2.70 GHz with 32 GiB of main memory. Both machines are connected by a Gigabit link in a local-area network.

On the server side, we start the service, wait 3 seconds for the clients to come up and then trigger a local-quiescence migration or global-quiescence barrier sync every 1.5 seconds. By this patch-request spreading, the impact of the barrier method can cool down before the next cycle starts. On the client side, we measure the end-to-end latency of each request. In total, we simulate at least 1000 patch requests for each benchmark.

For OpenLDAP, 200 parallel client connections send LDAP searches that result in 50 user profiles from a database with 1000 records. For Apache, we use ApacheBench to download a 4 MiB sample file 50,000 times using 10 parallel connections; due to the shared Gigabit link, a download takes about 350 ms when no threads are blocked on the global quiescence barrier. For Memcached, 50 client connections request a ran-

dom key from a pool of 1000 cached objects of 64 KiB. For MariaDB, which we operate in the one-thread-per-connection mode, four sysbench oltp_read_only connections continuously perform transactions with five simple SELECT statements, while four background connections – whose latency we do not monitor – execute transactions with 2000 statements. For Node.js, we developed an example web service that encodes a request parameter in a QR-code, wraps it in a PDF, and sends the resulting “ticket” back to the client. We use the wrk tool to simulate 10 parallel clients that repeatedly request a new ticket. For Samba, we mount the exported file system on the client machine (mount.cifs) and use the sysbench fileio benchmark with 32 threads, a block size of 16 KiB, and an R/W ratio of 1.5 to measure file I/O latencies.

Please be aware that these scenarios are chosen as examples to demonstrate the possible impact of barrier synchronization. Resulting latencies are highly dependent on the workload and can be smaller, but also vastly larger in other scenarios. For example, by executing long-running SQL queries on MariaDB or downloading large files from an Apache server, the barrier-wait times, and therefore the latency of the global-quiescence method, can be increased arbitrarily.

Figure 5 shows latency histograms (with logarithmic y axis) for local and global quiescence, as well as the 99.5 response-time percentile. In all benchmarks, we see a significant increase in tail latency which ranges from a factor of $0.97\times$ (Node.js) to $41\times$ for MariaDB. While the results for OpenLDAP, MariaDB, and Samba directly show the latency impact of a global barrier, the other results require explanations. For Memcached, three out of ten threads perform one-second waits, resulting in latencies of up to one second. For Apache, local quiescence shows a narrow latency distribution with the predicted peak at 350 ms while global quiescence shows a broadened distribution. This is due to the benchmark's network-bound nature: the last worker to reach the barrier enjoys the unshared 1 Gigabit link to finish its last request, while all requests arriving after the patch request are impacted by the barrier-wait time. In Node.js, the percentiles

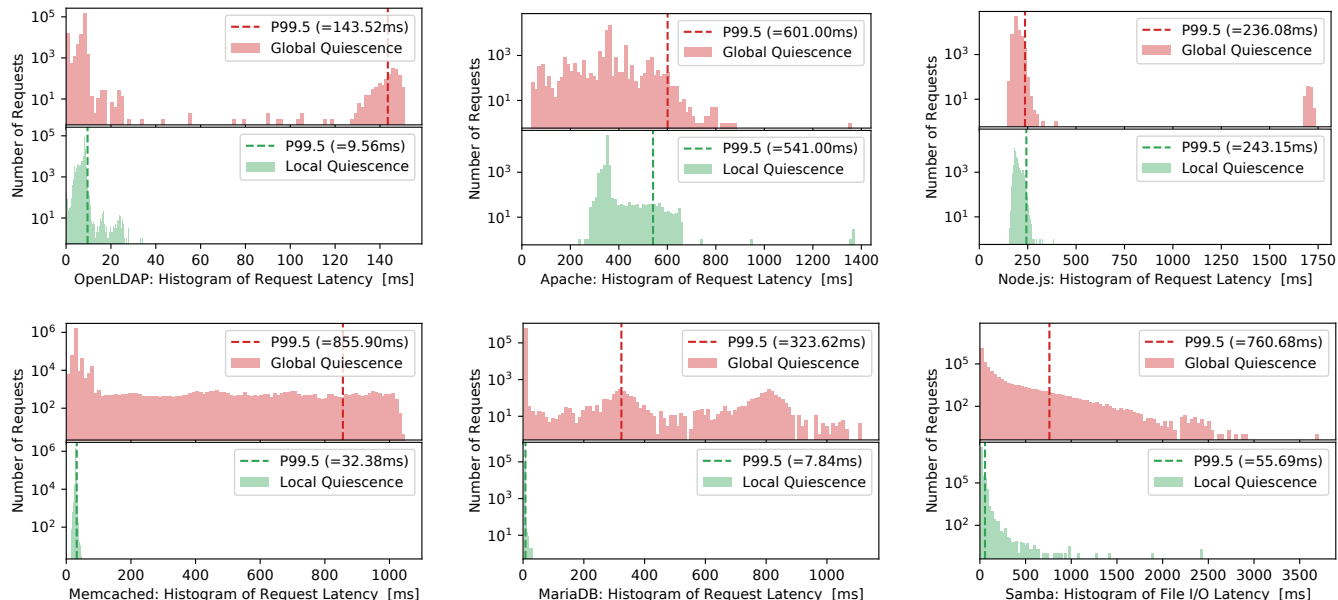

Figure 5: Request Latencies during Live Patching

Figure 6: OpenLDAP Response Rates during Quiescence

are almost equal as the longest encountered barrier-wait time (18 ms) is still shorter than the average request duration’s jitter (193 ± 53 ms). However, we observe individual barrier-wait times of more than 1.5 seconds.

For a deeper understanding of the encountered service quality directly after a patch request, we analyze OpenLDAP responses during 1000 patch requests. We correlate each received response to the previous patch request and plot them according to their relative receive time; zero being the patch request. Figure 6 shows response rate and maximum observed latency. After a patch request, the response rate in the global-quiescence case rapidly decreases, while the latency stays at its normal value. After the workers reach the barrier, no responses are recorded until the listener has reached the barrier. After global quiescence is reached, `slapd` ramps up again and processes the request backlog built up in the meantime. This causes the response rate to spike, but those responses are so late that we see a significant latency increase before the ser-

vice returns to normal operation. With `WFPATCH`, no impact, neither on the response rate nor on the maximum latency, can be observed.

4.4 Memory and Run-Time Overheads

For each patch application, our kernel extension duplicates the MMU configuration, creates a new AS generation, and performs one AS switch per thread in order to migrate it to the new generation. To quantify the impact of these operations, we measure the MMU configuration size and perform run-time micro benchmarks of AS creation and switching times for each server application. We run the benchmarks under load (see Section 4.3) to provoke disturbance and lock contention in the kernel.

We measure the memory overhead caused by duplicate MMU configurations by sequentially applying as many patches as possible. In Table 2, we report the difference in MMU configuration size before and after the patch application. As the other data-structure additions required for our extension are negligible in size, this is the total memory overhead during patch application. Due to the non-deletable master MM (see Section 3.2), this overhead becomes permanent for patched processes: starting with the first additional generation, we carry the load of this additional MM. We do not introduce a memory overhead for processes which do not use AS generations.

For the run-time overhead, we perform two micro benchmarks. (1) The patcher thread creates a new AS generation and immediately destroys it. (2) The patcher thread migrates back and forth between two AS generations (2 switches). We

	Memory [KiB]	Runtime Penalty	
		Create [μs]	Switch [μs]
OpenLDAP	412	298±47	7±7
Apache	680	429±17	7±6
Memcached	132	88±23	7±6
MariaDB	516	1339±38	7±6
Node.js	1808	2171±139	8±7
Samba	256	672±54	5±5

Table 2: Address Space Management Overhead

	Upstream [μs]	WFPATCH [μs]
(a) Anonymous Mapping	0.40±0.12	0.42±0.15
(b) File Mapping	0.50±0.14	0.50±0.15
(c) Read Fault	0.87±0.18	0.87±0.20
(d) Write Fault	1.23±0.29	1.25±0.32
(e) COW Fault	1.79±0.35	1.81±0.39

Table 3: Steady-State Run-Time Overhead

execute each scenario a million times in a tight loop and report, in Table 2, the average operation time alongside its standard deviation. We see that the creation and destruction of AS generations scales with the size of the process’s virtual address space. Only for Samba and MariaDB, the creation overhead is, compared to the MM size, disproportionately higher than for the other four benchmarks. This is caused by a higher number of file-backed VMAs in Samba and MariaDB that take longer to duplicate. The `wf_migrate()` call is a constant-time operation.

In the implementation of our approach, we tried to minimize overhead for applications that do not use WFPATCH. Memory consumption overhead is limited to few additional fields in the thread control block (2 pointers + 2 integer fields), the memory map (3 pointers), and the structure that represents a memory mapping (1 boolean field). In terms of run-time overhead, WFPATCH adds code in two critical places in the kernel: the mapping modification functions and the page-fault handler. In order to assess the run-time impacts, we performed micro benchmarks on our modified kernel and on an upstream kernel with the same version and configuration. To evaluate mapping modifications, we map and unmap either (a) an anonymous memory region or (b) a file mapping and measure the time of the `mmap()` system call. The results do not show a significant difference between the kernels (see Table 3). For page faults, we issue (c) a read operation or (d) a write operation on a previously untouched portion of an anonymous mapping. To also capture (e) copy-on-write resolution, we write to a page that is also mapped by a forked process. Each of the five measurements was repeated 10 million times.

5 Discussion

Benefits of Local Quiescence The main benefit of patching threads individually is the simplified establishment of quiescence and the avoidance of a global barrier that causes a deterioration in performance. Thereby, WFPATCH provides latency hiding for Problem 1 and 2 (Section 4.1) and mitigates Problem 3.

Nevertheless, in the light of the rare event of applying a live patch to an application, the overhead and tail latency of global quiescence may seem negligible. However, the benchmarks presented in Section 4.3 do not necessarily represent a real-world or worst-case scenario: We use a single client machine with a fast, stable, and reliable local network connection to the server. Furthermore, we aimed for a controlled and uniformly distributed load pattern for the sake of reproducibility and in order to fairly compare the relative impact of global vs. local quiescence. In a real-world scenario, connection latencies will vary wildly or may be even under control by an active attacker. As barrier-synchronized global quiescence couples the progress of all threads in the system, it is much more prone to such latency variations – the latency impact is dictated by the slowest (in case of an attacker: stalling) thread to reach the barrier. With WFPATCH and local quiescence, all other threads will not only continue working, but also have the patch applied immediately. Even if a thread stalls forever, the only damage is an AS generation that will never get freed, while the patched server continues to answer requests.

Lightweight AS Generation For the lightweight AS generation, our current implementation copies the whole MM in `wf_create()`, including VMAs and the page directories. This leads to the differing memory and creation overheads that we observed for our benchmark scenarios (Table 2).

While we consider these overheads as reasonable for the purpose, they could nevertheless be reduced further if we implement the different generations to share parts of their page-directory structure. This is possible for shared VMAs, as the underlying page tables always reference the same physical pages. In fact, we currently even pay for not sharing them by extra efforts to keep page tables synchronized among AS generations via the master MM. However, VMAs cover page ranges with arbitrary start/end index, while the page-directory tree covers page ranges on a power-of-two basis, so implementing such sharing is not trivial. To the best of our knowledge, Linux itself does not employ page-table sharing between address spaces, even though this would probably be beneficial for the implementation of the fork system call.

Code Complexity The current implementation of WFPATCH adds a certain amount of complexity to the kernel (see Section 3.2). This stems from its interaction with the already-complex kernel memory-management subsystem. One reason is that Linux targets numerous different architectures and exploits most of their individual capabilities. Secondly, the

kernel itself provides many features and often chooses performance over simplicity (e.g., fine granular page table locking or code duplication in the mapping functions). Apart from that, WFPATCH's complexity is also caused by the tight connection between address spaces and processes in Linux. As the idea of AS generations itself is straightforward, the complexity of our kernel extension could be reduced significantly if we decoupled the two concepts of address spaces and processes in general. That would not only serve our approach, but may even promote other ideas and development [21, 9], such as the decoupling between threads and processes did.

Applicability The general applicability of WFPATCH is potentially limited by (a) the restriction to `.text/.rodata`-patches only and (b) the preparation of the respective target program. With respect to (a) this depends on the intended use case: We consider WFPATCH currently as an approach to apply hot fixes to a server process under heavy load – in order to prolong the time it needs to be restarted until the next maintenance window. For this use case, our results show that the vast majority of patches (87%) are `.text`-only and, therefore, applicable; for critical patches (CVE mitigations) this number is even higher (88%). Regarding (b), the WFPATCH user-space library simplifies the preparation of the target program to support hot patching, but like in other approaches that support multi-threaded applications, it is up to the developer to identify and model the respective safe points to apply a patch. With WFPATCH, however, it becomes significantly easier to find these points as they need to be only locally quiescent. In our evaluation, the hardest part of integrating WFPATCH into the six multi-threaded server programs was the global barrier we needed solely for the comparison between local and global quiescence.

Soundness and Completeness Proving the soundness of a dynamic update is an undecidable problem [14], even though type checking and static analysis can help to mitigate the situation in some cases [1]. With WFPATCH, we have the additional complexity of *incomplete patches*, that is, some threads still execute the old code, while others already use the patched version. This, however, imposes additional correctness issues only if the code change actually influences inter-thread data/control dependencies, such as the implementation of a producer–consumer protocol. In practice, this is a rare situation – none of the analyzed 90 `.text`-only patches fell into this category. Nevertheless, a possible solution in such cases would be to gradually give up the wait-free property by implementing *group quiescence* among the dependent threads, while all other threads can still migrate wait-free at their local quiescence point. Compared to global quiescence, group quiescence would still be less debilitating for overall response time and easier to implement in a deadlock-free manner.

In general, if some thread has not yet passed its point of local quiescence, it is either blocking somewhere in an I/O or still actively processing a request that arrived before the patch was triggered. In both cases, it is at most this one request that

may still be processed using the old version. This would also be the case with global quiescence – only that with global quiescence based on barriers all other threads have to wait (see Figure 6); if global quiescence is determined by probing for a safe state (such as in Ksplice [3]), the other threads continue processing requests using the unpatched version. If the respective thread hangs forever, global quiescence based on barriers would result in a deadlock, while with probing the patch would never get applied. With WFPATCH, the patch will be applied as far as possible: All new requests will be processed with the new code – a server may even be patched while under an active DDOS attack. Technically, an incomplete patch means that the process will stay in two (or even more) ASs forever.

Overall, local and global quiescence make a different trade-off between correctness requirements and ease of patch applicability: While applying patches with global quiescence requires less upfront thought about the correctness of a patch as it provokes no transition period, it may be hard or even impossible to introduce the patch in the system. On the other hand, although it is harder to show that a patch is suitable for local-quiescence patching, finding local-quiescence points is easier and patch application has only minimal impact on the system's operation. We believe that many time-critical updates (e.g., additional security checks) have such a localized impact on the code that the guarantees of local-quiescence patching are sufficient for a large number of changes.

Generalizability For the sake of simplicity, we chose to adapt the Kpatch binary-patch creation for our evaluation and implemented a loader for such patches for user-space programs (Section 3.3). Thereby, we also inherit the limitations of Kpatch regarding granularity and installation of patches: Patches work at the granularity of functions; they are installed by placing a jump at the original symbol address to redirect the control flow to the patched version. This bears some overhead, but is arguably the most widespread technique to apply run-time patches [1, 23, 3, 29, 30, 5, 6]. Furthermore, only quiescent (inactive) functions can be patched. While this limitation is a lot less problematic with WFPATCH due to the fact that quiescence is reduced to local quiescence (inactive in the currently examined thread), it nevertheless prevents patching of top-level functions.

It is important to note, though, that these are restrictions of the employed patching mechanism, not of its wait-free application offered by WFPATCH, which is the main contribution of this work. Integration with more sophisticated patching methods [17, 15, 22] could mitigate these limitations while keeping the WFPATCH benefits. For instance, UpStare can patch active functions by an advanced *stack reconstruction* technique [22]. Hence, it does not require quiescence, but nevertheless has to halt the whole process for patch application and reconstruction of all stacks. In conjunction with WFPATCH, this expensive undertaking could be performed in the background while other threads continue to make progress.

Data Patching While our toolchain already supports the introduction of new data structures and global variables, we currently do not support patches that change existing data-structures or the interpretation of data objects. Such patches are generally difficult [36] as a transform function that migrates the system state to the new representation must be applied to all modified objects in existence. Current live-patching systems rely on the developer to supply these transform functions [17, 15], while language-oriented methods for semi-automated transformer generation exists [20, 18, 25].

With local quiescence, state transfer becomes more difficult as two threads that touch the same data can execute in different patching states. Therefore, an extension to data patches would require bidirectional transform functions that are able to migrate program state back and forth as needed. MMU-based object migration on read and write accesses via page faults can be used to trigger the migration of individual objects between AS generations. Similar mechanisms are used to provide virtual shared memory on message-passing architectures [2]. However, for thread-local state only a uni-directional transform function is required.

Other Applications In a nutshell, WFPATCH provides means for run-time binary modifications in the background, which can then be applied wait-free to individual threads. Besides run-time binary patching, the fundamental mechanism could be useful for many further usage scenarios.

For example, every just-in-time (JIT) compiler has to integrate newer, more optimized versions of functions into the call hierarchy while the program is executing. With WFPATCH, the JIT could prepare complex changes and rearrangements across multiple functions in the background in a new AS generation and then apply them, without stopping user threads, by migrating the benefiting threads incrementally to the updated AS. Furthermore, as our kernel extension supports an arbitrary number of AS generations, the JIT could provide specialized thread-local function variants with the same start address, keeping all function pointers valid.

In a similar manner, an OS kernel could transparently apply path-specific kernel modifications [31] on a per-thread basis. For example, the kernel could use a different IRQ subsystem that is only used if a thread with real-time priority gets interrupted.

AS generations can not only be used to provide a differing code views between threads, but also data views. This can be employed to provide isolation for security and safety purposes. For example, a server application could make encryption keys only be present in a special AS generation; the other generations would have an empty mapping in this place. Even individual threads could live in their own AS generations in order to keep sensible data private but share all the other mappings with their sibling threads. The major benefit compared to using `fork()` with distinct processes is that all mappings are shared by default and modifications to the mapping are implicitly synchronized – the address spaces do not diverge.

Moreover, threads can easily switch back and forth between generations. Litton et al. [21] made a similar suggestion in form of thread-level address spaces, which, however are not synchronized, thus being similar to `fork()` in this respect.

In general, WFPATCH is able to provide classical cross-cutting concerns (debugging, tracing, logging) with a thread-local view of the text segment. For example, a debugger may limit the effect of trace- and breakpoints to the actually debugged threads or use the unoptimized program only during the debugging session. Also, the user could enable tracing, logging, assertions, or behavioral sanitizers (e.g., Clang’s UB-San) for individual threads.

6 Related Work

Dynamic patching of OS kernels has a long history in research [13, 4, 5, 12] and is now actually used in production systems [3, 29, 30]. In contrast, the suggested frameworks to patch user-level processes [20, 25, 6, 22, 17, 15, 12] are still not broadly employed.

The DAS [13] operating system incorporated an early run-time updating solution on module-level granularity. It requires absolute quiescence of a module to be patched, realized by locks. K42 [4] exploits its strict object-oriented design to enable live kernel updates. The event-driven nature with short-lived and non-blocking threads makes it relatively easy to define a safe state for concurrent patching.

The Proteos [12] microkernel provides built-in means for process-level live updates based on automatic state transfer. Like our wait-free patching technique, they employ MMU-based address spaces, but unlike our approach the goal is not a seamless thread-by-thread migration. Instead, the process is halted during the update procedure, while the separate address space provides for an easy rollback.

Most live-patching frameworks work on function-level granularity [1, 23, 3, 29, 30, 5, 6], which can be considered as a natural scope for changes while still providing for relatively fine-grained updates. A patched version of the function is loaded and installed via placing a trampoline jump at the beginning of the old function body (function indirection). Barrier blocking is the classical way to reach global quiescence to safely apply the trampoline. Ksplice [3] avoids this by polling for global quiescence instead: The whole kernel is repeatedly stopped and checked for a safe state before the function indirection gets installed. While this avoids a global barrier, all threads have nevertheless to be halted for the check and to apply the patch. Furthermore, probing is an unbounded operation, so the patch may be applied late or never.

DynAMOS [23] and kGraft [29] also avoid global barriers by extending the function indirection method: By (atomically) placing additional redirection handlers between the trampoline and the jump target, they can decide on a per-call basis which version of a function (original/updated) should be used. This has some similarities to our address-space migration

technique as in both methods the patched and the unpatched universe coexist while the transition is in progress; however, in contrast to our approach, the redirection method induces a performance penalty in this phase. Atomicity is reached by rerouting the call through debug breakpoints during the patch process; on SMP systems this furthermore requires IPIs to all other cores to flush instruction caches. This approach is limited to patching on function granularity and has only been explored for kernel-level patching, whereas WFPATCH targets user-level processes and allows for arbitrary large (or small) in-place binary modifications, which in principle also includes changes to (read-only) data.

LUCOS [5] tries to solve this by requiring the to-be-patched kernel to run inside a modified XEN hypervisor, which is able to atomically install trampoline calls by halting the VM. The virtualization layer is also used to enable page-granularity state synchronization between the different versions of a function. POLUS [6] brings this idea to user space and relies on the underlying operating system (ptrace, signals and mprotect) instead of a hypervisor. Again, all threads are halted while the trampoline gets installed.

Ginseng [25] makes use of source-to-source compilation in order to prepare C programs for dynamic updating. It inserts indirection jumps for every function call and every data access, but does not support multi-threaded programs. Function indirections are also used by many other language-oriented dynamic-variability methods, such as dynamic aspect weaving [7, 10, 34] or function multiverses [33], which, however, do not address quiescence in multi-threaded environments.

Eکیدen [17] and Kitsune [15] provide dynamic updates by replacing the whole executable code and transferring all program state at dedicated *update points*, which constitute points of global quiescence implemented by barriers in the case of multi-threading. UpStare [22] goes one step further by allowing run-time updates at arbitrary program states, enabled by its *stack reconstruction* technique. However, updating multi-threaded programs is also based on halting all threads. The authors even suggest inserting the respective checks in long-lived loops and to avoid blocking I/O.

Duan et al. present a comprehensive solution for patching vulnerable mobile applications on the binary level [8]. However, patching takes place when the program starts and not during later run time.

The idea of decoupling address spaces and processes has also been described before: El Hajj et al. [9] provide freely switchable address spaces in order to enlarge virtual memory and to support persistent long-lived pointers. However, they do not target live patching and their address spaces are intended to be decoupled from each other, whereas WFPATCH provides extra means to synchronize most regions among address space generations.

Litton et al. [21] allow for multiple “light-weight execution contexts” (lwC) per process and the possibility for threads to switch between them. After creation, where the file-descriptor

table and the AS are copied (like fork), lwCs are decoupled entities and can diverge significantly from each other. In contrast, our AS generations offer a gradually differing view of the same AS without decoupling other parts of the execution context (i.e. file-descriptor tables). Thereby, all threads retain a synchronized view of process state, which is necessary for incremental thread migration.

7 Conclusion

WFPATCH provides a wait-free approach to apply live code patches to multi-threaded processes without “stopping the world.” The fundamental principle of WFPATCH is that a code change is not applied to the whole process at once, which requires a state of global quiescence to be reached by all threads simultaneously, but incrementally to each thread individually at a thread-specific state of local quiescence. Hence, (1) no thread is ever halted, (2) a single hanging thread cannot delay or even prevent patching of all other threads, and (3) the implementation gets easier as quiescence becomes a (composable) local property. The incremental migration is provided by means of multiple generations of the virtual address space within the updated process. After preparation of an updated address space, threads switch generations at their local quiescence points, while they are still able to communicate with threads in other generations via shared memory mappings.

We implemented WFPATCH as a Linux 5.1 kernel extension and a user-space library, and evaluated our approach with six major network services, including MariaDB, Apache and Memcached. While live patching at points of global quiescence with a barrier increases the tail-latency of client requests by up to a factor of $41\times$, we could not observe any disruption in service quality when live patches were applied wait-free with WFPATCH. In total, we successfully applied 33 different binary patches into running programs while they were actively servicing requests; 15 patches had a CVE number or were other critical updates.

WFPATCH brings us closer to an ideal live patching solution for multi-threaded applications by solving the response-time issue with a latency hiding patch-application mechanism. This opens further research opportunities on advanced patching techniques.

Acknowledgments

We thank our anonymous reviewers and our shepherd Andrew Baumann for their constructive feedback and the efforts they made to improve this paper. We also thank Lennart Glauer for his work on an early WFPATCH prototype.

Testing Database Engines via Pivoted Query Synthesis

Manuel Rigger Zhendong Su
Department of Computer Science, ETH Zurich

Abstract

Database Management Systems (DBMSs) are used widely, and have been extensively tested by fuzzers, which are successful in finding crash bugs. However, approaches to finding *logic bugs*, such as when a DBMS computes an incorrect result set, have remained mostly untackled. To this end, we devised a novel and general approach that we have termed *Pivoted Query Synthesis*. The core idea of this approach is to automatically generate queries for which we ensure that they fetch a specific, randomly selected row, called the *pivot row*. If the DBMS fails to fetch the pivot row, the likely cause is a bug in the DBMS. We tested our approach on three widely-used and mature DBMSs, namely SQLite, MySQL, and PostgreSQL. In total, we found 121 unique bugs in these DBMSs, 96 of which have been fixed or verified, demonstrating that the approach is highly effective and general. We expect that the wide applicability and simplicity of our approach will enable improving the robustness of many DBMSs.

1 Introduction

Database management systems (DBMSs) based on the relational model [10] are a central component in many applications, since they allow efficiently storing and retrieving data. They have been extensively tested by random query generators such as SQLsmith [45], which have been effective in finding queries that cause the DBMS process to crash (e.g., by causing a buffer overflow). Also fuzzers such as AFL [2] are routinely applied to DBMSs. However, these approaches cannot detect *logic bugs*, which we define as bugs that cause a query to return an incorrect result, for example, by erroneously omitting a row, without crashing the DBMS.

Logic bugs in DBMSs are difficult to detect automatically. A key challenge for automatic testing is to come up with an effective *test oracle*, that can detect whether a system behaves correctly for a given input [21]. In 1998, Slutz proposed to use *differential testing* [33] to detect logic bugs in DBMSs, by constructing a test oracle that compares the results of a

query on multiple DBMSs, which the author implemented in a tool RAGS [46]. While RAGS detected many bugs, differential testing comes with the significant limitation that the systems under test need to implement the same semantics for a given input. All DBMSs support a common and standardized language *Structured Query Language (SQL)* to create, access, and modify data [8]. In practice, however, each DBMS provides a plethora of extensions to this standard and deviates from it in other parts (e.g., in how **NULL** values are handled [46]). This vastly limits differential testing, and also the author stated that the small common core and the differences between different DBMSs were a challenge [46]. Furthermore, even when all DBMSs fetch the same rows, it cannot be ensured that they work correctly, because they might be affected by the same underlying bug.

To efficiently detect logic bugs in DBMSs, we propose a general and principled approach that we termed *Pivoted Query Synthesis (PQS)*, which we implemented in a tool called SQLancer. The core idea is to solve the oracle problem for a single, randomly-selected row, called the *pivot row*, by synthesizing a query whose result set must contain the pivot row. We synthesize the query by randomly generating expressions for **WHERE** and **JOIN** clauses, evaluating the expressions based on the pivot row, and modifying each expression to yield **TRUE**. If the query, when processed by the DBMS, fails to fetch the pivot row, a bug in the DBMS has been detected. We refer to this oracle as the *containment oracle*.

Listing 1 illustrates our approach on a test case that triggered a bug that we found using the containment oracle in the widely-used DBMS SQLite. The **CREATE TABLE** statement creates a new table `t0` with a column `c0`. Subsequently, an index is created and three rows with the values 0, 1, and **NULL** are inserted. We select the pivot row `c0=NULL` and construct the random **WHERE** clause `c0 IS NOT 1`. Since **NULL IS NOT 1** evaluates to **TRUE**, we can directly pass the query to the DBMS, expecting the row with value **NULL** to be contained in the result. However, due to a logic bug in the DBMS, the partial index was used based on the incorrect assumption that `c0 IS NOT 1` implied `c0 NOT NULL`, resulting in the pivot row

Listing 1: Illustrative example, based on a *critical* SQLite bug. The check symbol denotes the expected, correct result, while the bug symbol denotes the actual, incorrect one.

```
CREATE TABLE t0(c0);
CREATE INDEX i0 ON t0(1) WHERE c0 NOT NULL;
INSERT INTO t0(c0) VALUES (0), (1), (NULL);
SELECT c0 FROM t0 WHERE c0 IS NOT 1; -- {0}✖ {0,
NULL}✓
```

not being fetched. We reported this bug to the SQLite developers, who stated that it existed since 2013, classified it as critical and fixed it quickly. Even for this simple query, differential testing would have been ineffective in detecting the bug. The **CREATE TABLE** statement is specific to SQLite, since, unlike other popular DBMSs, such as PostgreSQL and MySQL, SQLite does not require the column `c0` to be assigned a column type. Furthermore, both MySQL’s and PostgreSQL’s **IS NOT** cannot be applied to integers; they only provide an operator **IS DISTINCT FROM**, which provides equivalent functionality. All DBMSs provide an operator **IS NOT TRUE**, which, however, has different semantics; for SQLite, it would fetch only the value 0, and not expose the bug.

To demonstrate the generality of our approach, we implemented it for three popular and widely-used DBMSs, namely SQLite [49], MySQL [36], and PostgreSQL [40]. In total, we found 96 unique bugs, namely 64 bugs in SQLite, 24 bugs in MySQL, and 8 in PostgreSQL, demonstrating that the approach is highly effective and general. 61 of these were logic bugs found by the containment oracle. In addition, we found 32 bugs by causing DBMS-internal errors, such as database corruptions, and for 3 bugs we caused DBMS crashes (*i.e.*, **SEGFaults**). One of the crashes that we reported for MySQL was classified as a security vulnerability (CVE-2019-2879). 78 of the bugs were fixed by the developers, indicating that they considered our bug reports useful.

Since our method is general and applicable to all DBMSs, we expect that it will be widely adopted to detect logic bugs that have so far been overlooked. In fact, after releasing a preprint of the paper, we received a number of requests by companies as well as individual developers indicating their interest in implementing PQS to test the DBMSs that they were developing. Among these, PingCAP publicly released a PQS implementation that they have been successfully using to find bugs in TiDB. For reproducibility and to facilitate further research on this topic, we have released SQLancer at <https://github.com/sqlancer/>. In addition, the artifact associated with the paper contains SQLancer as well as a database of all reported bugs [44]. PQS inspired complementary follow-up work, such as NoREC and TLP, which focus on finding sub-categories of logic bugs [42, 43]. Despite this, PQS has notable limitations; it only partly validates a query’s result, and cannot be used, for example, to test aggregate functions, the size of the result set, or its ordering. Furthermore, the effort required to implement the technique depends on the

complexity of the operations to be tested, which can be high for complex operators or functions.

In summary, we contribute the following:

- A general and highly-effective approach to finding bugs in DBMSs termed *Pivoted Query Synthesis (PQS)*.
- An implementation of PQS in a tool named SQLancer, used to test SQLite, MySQL, and PostgreSQL.
- An evaluation of PQS, which uncovered 96 bugs.

2 Background

This section provides important background information on relational DBMSs, SQL, and the DBMSs we tested.

Database management systems. We primarily aim to test *relational* DBMSs, that is, those that are based on the *relational data model* proposed by Codd [10]. Most widely-used DBMSs, such as Oracle, Microsoft SQL, PostgreSQL, MySQL, and SQLite are based on it. A relation R in this model is a mathematical relation $R \subseteq S_1 \times S_2 \times \dots \times S_n$ where S_1, S_2, \dots, S_n are referred to as domains. More commonly, a relation is referred to as a *table* and a domain is referred to as a *data type*. Each tuple in this relation is referred to as a row. SQL [8], a domain-specific language that is based on relational algebra [11], is the most commonly used language to interact with the DBMSs. ANSI first standardized SQL in 1987, and it has since been developed further. In practice, however, DBMSs lack functionality described by the SQL standard and deviate from it. In this paper, we assume basic familiarity with SQL.

Test oracles. An effective *test oracle* is crucial for automatic testing approaches [21]. A test oracle assesses whether a given test case has passed. Manually written test cases encode the programmer’s knowledge who thus acts as a test oracle. In this work, we are interested only in automatic test oracles, which would allow comprehensively testing a DBMS. The most successful automatic test oracle for DBMSs is based on *differential testing* [46]. Differential testing refers to a technique where a single input is passed to multiple systems that implement the same language to detect mismatching outputs, which would indicate a bug. In the context of DBMSs, the input corresponds to a database as well as a query, and the systems to multiple DBMSs—when their fetched result sets mismatch, a bug in one of the DBMS would be detected. However, SQL dialects vary significantly, making it difficult to use differential testing effectively. This is also acknowledged by industry. For example, Cockroach Labs state that they “*are unable to use Postgres as an oracle because CockroachDB has slightly different semantics and SQL support, and generating queries that execute identically on both is tricky [...]*” [22]. Furthermore, differential testing is not a *precise* oracle, as it fails to detect bugs that affect all the systems.

Table 1: The DBMSs we tested are popular, complex, and have been developed for a long time.

DBMS	Popularity Rank		LOC	Released
	DB-Engines	Stack Overflow		
SQLite	11	4	0.3M	2000
MySQL	2	1	3.8M	1995
PostgreSQL	4	2	1.4M	1996

Tested DBMSs. We focused on three popular and widely-used open-source DBMSs: SQLite, MySQL, and PostgreSQL (see Table 1). According to the DB-Engines Ranking [1] and the Stack Overflow’s annual Developer Survey [38], these DBMSs are among the most popular and widely-used ones. Furthermore, the SQLite website speculates that SQLite is likely used more than all other databases combined; most mobile phones extensively use SQLite, it is used in most popular web browsers, and many embedded systems (such as television sets) [48]. All DBMSs are production-level systems, and have been maintained and developed for about 20 years.

3 Pivoted Query Synthesis

We propose *Pivoted Query Synthesis* as an automatic testing technique for detecting logic bugs in DBMSs. Our core insight is that by considering only a single row at a time, a conceptually-simple test oracle can be created that can effectively detect logic bugs. Specifically, our idea is to select a random row, to which we refer as the pivot row, from a set of tables and views in the database. Subsequently, we randomly generate a set of boolean predicates, which we then modify so that they evaluate to **TRUE** for the values of the pivot row based on an Abstract Syntax Tree (AST) interpreter. By using these expressions in **WHERE** and **JOIN** clauses of an otherwise randomly-generated query, we can ensure that the pivot row must be contained in the result set. If it is not contained, a bug has been found. Basing the approach on an AST interpreter provides us with an exact oracle. While implementing this interpreter requires moderate implementation effort for complex operators (such as regular expression operators), other challenges that a DBMS has to tackle, such as query planning, concurrent access, integrity, and persistence can be disregarded by it. Furthermore, the AST interpreter can be naively implemented without affecting the tool’s performance, since it only operates on a single record, whereas the DBMS has to potentially scan through all the rows of a database to process a query.

3.1 Approach Overview

Figure 1 illustrates the detailed steps of PQS. First, we create a database with one or multiple random tables, which we fill with random data (see step ①). We ensure that each table, and randomly generated view, holds at least one row, to enable selecting a random pivot row in step ②. A pivot row is only conceptually a row, and can be composed of columns that refer to rows of multiple tables and/or views. Its purpose is to use it to derive a test case as well as a test oracle to validate the correctness of the DBMS. The pivot row shown in Figure 1 consists of both columns from table t_0 and t_1 . In the next steps, we proceed by constructing a test oracle based on the pivot row. To this end, we randomly create expressions based on the DBMS’ SQL grammar and valid table column names (see step ③). We evaluate these expressions, substituting column references by the corresponding values of the pivot row. Then, we modify the expressions so that they yield **TRUE** (see step ④). We use these expressions in **WHERE** and/or **JOIN** clauses for a query that we construct (see step ⑤). We pass this query to the DBMS, which returns a result set (see step ⑥), which we expect to contain the pivot row, potentially among other rows. In a final step, we check whether the pivot row is indeed contained in the result set (see step ⑦). If it is not contained, we have likely detected a bug in the DBMS. For the next iteration, we either continue with step ② and generate new queries for a newly-selected pivot row, or continue with ① to generate a new database.

Our core idea is given by how we construct the test oracle (see steps ② to ⑦). Thus, Section 3.2 first explains how we generate queries and check for containment, assuming that the database has already been created. Section 3.3 then explains step ①, namely how we generate the tables and data. Section 3.4 provides important implementation details.

3.2 Query Generation & Checking

The core idea of our approach is to construct a query for which we anticipate that the pivot row is contained in the result set. We randomly generate expressions to be used in **WHERE** and/or **JOIN** clauses of the query, and ensure that each expression evaluates to **TRUE** for the pivot row. This subsection describes how we generate random predicates that we rectify and then use in the query (*i.e.*, steps ③ to ⑤).

Random predicate generation. In step ③, we randomly generate Abstract Syntax Trees (ASTs) up to a specified maximum depth by constructing a random expression tree based on the database’s schema (*i.e.*, the column names and types). For SQLite and MySQL, SQLancer generates expressions of any type, because they provide implicit conversions to boolean. For PostgreSQL, which performs few implicit conversions, the generated root node must produce a boolean value, which we achieve by selecting one of the appropriate operators (*e.g.*, a comparison operator). Algorithm 1 illustrates how generat-

Figure 1: Overview of the approach implemented in SQLancer. Dotted lines indicate that a result is generated.

```

Function generateExpression(int depth):
    node_types ← {LITERAL, COLUMN}
    if depth < maxdepth then
        node_types ← node_types ∪ {UNARY, ...}
    type ← random(node_types)
    switch type do
        case LITERAL do
            return Literal(randomLiteral());
        case COLUMN do
            return Column-
                Value(randomTable().randomColumn());
        case UNARY do
            return
                UnaryNode(generateExpression(depth+1),
                UnaryNode.getRandomOperation());
        case ... do
            ...
    end

```

Algorithm 1: The `generateExpression()` function generates a random AST.

ing the expressions is implemented for MySQL and SQLite. The input parameter `depth` ensures that when a specified maximum depth is reached, a leaf node is generated. The leaf node can either be a randomly-generated constant, or a reference to a column in a table or view. If the maximum depth is not yet reached, also other operators are considered (e.g., a unary operator such as `NOT`). Generating these expressions is dependent on which operators the respective DBMS supports. The random expression generation by itself is not a contribution of this paper; random query generators, such as RAGS [46] and SQLsmith operate similarly [45]. We implemented the expression generators manually for each DBMS under test, based on the respective DBMS SQL dialect’s documentation; as part of future work, we will consider automatically deriving them based on the SQL dialect’s grammar.

Expression evaluation. After building a random expression tree, we must check whether the condition yields `TRUE` for the

pivot row. To this end, every node must provide an `execute()` method that computes the node’s result, which needs to be manually implemented. Leaf nodes directly return their assigned constant value. Column nodes are assigned the value that corresponds to their column in the pivot row. For example, in Figure 1 step ③, the leaf node $t_0.c_1$ returns `TRUE`, and the constant node 3 returns an integer 3. Composite nodes compute their result based on the literals returned by their children. For example, the `NOT` node returns `FALSE`, because its child evaluates to `TRUE` (see Algorithm 2). The node first executes its subexpression, and then casts the result to a boolean; if the result is a boolean value, the value is negated; otherwise `NULL` is returned. Note that our implementation is simpler than AST interpreters for programming languages [50], since all nodes operate on literal values (i.e., they do not need to consider mutable storage). It is also simpler than query engine models, such as the well-known Volcano-style iteration model [16], and widely-used models based on it, such as the vectorized model or the data-centric code generation model, which all need to consider multiple rows [26]. Since the bottleneck of our approach is the DBMS evaluating the queries rather than SQLancer, all operations are implemented naively and do not perform any optimizations. Some operations require moderate implementation effort nevertheless; for example, the implementation of the `LIKE` regular expression operator has over 50 LOC in SQLancer.

Expression rectification. After generating random expressions, step ④ ensures that they evaluate to `TRUE`. SQL is based on a three-valued logic. Thus, when evaluated in a boolean context, an expression either yields `TRUE`, `FALSE`, or `NULL`. To rectify an expression to yield `TRUE`, we use Algorithm 3. For example, in Figure 1 step ④, we modify the expression by adding a preceding `NOT`, so that the expression evaluates to `TRUE`. Note that our approach works also for other logic systems (e.g., four-valued logic), by adjusting this step. Alternatively, it could be checked that the pivot row is ex-

Method NotNode::execute():

```

    value ← child.execute()
    switch asBoolean(value) do
    case TRUE do
    | result ← FALSE
    case FALSE do
    | result ← TRUE
    case NULL do
    | result ← NULL
    end
    return result;

```

Algorithm 2: The execute() implementation of a **NOT** node.

Function rectifyCondition(randexpr):

```

    switch randexpr.execute() do
    case TRUE do
    | result ← randexpr
    case FALSE do
    | result ← NOT randexpr
    case NULL do
    | result ← randexpr ISNULL
    end
    return result;

```

Algorithm 3: The expression rectification step applied to a randomly-generated expression.

pectedly not contained in the result set, by ensuring that the expression evaluates to **FALSE**.

Query generation. In step ⑤, we generate targeted queries that fetch the pivot row. Most importantly, the expressions evaluating to **TRUE** are used in **WHERE** clauses, which restrict which rows a query fetches, and in **JOIN** clauses, which are used to join tables. Since the expressions evaluate to **TRUE**, the pivot row is guaranteed to be contained in the result set. **JOIN** clauses are not treated specially; as we create the clause's predicate to yield **TRUE** for the pivot row, inner, full, left, and right joins all behave in the same way as a **WHERE** clause with respect to the pivot row. **SELECT** statements typically provide various keywords to control the query's behavior, from which we randomly select applicable options. Specifically, we considered the following elements:

- **DISTINCT** clauses, which filter out duplicate rows, while retaining the guarantee that the pivot row is contained in the result set;
- **GROUP BY** clauses that contain all pivot row columns to guarantee that the pivot row is contained in the result set;
- **ORDER BY** clauses, which influence only the order of the result set, which is not validated by PQS;
- aggregate functions, which compute values over multiple rows, when only a single row is present in a table, which allows partially testing them;

- DBMS-specific query options, such as the MySQL-specific **FOR UPDATE** clause, which must not influence the result set.

These additional elements are an optional extension to our core approach, and allowed PQS to find additional bugs by stressing the DBMSs' query optimizer. However, they do not comprehensively test these features.

Checking containment. After using the DBMS to evaluate the query in step ⑥, checking whether the pivot row is part of the result set is the last step of our approach. While the checking routine could have been implemented in SQLancer, we instead construct the query so that it checks for containment, effectively combining steps ⑥ and ⑦. DBMSs provide various operators to check for containment, such as the **IN** and **INTERSECT** operators. For example, for checking containment in Figure 1 step ⑦, we can check whether the row (3, **TRUE**, -5) is contained in the result set using the query shown in Listing 2, which returns a row if the pivot row is contained.

Checking arbitrary expressions. An extension of the initial idea of PQS is to use arbitrary expressions to specify which data to fetch in the query of step ⑤, rather than referring to columns only. For example, rather than referring to `t0.c0`, we might want to check whether `t0.c0 + 1` evaluates correctly. To this end, we can generalize the definition of a pivot row to refer to arbitrary computed values. For example, the pivot row value for `t0.c0 + 1` must be 4, which can be derived based on the expression evaluation mechanism already explained for step ②. In terms of implementation, this thus requires that first the expressions to be used in step ⑤ must be generated, so that they can be evaluated to derive the pivot row values as part of step ②.

3.3 Random State Generation

In step ①, we generate a random database state. Similarly to the generation of queries, we heuristically and iteratively select a number of applicable options. The first step is fixed and consists of creating a number of tables, using the **CREATE TABLE** statement. Subsequent statements are chosen heuristically. Among the applicable options is the **INSERT** statement, which allows inserting data rows. By generating Data Definition Language as well as Data Manipulation Language statements, we can explore a larger space of databases, some of which exposed DBMS bugs. For example, we implemented **UPDATE**, **DELETE**, **ALTER TABLE**, and **CREATE INDEX** commands

Listing 2: Checking containment using the **INTERSECT** operator in SQLite.

```

SELECT (3, TRUE, -5) INTERSECT SELECT t0.c0, t0.c1
, t1.c0 FROM t1, t2 WHERE NOT(NOT(t0.c1 OR (t1
.c0 > 3)));

```

for all databases, as well as DBMS-specific run-time options. A number of commands that we implemented were unique to the respective DBMS. Statements unique to MySQL were `REPAIR TABLE` and `CHECK TABLE`. The statements `DISCARD` and `CREATE STATISTICS` were unique to PostgreSQL. Since the statements are chosen heuristically, the database state generation step might yield an empty database (*e.g.*, because a `DELETE` statement might have deleted all rows, or because a table constraint might make it impossible to insert any rows); in such a case, the current database is discarded and a new database is created. The random database generation is not a contribution of this paper; in fact, many database generation approaches have been proposed, any of which could be paired with PQS [5, 6, 17, 20, 27, 37].

3.4 Important Implementation Details

This section explains implementation decisions, which we consider significant for the outcome of our study.

Error handling. We attempt to generate statements that are correct both syntactically and semantically. However, generating semantically correct statements is sometimes impractical. For example, an `INSERT` might fail when a value already present in a `UNIQUE` column is inserted again; preventing such an error would require scanning every row in the respective table. Rather than checking for such cases, which would involve additional implementation effort and a run-time performance cost, we defined a list of error messages that we might expect when executing the respective statement. Often, we associated an error message to a statement depending on presence or absence of specific keywords; for example, an `INSERT OR IGNORE` is expected to ignore many error messages that would appear without the `OR IGNORE`. If the DBMS returns an expected error, it is ignored. Unexpected errors indicate bugs in the DBMS. For example, in SQLite, a *malformed database disk image* error message is always unexpected, since it indicates the corruption of the database.

Performance. We optimized SQLancer to take advantage of the underlying hardware. We parallelized the system by running each thread on a distinct database, which also resulted in bugs connected to race conditions being found. To fully utilize each CPU, we decreased the probability of SQL statements being generated that cause low CPU utilization (such as `VACUUM` in PostgreSQL). Typically, SQLancer generates 5,000 to 20,000 statements per second, depending on the DBMS under test. Since the DBMSs we tested processed queries much faster than other statements, SQLancer generates 100,000 random queries for each database. We implemented the system in Java. However, any other programming language would have been equally well suited, as the performance bottleneck was the DBMS executing the queries.

Number of rows. We found most bugs by restricting the number of rows inserted to a low value (10–30 rows). A higher

number would have caused queries to time out when tables are joined without a restrictive join clause. For example, in a query `SELECT * FROM t0, t1, t2`, the largest result set for 100 rows in each table would already be $|t0| * |t1| * |t2| = 1,000,000$, significantly lowering the query throughput. A potential concern is that this might prevent PQS from detecting bugs that are triggered only for tables with many rows. We believe that future work could tackle this by generating targeted queries for which the cardinality of the result is bounded.

Database state. For the generation of many SQL statements, knowledge of the database schema or other database state is required; for example, to insert data, SQLancer must determine the name of a table and its columns. We query such state dynamically from the DBMS, rather than tracking or computing it ourselves, which would require additional implementation effort. For example, to query the name of the tables, both MySQL and PostgreSQL provide an information table `information_schema.tables` and SQLite a table `sqlite_master`.

Bailouts. For some operators or functions, corner-case behavior (*e.g.*, how an integer operation behaves on an integer overflow) might be difficult to implement, and—at least initially—be less important to test. Unlike the DBMS, the expression evaluation step in our approach is not required to compute a result for every possible input; in our implementation, each operation can bail out during evaluation by throwing an exception, indicating that a new expression should be generated. We also use this mechanism to prevent reporting known bugs, by bailing out when input is encountered that is known to potentially trigger an already-reported bug.

Value caching. When randomly generating values, SQLancer stores values in a cache, which are subsequently re-used with a given probability. Our intuition was that this would more likely trigger interesting corner cases (*e.g.*, when comparing the same values such as $3 > 3$). Additionally, we expected this to increase the chance of successfully generating rows for tables that constraint a column to refer to another table (*i.e.*, foreign key constraints).

Implementation scope. Each testing implementation that we realized is extensive, but incomplete. For each DBMS, we implemented at least integer and string data types; for the SQLite implementation, which is the most complete one, we also support floating-point numbers and binary data. We implemented the generation of many common statements, operators, and functions. Given the size of the implementation, exhaustively enumerating all supported features is infeasible; the artifact associated with the paper can be used to investigate which features are supported. Section 5.3 gives an overview of the size of each testing implementation.

4 Evaluation

We evaluated whether the proposed approach is effective in finding bugs in DBMSs. We expected it to detect logic bugs, which cannot be found by fuzzers, rather than crash bugs. This section overviews the experimental setup, bugs found, and characterizes the SQL statements used to trigger the bugs. We then present a DBMS-specific bug overview, where we present interesting bugs and bug trends. To put these findings into context, we measured the size of SQLancer’s components and the coverage it reaches on the tested DBMSs.

4.1 Experimental Setup

To test the effectiveness of our approach, we implemented SQLancer and tested SQLite, MySQL, and PostgreSQL in a period of about three months. We conducted all experiments using a laptop with a 6-core Intel i7-8850H CPU at 2.60 GHz and 32 GB of memory running Ubuntu 19.04. Typically, we enhanced SQLancer to test a new operator or DBMS feature, let the tool run for several seconds up to a day, and inspected the bugs found during this process. We automatically reduced test cases to minimal versions [41], and reduced them further manually when this helped to better demonstrate the underlying bug. Finally, we reported any new bugs found during this process. Where possible, we waited for bug fixes before continuing testing and implementing new features.

Baseline. There is no applicable baseline to which we could compare our work. RAGS [46], which was proposed more than 20 years ago, would be the closest related work, but is not publicly available. Due to the small common SQL core, we would expect that RAGS could not find most of the bugs that we found. Khalek et al. worked on automating testing DBMSs using constraint solving [3, 27], with which they found a previously unknown bug. Also their tool is not available publicly. SQLsmith [45], AFL [2] as well as other random query generators and fuzzers [39] only detect crash bugs in DBMSs. Thus, the only potential overlap between these tools and SQLancer would be the crash bugs that we found, which are not the focus of this work.

DBMS versions. For all DBMSs, we started testing the latest release version, which was SQLite 3.28, MySQL 8.0.16, and PostgreSQL 11.4. For SQLite, we switched to the latest trunk version (*i.e.*, the latest non-release version of the source code) after the first bugs were fixed. For MySQL, we also tested version 8.0.17 after it was released. For PostgreSQL, we switched to the latest beta version (PostgreSQL Beta 2) after opening duplicate bug reports. Eventually, we continued to test the latest trunk version.

Bottleneck. We found that duplicate bugs were a significant factor that slowed down our testing. After reporting a bug, we typically waited for bug fixes before continuing our bug-finding efforts; for bugs that were not quickly fixed, we attempted to avoid generating bug-inducing test cases that trig-

Table 2: Total number of reported bugs and their status.

DBMS	Fixed	Verified	Closed	
			Intended	Duplicate
SQLite	64	0	4	2
MySQL	17	7	2	4
PostgreSQL	5	3	7	6

gered known bugs. For SQLite, the developers reacted to most of our bug reports shortly after reporting them, and fixed issues typically within a day. Consequently, we focused our testing efforts on this DBMS. For SQLite, we also tested `VIEWS`, non-default `COLLATES` (which define how strings are compared), floating-point support, and aggregate functions, which we omitted for the other DBMSs. For MySQL, bug reports were typically verified within a day by a tester. MySQL’s development is not open to the general public. Although we tried to establish contact with MySQL developers, we could not obtain any information that went beyond what is visible on the public bug tracker. Thus, it is likely that some of the verified bug reports will subsequently be considered as duplicates or classified to work as intended. Furthermore, although MySQL is available as open-source software, only the code for the latest release version is provided, so any bug fixes could be verified only with the subsequent release. This was a significant factor that restricted us in finding bugs in MySQL; due to the increased effort of verifying whether a newly found bug was already reported, we invested limited effort into testing MySQL. For PostgreSQL, we received feedback to bug reports within a day, and it typically took multiple days or weeks until a bug was fixed, since possible fixes and patches were discussed intensively on the mailing list. As we found fewer bugs for PostgreSQL overall, the response time did not restrict our testing efforts. Note that not all confirmed bugs were fixed. For example, for one reported bug, a developer decided to “*put this on the back burner until we have some consensus how to proceed on that*”; from the discussion, we speculate that the changes needed to address the bug properly were considered too invasive.

4.2 Bug Reports Overview

Table 2 shows the number of bugs that we reported (121 overall). We considered 96 bugs as true bugs, as they resulted in code fixes (78 reports), documentation fixes (8 reports), or were confirmed by the developers (10 reports). Each such bug was previously unknown and has a unique fix associated with it, or has been confirmed by the developers to be a unique bug. We opened 25 bug reports that we classified as false bugs, because behavior exhibited in the bug reports was considered to work as intended (13 reports) or because bugs that we reported were considered to be duplicates (12 reports).

Table 3: A classification of the true bugs by the bug kind.

DBMS	Logic	Error	SEGFAULT
SQLite	46	16	2
MySQL	14	9	1
PostgreSQL	1	7	0
Sum	61	32	3

Severity levels. Only for SQLite, bugs were assigned a severity level by the DBMS developers. 14 bugs were classified as *Critical*, 8 bugs as *Severe*, and 16 as *Important*. For 13 bugs, we reported them on the mailing list and no entry in the bug tracker was created. The other bug reports were assigned low severity levels such as *Minor*. While the severity level was not set consistently, this still provides evidence that we found many critical bugs.

Bug classification. Table 3 shows a classification of the true bugs. The containment oracle, which found all logic bugs, accounts for most of the bugs that we found, which is expected, since our approach mainly builds on this oracle. Perhaps surprisingly, encountering unexpected errors also allowed us to detect a large number of bugs. For PostgreSQL, we even found 7 unexpected-error bugs, while finding only 1 logic bug. We believe that this observation could be used when using fuzzers to test DBMSs, for example, by checking for specific error messages that indicate database corruptions. Our approach also detected a number of crash bugs, one of which was considered a security vulnerability in MySQL (CVE-2019-2879). These bugs are less interesting, since they could also have been found by traditional fuzzers. In fact, a duplicate bug report was reported for PostgreSQL, based on a SQLsmith finding, shortly after we found and reported it.

4.3 SQL Statements Overview

Test case length. Our automatically and manually reduced test cases—which comprise both the statements used to generate the state, as well as the bug-inducing query—typically comprised only a few SQL statements (3.71 LOC on average). For 13 test cases, a single line was sufficient. Such test cases were either **SELECT** statements that operated on constants, or operations that set DBMS-specific options. The maximum number of statements required to reproduce a bug was 8. A PostgreSQL crash bug that had already been fixed when we reported it required even 27 statements to be reproduced. Overall, the small number of statements required to reproduce a bug suggests that statements and queries could be systematically generated to efficiently, rather than randomly, explore the space (*e.g.*, such as the bounded black-box testing approach implemented in *ACE* [35]).

Statement distribution. Figure 2 shows the distribution of statements. Note that for some bug reports, we had to se-

lect the simplest test case among multiple failing ones, which might skew these results. The **CREATE TABLE** and **INSERT** statements are part of most bug reports for all DBMSs, which is expected, since only few bugs can be reproduced without manipulating or fetching data from a table. 91.0% of the bug reports included only a single table. The **SELECT** statement also ranks highly, since the containment oracle relies on it. In all DBMSs, the **CREATE INDEX** statements rank highly; especially for SQLite, we reported a number of bugs where creating an index resulted in a malformed database image or in a row not being fetched. We found that statements that compute or recompute table state were error-prone, for example, **REPAIR TABLE** and **CHECK TABLE** in MySQL, as well as **VACUUM** and **REINDEX** in SQLite and PostgreSQL. DBMS-specific options, such as **SET** in MySQL and PostgreSQL, and **PRAGMA** in SQLite also resulted in bugs being found. For PostgreSQL, some test cases contained **ANALYZE**, which gathers statistics to be used by the query planner.

Column constraints. Column constraints, which can be used to restrict the values stored in a column, were often part of test cases. The most common constraint was **UNIQUE** (appearing in 21.9% of the test cases). Also **PRIMARY KEY** columns were frequent (16.7%). Typically, the DBMSs enforce **UNIQUE** and **PRIMARY KEY** by creating indexes; explicit indexes, created by **CREATE INDEX** were more common, however (27.1%). Other constraints were uncommon, for example, **FOREIGN KEYS** appeared only in 1.0% of the bug reports.

5 Interesting Bugs

In this section, we present bugs that we found using PQS. We chose bugs that we considered to be interesting, meaning that the selection is necessarily subjective.

5.1 Containment Bugs

We consider bugs found by the containment oracle to be the most interesting, and we designed PQS to specifically find these kind of bugs.

First SQLite bug. Listing 3 shows a test case for the first bug that we found with our approach, and where SQLite failed to fetch a row. The **COLLATE NOCASE** clause instructs the DBMS to ignore the casing when comparing strings; in this test case, it unexpectedly caused the upper-case 'A' to be omitted from the result set. The bug was classified as *Severe* and goes back to when **WITHOUT ROWID** tables were introduced in 2013. It is a typical bug that we found in SQLite, since it relies on multiple features. As with this bug, 17 of our SQLite bug reports included indexes, 11 included **COLLATE** sequences, and 5 **WITHOUT ROWID** tables.

SQLite skip-scan optimization bug. A number of SQLite bugs stem from incorrect optimizations, such as the one in

Figure 2: The distribution of the SQL statements used in the bug reports to reproduce the bug. A non-white filling indicates that a statement of the respective category triggered the bug, which was exposed by the test oracle as indicated by the filling (*i.e.*, it was the last statement in the bug report).

Listing 3: The first bug that we found with our approach involved a `COLLATE` index, and a `WITHOUT ROWID` table.

```
CREATE TABLE t0(c0 TEXT PRIMARY KEY)
  WITHOUT ROWID;
CREATE INDEX i0 ON t0(c0 COLLATE NOCASE);
INSERT INTO t0(c0) VALUES ('A');
INSERT INTO t0(c0) VALUES ('a');
SELECT * FROM t0; -- {'A'} ✗ {'A', 'a'} ✓
```

Listing 4: SQLite’s skip-scan optimization was implemented incorrectly for `DISTINCT`.

```
CREATE TABLE t0(c0, c1, c2, c3, PRIMARY KEY (c3,
  c2));
INSERT INTO t0(c2) VALUES (0), (0), (0), (0), (0),
  (0), (0), (0), (0), (0), (NULL), (1), (0);
UPDATE t0 SET c1 = 0;
INSERT INTO t0(c0) VALUES (0), (0), (NULL), (0),
  (0);
ANALYZE t0;
UPDATE t0 SET c2 = 1;
SELECT DISTINCT * FROM t0 WHERE c2 = 1; -- {NULL
  |0|1|NULL} ✗ {NULL|0|1|NULL, 0|NULL|1|NULL,
  NULL|NULL|1|NULL} ✓
```

Listing 4. For the query in this test case, the skip-scan optimization, where an index is used even if its columns are not part of the `WHERE` clause, was implemented incorrectly for `DISTINCT` queries. The bug was classified as *Severe*.

SQLite unexpected type. Listing 5 shows a bug where an optimization for the `LIKE` operator was implemented incorrectly when applied to `INT` values. The operator was expected to fetch the row, since it checks for an exact string match, but omitted the row from the result set. While this is a minor bug, it is nevertheless interesting, considering that only SQLite allows storing a value of a type that does not match the column declaration. We found this feature to be error-prone, and discovered 8 bugs related to it.

MySQL engine-specific bug. Unlike the other DBMSs we tested, MySQL provides various engines that can be assigned to tables. Listing 6 demonstrates one bug where a row was not

Listing 5: We discovered 4 bugs in a `LIKE` optimization, one demonstrated by this test case.

```
CREATE TABLE t0(c0 INT UNIQUE COLLATE NOCASE);
INSERT INTO t0(c0) VALUES ('./');
SELECT * FROM t0 WHERE c0 LIKE './'; -- {} ✗
  {'./'} ✓
```

Listing 6: We found 5 bugs using non-default engines in MySQL.

```
CREATE TABLE t0(c0 INT);
CREATE TABLE t1(c0 INT) ENGINE = MEMORY;
INSERT INTO t0(c0) VALUES (0);
INSERT INTO t1(c0) VALUES (-1);
SELECT * FROM t0, t1 WHERE CAST(t1.c0 AS
  UNSIGNED) > IFNULL("u", t0.c0); -- {} ✗ {0|-1} ✓
```

Listing 7: Custom comparison operator results in incorrect result.

```
CREATE TABLE t0(c0 TINYINT);
INSERT INTO t0(c0) VALUES (NULL);
SELECT * FROM t0 WHERE NOT(t0.c0 <=> 2035382037);
  -- {} ✗ {NULL} ✓
```

fetching when using the `MEMORY` engine. This was one of 5 bugs that were triggered only when using a non-default engine. This test case is also interesting, as it is one of 4 MySQL test cases that relies on a cast to an unsigned integer, a type that is not provided by the other DBMSs we tested.

MySQL value range bug. We found bugs in MySQL where queries were handled incorrectly depending on the magnitude of an integer or floating-point number. For example, Listing 7 shows a bug where the MySQL-specific `<=>` inequality operator, which yields a boolean value even when an argument is `NULL`, yielded `FALSE` when the column value was compared with a constant that was greater than what the column’s type can represent.

MySQL double negation bug. Listing 8 shows an interesting optimization bug that we found in MySQL. MySQL optimized away the double negation, which appears to be cor-

Listing 8: Double negation bug in MySQL.

```
CREATE TABLE t0(c0 INT);
INSERT INTO t0(c0) VALUES(1);
SELECT * FROM t0 WHERE 123 != (NOT (NOT 123)); --
{} ✖ {1} ✔
```

Listing 9: Table inheritance bug in PostgreSQL.

```
CREATE TABLE t0(c0 INT PRIMARY KEY, c1 INT);
CREATE TABLE t1(c0 INT) INHERITS (t0);
INSERT INTO t0(c0, c1) VALUES(0, 0);
INSERT INTO t1(c0, c1) VALUES(0, 1);
SELECT c0, c1 FROM t0 GROUP BY c0, c1; -- {0|0} ✖
{0|0, 0|1} ✔
```

Listing 10: This bug report caused the SQLite developers to disallow double quotes in indexes.

```
CREATE TABLE t0(c0, c1);
INSERT INTO t0(c0, c1) VALUES ('a', 1);
CREATE INDEX i0 ON t0("C3");
ALTER TABLE t0 RENAME COLUMN c0 TO c3;
SELECT DISTINCT * FROM t0; --{'C3'|1} ✖ {'a'|1} ✔
```

rect on the first sight. However, since MySQL’s flexible type system allows, for example, integers as argument to the **NOT** operator, this optimization is not generally correct. Applying **NOT** to a non-zero integer value should yield 0, and negating 0 should yield 1, which is why the predicate in the **WHERE** clause must yield **TRUE**. However, after optimizing away the double negation, the predicate effectively corresponded to `123 != 123`, which evaluated to **FALSE**, and omitted the pivot row. We considered this case as a duplicate, since the underlying bug that this test case demonstrates seems to have been fixed already in a version not released to the public. We believe that the implicit conversions provided by MySQL (and also SQLite) is one of the reasons that we found more bugs in these DBMSs than in PostgreSQL.

PostgreSQL inheritance bug. In PostgreSQL, we found only one logic bug. The bug was related to table inheritance, a feature that only PostgreSQL provides (see Listing 9). Table `t1` inherits from `t0`, and PostgreSQL merges the `c0` column in both tables. As described in the PostgreSQL documentation, `t1` does not respect the **PRIMARY KEY** restriction of `t0`. This was not considered when implementing the **GROUP BY** clause, which caused PostgreSQL to omit one row in its result set.

SQLite double quote bug. Listing 10 shows a test case, for which, after the **RENAME** operation, it is ambiguous whether the index refers to a string or column. The **SELECT** fetches `c3` as a value for the column `c3`, which is incorrect in either case. SQLite allowed both single quotes and double quotes to be used to denote strings; depending on the context, either can refer to a column name. After we reported the bug, a breaking change that disallowed strings in double quotes when creating indexes was introduced.

Listing 11: We found 4 malformed database errors in SQLite using the error oracle, such as this one.

```
CREATE TABLE t1 (c0, c1 REAL PRIMARY KEY);
INSERT INTO t1(c0, c1) VALUES (TRUE,
9223372036854775807), (TRUE, 0);
UPDATE t1 SET c0 = NULL;
UPDATE OR REPLACE t1 SET c1 = 1;
SELECT DISTINCT * FROM t1 WHERE c0 IS NULL; --
Error: database disk image is malformed ✖
```

Listing 12: Unexpected null value bug in PostgreSQL.

```
CREATE TABLE t0(c0 TEXT);
INSERT INTO t0(c0) VALUES('b'), ('a');
ANALYZE;
INSERT INTO t0(c0) VALUES (NULL);
UPDATE t0 SET c0 = 'a';
CREATE INDEX i0 ON t0(c0);
SELECT * FROM t0 WHERE 'baaaaaaaaaaaaaaaaaaaaaa
aaaaaaaaaaaaaaaaaaaaaaaaa' > t0.c0; -- Error: found
unexpected null value in index "i0" ✖
```

5.2 Error Bugs

While finding error bugs was not the main goal of our work, they were common, which is why we discuss two such cases.

SQLite database corruption. Listing 11 shows a test case where manipulating values in a **REAL PRIMARY KEY** column resulted in a corrupted database. We found 4 such cases, as indicated by *malformed database schema* errors. This specific bug was introduced in 2015, and went undetected until we reported it in 2019; it was assigned a *Severe* severity level.

PostgreSQL multithreaded error. Listing 12 shows a bug that was triggered only when another thread opened a transaction, holding a snapshot with the **NULL** value. In order to reproduce such bugs, we had to record and replay traces of all executing threads. 4 reported PostgreSQL bugs (including closed/duplicate ones) could be reproduced only when running multiple threads.

5.3 Implementation Size and Coverage

Implementation effort. It is difficult to quantify the effort that we invested in implementing support for each DBMS, since, for example, we got more efficient in implementing support over time. The LOC of code of the individual testing components (see Table 4) reflects our estimates that we invested the most effort to test SQLite, then PostgreSQL, and then MySQL. The code part shared by the components is rather small (918 LOC), which provides evidence for the different SQL dialects that they support. We believe that the implementation effort for SQLancer is small when compared to the size of the tested DBMSs. The LOC in this table were derived after compiling the respective DBMS using default configurations, and thus include only those lines reachable in the binary. Thus, they are significantly smaller than the ones we derived statically for the entire repositories in Table 1.

Table 4: The size of SQLancer’s components specific and common to the tested databases.

DBMS	LOC			Coverage	
	SQLancer	DBMS	Ratio	Line	Branch
SQLite	6,501	49,703	13.1%	43.0%	38.4%
MySQL	3,995	707,803	0.6%	24.4%	13.0%
PostgreSQL	4,981	329,999	1.5%	23.7%	16.6%

Coverage. To estimate how much code of the DBMSs we tested, we instrumented each DBMS and ran SQLancer for 24 hours (see Table 4). The coverage appears to be low (less than 50% for all DBMSs); however, this is expected, because we were only concerned about testing data-centric SQL statements. MySQL and PostgreSQL provide features such as user management, replication, and maintenance functionalities, which we did not test. Furthermore, all DBMSs provide consoles to interact with the DBMS and programming APIs. We currently do not test many data types, language elements such transaction savepoints, many DBMS-specific functions, configuration options, and operations that might conflict with other threads running on a distinct database. The coverage for SQLite is the highest, reflecting that we invested the most effort in testing it, but also that it provides fewer features in addition to its SQL implementation.

6 Discussion

Number of bugs and code quality. The number of bugs that we found in the respective DBMSs depended on many, difficult-to-quantify factors. We found most bugs in SQLite. A significant reason for this is that we focused on this DBMS, because the developers quickly fixed all bugs. Furthermore, while the SQL dialect supported by SQLite is compact, we perceived it to be the most flexible one; for example, column types are not enforced, leading to bugs that were not present in PostgreSQL, and to a lesser degree in MySQL. MySQL’s release policy made it difficult to test it efficiently, limiting the number of bugs that we found in this DBMS. In PostgreSQL, we found the least number of bugs, and we believe that a significant reason for this is that the SQL dialect support is strict, and few implicit conversions are performed.

False positives. In principle, PQS does not report false positives; that is, bugs found by PQS are always real bugs. Nevertheless, false positives can be due to a limited understanding of the DBMS operator’s expected behavior when implementing the operator’s `execute()` method. Consequently, the 13 bug reports that were considered to work as intended were either due to (1) an incorrect implementation of an operator in PQS, or (2) a bug found by the *error* oracle where the error was expected. False bug reports allowed us to refine our implementation based on the DBMS developer’s feedback. In

8 cases, bug reports also led to documentation enhancements or fixes.

Common bugs. Common bugs that we found among all DBMSs were optimization bugs (*i.e.* where a performance optimization caused correctness issues). Often, these were related to indexes created either explicitly (*i.e.* using **CREATE INDEX**) or implicitly (*e.g.*, using a **UNIQUE** constraint), as described in Section 4.3. A number of bugs were related to the handling of **NULL**, which seems to be difficult to reason about for DBMS developers. Most of the other bugs we found were unique to the respective DBMS.

Existing test efforts. All three DBMSs are extensively tested. For example, SQLite, for which we found most bugs, has 662 times as much test code and test scripts than source code [47]. The core is tested by three separate test harnesses. The TCL tests comprise 45K test cases, the TH3 proprietary test harness contains about 1.7 million test instances and provides 100% branch test coverage and 100% MC/DC test coverage [25], and the SQL Logic Test runs about 7.2 million queries based on over 1 GB of test data. SQLite uses various fuzzers such as a random query generator called *SQL Fuzz*, a proprietary fuzzer *dbsqlfuzz*, and it is fuzzed by Google’s OSS Fuzz project [14]. Other kinds of tests are also applied, such as crash testing, to demonstrate that the database will not go corrupt on system crashes or power failures. Considering that SQLite and other DBMSs are tested this extensively, we believe that it is surprising that SQLancer could find any bugs.

Deployment. One question is how DBMS developers would use PQS during development. Similarly to fuzzers, dynamic testing approaches like PQS cannot provide any guarantees in terms of bug-finding outcomes. Consequently, it is also unclear on how long SQLancer should be run to find all bugs it would be able to find. In practice, it might be useful to run SQLancer similarly to fuzzers, for example, either for a limited period as part of an overnight continuous integration process, or constantly to maximize the chances of finding new bugs. Future work might investigate the systematic enumeration of queries, while also pruning the infinitely large space of possible queries, to give bounded guarantees.

Specification. In order to implement the expression evaluation, we implemented AST interpreters that evaluate the operators based on the pivot row. This evaluation step essentially encodes the specification against which the DBMS is checked. We implemented the expression evaluation primarily based on each DBMS’ documentation. Where we deemed the documentation to be insufficient, we used a trial-and-error approach to implement the correct semantics. In contrast to differential testing, where a difference in the semantics between two DBMSs’ SQL dialect would result in repeated false positives, diverging behavior in an implementation of PQS (*e.g.*, caused by implementation errors) can be addressed by code fixes. In fact, this observation can be used to effectively test the PQS implementation, by running it against the DBMS under test,

rather than—or in addition to—using manually-written unit tests.

Limitations. PQS has a number of limitations in terms of what logic bugs it can find. PQS only partly validates a query’s result, and thus, in general, is inapplicable to, for example, check the correct insertion or deletion of records, detect concurrency bugs, bugs related to transactions, or bugs in the access control layer of DBMSs [19]. Conceptually, PQS cannot detect duplicate rows that are mistakenly omitted from or included in the result set, since duplicate records are indistinguishable for PQS. Consequently, it also cannot be used to validate the cardinality of a result set, even when each of its rows is once selected as a pivot row. PQS is not suited for testing the `OFFSET` and `LIMIT` clauses, since they might exclude the pivot row from the result set. Although PQS has found 3 bugs in aggregate functions, it can only do so in corner cases, such as when aggregate functions are used in a view that is queried, or when a table contains only a single row, in which case the result of the aggregate function can be determined easily. Similarly, PQS cannot find bugs in window functions, which also compute their result over multiple rows in a window. While SQLancer generates `ORDER BY` clauses, PQS cannot validate the result set’s ordering. Similarly, for `GROUP BY` clauses, PQS cannot confirm that all duplicate values are grouped. PQS cannot be used to test `NOT EXISTS` predicates that reference tables (*i.e.*, semi-joins), since the approach cannot ensure that a row is not contained based on only the pivot row. Similarly, while PQS can be used to test joins, it can only test for combinations where a `JOIN` clause matches rows on both the left and right side of a join; for example, for a `LEFT JOIN`, it is inapplicable to test cases where only values for the left table are fetched, but not the right one. PQS is unable to test the results of ambiguous queries and queries that rely on nondeterministic functions (such as used to generate random numbers), since it is based on the assumption that the result set is unambiguous. It is also unable to test user-provided functions or operators, unless they are re-implemented in PQS. Supporting these makes interesting future work. PQS, as the first practical technique for finding logic bugs in DBMSs, has demonstrated its effectiveness by finding a wide variety of bugs such as in operator implementations and optimizations.

Implementation effort. Since the supported SQL dialects differ vastly between DBMSs, we had to implement DBMS-specific components in SQLancer. It could be argued that the implementation effort is too high, especially when the full support of a SQL dialect is to be tested, which could arguably be similar to implementing a new DBMS. Indeed, we could not test complex functions such as SQLite’s `printf`, which would have required significant implementation effort. However, we still argue that the implementation effort is reasonably low, and allows testing significant parts of a DBMS. Specifically, based on our experiments, implementing sargable predicates (*e.g.* those predicates for which the DBMS can use an index), already allows finding the majority of optimiza-

tion bugs. Furthermore, our approach effectively evaluates only literal expressions, and does not need to consider multiple rows. This obviates the need of implementing a query planner, which typically is the most complex component of a DBMS [13]. Furthermore, the performance of the evaluation engine is insignificant; the performance bottleneck was the DBMS evaluating the queries, rather than SQLancer. Thus, we also did not implement any optimizations, which typically require much implementation effort in DBMSs [15]. Finally, we did not need to consider aspects such as concurrency and multi-user control as well as integrity [53].

7 Related Work

Testing of software systems. This paper fits into the stream of testing approaches for important software systems. Differential testing [33] is a technique that compares the results obtained by multiple systems that implement a common language; if results deviate, one or multiple of the systems are likely to have a bug. It has been used as a basis for many approaches, for example, to test C/C++ compilers [51, 52], symbolic execution engines [24], and PDF readers [30]. Metamorphic testing [9], where the program is transformed so that the same result as for the original program is expected, has been applied to various systems; for example, *equivalence modulo inputs* is a metamorphic-testing-based approach that has been used to find over one thousand bugs in widely-used compilers [31]. As another example, metamorphic testing has been successfully applied to test graphic shader compilers [12]. We present PQS as a novel approach to testing DBMSs, which solves the *oracle problem* in a novel way, namely by checking whether a DBMS works correctly for a specific query and row. We believe that our approach can also be extended to test other software systems that have an internal state, of which a single instance can be selected.

Metamorphic testing of DBMSs. PQS inspired two follow-up testing approaches, namely Non-Optimizing Reference Engine Construction (NoREC) [42] and Ternary Logic Partitioning (TLP) [43], both of which were implemented in SQLancer. Conceptually, NoREC translates a query that is potentially optimized by the DBMS (called the *optimized query*) to a query that cannot effectively be optimized, thus detecting *optimization bugs*—which are a subcategory of logic bugs—when the two query’s result sets differ. TLP translates a given query to multiple so-called *partitioning queries*, each of which computes a part of the result, whose combined result is then compared with the given query’s result sets. Both are metamorphic testing approaches. Thus, the effort required for implementing them is negligible; however, they cannot establish a ground truth, which PQS can. NoREC could find only 52.7% of the bugs detected by PQS, which is expected due to its narrower scope [42]. Considering that our PQS implementation could also check for non-containment, which

is a straightforward implementation enhancement, it could have detected 82.4% of the NoREC bugs. The remaining bugs found only by NoREC are due to bugs in the implementation of the `SUM()` and `COUNT()` aggregate functions, which NoREC uses for a more efficient implementation of the test oracle; it does not provide testing support for aggregates in general.

Differential testing of DBMSs. Slutz proposed an approach *RAGS* for finding bugs in DBMSs based on differential testing [46]. In *RAGS*, queries are automatically generated and evaluated by multiple DBMSs. If the results are inconsistent, a bug has been found. As acknowledged by the author, the approach was very effective, but applies to only a small set of common SQL statements. In particular, the differences in `NULL` handling, character handling, and numeric type coercions were mentioned as problematic. Our approach can detect bugs also in SQL statements unique to a DBMS, but requires separate implementations for each DBMS.

Database fuzzing. SQLsmith is a popular tool that randomly generates SQL queries to test various DBMSs [45]. SQLsmith has been highly successful and has found over 100 bugs in popular DBMSs such as PostgreSQL, SQLite and MonetDB since 2015. However, it cannot find logic bugs found by our approach. Similarly, general-purpose fuzzers such as AFL [2] are routinely applied to DBMSs, and have found many bugs, but also cannot detect logic bugs.

Consistency checking. Kingsbury has developed Jepsen, a framework to test safety properties of distributed systems (such as violations of consistency models), which found many critical bugs in distributed DBMSs [28]. As part of Jepsen, Kingsbury et al. proposed Elle [29], which is a transactional consistency checker. In contrast to PQS, Jepsen aims to find logic bugs primarily in the transaction processing of a DBMS.

Queries satisfying constraints. Some approaches improved upon random query generation by generating queries that satisfy certain constraints, such as cardinalities or coverage characteristics. The problem of generating a query, whose subexpressions must satisfy certain constraints, has been extensively studied [7, 34]; since this problem is complex, it is typically tackled by an approximate algorithm [7, 34]. An alternative approach was proposed by Bati et al. where queries are selected and mutated based on whether they increase the coverage of rarely executed code paths [4], increasing the coverage of the DBMS component under test. Rather than improved query generation, Lo et al. proposed an approach where a database is generated based on specific requirements on test queries [32]. While these approaches improve the query and database generation, they do not help in automatically finding errors, since they do not propose an approach to automatically verify the queries' results.

DBMS testing based on constraint solving. Khalek et al. worked on automating testing DBMSs using constraint solving [3, 27]. Their core idea was to use a SAT-based solver to automatically generate database data, queries, and a test

oracle. In their first work, they described how to generate query-specific data to populate a database and enumerate the rows that would be fetched to construct a test oracle [27]. They could reproduce previously-reported and injected bugs, but discovered only one new bug. In follow-up work, they also demonstrated how the SAT-based approach can be used to automatically generate queries [3]. As with our approach, they provide a test oracle, and additionally a targeted data generation approach. While both approaches found bugs, our approach found many previously undiscovered bugs. Furthermore, we believe that the simplicity of our approach could make it wider applicable.

Testing other aspects. Rather than trying to improve the correctness of DBMSs, several approaches were proposed to test other aspects of DBMSs. Poess et. al proposed a template-based approach to generating queries suitable to benchmark DBMSs, which they implemented in a tool QGEN [39]. Similarly to random query generators, QGEN could also be used to test DBMSs. Gu et al presented an approach to quantify an optimizer's accuracy for a given workload by defining a metric over different execution plans for this workload, which were generated by using DBMS-specific tuning options [18]. Jung et al. found performance bugs based on several versions of a given DBMS [23]. Zheng et al. tested the ACID properties provided by the DBMS in the presence of power faults [53]. These approaches, however, cannot be used to find logic bugs.

8 Conclusion

We have presented an effective approach for detecting bugs in DBMSs, which we implemented in a tool SQLancer, with which we found over 96 bugs in three popular and widely-used DBMSs. The effectiveness of SQLancer is surprising, considering the simplicity of our approach, and that we only implemented a small subset of features that current DBMSs support. There are a number of promising directions that could help uncover additional bugs or improve PQS otherwise, which we regard as future work. SQLancer generates tables with a low number of rows to prevent timeouts of queries when multiple tables are joined with non-restrictive conditions. By generating targeted queries with conditions based on table cardinalities [7, 34], we could test the DBMSs for a large number of rows, better stressing the query planner [13]. A disadvantage of PQS is that it needs to be implemented for every DBMS to be tested. As part of future work, this effort could be reduced, for example, by providing common building blocks that could be combined to implement operators and functions more efficiently. Finally, PQS could be extended to also test for rows that are incorrectly fetched by selecting a pivot row, ensuring that the randomly-generated predicates evaluate to `FALSE` or `NULL` for it, and then check that the pivot row is not contained in the result set.

Acknowledgements

We thank the anonymous reviewers and our shepherd, Yuanyuan Zhou, for their insightful feedback. We want to thank all the DBMS developers for responding to our bug reports as well as analyzing and fixing the bugs we reported. We especially want to thank the SQLite developers, D. Richard Hipp and Dan Kennedy, for taking all bugs we reported seriously and fixing them quickly. Furthermore, we are grateful for the feedback received by our colleagues at ETH Zurich.

Gauntlet: Finding Bugs in Compilers for Programmable Packet Processing

Fabian Ruffy, Tao Wang, and Anirudh Sivaraman
New York University

Abstract

Programmable packet-processing devices such as programmable switches and network interface cards are becoming mainstream. These devices are configured in a domain-specific language such as P4, using a compiler to translate packet-processing programs into instructions for different targets. As networks with programmable devices become widespread, it is critical that these compilers be dependable.

This paper considers the problem of finding bugs in compilers for packet processing in the context of P4₁₆. We introduce domain-specific techniques to induce both abnormal termination of the compiler (crash bugs) and miscompilation (semantic bugs). We apply these techniques to (1) the open-source P4 compiler (P4C) infrastructure, which serves as a common base for different P4 back ends; (2) the P4 back end for the P4 reference software switch; and (3) the P4 back end for the Barefoot Tofino switch.

Across the 3 platforms, over 8 months of bug finding, our tool Gauntlet detected 96 new and distinct bugs (62 crash and 34 semantic), which we confirmed with the respective compiler developers. 54 have been fixed (31 crash and 23 semantic); the remaining have been assigned to a developer. Our bug-finding efforts also led to 6 P4 specification changes. We have open sourced Gauntlet at [p4gauntlet.github.io](https://github.com/p4gauntlet/p4gauntlet) and it now runs within P4C's continuous integration pipeline.

1 Introduction

Programmable packet-processing devices in the form of programmable switches and network interface cards (NICs) are now common. Such devices provide network flexibility, allowing network operators to customize their network, researchers to experiment with new network algorithms, and equipment vendors to upgrade features rapidly in firmware rather than waiting for new hardware. At the core of this move to programmable packet processing are the domain-specific languages (DSLs) for packet processing, along with the compilers that compile DSL programs.

Several commercial products now use such DSLs for packet processing. For instance, Intel [4], Broadcom [8], Nvidia [39], and Cisco [17] have switches and NICs programmable in DSLs such as NPL [9] and P4 [7]. Other efforts (e.g., from Google and the Open Networking Foundation (ONF)) use the P4 language to model the behavior of fixed-function devices [50].

These devices, whether fixed or programmable, are a critical part of the network infrastructure because they process every packet going through the network. Hence, a miscompiled program can persistently affect packet processing. It can also be very hard to track down miscompilations due to the lack of sophisticated debugging support on these devices. As network programmability becomes increasingly common, these DSL compilers will need to be as dependable as general-purpose compilers such as GCC and LLVM.

Motivated by these concerns, this paper considers the problem of finding bugs in compilers for packet processing. Because of the large open-source community around it, we build our work on the P4 [7] language, but our ideas also extend to similar DSLs such as NPL [9].

Bug finding in compilers is a well-studied topic, especially in the context of C [15, 41, 42, 70, 74]. Past approaches (§2) to bug finding in C compilers include fuzz testing by using randomly generated C programs [41, 74], translation validation (i.e., proving that a compiler correctly translated a given input program to an output program) [48, 52], and verification of individual compiler passes [45]. These prior approaches have to contend with many difficulties inherent to a general-purpose language like C, e.g., generating random programs that avoid undefined and unspecified behavior [41, 74], providing semantics for pointers and memory aliasing [45], and inferring loop invariants and simulation relations to successfully perform translation validation [52].

Our key insight is that the restricted nature of a DSL such as P4 allows us to avoid much of the complexity associated with bug finding in general-purpose language compilers. In particular, the simpler nature of P4 (e.g., no loops or pointers) allowed us to more easily develop formal semantics, which

can then be used as the basis for both automated high-accuracy translation validation and model-based testing [19]. We leverage this insight to build a compiler bug-finding tool for P4 called Gauntlet. Gauntlet uses three key ideas: random program generation, translation validation, and model-based testing. We now describe these ideas and show how the restrictions of P4 allows them to be simpler than prior work.

First, we use random program generation (§4) to produce syntactically correct and well-typed P4 programs that still induce P4 compiler crashes. Because P4 has very little undefined behavior [18, §7.1.6], random program generation is considerably simpler for P4 than for C [74]. The generator does not have to painstakingly avoid generating programs with undefined and unspecified behavior, which can be interpreted differently across different compilers. The smaller and simpler grammar of P4 relative to C also simplifies the development of a random program generator.

Second, we use translation validation (§5) [48, 52] to find miscompilations in P4 compilers in which we can access the transformed program after every compiler pass. Translation validation has been used in the context of C compilers before, but has suffered one of two shortcomings. It either needs considerable manual effort per compiler pass (e.g., Crelvm [37] requires several 100 lines of manual proof-generation code for each pass; Alive [45] requires manual translation of optimizations into the Alive DSL) or suffers from a small rate of false positives and false negatives (e.g., [34, 48]). Fundamentally, this is inevitable for unrestricted C: proving program equivalence in the presence of unbounded loops is undecidable. In our case, however, the finite nature of P4¹ makes P4 program equivalence decidable and addresses both shortcomings. Thus, our use of translation validation is both precise and fully automated, requiring manual effort only to develop semantics for the P4 language—not manual effort per compiler pass.

Third, we use model-based testing (§6) to generate input-output test packets for P4 programs based on the semantics we had to develop for translation validation. We use these test packet pairs to find miscompilations in black-box and proprietary P4 compilers where we can not access the transformed program after every compiler pass. Testing for general-purpose languages [13] is effective at generating inputs that provide sufficient path coverage by finding inputs satisfying path conditions. But without language semantics, determining the correct output for these test inputs is hard. By creating formal semantics for P4 for translation validation, we are able to generate both input and output test packets, which can then be used to test the implementation produced by the compiler for a P4 program.

We applied Gauntlet to 3 platforms (§7): (1) the open-source P4 compiler infrastructure (P4C) [12], which serves as a common base for different P4 compiler implementations; (2) the P4 back end for the open-source P4 behavioral model

(BMv2) [6], a reference software switch for P4; and (3) the P4 back end for Barefoot Tofino, a high-speed programmable switching chip [4]. Across these 3 platforms, and over 8 months of testing, we found a total of 96 new and distinct bugs, all of which were confirmed and assigned to a compiler developer. Our efforts also led to 6 changes [18, §A.1] to the P4 specification. 54 of these bugs have already been fixed. We analyze these bugs in detail and describe where they were found, their root causes, and which commits introduced them. Gauntlet has been merged into the continuous integration pipeline of the official P4 reference compiler [57]. Our tools are open source and available at [p4gauntlet.github.io](https://github.com/p4gauntlet/p4gauntlet). To our knowledge, Gauntlet is the first example of using translation validation for compiler bug finding on a production compiler as part of its continuous integration workflow.

While Gauntlet has been very effective, it is still restricted in the kinds of bugs, compiler passes, and language constructs it can handle. We describe these restrictions to motivate future work (§8). Further, while we developed these bug-finding techniques in the context of P4, we believe the lessons we have learned (§7.4) apply beyond P4 to other DSLs with simpler semantics relative to general-purpose languages (e.g., the HLO IR for the TensorFlow [1] XLA compiler [71]).

2 Background and Motivation

2.1 Approaches to Testing Compilers

Levels of compiler testing. A compiler must reject incorrect programs with an appropriate error message and accurately translate correct programs. However, a program can be correct to varying levels. McKeeman [46] provides a taxonomy of these levels in the context of C (Table 1). Each level corresponds to the program getting deeper into the compiler before it is rejected (e.g., lexer, parser, type checker, optimizer, code generator). The difficulty of generating test programs also goes up with increasing input level. For instance, while general-purpose fuzzers such as AFL [75] are sufficient to stress test the lexer, more sophistication is required to generate syntactically correct and well-typed programs, which are required to test the optimizer. In the context of the P4 compiler, we observed very limited success in bug finding using a general-purpose fuzzer such as AFL. This is because testing at the first few levels of Table 1 is already handled adequately by P4’s open-source compiler test suite [12, §3.4].

Hence, for this paper, we only consider programs at the higher levels: static, dynamic, and model-conforming. These are programs that pass the lexing, parsing, type checking, and semantic analysis phases of the compiler, but still trigger compiler bugs. Like Csmith [74], we categorize bugs into *crash bugs* and *semantic bugs*. A crash bug occurs when the compiler abnormally terminates on an input program without producing either an output program or a useful error message. Crash bugs include segmentation faults, assertion violations,

¹Finite in that input and output packets and state are finite bit vectors. Loops are bounded (parsing [18, §12]) or forbidden (control flow [18, §13]).

Level	Input Class	Example of incorrect input
1	Sequence of ASCII characters	Binary files
2	Sequence of words and spaces	Variable name beginning with \$
3	Syntactically correct	Missing semicolon
4	Type correct	Adding int to string
5	Statically conforming	Undefined variables
6	Dynamically conforming	Program throwing exceptions
7	Model-conforming	Program producing wrong outputs

Table 1: McKeeman’s [46] 7 levels of C compiler correctness.

incomplete error messages, and out-of-memory errors. A semantic bug occurs when the compiler produces an output executable, but the executable’s behavior is different from the input program, e.g., due to an incorrect program transformation in a compiler optimization pass. In P4, semantic bugs manifest as any packet output that differs from the expected packet output given an input packet. Crash bugs we are interested in correspond to level 5 in Table 1; semantic bugs correspond to levels 6 and 7.

Bug-finding strategies. We now look at how compiler bugs are found. A key challenge in compiler bug finding is the oracle problem. Given an input program to a compiler, the expected outcome (i.e., should it accept/reject the program and what should the output be?) is unclear unless one consults an all-knowing oracle. Below, we outline the major techniques used to approximate this oracle knowledge.

In differential testing [46], given two compilers, which both receive the same input program, if compiler A’s output (after compiling and running the program) differs from compiler B’s output, there is a bug in one of them. This works as long as there are at least two independent compiler implementations for the same language. Csmith [74] is one example of this approach; it feeds the same randomly generated C program to multiple C compilers and checks whether the outputs generated by executing the binary produced by each compiler differ. Another example is Different Optimization Levels (DOL) [15], which selectively omits compiler optimizations and compares compiler outputs with and without these optimization passes. If the end result differs after specific passes have been skipped or added, it points to a bug. This technique can be used in any compiler framework that supports selective omission of optimizations.

Metamorphic testing [16] can serve a similar role as differential testing, especially when multiple compilers are not readily available or optimization passes can not be easily disabled. Instead of feeding the same input program to different compilers, different input programs that are expected to produce the same compiler output are fed to the same compiler. The run-time outputs after compiling these different input programs are compared to determine if there is a bug or not. EMI is an example of this approach [41]. Given a randomly generated C program P , and random input I to this program, EMI uses the path coverage tool gcov [53] to identify dead code in P when run on input I . EMI then prunes away this

dead code to produce new programs P' whose output must agree with P ’s output when run on the input I . Then EMI compiles and runs both P and P' to check whether they indeed produce the same output when given I as input.

Translation validation is a bug-finding technique that converts the program before and after a compiler optimization pass into a logical formula and checks if both programs/formulas are equivalent using a constraint solver [45, 48, 52, 76]. A failed check indicates a semantic bug. Program equivalence is an undecidable problem for Turing-complete languages such as C, requiring manual assistance to perform translation validation. Typical examples of manual assistance are (1) simulation relations, which encode correspondences between variables in two programs; and (2) loop invariants, required to prove the equivalence of programs with loops. While it is possible to just unroll loops a constant number of times [34] or learn these relations [48, 66], these techniques are not guaranteed to be precise and occasionally generate false alarms [37]. The occurrence of false alarms makes translation validation an unlikely choice for recurring use in compiler testing for general-purpose languages (e.g., for continuous integration). This is because the number of false alarms typically exceeds compiler developer tolerance.

2.2 Motivating Gauntlet’s Design

Random program generation for crash bugs. From EMI and Csmith, we borrow the idea of generating random programs that are lexically, syntactically, and semantically correct. Unlike EMI and Csmith, however, our random program generation is simpler. It does not have to avoid undefined behavior, which, by design, is quite limited in P4₁₆. Further, generating programs with undefined behavior helps us flag compiler passes that might exploit undefined behavior in counter-intuitive ways [73]. We feed these randomly generated programs to the compiler to see if it generates a crash, typically a failure of an assertion written by the P4 compiler developers.

Translation validation for semantic bugs. Differential and metamorphic testing allow us to compare different run-time outputs from compiled programs to detect semantic bugs. However, we can not directly apply either to P4 compilers. Differential testing requires two or more independent compiler implementations that are comparable in their output. P4₁₆ compilers for different hardware and software targets are not comparable because program behavior is target-dependent [12, §2.1]. Presently there aren’t multiple independent compilers for the same target. Developing an entirely new compiler exclusively for the sake of testing the existing compiler is not productive because it can only be reused for one target. Metamorphic testing [41], on the other hand, requires the use of code-coverage tools such as gcov to determine which parts of the program are touched by a given input. Concurrent research [40] has proposed such tools for

P4, but these tools were not available when we commenced work on Gauntlet.

On the other hand, P4’s domain-specific restrictions make translation validation easier relative to general-purpose languages such as C. P4 programs are finite-state and finite-time, which makes program equivalence decidable at a theoretical level. At the practical level, P4’s lack of pointers, memory aliasing, and unstructured control flow (e.g., goto) allow for easier generation of language semantics. Furthermore, using an SMT solver together with translation validation is more precise than randomized testing approaches such as EMI and Csmith because the solver exhaustively searches over all packet inputs to a program to find semantic bugs.

To perform translation validation, we convert P4 programs before and after a compiler pass into logic formulas and assert equivalence of these formulas. To do so, we could have converted P4 programs into C code and then asserted equality using Klee’s equivalence-checking mode [13]. However, instead, we directly converted P4 programs into logic formulas in Z3 [20] for two reasons. First, the effort to convert P4 to semantically equivalent C is about the same as producing Z3 formulas directly. The difficulty lies in correctly formalizing all the language constructs of P4, not in the output format. Second, generating Z3 formulas directly gives us more control and allows us to leverage domain-specific techniques to optimize these formulas.

Model-based testing for black-box compilers. Some industry compilers do not have an open specification of their internal program representation or machine code format. In such cases, we cannot use our translation validation technique because it relies on comparing semantics before and after the compiler has transformed the program. Instead, we reuse the semantics we have generated for the input P4 program to determine test cases (i.e., input-output packet pairs) for these random programs. These test cases are then used to directly check the implementations of the P4 programs produced by these compilers. This is effectively model-based testing [19], with the Z3 semantics serving as a model of the P4 program and the compiler-generated binary being the entity under test.

2.3 Goals and Non-Goals

Find many, but not all bugs. Our goal is to find many crash and semantic bugs in the P4 compiler, but our tool is not exhaustive. Specifically, we do not intend to build or replace a fully verified compiler like CompCert [43], given the large labor and time cost associated with such an undertaking with respect to the breadth of P4 back ends. We want to strengthen existing P4 compilers, not write a safe replacement.

Check the compiler, not the programmer. We are not verifying that a particular P4 program is devoid of certain kinds of bugs. This problem is addressed by orthogonal work on P4 program verification [22, 25, 32, 44, 68] and P4 testing [67].

Although Gauntlet can in principle be used in for verifying a P4 program, we have not designed it for such use cases. The random programs we generate to find bugs in the P4 compiler are much smaller and more targeted than a typical P4 switch program. Our tool does not need to be able to generate and efficiently solve Z3 formulas for large P4 programs to tease out compiler bugs, although it achieves acceptable performance on large programs (Table 4).

Unlike p4v [44] and Vera [68], whose goal is to provide semantics to find bugs in large programs such as `switch.p4`, we have developed our semantics for efficient equality checks of diverse, but relatively small, P4 programs. Because of this difference in goals, we believe our semantics cover a broader set of P4 language constructs and corner cases than p4v and Vera—broad enough that we have found bugs in the P4 specification.

Develop target-independent techniques. We designed our tools to be as target-independent as possible and specialize them to test the front and mid end of the compiler. While we support restricted forms of back-end testing (§6), we do so in a way that allows us to quickly integrate and adapt to new back ends without having to understand detailed target-specific behavior. In particular, we do not cover target-specific semantics such as externs [18, §4.3]. We do this by generating programs that are defined in a target-neutral manner with respect to P4₁₆’s semantics, i.e., we avoid generating target-specific extern calls.

Only test mature compilers. We only test mature compilers such as P4C and the corresponding behavioral model² as well as the commercial Tofino compiler. For example, P4C supports other back ends such as the eBPF, uBPF, and PSA targets, which are pre-alpha quality and preliminary compiler toolchains. Finding bugs is likely unhelpful for the respective compiler developers at this moment.

3 Background on P4

P4 is a statically typed DSL designed to describe computations on network packet headers. This paper focuses on P4₁₆, the latest version of P4 [18]. Figure 1 shows the main P4₁₆ concepts, explained below.

Packages and targets. A P4 program consists of a set of procedures; each procedure is loaded into a programmable block of the target (e.g., a switch [4] or NIC [51]). These programmable blocks correspond to various subsystems such as the parser or the match-action pipeline. The *package* lists the available programmable blocks in a target. One example of a package for a target is the `v1model`, which models the architecture of a particular BMv2 [6] software switch target, referred to as “simple switch” [26]. For simplicity, we will

²Both have entered “permanent beta-status” since November 2019: <https://github.com/p4lang/p4c/issues/2080>

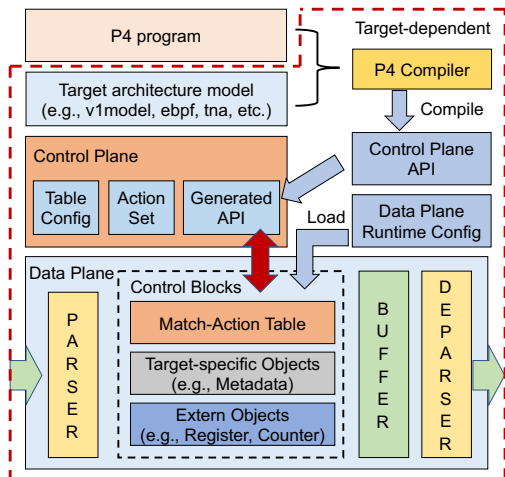

Figure 1: An example P4 compilation model.

refer to BMv2 as the target instead of simple switch.

P4 compilers. A P4₁₆ compiler translates a P4₁₆ program and the target package model into target-dependent instructions. These target instructions are combined with the non-programmable blocks (e.g., a fixed scheduler) to form the target’s data plane. These instructions also specify how this data plane can be accessed and configured by the control plane (Figure 1). P4C [12] is the official open-source reference compiler infrastructure of the P4₁₆ language and implements the current state of the specification. P4C employs a nanopass design [65]: a composable library of front- and mid-end compiler passes that perform code analysis, transformation, and optimization on input programs. We analyze these nanopasses using translation validation.

Compiler back ends. To implement a P4₁₆ compiler, developers write P4C back ends, which use P4C’s front- and mid-end passes along with their own back-end specific transformations, to translate P4₁₆ code at the conclusion of the mid end into instructions for their own target. In this paper, we focus on 2 production-grade P4C back ends: the Tofino [4] and BMv2 [6] back ends.

Parsers and control blocks. A P4 parser is a finite state machine that transforms an incoming byte sequence received at the target into a structured representation of header definitions. For example, incoming bytes may be parsed as packets containing Ethernet, IP, and TCP/UDP headers. A deparser converts this representation back into a byte sequence. Control blocks describe the per-packet operations that are performed on the input header. These operations are expressed in the form of the core primitives of the language: tables, actions, metadata, and extern objects.

Tables. Tables are objects in the control block similar to a Python dictionary. Table entries are match-action pairs inserted by the network’s control plane [14, 47]. When a table

is applied to a packet traversing the control block, its header is compared against the match key of all match-action entries in the table. If any entry’s key matches the header, the action associated with the match is executed. Actions are procedures that can modify state and/or input headers.

Calling conventions. P4₁₆ uses “copy-in/copy-out” [18, §6.7] semantics for method calls. For any callable object in P4, the parameter direction (also known as mode [36, §8.2]) explicitly specifies which parameters are read-only and which parameters can be modified, with the modifications persisting after function termination. Modifiable parameters are labelled with the direction `inout` or `out` in the definition of the procedure. Read-only values are marked `in`. At the start of a procedure call, the arguments are copied left-to-right into the associated parameter slots. Parameters with `out` label remain uninitialized. Once the procedure has terminated, all procedure parameters with the label `inout` or `out` are copied back towards the original input arguments.

Metadata. Metadata is programmer-defined or target-specific data that is associated with a packet header, while it traverses the target. Examples of metadata include the packet input port, packet length, queue depth, or priority; this information is interpreted by the target according to target-specific rules. Metadata can also be modified during the execution of the control block.

Externs. Externs are an extensibility mechanism, which allows targets to describe built-in functionality. Externs are object-like and have methods. Examples include calls to checksum units, hash units, counters, and meters. P4’s “copy-in/copy-out” semantics allow reasoning about externs to some degree; we can discern which input arguments can take on an arbitrary value and which arguments are read-only.

4 Random Program Generation

Gauntlet’s random program generator produces valid P4₁₆ programs to directly trigger a crash bug. If these programs do not cause a compiler crash they serve as input for our translation validation and model-based testing techniques.

4.1 Design

We require diverse input programs to exercise code paths within many compiler passes—and hence bugs in those passes. P4C already contains a sample of over 600 programs as part of its test suite. During testing, the reference outputs of each of the test programs are textually compared to the actual outputs after the front- and mid-end passes to check for regressions [12, §3.4]. However, this comparison technique is inadequate for semantic bugs. Further, these programs are typically used to test the lexer and parser, not deeper portions of the compiler.

P4Fuzz [2] is a tool that can generate random P4 programs. However, when we tried using P4Fuzz, we found that the programs generated by it are not complex enough to find a large number of new crash or semantic bugs. For example, P4Fuzz generates programs with complex declarations (e.g., structs within structs), but does not generate programs with sufficiently complicated control flow. Hence, it does not cause P4C to execute a diverse set of compiler passes. We developed our own generator for random P4 programs that works by generating random abstract syntax trees (ASTs). With this generator we can exercise the majority of language constructs in P4. This leads to diverse test programs covering many combinations of P4 expressions. We can use these test programs to find programs that lead to unexpected crashes.

Gauntlet’s random program generator is influenced by Csmith [74] and follows its philosophy of generating only well-formed input programs that pass the lexer, parser, and type checker. The generator grows an AST corresponding to the random program by probabilistically determining what kind of AST node to add to the AST at each step. By adjusting the probabilities of generating each AST node, we can steer the generator towards the language constructs we want to focus on. We can also use these probabilities to keep the size of the average generated program small, in both the number of code lines as well as program paths. With this technique we can find an ample number of semantic bugs while also avoiding programs with too many paths; such “branch” programs pose challenges for translation validation and model-based testing.

Undefined behavior. We differ from Csmith in the treatment of undefined behavior. Whereas Csmith tries to avoid generating expressions that lead to undefined behavior, we accommodate such language constructs (e.g., reading from variables that are not initialized). We record the output affected by undefined behavior as part of the logic formulas that we generate from P4 programs during translation validation (§5.2). These formulas allow us to track changes in programs with undefined behavior across compiler passes, which we use to inform compiler developers of suspicious—but not necessarily incorrect—compiler transformations [73].

4.2 Implementation

We implement our random P4 program generator as extension to P4C. The generator uses the intermediate representation (IR) of P4C to automatically grow an abstract syntax tree (AST) by expanding branches of the tree at random. For example, a block statement may generate up to (say) 10 statements or declarations, which in turn may result in further sub nodes. The generated IR AST is then converted into a P4 program using P4C’s ToP4 module. Our random program generator can be specialized towards different compiler back ends by providing a skeleton of the back-end-specific P4 package, back-end-specific restrictions, and which package blocks

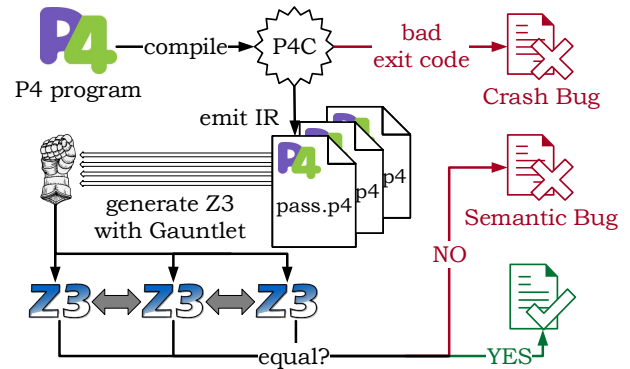

Figure 2: Translation validation in Gauntlet.

are to be filled in with randomly generated program snippets. We have currently implemented two back ends for our random program generator corresponding to the BMv2 [26] and Tofino [4] targets.

Programs generated by our random program generator are required to be syntactically sound and well-typed. Our aim is not to test if P4C can correctly catch syntax and type errors (levels 3 and 4 of Table 1). If P4C’s parser and type checker (correctly) reject a generated program, we consider this to be a bug in our random program generator. For example, if an action parameter has a inout or out qualifier, only writable variables may be passed as arguments.

5 Translation Validation

To detect semantic bugs, we employ translation validation [52], a classic technique from the compiler literature in which an external tool certifies that a particular compiler pass has correctly transformed a given input program.

5.1 Design

To perform translation validation for P4, we developed a symbolic interpreter for the P4₁₆ language to transform P4 programs into Z3 formulas [20]. Figure 2 describes our workflow. To validate a P4 program, the symbolic interpreter converts the program into a Z3 formula capturing its input-output semantics. An equivalence checker then submits the Z3 formulas of a program before and after a compiler pass to the Z3 SMT solver. The solver tries to find an input that violates equivalence of these two formulas. If it finds such an input, this is a semantic bug. Translation validation has two advantages over random testing. First, it can accurately detect subtle differences in program semantics without any knowledge about expected input packets or table entries. Second, when we can access intermediate P4 programs after each compiler pass, we can pinpoint the erroneous pass.

5.2 Implementation

Like our random program generator, we wrote the interpreter as an extension to P4C. We use the IR generated by the P4C parser to determine the semantics of a P4 program. Each programmable block of a P4 package represents an independent Z3 formula. For example, the `v1model` package [26] of the BMv2 back end has 6 different independent programmable blocks: Parser, VerifyChecksum, Ingress, Egress, ComputeChecksum, and Deparser. For each block, we generate a separate Z3 formula.

Developing the symbolic interpreter. Overall, it took us 5 months of implementation effort until our symbolic interpreter was reliable enough to find new semantic bugs in P4 compilers, instead of encountering false alarms that were actually interpreter bugs. The fact that P4C contains a sizeable test suite [12, §3.4] was helpful in stress testing our interpreter during development. We started our development process by performing translation validation on programs in the P4C test suite. A semantic bug on one of these test programs is probably a false alarm and a bug in our interpreter. This is because it is unlikely that the compiler miscompiles test suite programs. The reference outputs of each test after the front- and mid-end passes are tracked as part of regression testing, and the reference outputs themselves are audited by the compiler developers. We also continuously consulted with the compiler developers to ensure our understanding of the language semantics was correct.

However, we quickly realized that we also needed to generate random programs to achieve coverage and truly stress test our symbolic interpreter. Subsequently, we co-evolved the interpreter with our generator. We attribute part of our success in finding bugs to this development technique, since it forced us to consider many edge cases—more than P4C does. The test suite for our interpreter now has over 600 P4C tests plus over 100 of our own tests.

Eventually, our interpreter had become complete and trustworthy enough to perform translation validation for randomly generated programs so as to trigger semantic bugs in P4C. After we had detected the first semantic bug, we randomly generated around 10000 programs every week and added the resulting compiler bugs to our backlog. Adding support for new P4 language features as part of random program generation typically first led to a crash in our interpreter. After we fixed our own interpreter, we were frequently able to find new semantic bugs in the P4 compiler that pertained to those language features. Because any of the compiler passes may have bugs, our symbolic interpreter does not rely on any compiler pass of P4C. It only relies on the P4C parser and the ToP4 module to produce P4 code from the IR. Hence, we designed our interpreter to handle any P4 program that successfully passed the P4C parser, i.e., before the program is desugared into any normalized form. This allows us to detect semantic bugs in the earliest front-end passes.

```
1 struct Hdr { bit<8> a; bit<8> b; }
2
3 control ingress(inout Hdr hdr) {
4   action assign() { hdr.a = 1; }
5   table t {
6     key = hdr.a : exact;
7     actions = {
8       assign();
9       NoAction();
10    }
11   default_action = NoAction();
12 }
13 apply {
14   t.apply();
15 }
16 }
```

(a) Simplified P4 program applying a table.

```
1 Input:  t_table_key, t_action, hdr
2 Output: hdr_out
3
4 hdr_out =
5   if (hdr.a == t_table_key) :
6     if (1 == t_action) : Hdr(1, hdr.b)
7     otherwise : Hdr(hdr.a, hdr.b)
8   otherwise : Hdr(hdr.a, hdr.b)
```

(b) Its semantic interpretation in Z3 shown in functional form.

Figure 3: A P4 table converted to Z3 semantics.

Converting P4 programs into Z3 formulas. We now describe briefly how we convert a P4 program into a Z3 logic formula. Figure 3 shows an example. Conceptually, our goal is to represent P4 programs in a functional form so that the input-output behavior of the functional form is identical to the input-output behavior of the P4 program. To determine function inputs and outputs, we use the parameter directions of each P4 package. Parameters with the direction `inout` and `out` make up the output Z3 data type of the function whereas parameters with the `in` and `inout` are free Z3 variables that represent the input of the function.

To determine the functional form, the symbolic interpreter traverses each path through the P4 program, maintaining expressions representing path conditions for branching. Once it reaches a portion of the program where execution ends, it stores an if-then-else Z3 expression with the condition set to the path condition and the return value set to a tuple consisting of the `inout` and `out` parameters at that point. Ultimately, the interpreter will return a single nested if-then-else Z3 expression, with each branch corresponding to a unique output from the program under a set of conditions. Using this expression we can perform operations such as equivalence checking between two Z3 formulas for translation validation or querying Z3 to provide an output for particular input for test case generation.

Handling tables. The contents of a table are unknown at compile time. Since we want to make sure we cover any possible table content, we interpret match-action pairs in tables symbolically. Figure 3 describes a simplified exam-

ple of how Gauntlet interprets tables within a control block. Per match-action table call, we generate one symbolic match (`t_table_key`) and one symbolic action variable (`t_action`), which represent a single match key and its choice of action respectively. We compare the symbolic packet header with the symbolic match key (`hdr.a == t_table_key`). If the expression evaluates to true it implies the execution of a specific action, which is chosen based on the value of the symbolic action index (`t_action`). We express this as a series of nested if-then-else statements per action available to the table. Finally, if the key does not match, the default action is selected. For instance, in Figure 3, we execute action `assign` (action id 1) iff the symbolic match variable (`t_table_key`) equals the symbolic header (`hdr.a`) and the symbolic action variable (`t_action`) equals 1. With this encoding we can avoid having to use a separate symbolic match-action pair for every entry in the match-action table, which is a prohibitively large number of symbolic variables.

Header validity. The P4₁₆ specification does not explicitly restrict the behavior of header validity. We model our semantics to align with the implementation in P4C. We clarified these assumptions with the compiler and specification maintainers [62]. If a previously invalid header is marked valid, all fields in that header are initially undefined. If an invalid header is returned in the final output, all fields in the header are set to invalid as well.

Interpreting function calls. Any out parameter in a function call is initially set undefined. If the function returns, we also generate a new free Z3 variable. In our interpreter, externs are treated as a function call that returns an arbitrary value. In addition, each argument for a parameter that has the label `inout` and `out` is set to a new free Z3 variable because the behavior of extern is unknown. Copy-in/copy-out semantics, albeit necessary to control side effects in extern objects, have been a persistent source of bugs in the compiler. A significant portion of the semantic bugs we identified were caused by erroneous passes that perform incorrect argument evaluation and side effect ordering in relation to copy-in/copy-out.

Checking equivalence between P4 programs. We use `p4test` to emit a P4 program after each compiler pass. `p4test` is a P4C back end used to test P4C. It does not produce any executable output but exercises all the default front- and mid-end passes. We only examine passes that actually modify the input program and ignore any emitted intermediate program that has a hash identical to its predecessor. We explicitly reparse each emitted P4 file to also catch bugs in the parser and the ToP4 module.

For an input program A and the transformed output program B after a compiler pass we perform a pair-wise equivalence check for each programmable block. We use our interpreter to retrieve the Z3 formulas for all programmable blocks of the program package and compare each individual block of A to the corresponding block in B. The query for

the Z3 solver is a simple inequality. It is satisfiable only if there is a Z3 assignment (e.g., a packet header input or table match-action entry) in which the Z3 formula of A produces a different output from B.

If the inequality query is satisfiable, it produces the assignment that would lead to different results and saves the failed passes for later analysis. With this technique we can precisely pinpoint in which pass a semantic bug may have happened and we can also infer the packet values we need to trigger the bug. If the report turns out to be a false alarm and is not confirmed by compiler developers, this is a bug in our symbolic interpreter, which we fix. The generated Z3 formulas could in principle be very large and checking could take a long time. However, we use quantifier free formulas for the equality check, which can be solved efficiently in Z3 [20]. Even very large expression trees can be compared under a second.

Handling undefined behavior. We track changes in undefined behavior in which the undefined portion of a P4 program has more restricted (less undefined) behavior after a compiler pass. This means we can identify scenarios where the compiler transforms a program fragment based on undefined behavior. While not immediately harmful, such changes might still indicate problematic behavior in the compiler that may be surprising to a programmer [73].

To track undefined behavior, any time a variable is affected by undefined behavior (e.g., a header is set to invalid and then valid) we label that variable “undefined.” This undefined variable effectively acts as taint. Every read or write to this undefined variable is tainted. When comparing Z3 formulas before and after a pass, we can choose to replace tainted expressions with concrete values in the formula before a pass.³ With this, we can determine if a translation validation failure was caused by undefined behavior. If we find a failure based on undefined behavior, we classify it as unstable code [73] to avoid confusion with real bugs.

6 Model-Based Testing

Our approach to translation validation is applicable only in scenarios where we have access to the P4 IR (and hence the P4 program). This is because it rests on having semantics for P4. This is the case for P4C, which has a flag that allows us to emit the input P4 program after every compiler pass as a transformed P4 program [12, §3.3]. However, in the back end, a P4 compiler employs back-end-specific passes that translate P4 into proprietary formats. These formats are undocumented, making it hard to provide semantics for them. Hence, to find back-end bugs, we developed a bug-finding approach based on model-based testing [19].

³We only replace tainted expressions in the “before” formula so that we can detect compiler bugs where a previously well-defined expression turns undefined, which is an actual compiler bug, not just an unsafe optimization.

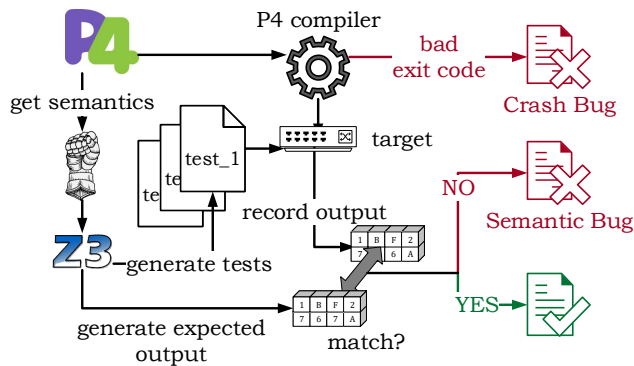

Figure 4: Model-based testing in Gauntlet.

6.1 Design

In this approach, we reuse our symbolic interpreter to produce a Z3 formula of a randomly generated P4 program (Figure 4). With this Z3 formula, we can produce input packets that traverse unique paths in the P4 program, by generating a path condition for every unique program path and asking Z3 for an input packet that satisfies this path condition. Using the same Z3 formula, we can also determine the output packet for this input packet. Thus, we generate a test case for each path and feed this case into the testing framework of the compiler’s target. If the framework reports a mismatch, we know that there is likely a bug. This test technique can identify semantic bugs without requiring access to the P4 program after every intermediate compiler pass. However, unlike the translation validation approach, it is harder to pinpoint the pass causing the bug. This is effectively model-based testing [19] with the Z3 formulas being the model and the compiler output being the system under test.

6.2 Implementation

Model-based testing requires a back-end testing framework that is capable of taking input packets and producing output packets, which can then be matched against the expected output from Z3. We test two back ends: (1) the BMv2 back end that uses the simple test framework (STF) [10], which feeds packets to a software test switch and records output packet capture files and (2) the Tofino back end that uses the Packet Test Framework (PTF) [5] to inject and receive packets. We use the Tofino software simulator to check for semantic bugs in Tofino. We initially reconfirmed every semantic bug we found on the Tofino hardware target, but ultimately switched to running only the simulator for faster testing. However, we confirmed all Tofino bugs with the Tofino compiler developers.

Undefined variables. Variables affected by undefined behavior (undefined variables) are difficult to model in model-based-

testing because any back end is free to perform arbitrary operations on these variables. We were left with two choices: (1) we could avoid undefined behavior in our P4 programs; (2) alternatively, we could ascribe specific values to undefined variables and check if these values conform with the implementation of the particular target. We picked the second approach because it allows independent testing of compiler optimizations in the face of undefined language constructs.

Computing input and output for test cases. We do not have control over program paths that involve undefined variables because we cannot force a target to assign specific values to such variables. Hence, we add conditions which will cause Z3 to only give us solutions for specific restricted program paths. For any path we can control (e.g., a branch that depends on the value of an input header) we compute all the possible input-output values that lead to a new path through the P4 program. This technique is computationally expensive because the number of paths can be exponential in the length of the program. However, in practice, because our P4 programs have a relatively small number of branches, test-case generation followed by testing on a P4 program still completes quickly. If members of an output header are undefined we mark those bits as “don’t care” and ignore that portion of the output packet. For any invalid header we omit its member bits from the expected test output.

For every path, we feed path conditions into Z3 and retrieve a candidate set of input-output values that would cause program execution to go down that path. Because there are typically many solutions for these input-output values, we configure the Z3 solver to give us a randomized, non-zero input and its corresponding output value. In some back ends, using zero values by default may mask erroneous behavior. For example, since BMv2 initializes any undefined variable with zero, the bug in program 5c would not have been caught, had we not asked Z3 for a non-zero input-output pair.

6.3 Limitations

In contrast to translation validation that runs entirely on a formal logic-based representation of the P4 program, model-based testing has several limitations that are caused by needing to run actual end-to-end tests on real targets.

Dropped packets in the testing framework. A key assumption in the model-based-testing approach is that the generated test cases can actually be fed to the testing framework of the back end. However, the semantics of the generated P4 program do not describe hardware-specific restrictions. For example, some devices impose minimum packet size requirements or drop packets with invalid MAC addresses. More generally, we have found that test cases where the input packets have certain values in their headers can be dropped silently by the back end without generating an output packet. Effectively, there is a mismatch between the Z3 semantics, which

Bug Type	Status	P4C	BMv2	Tofino
Crash	Filed	36	4	35
	Confirmed	33	4	25
	Fixed	27	4	8
Semantic	Filed	31	1	10
	Confirmed	26	1	7
	Fixed	22	1	0
Total	96	59	5	32

Table 2: Bug summary. Unfixed bugs have been assigned.

says that a certain output packet must be produced and the back end’s semantics, which produces no output packet. In such cases, we have had to discard these test cases, reducing the breadth of coverage for testing the compiler.

Unknown interfaces between programmable blocks. P4 also does not provide semantics on the treatment of packets in-between the individual control or parser blocks. This is not an issue for translation validation since we compare each programmable block individually. For an end-to-end test, however, we need to know how data is modified between these blocks so that we know what output packet to expect.

Test case complexity. Paths with many branches can generate a large number of distinct path conditions. Thus, millions of input-output packet pairs might be generated. Since small programs have sufficed so far for bug finding, we have not run into these issues. In the future, we may need an efficient path selection technique to tease out more complex bugs on closed-source compilers.

7 Results

We now analyze the P4 compiler bugs found by Gauntlet. A detailed breakdown can be found at p4gauntlet.github.io. Our main findings are summarized below.

1. We confirmed a total of 96 new, distinct bugs across the P4C framework and the BMv2 and Tofino P4 compilers. Of these bugs, 62 are crash and 34 are semantic bugs.
2. Our efforts led to 6 P4 specification changes [18, §A.1].
3. We achieved this in the span of only 8 months of testing with Gauntlet, and despite only generating random programs from a subset of the P4₁₆ language.
4. Model-based testing is effective enough to find semantic bugs in closed-source back ends such as the Tofino compiler, despite us not having access to the internal IR.

7.1 Sources of Bugs

We distinguish the bugs we found into three primary sources: bugs we found in the common P4C framework and bugs we found in the compiler back ends for BMv2 and Tofino. Both

Location	P4C	BMv2	Tofino	Total
Front End	38	-	-	38
Mid End	21	-	-	21
Back End	-	5	32	37
Total	59	5	32	96

Table 3: Distribution of bugs in the P4 compilers.

the BMv2 and Tofino back ends use the P4C front- and mid-end passes. Hence, most bugs detected in P4C also likely apply to these back ends. Note that since the Tofino back end is closed source, we don’t know which P4C passes it uses.

All semantic bugs in P4C were found by translation validation because we had full access to the compiler IR. Where applicable, we reproduced the semantic bugs using model-based testing and attached the failing input-output packet pair with our bug report. All the semantic bugs in the Tofino compiler were found with model-based testing.

Distribution of Bugs. Table 3 lists where we identified bugs. The overall majority of bugs were found in the P4C front- and mid-end framework, mainly because we concentrated on these areas. The majority of the back end bugs were found in the Tofino compiler. There are two reasons for this. First, the Tofino back end is more complex than BMv2 as it compiles for a high-speed hardware target. Second, we did not test the BMv2 back end as extensively as other parts of the compiler.

Bugs in the P4C infrastructure. As Table 2 shows, we were able to confirm 96 distinct bugs. 59 were uncovered in P4C, with a comparable distribution of crash bugs (33) and semantic bugs (26). Initially, the majority of bugs that we found were crash bugs. However, after these crash bugs were fixed, and as our symbolic interpreter became reliable, the semantic bugs began to exceed the crash bugs.

In addition, 6 of the bugs we found led to corresponding changes in the specification as they uncovered missing cases or ambiguous behavior because our interpretation of a specific language construct clashed with the interpretation of the compiler developers and language designers. We also continuously checked out the master branch to test the latest compiler improvements for bugs. Many bugs (16 out of 59) were caused after recent merges of pull requests during the months in which we used Gauntlet for testing. Gauntlet was able to quickly detect these bugs. To catch such bugs as soon they are introduced, the P4C developers have now integrated Gauntlet into P4C’s continuous integration (CI) pipeline.

Bugs in the Tofino compiler. Model-based testing on the Tofino compiler was also successful. We confirmed 25 crash bugs and 7 semantic bugs in the Tofino compiler. These bugs are all distinct from the bugs reported to P4C. The majority of bugs present in P4C could be reproduced in the Tofino compiler as well, because it uses P4C for its front and mid end.

Program	Arch	LoC	Time (mm:ss)
tna_simple_switch.p4	TNA	1940	00:05
switch_tofino_x0.p4	TNA	5751	00:51
switch_tofino2_y0.p4	TNA2	6024	00:53
fabric.p4	V1Model	958	00:02
switch.p4 (from P4 ₁₄)	V1Model	5894	10:20

Table 4: Time needed to get semantics from a P4₁₆ program.

Hence, our Tofino bug count does not include any front- and mid-end crash and semantic bugs already present in P4C. We also do not include Tofino compiler crashes that were caused by a missed transformation in the P4C front end. The Tofino back end was relying on these passes to correctly transform specific P4 expressions. We filed two of these crashes in the Tofino compiler as missed optimization issues in P4C.

Fixing the bugs. Out of the 96 new bugs we filed, 54 have been fixed. The remaining bugs have been assigned a developer, but are still open because we filed them very recently, they required a specification change to be resolved first, or they have been de-prioritized in favor of more pressing bug reports. We have received confirmation by the Tofino compiler developers that 8 bugs have already been resolved; the remainder are targeted to be resolved by the next release.

7.2 Performance on Large P4 Programs

We also measured the time Gauntlet currently requires to generate semantics for several large P4 programs (Table 4). Generating semantics is the slowest part of our validation check; comparing the equality of the generated formulas in Z3 is typically fast. We have observed that retrieving semantics for a single pass takes on the order of a minute for a large program. We believe we can substantially improve this performance for two reasons. First, large parts of our semantic interpreter are written in Python as opposed to C++. Second, we currently use a simple state-merging approach for parser branches. This approach does not sufficiently address the scaling challenge of dense branching. When run on switch.p4 retrieving semantics takes about 10 minutes. We note, however, that switch.p4 is not a representative switch program as the code is autogenerated from old P4₁₄ code. Programs like switch_tofino_x0.p4, which model the data plane of a data center switch, only require a minute per pass.

7.3 Deep Dive into Bugs

Ripple effects. A common crash we observed occurs because a compiler pass incorrectly transforms an expression or does not process it at all. Back end compiler developers rely on the front end to correctly transform the IR of the P4 program. But, if a pass misses a language construct it is responsible for, the back end often cannot handle the resulting expression and

```
1 control ig(inout Hdr h, ...) {
2   apply {
3     h.mac_src =
4       (h.mac_src > 2 ? 48w1 : 48w2) + h.mac_src;
5   }
6 }
```

(a) A bug caused by a defective pass.

```
1 control ig(inout Hdr h, ...) {
2   apply {
3     h.mac_src = (1 << h.modifier) + 8w1;
4   }
5 }
```

(b) A crash in the type checker.

```
1 control ig(inout Hdr h, ...) {
2   apply {
3     bool tmp = 1 != 8w2[7:0];
4   }
5 }
```

(c) An incorrect type checking error.

```
1 control ig(inout Hdr h, ...) {
2   action assign_eth_type(inout bit<8> val) {
3     h.eth_type[15:8] = 0xFF;
4   }
5   apply {
6     assign_eth_type(h.eth_type[7:0]);
7   }
8 }
```

(d) Incorrect deletion of an assignment.

```
1 control ig(inout Hdr h, ...) {
2   apply {
3     h.ipv4.setInvalid();
4     h.ipv4.src_addr = 1;
5     h.eth.src_addr = h.ipv4.src_addr;
6     if (h.eth.src_addr != 1) {
7       h.ipv4.setValid();
8       h.ipv4.src_addr = 1;
9     }
10  }
11 }
```

(e) An unsafe compiler optimization.

```
1 control ig(inout Hdr h, ...) {
2   action assign_and_exit(inout bit<16> val) {
3     val = 0xFFFF;
4     exit;
5   }
6   apply {
7     assign_and_exit(h.eth_type);
8   }
9 }
```

(f) Incorrect interpretation of exit statements.

Figure 5: Examples of bugs that were caught by Gauntlet.

generates an assertion failure. For example, in program 5a, the front end SideEffectOrdering [10] pass should have converted the conditional operator in line 3 into normal if-then-else control flow. However because of the addition ex-

pression, the pass failed to transform the conditional operator, which ultimately caused an assertion to fire in the Tofino back end [61]. In another case, the InlineFunctions [10] pass did not fully inline all functions calls, causing a crash in back ends that were not able to understand function calls and expected them to have been inlined by then [58].

Crashes in the type checker. Many of the crashes (21 out of 33) were in the type checker infrastructure. The code in 5b shows an expression that crashed type checking [60]. It is not possible to shift this value since its width is unknown at compile-time. This program was deemed illegal, but the specification did not explicitly forbid it. The type checker tried to infer a type regardless and crashed. This bug also triggered an update to the P4₁₆ specification [27]. In other cases, the type checker was incorrectly forbidding a valid expression. In example 5c, the program was legal, but because a safety check in the StrengthReduction [10] pass was incorrectly implemented, the resulting slice index was overflowing and turned negative, which prompted the type checker to terminate with an error message [60].

Handling side effects. Side effects from a function operate on the concept of copy-in/copy-out semantics, described earlier. However, these semantics, while seemingly simple, turn out to be hard to implement correctly in the compiler. A particularly tricky case can be seen in 5d [64].

In the program, a slice of a variable is passed as an inout parameter. At the same time, a disjoint subset of the variable is assigned within the function. The correct behavior here is to leave the assignment unchanged, and copy back the sliced portion of the variable alone. However, the compiler assumed that the entire variable would be copied back and removed the assignment in line 3, an incorrect optimization.

A large subset of the semantic bugs we found in P4C (at least 11 out of 26) can be traced to incorrect handling of side effects and copy-in/copy-out. Copy-in/copy-out is difficult to handle because for a compiler pass that reorders expressions or statements, side-effects can be translated incorrectly.

Unstable code. Even though the P4₁₆ language has limited undefined behavior, we also found incidents of unstable code [73]. This unstable code conforms with the specification but may lead to instability in specific back end targets. Dumitru et al. also discuss the potential safety consequences of undefined variable access [24]. Program 5e is a concrete example. The compiler collapses the assignment of line 4 into line 5, setting `h.eth.src_addr`, which is still part of a valid header, to 1. All of this is legal behavior, since read and write operations on invalid header values are undefined as part of the P4 specification. The compiler is free to perform these optimizations. However, these changes may cause issues in specific back ends, e.g., back ends in which assignments to invalid headers are no-ops. In this case, the compiler has chosen a particular subset interpretation of undefined behavior, which may clash with the expectations of programmers for

that back end. We raised this with the compiler developers, who agreed to print a warning [62].

Consequences of compiler changes. Once we started actively monitoring the master branch of P4C we observed that many (19 out of 59) of the bugs we filed in P4C were caused by recent merges into master. A notable example is a recent change to the Predication [10] pass, which caused at least 6 (1 crash and 5 semantic) new bugs. We caught and filed these bugs quickly during our weekly routine random code generation. The compiler pass has become so complicated that the compiler maintainers are now relying on Gauntlet to ensure correctness [3]. A P4 programmer also filed a bug on this issue [28]. The report was considered a duplicate because of our earlier reports, highlighting that the bugs we find do affect actual P4 programmers.

Specification changes. Some of our bug reports kicked off larger discussions and changes around the P4 language specification. Our bug reports and questions have led to at least 6 distinct specification changes. For example, a concern we had about the validity of uninitialized headers (at what point does a header variable become valid?) led to three clarification pull requests on the specification and a suggestion to propose more fundamental changes for the next language version [30].

Another prominent example was caused by ambiguity in the specification. In example 5f, the `RemoveActionParameters` [10] compiler pass moved the statement in line 3 after the exit statement, because the assumption was that exits called within functions ignores the copy-in/copy-out semantics. We instead interpreted exit statements to still respect copy-in/copy-out semantics and caught the discrepancy. This is a significant difference. A packet that traverses the control program could lose all the modifications that have been written to its header, a potential security risk. We filed this as a concern with the open-source community [59] and our interpretation was deemed reasonable, which required a specification update [31]. The corresponding compiler changes resulted in at least 3 new bugs, which we detected and filed.

Invalid transformations. Because P4C provides the option to emit transformed programs after each pass as a valid P4 program, the compiler developers maintain an invariant that each compiler pass in the front and mid end needs to emit syntactically correct P4. We uncovered several bugs with how P4 code is emitted and transformed across compiler passes. We detected these bugs by reparsing each P4 program after it had been emitted by the ToP4 compiler module. If the emitted program can not be reparsed, it indicates a bug in one of three compiler components: the ToP4 module, the P4C parser, or the compiler pass. While these bugs typically do not harm correctness, they affect compiler debugging. Overall, we identified 4 bugs of invalid intermediate P4, all of which were fixed; these 4 are not included in our count of 96. Additionally, because we reparse P4 after each compiler pass, we found a

case where the emitted program being parsed incorrectly was a symptom of a larger bug in the P4C parser [63].

7.4 Lessons Learned

P4C debugging support. P4C has several facilities that were useful for bug finding. The ability to dump the intermediate representation, specify which passes to dump, and the ToP4 tool, which converts the P4 IR to P4 programs accelerated our development process. In addition, the compiler has comprehensive assert instrumentation with distinct messages, which we used to identify unique crash bugs and to distinguish them from valid error messages. The AST visitor library in P4C allowed us to develop extensions like our random program generator and interpreter.

P4C’s nanopass architecture, which factors the compiler into a large number of “thin” passes, helps with bug fixing, especially for semantic bugs that were narrowed down to one pass by translation validation. A different architecture that has fewer “thick” passes would need more developer effort to fix semantic bugs. We also observed that almost all crash bugs were assertion violations where an invariant was violated in a particular compiler pass due to an incorrect or absent compiler transformation from a previous pass. In the absence of such assertions, these crash bugs could have easily manifested as semantic bugs that are harder to detect.

Reporting bugs. This project would not have been possible without the responsiveness and receptiveness of the P4 community. Our questions, concerns, and bug reports were answered within a day and in great detail. The developers were able to even dissect our initial questions and confusions into bug reports, guiding us further in our development effort. We were encouraged to participate in the language design working group that discusses changes to the P4 specification.

Likewise, when we filed bugs for the closed-source and proprietary Tofino compiler, we found the developers to be receptive and responsive. Still, the pace of bug finding and fixing with the Tofino compiler was slower than the open-source compiler because of two unavoidable reasons. First, we naturally didn’t have access to the company bug tracker to assess the life cycle of our bug once it had been filed. Second, the official binary of the Tofino compiler updates less frequently than P4C, which can be rebuilt from source after every commit. Hence, we would trigger the same bugs repeatedly in our testing until a new Tofino compiler version with a bug fix was released. Neither of these two problems would manifest, if our tool was to be used internally as part of the compiler development process for Tofino.

8 Future Work

New types of bugs. Gauntlet can not find compiler bugs that affect performance or resource usage of generated code. For

a switching ASIC that guarantees line-rate performance, the compiler must produce code that consumes a small number of computational and memory units [33]. For software targets where line rate performance is not guaranteed, the generated code must have good performance. For example, the P4-eBPF compiler, which converts P4 to eBPF/XDP [35] byte code, occasionally produces code with poor performance [72]. We are investigating methods that allow us to identify when a compiler pass negatively affects performance and resource usage. We anticipate that handling such bugs would require techniques that are conceptually very different from our methods, which deal with correctness bugs.

Supporting aggressive compiler optimizations. Similar to credible compilation [55], we plan to repurpose Gauntlet as an attachable compiler plugin to facilitate development of experimental compiler optimizations. During compilation, if a newly added optimization produces semantically incorrect code, Gauntlet will notify the compiler to discard the optimization. With this technique, a developer can integrate potentially buggy code into the compiler while still guaranteeing a safe compilation process. However, for the plugin to be useful, Gauntlet’s translation validation needs to be fast enough so that compilation time remains acceptable.

Extending translation validation to the compiler back end. So far we have applied translation validation only to compiler front and mid ends. This is because these passes allow us to dump the P4 program before and after the pass has run, allowing us to compare the before and after programs for equality. The back end is typically proprietary, inaccessible, and uses an opaque intermediate representation. To understand the constraints of these back ends we are currently working with industry compiler developers to integrate translation validation into their compilers. We will develop translation validation techniques that allow us to compare a P4 program’s semantics with the semantics of a back end language that is not P4.

Long-term study on translation validation in CI. Now that translation validation is running as part of the CI pipeline of P4C we would like to perform empirical, long-term studies. We want to identify which passes frequently cause semantic issues and understand why they do. We would also like to observe how developer-friendly our tool is. For example to avoid confusing compiler developers, we already had to make sure that Gauntlet does not report changes in undefined behavior [29] or fails gracefully when Gauntlet does not support a particular language construct [11].

Automatic test case reduction. We have not developed an automatic test-case reduction suite (e.g., C-Reduce [54]) and reduce buggy programs in a manual fashion. After our testing pipeline has identified problematic programs in a randomly generated batch, we inspect each P4 program individually. We prune the random P4 program that caused the bug until we get a sufficiently small program that can be attached to a

bug report. We are currently automating this process.

Better coverage of the compiler and P4₁₆ language. While our symbolic interpreter provides semantics for the majority of the P4₁₆ language constructs, we currently do not generate programs that contain several P4₁₆ language features: extern calls, method overloading, type definitions, variable bit vectors, run-time indices, match types such as longest prefix or ternary matches, type-inference for generic types in function bodies, annotations, and various custom table properties. We expect that adding most of these will be conceptually straightforward, although adding each language construct is a fair amount of additional engineering. One particular construct that we anticipate being hard to support is externs. While our interpreter includes an extension model to add custom semantics for each extern, extern behavior is very back-end-specific. It is hard to develop accurate semantics for these externs without detailed hardware knowledge of each target. We also do not track how much of the compiler source code we actually cover with our program generator. For future work, we would like to measure the compiler code coverage of a generated P4 program with gcov to understand avenues for improvement.

9 Related Work

P4K [38] was an effort to formalize the P4 language using the K-framework [56]. In the process of defining these semantics, the authors found several issues in the P4 specification. P4K supports the use of translation validation similar to our tool. netdiff [23] uses symbolic execution to verify the equivalence of data planes, such as those written in P4. They do so by converting P4 and other data plane programs into the SEFL language [69], which in turn can be converted to Z3. The Z3 expressions corresponding to different data planes can then be compared for equality. netdiff’s equivalence checking technique is comparable to our translation validation technique. However, neither P4K nor netdiff were explicitly designed for finding compiler bugs. To enable such bug finding, we need both a source of random P4 programs and a translation validation technique to compare intermediate versions of these programs. Further, for some back ends such as the Tofino compiler, translation validation is insufficient, requiring us to use model-based testing instead.

p4pktgen [49] is a P4 test-case generation tool, similar to our model-based testing technique. p4pktgen parses the JSON file generated by the BMv2 back end and outputs a Z3 formula, which it uses to create test cases. Using p4pktgen, the authors were able to find several bugs in how BMv2 executes JSON files. However, because it operates on output JSON instead of the input P4 program, unlike Gauntlet, p4pktgen can not find bugs in intermediate compiler passes.

petr4 [21] is a project with the goal of providing independent and complete formal foundations for the P4₁₆ language. petr4 is complementary to our work. While we are explic-

itly targeting the official P4₁₆ compiler and specialized our tools to find bugs during compilation, petr4 aims to find inconsistencies and mistakes in the official P4₁₆ specification and type system. petr4 provides an interpreter that aims to establish unambiguous semantics for a given P4₁₆ program. This semantic interpretation can potentially be used to guide the development of our own interpreter semantics.

10 Conclusion

This paper presented Gauntlet, a tool for finding bugs in packet-processing compilers for languages such as P4. Gauntlet combines random program generation, translation validation, and model-based testing to find both crash and semantic bugs in P4 compilers. It has been highly effective, uncovering 96 new and confirmed bugs. 54 of these have been fixed and the rest have been assigned to a compiler developer. We have open sourced Gauntlet at p4gauntlet.github.io and it now runs as part of the CI infrastructure of P4C.

While we developed Gauntlet for P4, we believe the core technique that makes Gauntlet effective is much more general. In particular, Gauntlet exploits the fact that P4 is a DSL with significant restrictions such as the lack of loops. These restrictions allow us to revive and simplify prior techniques such as translation validation and take them much further in the context of a DSL. For example, to our knowledge, Gauntlet is the first instance of translation validation running as part of a compiler’s CI infrastructure. We believe this ability to exploit domain specificity for more effective compiler bug finding will increasingly be applicable to other DSLs beyond P4.

Acknowledgements

We would like to thank our shepherd, Madan Musuvathi, and the anonymous OSDI reviewers for their valuable feedback. We would also like to thank Amy Ousterhout, Aurojit Panda, Thomas Wies, Michael Walfish, Srinivas Narayana, and Mihai Budiu for their insightful feedback on paper drafts and the project. We are grateful to the P4 compiler team at Barefoot Networks and the open-source P4 community for their feedback and willingness to engage with our bug reports. In particular we would like to thank Mihai Budiu, Nate Foster, Andy Fingerhut, Han Wang, and Antonin Bas for their prompt responses to our many bug reports. We also thank Aatish Varma and Peixuan Gao for experimenting with using AFL for finding bugs in P4C as part of their course project.

Aragog: Scalable Runtime Verification of Shardable Networked Systems

Nofel Yaseen[◊], Behnaz Arzani[†], Ryan Beckett[†], Selim Ciraci[§], and Vincent Liu[◊]

[◊]University of Pennsylvania [†]Microsoft Research [§]Microsoft

Abstract

Network functions like firewalls, proxies, and NATs are instances of distributed systems that lie on the critical path for a substantial fraction of today’s cloud applications. Unfortunately, validating these systems remains difficult due to their complex stateful, timed, and distributed behaviors.

In this paper, we present the design and implementation of *Aragog*, a runtime verification system for distributed network functions that achieves high expressiveness, fidelity, and scalability. Given a property of interest, *Aragog* efficiently checks running systems for violations of the property with a scale-out architecture consisting of a collection of global verifiers and local monitors. To improve performance and reduce communication overhead, *Aragog* includes an array of optimizations that leverage properties of networked systems to suppress provably unnecessary system events and to shard verification over every available local and global component. We evaluate *Aragog* over several network functions including a NAT Gateway that powers Azure, identifying both design and implementation bugs in the process.

1 Introduction

An emerging bottleneck to correctness and availability in modern cloud systems are the various network functions (*e.g.*, firewalls, NATs, and load balancers) that interpose on the majority of application requests flowing to, from, and between servers in the cloud. Over time, these network functions (NFs) have become increasingly complex. Today, many of these functions are full-fledged distributed systems whose correctness depends on the coordination of multiple devices as well as on stored state and system timing.

Configuration errors and software bugs in these components can have an outsized impact on SLAs [4] not only because of the complexity of these systems, but also because they are on the critical path of most application requests. For instance, a production NAT gateway we verify in this work manages (replicated) states for millions of flows and errors in this system can lead to black holes, broken connectivity, forwarding loops, and more. Public incident reports from providers show multiple outages due to errors like these [4, 19].

To improve availability, recent proposals suggest using *static verification* to prove the correctness of these systems [21, 25, 29, 34, 40–42, 44]. While powerful, the need

to reason about every possible interleaving of inputs and control flows presents a significant obstacle to the application of these techniques in today’s network functions. Attempting to explore the full space of control flow paths often leads to state/path explosion [25, 29, 40]. Mitigations to this problem, broadly speaking, can be categorized in a few ways. The first is to require the use of special programming languages or other types of programmer interaction [21, 43]. The second is to use model checking techniques to more efficiently explore all possible system behaviors. Finally, many systems—to reduce the state space they must verify and to make verification more tractable—limit the set of verifiable behaviors, *e.g.*, to those that are unordered [34], abstract [10], or restricted to a single machine [42, 44].

While effective in many cases, each of these approaches also comes with significant drawbacks. With the first, programmers are saddled with a substantial burden that can overwhelm the development of the system. With the second, model checking still typically relies on hand-written models of functionality, which may be difficult to provide for a rapidly evolving or complex system. Finally, limiting the scope of verification fails to extend to the increasingly complex services found in modern networks—services that arguably need verification the most.

An alternative approach to static verification is runtime verification of distributed systems. In runtime verification, a tool extracts information about the current state of a running system (testbed, canary, or production) to verify that invariants hold throughout execution [13, 14, 28, 30, 31, 33, 36, 39]. Compared to static verification, runtime verifiers only test inputs and control flows that are seen in practice, thus improving scalability and enabling verification of actual deployments running over actual data. In return, they sacrifice a principled exploration of the system’s behavior and the ability to catch bugs early. We argue that these tradeoffs are a better fit for our operators’ requirements.

We find today’s runtime verifiers cannot be applied as-is to deployed network functions. The challenge (for network functions) is the need, at runtime, to: (1) reason about the coordination between events issued at different locations, (2) efficiently aggregate global state after each event, and (3) scale sub-linearly with the size of the original system—after all, a verifier that requires the same amount of resources as the system itself is untenable for most production environments.

In this paper, we present the design of a scale-out, runtime

verification tool for network functions called *Aragog* that overcomes the above challenges. *Aragog* provides a simple, but expressive language for describing violations of invariants, with a focus on supporting network functions. Examples of network-centric language features that are found in *Aragog*'s Invariant Violation (IV) specifications, but that are uncommon in other runtime verifiers are support for properties that are parametric over the "location" of events, properties that reference stateful variables, the ability to execute partial matches over packet fields, and support for temporal predicates.

Aragog translates these IV specifications to a set of symbolic automata that can efficiently verify the current global state of the system. In addition, to ensure that the system can scale out to a near-unlimited number of machines, *Aragog* implements the core of these checks on top of production stream processing systems [2, 3]. To efficiently coordinate between distributed verifiers, *Aragog* relies on hardware-supported time synchronization protocols like PTP. Finally, to minimize the overhead of the verification system, *Aragog* leverages observations that network events/invariants are typically:

Flow- or connection-based: For most network functions, correctness is defined on a per-flow or per-connection basis. From the IV specification, *Aragog* derives sharding keys that allow it to distribute the verification task across independent workers. These shards also expose boundaries on which we can gracefully scale down to a sampled subset of the input.

Partially suppressible: Rather than aggregate all events in the system to a logically centralized verifier, most network events have limited windows of relevance depending on the state of the system, e.g., only if the connection has recently been closed. *Aragog* includes an optimization scheme to suppress such messages before they ever leave the NF instance.

Aragog does not guarantee perfect accuracy under asynchrony—to do so would require atomicity guarantees in the critical path of the network functions. *Aragog* instead handles these situations speculatively and notifies users after-the-fact¹ about transient inconsistency (§7.3). Despite this, *Aragog* identified at least four bugs in an early (limited) deployment of a real distributed network function: Azure's new NAT gateway (NATGW). These bugs were detected within ~100 ms of occurrence. Compare this to the hours our operators typically spend searching for similar bugs.

To summarize, our work makes the following contributions:

- We present a case study of the needs of a large modern network function from Microsoft's Azure. The system exhibits several interesting characteristics and suggests key requirements for verifier design.
- We synthesize ideas from timed regular expressions, symbolic automata, and parametric verification. To the best of

¹This reporting happens in under 1 s. This delay is on the same order as other alerting systems used in our production networks.

Figure 1: The architecture of our NATGW. The bolded blue arrows show the sequence of communication to handle the SYN packet of an incoming flow: it is sent to a random packet worker, which forwards it to the flow decider in charge of that flow. The flow decider chooses a target server and replicates the mapping to other deciders, then installs it in the original packet worker. The three dashed red arrows trace the allocation of the mapping for the reverse flow.

our knowledge, ours is the first to demonstrate a concrete need and method for combining these concepts.

- We introduce the design and implementation of *Aragog*, a system for at-scale runtime verification. When needed, *Aragog* can also run on traces (offline) and therefore complement static verification to find implementation bugs in distributed networked systems. Among other innovations, *Aragog* includes a novel method for computing location-dependent suppression of network events.
- We introduce a collection of *Aragog* invariant violations for a set of distributed network functions, and we evaluate *Aragog* on NATGW and a distributed firewall.

2 Motivation: A Cloud-scale NAT Gateway

Our work is grounded in experience with Azure's large-scale NF that we call NATGW. NATGW is a cloud-scale NAT gateway that balances incoming requests over available servers and supports almost all external traffic.

Like many other NFs of similar scale [16, 35], NATGW is implemented entirely in software, is distributed across a pool of servers, and replicates state for fault tolerance. Routers use ECMP-based anycast to randomly direct packets to NATGW workers, which then rewrite the destination IP and port to point at a target server. A similar translation occurs for packets in the reverse direction (from the server to the client).

Figure 1 depicts the NATGW architecture. It is composed of two types of nodes: packet workers and flow deciders. Packet workers process every packet passing through the NATGW, parsing its header, looking up the target server, and rewriting the packet header to point to that target. The mapping of a flow to a target server is decided with the help of a sharded set of flow deciders. The deciders cache and replicate these mappings to other deciders to ensure availability.

Flow allocation. When a packet worker receives the first packet of a new flow, it uses a hash of the 5-tuple to identify

the “primary” flow decider that owns the flow and forwards the packet to that decider. The primary then:

1. Decides the target server to which to send the new flow and installs the mapping in the local flow cache.
2. Sends the reverse mapping to the flow decider that “owns” the other end of the flow. Together, these two mappings cover translation for both incoming and outgoing traffic.
3. With its counterpart primary, greedily copies the mappings to the cache of other flow deciders in a manner akin to chain replication: decider i will try to copy to deciders $(i + 1) \bmod N$ and $(i + 2) \bmod N$, where N is the number of deciders. If one is down, it switches to $(i + 3) \bmod N$.
4. Installs the mapping into the originating packet worker.

After the above flow allocation, the packet worker can process all subsequent packets of the flow without coordination with any other node. If the packet worker fails, anycast redirects the packet to another worker; the new worker will send the packet to the primary flow decider, fetching the existing mapping. If the flow decider fails, packet workers will query the next deciders in the sequence until they find the mapping.

Flow mapping timeouts. All components time out their flow mappings to ensure stale entries are eventually removed.

To ensure NATGW maintains mappings for active flows, packet workers periodically send a keepalive message to the primary decider. The primary forwards the keepalive to all replicas, refreshing the timeout on every instance of the mapping in the system. In parallel, the primary forwards the keepalive to the primary in charge of the reverse mapping.

Eventual consistency. This NATGW design exhibits some interesting properties. One of them is a choice to allow for temporary inconsistency in the presence of node failures in order to satisfy certain practical and performance constraints.

For example, consider three replicas of a flow mapping R_P , R_{P+1} , and R_{P+2} , where R_P is the primary. To delete the mapping, R_P would send a delete request to both of the other nodes. Now imagine the message to R_{P+1} is dropped. Rather than waiting for R_{P+1} , the others will go ahead and delete f . If, later, R_P fails, packet workers will contact R_{P+1} for the mapping, which will return a stale/inconsistent result until a timeout or periodic sync eliminates the inconsistency.

There are known mitigations to the above behavior (e.g., querying a quorum on every packet or initiating a view change algorithm on R_P ’s failure); however, these come with significant performance costs. Instead, the NATGW is an example of a *deployed* architecture that chooses eventual consistency after careful consideration of its drawbacks and alternative solutions. Our work is motivated by our operators’ experience with such behaviors.

3 Design Goals

Our runtime verifier targets the following design goals:

Practicality. Network functions are complex; written in a variety of languages; and frequently rely on external libraries, drivers, and other components. NATGW, for example, is built using libraries like DPDK and interacts with an ecosystem of networking hardware and configurations. The intricacies of the systems, the richness of their dependencies, and the rapid evolution of all the associated components mean the system is not easily modeled or accurately simplified. Instead, verification should be of the end-to-end system, *in situ*.

In the same vein, *Aragog* should not place undue burden on developers, e.g., by requiring engineers to perform non-trivial proof writing (as mandated by many deductive reasoning techniques). NATGW has over 40 thousand lines of code—*Aragog* should avoid incurring a proportional overhead.

Expressiveness. Prior work has observed a gap between state-of-the-art verification tools and the requirements of modern networks [33]. In particular, it is challenging to specify invariants related to: (1) parametric variables over values like locations or identifiers, (2) coordination between network devices, and (3) timing of events. Moreover, since the number of devices (e.g., flow deciders) may vary over time as the system scales out, it is useful to express properties in a way that does not require explicitly naming components. *Aragog* should provide syntax and semantic support for these behaviors.

Scalability. Just as a single machine cannot handle all traffic entering a large network, it also cannot be expected to verify the correctness of the entire network. Rather, the verifier should scale out to arbitrary size and require fewer resources than the original system. Therefore, *Aragog* should attempt to minimize the number of messages exported from each NF, e.g., by exporting events (resulting from the execution of the NF) rather than packets (the inputs to the NF).

Graceful degradation of accuracy. As we describe in Section 7.3, perfect precision and recall is impossible in an asynchronous system without substantial overhead. Instead, *Aragog*’s correctness goal is in the same spirit as NATGW’s: perfect recall under the assumption of ‘partial synchrony’ [15] and notifications of potential false positives/negatives after-the-fact. Our operators find this is sufficient for most cases.

Near-real-time alerts. Diagnosing bugs manually can take hours of operator time and the network could worsen the longer the bug persists: *Aragog* should raise alerts within seconds of observing the offending sequences of events.

4 Aragog’s Architecture

We present the design and implementation of a practical, expressive, and scalable verifier for large and complex NF deployments. Our system, *Aragog*, is a combination of a language for specifying invariant violations and a scale-out runtime system. *Aragog* takes a grey-box approach, requiring small changes to the underlying source code in order to export events of interest to the verifier. Thus, *Aragog* verifies by:

Figure 2: The architecture of *Aragog*. NF instances generate and feed events into a set of local state machines. The NF instances use these state machines to determine if they can hide unnecessary messages before exporting the rest to the global verifier. These messages pass through a Kafka cluster and are streamed to a set of Flink-based verification engines.

Specifying invariant violations over user-defined events.

To provide operators with sufficient expressiveness to check network-level events, *Aragog* comes equipped with a new language for specifying invariant violations that is based on writing symbolic regular expressions over a global trace of events (and their locations) in the system. *Aragog*’s language includes a notion of parameterized “variables” that allows violations to be described in a way that holds for any combination of variable instantiations subject to constraints.

Checking for invariant violations. NF developers export any relevant events to *Aragog*. To scale up checking of the event stream, *Aragog* does two things. The first is to automatically analyze and split verification into local and global components. The local level resides at the NF instances themselves, where *Aragog* infers (only using the state of the local instance) whether it can safely suppress the event before exporting it to the global *Aragog* verifier. The second is to leverage the fact that most network invariants are defined across *related flows* rather than globally—for instance, on the granularity of a 5-tuple. As a result, events can be automatically sharded across a cluster of scale-out stream processing workers using Kafka [26] and Flink [11].

Note that, because the invariants are defined and checked only across related flows, we only need to know the correct ordering for events pertaining to those flows: event timestamps that use the sub-microsecond-scale synchronization of PTP suffices for our needs. For many production networks, these types of event exports are already common.

Overview. Figure 2 shows *Aragog*’s design. Users describe a set of invariant violations that identify classes of incorrect behavior. *Aragog* translates these to a set of symbolic automata and then splits the automata into local and global components. It then deploys these to NF instances and global verifiers.

At runtime, NF instances stream events into the pipeline. The local *Aragog* agent filters, maps, and shards events. The message brokers aggregate and compact those streams. The global verifiers determine, for the shard, whether a violation occurred. Kafka and Flink will automatically allocate

resources and load balance requests to ensure scalability.

5 Specification Language

Users define both events and policies over the events using two types of specifications that are inputs to *Aragog*: event definitions and Invariant Violation (IV) specifications. While both of these require the user to have some knowledge of the inner workings of the NF to specify how it can fail, our network operators determined that event-based violations struck a reasonable balance between precision and ease-of-use.

5.1 Event Definitions

Users specify the format of the event messages that arrive at the local verifier. *Aragog* expects these messages to be in the form of packed arrays of raw binary data whose format is defined with a JSON configuration file. For example, Figure 3 shows a selected subset of the definition for NATGW event messages. ‘fields’ contains the ordered list of expected fields in the message. Each field is defined by a JSON dictionary specifying the field’s name and its length in bits—for instance, the first 16 bits of the event message is an *eventType*.

Conditionals. In addition to specifying the length of each field and their ordering, *Aragog* allows users to implement simple conditional parsing logic. The example event definition shows one such use where *srcIP* can be either IPv4 or IPv6. In the configuration shown, event messages include a 8-bit field that specifies the IP version number. Depending on the value of that version number, the next field is either a 32-bit or 128-bit *srcIP* field. These branches can define entire sub-headers and can contain nested conditionals.

Named constants. *Aragog* also allows users to define named constants representing integer values represented in decimal, hexadecimal, or binary notation. We show four such constants in Figure 3: two for values of the *eventType* field and one for the *nodeType* field. These are intended for use in IV specifications to make them more readable.

```

1 FILTER((eventType == FLOWCACHE_PRIMARY_ADD
2      || eventType == FLOWCACHE_REMOVE_ENTRY)
3      && workerType == FD)
4 GROUPBY(srcIP, dstIP, srcPort, dstPort, proto)
5 MATCH
6 (eventType == FLOWCACHE_PRIMARY_ADD) @ $X
7 ((eventType == FLOWCACHE_REMOVE_ENTRY) @ NOT $X)*
8 (eventType == FLOWCACHE_PRIMARY_ADD) @ NOT $X

```

Figure 4: An example IV specification that ensures at most one primary is ever active for a given flow.

5.2 Invariant-Violation (IV) Specifications

Aragog parses incoming event messages and checks them against a set of user-defined policies that describe sequences of events that violate the invariants of the system. Operators specify these policies using *Aragog*’s domain-specific language, which we detail in this subsection.

Figure 4 shows an example specification for our NATGW. The policy only pertains to a subset of events (lines 1–3), and *Aragog* verifies it on a per-5-tuple basis (line 4). A violation occurs when some node $\$X$ adds a primary mapping (line 6) and then a different node (NOT $\$X$) adds the same mapping (line 8) without $\$X$ removing it. The full grammar for IV specifications is shown in Figure 5. Briefly, an IV specification consists of (1) a collection of event transformations followed by (2) a regex-like expression over the generated events.

5.2.1 Transformations

Aragog allows users to define a set of policy-specific transformations. In addition to enabling greater flexibility and expressiveness, *Aragog* also uses these transformations to perform an initial filtering and aggregation as well as to identify valid sharding strategies. *Aragog* currently supports three transformations: **GROUPBY**, **FILTER**, and **MAP**.

Operators can use **GROUPBY** to indicate which events need to be considered together and which can be considered separately. For example, when an operator wishes to guarantee at most one primary is active (Figure 4) for *each flow*, the **GROUPBY** is used to classify events into unique flows. *Aragog* uses this transformation to both simplify policy logic and to assist in the sharding of verification.

Operators can also use the **FILTER** transformation to indicate which events should be considered at all and which should be ignored. In the above example, we only care about flow deciders—specifically when they add a flow as a primary and when they delete the flow mapping from the cache; we can filter events of any other type or from any other type of node. **FILTERS** are critical for reducing the number of events handled by the verification framework.

Finally, operators can use the **MAP** transformation to generate entirely new fields based on mathematical expressions over existing fields of the event message.

```

<IVspec> ::= <transformations> 'MATCH' <events>

<transformations> ::= <transformations> <transformations>
| 'GROUPBY' '(' <fields> ')'
| 'FILTER' '(' <filter_matches> ')'
| 'MAP' '(' <field_expression> ',' <field_name> ')'

<fields> ::= <field_name> ['<fields>']
| 'LOCATION' ['<fields>']

<filter_matches> ::= '(' <filter_matches> ')'
| <filter_matches> '|' <filter_matches>
| <filter_matches> '&&' <filter_matches>
| <filter_match>

<filter_match> ::= <field_name> <compare_op> <field_name>
| <field_name> <compare_op> <value>

<events> ::= '.' '@' <location_spec>
| '[' '!' '(' <event_match> ')' '@' <location_spec>
| '(' <events> ')'
| <events> <events>
| <events> <regex_op>
| 'SHUFFLE' '(' <events_list> ')'
| 'CHOICE' '(' <events_list> ')'

<events_list> ::= <events> ['<events_list>']

<location_spec> ::= 'ANY'
| <loc_matches>

<loc_matches> ::= '[' 'NOT' '$' <loc_name> ['<loc_matches>']

<event_match> ::= <field_match> ['<event_match>']

<field_match> ::= <terminal> <compare_op> <terminal>

<terminal> ::= <field_name>
| <value>
| '$' <variable_name>
| 'TIME'

```

Figure 5: Grammar for *Aragog*’s IV specification language. Tokens ending in ‘_name’ are identifiers that must begin with a letter; the ‘compare_op’ token refers to the class of operators ‘=’, ‘!=’, ‘<’, etc; ‘value’ indicates a constant number; and ‘field_expression’ is a mathematical expression over fields.

5.2.2 Event Expressions

Users define invariant violations over the transformed event streams by specifying sequences of events that result in a violation of a particular policy. Users specify these sequences with a regular-expression-like language, which describes patterns over pre-defined elements. In *Aragog*’s case, the elements take the form of a set of matching operations over the fields of the event message; the example in Figure 4 shows matches on one such field, the `eventType`. A match can occur at any point in the stream of events and triggers on every occurrence of the match, not just the first. For example, if events $A \rightarrow B \rightarrow A$ form a violation and (at runtime) we observe the sequence *CABABAC*, *Aragog* will alert twice.

As in other regular languages, users can list the sequence of expected elements and use operators like ‘*’, ‘+’, and ‘?’ to signify repetitions. Users can also leverage the functions **CHOICE** and **SHUFFLE**. In **CHOICE**, an occurrence of any one of

```

1 FILTER(eventType == INIT || eventType == DROP)
2 GROUPBY(LOCATION)
3 MATCH
4   (eventType == INIT, srcIp == $S, dstIp == $D,
5     srcPort == $P, dstPort == $Q) @ ANY
6   (. @ ANY)*
7   (eventType == DROP, srcIp == $D, dstIp == $S,
8     srcPort == $Q, dstPort == $P) @ ANY

```

Figure 6: An example specification that checks that a stateful firewall does not drop reverse traffic for an open connection.

the contained expressions matches. In **SHUFFLE**, the contained events can arrive in any order, but must all arrive.

Event expressions come after the set of transformations and must appear after a **MATCH** statement.

Locations. In distributed NFs, an important feature is that correct behavior is defined not only on the events and their order, but on *where* the events occurred. Therefore, every event match is accompanied by a location specifiers. This is useful for specifying matches, but it is also important for determining how we might partition evaluation of the IV specification across both local and global verifiers (see Section 6). In both cases, the goal is to determine whether each pair of events are expected to occur at the same or at different NF instances.

Consider again the example in Figure 4. The example contains a single named location, \$X, corresponding to the original primary node for the current flow. One way to use this named location is to specify that another event in the sequence must *also* occur at \$X. Another, demonstrated in lines 7&8, is to specify that the event occurs at a location distinct from \$X. Note that the syntax does not constrain the relationship between the locations of the events of lines 7&8.

Every event can reference one or more named locations, or it alternatively use the location ANY, which indicates no special semantic meaning of the location of the event. In the case of multiple locations, users specify multiple predicates (one per location). For example, to ensure three events with distinct locations: one could specify ev_1 at ($\$X, \text{NOT } \Y); ev_2 at ($\text{NOT } \$X, \Y); and ev_3 at ($\text{NOT } \$X, \text{NOT } \Y).

One possible method of implementing locations is to enumerate all possible locations in the system and expand the event expression accordingly. While this would allow the usage of more traditional state-machine evaluation techniques, it would also lead to an unacceptably inefficient implementation. Further, any change in membership would require us to fully recompile and re-install all IV specifications across the system. Instead, *Aragog* lazily tracks all potential candidates for location variables at runtime using a multi-leveled tree data structure, which we describe in detail in Section 6.

Variables. *Aragog* generalizes the state tracking afforded to locations in order to track other types of state in the IV specification. Examples of non-location stateful properties include the IP/port NAT mappings of the NATGW and connection tracking in a firewall. An example of the latter is shown in Fig-

```

1 MAP(srcIP < dstIP ? srcIP : dstIP, IP1)
2 MAP(srcIP < dstIP ? dstIP : srcIP, IP2)
3 MAP(srcIP < dstIP ? srcPort : dstPort, port1)
4 MAP(srcIP < dstIP ? dstPort : srcPort, port2)
5 FILTER(flag == FIN || flag == ACK || flag == FIN_ACK)
6 GROUPBY(IP1, IP2, port1, port2)
7 MATCH
8   (flag == FIN) @ $X
9   SHUFFLE(
10     (flag == FIN, TIME == $s) @ $Y,
11     (flag == ACK, TIME == $t) @ $Y)
12   (flag == SYN, TIME - min($s, $t) <= 30000) @ $X

```

Figure 7: An example of a timing violation specification that checks the behavior of TCP’s TIME-WAIT state [22]. The SYN *must not* arrive by a deadline. This specification assumes that only packet sends are captured.

```

1 FILTER(flag == FIN || flag == FIN_ACK)
2 GROUPBY(IP1, IP2, port1, port2)
3 (eventType == FIN, TIME == $t) @ ANY
4 ((eventType != FIN_ACK, TIME - $t <= 30000) @ ANY)*
5 (TIME - $t > 30000) @ ANY

```

Figure 8: An example of a timing-related IV specification that checks timely arrival of a FIN_ACK after a FIN. The FIN_ACK *must* arrive by a deadline.

ure 6, which verifies that if an outbound flow from source IP \$S and destination IP \$D is properly initialized, then packets in the reverse direction are also allowed.

As these variables do not indicate or impose restrictions on the location of the event, we do not use them for the partitioning procedure of Section 6.

Timing. Timeouts and deadlines are also common in NFs. To specify them, users can use parameterized variables in conjunction with a builtin TIME field to compare the time between multiple events. For example, Figure 7 defines a violation of the TIME-WAIT semantics of a TCP flow in which SYN packets should not be sent within 30 s of a passive closer’s FIN/ACK. The same SYN packet 31 s after the FIN/ACK would not be a violation. On the other end of the spectrum, Figure 8 defines a violation where a FIN-ACK does not arrive in time (within 30 s of the FIN). Any intervening FIN-ACK will mean that the violation does not match.

6 State Machine Generation

Aragog checks for invariant violations efficiently by translating each of the IV specifications into a state machine. In contrast to traditional finite-state automata, *Aragog* requires a combination of complex features, e.g., timing, arithmetic, field/location variables, and regular expression-event patterns.

Aragog, thus, generates its state machines in three stages. First, it creates a symbolic non-deterministic finite automaton (SFA) [12] whose alphabet is based around a theory of arithmetic and boolean algebra, and whose predicates can include the placeholder variables described in the previous section.

Figure 9: SFA for Figure 4 with some field names and constants abbreviated as well. p indicates location.

Second, it determinizes the SFA to a symbolic deterministic finite automaton (SDFA) to reduce runtime overhead of state machine execution. Finally, it constructs localized versions of the SDFA that can be used to infer the global state of the system from only locally observed events.

6.1 Constructing the SFA

We first convert all predicates on events into boolean logic with equalities/inequalities by taking the conjunction of all event field matches and the location specifier. For example, we transform an event match $(A==B, C==D) @ \text{NOT } \X to the predicate $(A==B \wedge C==D \wedge p!=\$X)$, where p is the placeholder for the event’s location, which we determinize at runtime. A ‘!’ modifier on the event would negate this predicate.

Aragog performs an additional check on the sequence of generated predicates to facilitate efficient variable checking (Section 7.2). Specifically, it checks via reachability analysis that all uses of variables in either an arithmetic expression or non-equality comparison ($<$, \leq , $>$, and \geq) strictly follow after their introduction via an equality comparison.

With the resulting predicates, *Aragog* constructs the SFA by creating a start state, S , with a self-loop for any event (TRUE). This self-loop ensures the pattern will match starting from anywhere in the event trace. From the initial state S , *Aragog* recursively builds out the state machine using Thompson’s construction [38], treating **CHOICE** as a choice operator, and expanding **SHUFFLE** to all permutations. Figure 9 shows a (minimized) SFA for the example violation specification from Figure 4. We mark the final state in the SFA as the accepting state, which indicates a violation when reached.

The specified transitions may not cover the complete space of possible events. All events that do not match any transition out of the current state will never lead to a match.

Aragog next determinizes the SFA: it generates an efficiently executable DSFA from the SFA using standard symbolic automata techniques [12]. The result is a state machine where all transitions are unambiguous and exhaustive. Figure 10 shows the DSFA for the example. Each state in the DSFA stores the corresponding set of SFA states the machine is in at that given point in time.

6.2 Local State Machines

Conceptually, the DSFA provides an efficient method for checking whether a stream of events leads to an invariant violation. In principle, we could simply funnel all events to a

Figure 10: DSFA for the SFA in Figure 4. Colored, dashed edges represent suppressible transitions.

central verifier, which would then apply the relevant DSFA transition and report a violations upon reaching an accepting state. Unfortunately, doing so would require the verifier to process *all* unfiltered events in the system. Instead, we further improve *Aragog*’s scalability by generating a localized version of the state machine that is executed on the same machine as the NF before sending the event to the global verifier.

6.2.1 Suppressible Transitions

The local state machine needs to identify events that will not impact the detection (or lack of detection) of a user-specified violation whether or not it is sent to the global verifier. Our key observation is that there are transitions in the global DSFA that do not affect the end result of the state machine. We term these transitions *suppressible transitions*. More formally:

Definition 1. An event stream s is either empty $s = \epsilon$ or it consists of an event followed by another stream $s = e \cdot s'$.

Definition 2. $q \xrightarrow{e} q'$ indicates that, from state q , event e transitions to state q' . We lift this to event streams inductively as $q \xrightarrow{\epsilon} q$, and $q \xrightarrow{e \cdot s} q''$ iff $q \xrightarrow{e} q'$ and $q' \xrightarrow{s} q''$.

Definition 3. Transition t is suppressible if for any event e matching t from state q , then (1) $q \xrightarrow{e} q'$ means q' is not an accepting state, and (2) for any event stream s , and accepting state q_a then $q \xrightarrow{e \cdot s} q_a$ iff $q \xrightarrow{s} q_a$.

In the running example DSFA in Figure 10, the three dashed transitions are suppressible given the above definition. The two self-loops are clearly suppressible (satisfy Definition 3) since an event processed by such a loop will not change the global state—(not) observing the event has no effect, and the loops do not occur on accepting states. Perhaps less obvious is that the bottom-most edge is also suppressible since, from either state $\{S\}$ or $\{S, 2\}$, one needs to see the same two events to get back to the accepting state $\{S, 2\}$. For example, an **ADD** event at $\$X$ followed by another at **NOT** $\$X$ will take either state $\{S\}$ or $\{S, 2\}$ back to $\{S, 2\}$. We never mark transitions with time constraints as suppressible—we assume the timing of an otherwise irrelevant event might still be significant.

Algorithm 1 Create a local state machine for a variable

```
1: input: Global DSFA G, variable V, filter F
2: output: Local DSFA L
3: procedure CREATELOCALDFA(G, V, F)
4:   L := CopyStates(G)
5:   for S ← States(G) do
6:     for T ← Transitions(G, S) do
7:       P := Predicate(G, T)
8:       if SAT((F ∧ P) ≠ (p = V)) then
9:         AddTransition(L, TargetState(T), ε)
10:      P' := Simplify(P, p=V)
11:      AddTransition(L, TargetState(T), P')
12:   return Determinize(L)
```

6.2.2 Local State Machine Construction

Arago uses local knowledge to determine whether an event will be processed by a suppressible transition. Since each local component is unaware of what might be happening at other components, it must conservatively account for all possibilities. To determine (locally) whether an event is suppressible, we create a local state machine for every location variable in every IV specification such that each machine assumes it is playing the role of that location (*e.g.*, one machine for “I might be $\$X$ in a violation” and another for “I might be $\$Y$ in a violation”). In the example from Figure 10, there is only a single local state machine: the one for $\$X$.

The first step in creating a local state machine, L, is to model the uncertainty other locations may introduce (Algorithm 1). The algorithm takes the global state machine G, the location variable V (*e.g.*, $\$X$), and a predicate F corresponding to the user-defined **FILTER** statements. It returns a new localized DSFA.

The algorithm considers each transition T in G where T has predicate P, and checks whether the formula $(F \wedge P) \not\models (p = V)$ is satisfiable (line 8). If it is, then there exists a potential event that makes it through the filter F and uses transition T but which takes place at a location other than V. To model the fact that other NF instances might send events that use this transition, the algorithm adds to L an epsilon (ϵ) transition (line 9). An ϵ transition is one which the local SFA can take immediately and unconditionally. It accounts for the possibility of concurrent execution of other NF instances to represent that the global state could be in either state (the one before or the one after the ϵ transition).

In either case, the algorithm then adds a local transition to L by simplifying the existing transition predicate (P) to account for the fact that the location is known (line 11). It does so by partially evaluating the predicate with the assumption that $p=V$ (line 10). In Figure 10, for example, the transition $(ET==REMOVE \wedge p==\$X)$ is simplified to $ET==REMOVE$.

Figure 11 shows the local SFA for location $\$X$ and its determinized (DSFA) form. By executing the DSFA in Figure 11 locally, an NF instance can learn some partial information about the state of the overall system. For example, after seeing

Figure 11: Local machine for $\$X$ from Figure 10. SFA is shown on top and its equivalent DSFA is shown below. Colored, dashed edges indicate locally suppressible transitions.

an ADD event, the NF instance recognizes that (if it is $\$X$) the global state machine can be in any state: $\{S\}$, $\{S, 1\}$, or $\{S, 2\}$. However, after locally processing a REMOVE event, the local machine now knows it must be in state $\{S\}$ once more.

6.2.3 Suppressing Events Locally

The local machine can hide events when it can prove they would otherwise be processed by suppressible transitions in the global machine. Algorithm 2 is used to create all the data structures needed to suppress events locally. It takes the global state machine G as input along with the user-defined filters F and produces, as output, a collection of local state machines (L_i) as well as a negated condition (NC), explained below.

The algorithm works by iterating over every location or variable in the IV specification (line 5) and calling CreateLocalDFA to build the local state machine (line 6). It then walks over each local transition (T) and attempts to mark the transition as locally suppressible. To do so, it looks up all the possible global states corresponding to this local state (line 11) and checks whether the local transition can process an event that is also processed by, and is not suppressible for, some global transition T' from one of these states (line 16). If not, then all events that trigger T must be part of a suppressible transition in the global DSFA, so the event is suppressed.

In Figure 11, events matching $ET!=ADD$ in state $\{\{S\}\}$ are suppressible: for each global state in the set $\{\{S\}\}$, this event must be processed by a suppressible global transition.

Negated condition. The final part of the algorithm (lines 20 to 23) computes a “negated condition.” This condition captures the case where the local NF may not correspond to any named location in the IV specification, *e.g.*, the NF instance is not $\$X$, but it still may observe a relevant event as NOT $\$X$. We observe, in such a case, the current machine can not possibly know anything about the global automaton

Algorithm 2 Construct local state machines

```
1: input: Global DSFA  $G$ , filter  $F$ 
2: output: Local state  $\Theta = \langle \{L_1, \dots, L_k\}, NC \rangle$ 
3: procedure LOCALIZE( $G, F$ )
4:    $NC := \text{false}$ ,  $LS := \emptyset$ 
5:   for  $V \leftarrow \text{Variables}(G)$  do
6:      $L := \text{CreateLocalDFA}(G, V, F)$ 
7:     for  $S \leftarrow \text{States}(L)$  do
8:       for  $T \leftarrow \text{Transitions}(L, S)$  do
9:          $\text{suppress} := \text{true}$ 
10:         $P := \text{Predicate}(L, T)$ 
11:        for  $S' \leftarrow \text{GlobalStates}(L, S)$  do
12:          for  $T' \leftarrow \text{Transitions}(G, S')$  do
13:            if  $\text{CanSuppress}(G, T')$  then
14:              continue
15:             $P' := \text{Predicate}(G, T')$ 
16:            if  $\text{SAT}(P \wedge (p = V) \wedge P')$  then
17:               $\text{suppress} := \text{false}$ 
18:            if  $\text{suppress}$  then  $\text{MarkSuppressed}(L, T)$ 
19:           $LS := LS \cup \{L\}$ 
20:        for  $S' \leftarrow \text{States}(G)$  do
21:          for  $T' \leftarrow \text{Transitions}(G, S')$  do
22:            if  $\text{CanSuppress}(G, T')$  then continue
23:           $NC := NC \vee \text{Simplify}(\text{Predicate}(G, T'), p == \text{Fresh}())$ 
24:  return  $\langle LS, NC \rangle$ 
```

state since the other NF instances that also are not $\$X$ may be sending events that match $\text{NOT } \$X$ transitions. The fix is simple: the algorithm computes the disjunction of all the transition predicates in the global state machine subject to the knowledge that the location p does not match any variable (line 23).

In the running example, the algorithm computes: $(ET == \text{ADD} \wedge Z == \$X) \vee (ET == \text{ADD} \wedge Z != \$X) \vee (ET == \text{REMOVE} \wedge Z == \$X)$, where Z is a fresh variable that is guaranteed to not match any location in the predicate. The above condition simplifies to $ET == \text{ADD}$. This means that the local machine *must* send any `FLOWCACHE_PRIMARY_ADD` events to the global verifier regardless of its local state.

Note that non-location variables may introduce some uncertainty at the local verifier, which may not be sure what other NF instances have observed for their value. To address this, *Aragog* first tries to generate a predicate that accounts for any possible variable assignment by enumerating all possible assignments from their $==/!=$ expressions, replacing their occurrences in the negated condition, and computing the disjunction of the resulting predicates. If any variables or arithmetic operations remain in the disjunction, *Aragog* will simply not suppress any events, which is always safe.

7 Runtime System

We next describe the *Aragog* runtime.

7.1 Workflow Overview

We begin with the common case: NF instances synchronized via PTP send events—at runtime—to a co-located local agent

via traditional IPC mechanisms. This local agent applies transformations, computes suppressions using local state machines, and then sends any non-suppressible events to the global verifier via a set of Kafka brokers.

Filtering, mapping, and grouping. After ingesting the stream of PTP-timestamped events, local *Aragog* agents co-located with the NF first apply any applicable transformations—**FILTER**, **MAP** or **GROUPBY**—to the raw stream. As each IV specification can have a different set of transformations, this may require *Aragog* to duplicate the incoming stream of raw events (it tries to avoid doing so when possible). The end result is a set of keyed event streams: one stream for each combination of policy and **GROUPBY** key.

Computing suppression. The next step, also performed locally, is to determine whether events in each keyed stream are suppressible. *Aragog* passes the events through the localized state machines — one for each location referenced in each IV specification. For a given event and IV, *Aragog* suppresses the event when (1) all localized instances of the IV specification would take a suppressible transition when fed the current event and (2) the event does not satisfy the negated condition. If either constraint is false, *Aragog* sends the event to a Kafka queue for the given keyed event stream.

As a concrete example, Figure 12 shows processing of a series of events with the specification in Figure 4 and with the same **GROUPBY** key. The first event is an `ADD` event at flow decider FD_1 . After seeing this event, FD_1 will transition locally from state q_0 ($\{S\}$) to state q_1 ($\{\{S\}, \{S, 1\}, \{S, 2\}\}$). Since this transition is not suppressible, the event is sent to the verifier. The next event is a `REMOVE` event that takes place at FD_3 . This particular transition *is* suppressible and the negated condition $(ET == \text{ADD})$ is not satisfied, thus, the event is suppressed.

This suppression can substantially reduce the number of events received by the global verifier. For example, with three replicas (including the primary), a correct execution of Figure 4 *Aragog* would receive—after suppression—just 2 out of 4 events (the add and remove at the primary but not the 2 suppressed removes at nodes other than $\$X$).

Global state machines. Pulling from Kafka is a cluster of Flink instances running the global versions of the IV state machines. Both the Kafka and Flink instances are automatically provisioned, checkpointed, assigned **GROUPBY** keys, and load balanced to worker nodes. As Flink does not guarantee that events from different NF instances will arrive in order, *Aragog* temporarily stores and reorders events in the Flink workers with an efficient priority queue before passing them to the associated state machine.

One challenge is how long to wait for delayed events. One approach is to maintain a list of all NF instances along with the timestamp of the last event they sent to this partition and only process time t when we have seen events from all instances up to $t + \text{latency}$. Unfortunately, most NF instances do not interact with most flows/policies and sending ‘null’

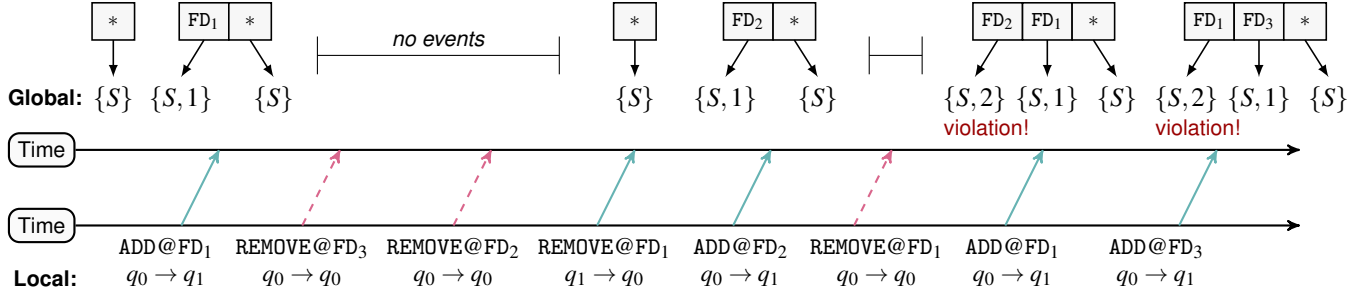

Figure 12: Distributed execution for the example from Figure 4 on an example sequence of events for N flow deciders. Time progresses from left to right. Local events are shown along the bottom line with the local state of the flow decider. We use $q_0 = \{\{S\}\}$ and $q_1 = \{\{S\}, \{S, 1\}, \{S, 2\}\}$. The global verifier’s state is shown at the top. Red, dashed edges indicate suppressed events.

events to advance the timestamps of every partition would be costly. Instead, *Aragog* relies on the assumption of a maximum latency t_{max} and handles violations of this assumption with the techniques in Section 7.3.

Aragog will hold each event for t_{max} time before running it through the global DSFA. While processing events for a given IV specification, the verifiers will track all of the possible states in which the associated state machine could be, as well as all potential values of the IV specification’s variables (see Section 7.2 for details). If any of the possible states is a ‘final’ state in the IV’s DSFA, *Aragog* will raise an alert.

Consistent sampling. If scaling is still challenging despite sharding the verifier, filtering relevant events, and suppressing events locally, *Aragog* provides a final mechanism that lets users trade performance for completeness by sampling a consistent set of events with consistent hashing based on the **GROUPBY** key (e.g., a 5-tuple for NATGW). In this way, each group is itself complete though false negatives remain possible when violations occur for keys that are not sampled.

7.2 (Location) Variable Tracking

Aragog tracks *all* possible instantiations of variables (location or otherwise) at runtime using a multi-level tree data structure (shown at the top of Figure 12). Intuitively, the tree captures the state the global automaton would be in for every possible instantiation, with the leaves of the tree as the state and the interior nodes as variable assignments. Every variable is assigned a single level of the tree.

Let the number of variables (location or otherwise) for an IV specification be n . When the system starts, the DSFA is in the start state, $\{S\}$, for all possible variable assignments. This is represented as a degenerate tree with height $n + 1$ and a single leaf pointing at the start state $\{S\}$. The interior nodes are all set to $*$, indicating no constraints on the n variables. For every incoming event, we advance the DSFA using the state and variable assignments of every leaf. Whenever a predicate is encountered that references a variable, V_i , if $V_i = *$ is an ancestor of the current leaf we split execution into a case where V_i satisfies the predicate and a case where it does not.

The $(n - i)$ -height subtree under $V_i = *$ may need to be cloned.

In the example of Figure 12, there is only one variable ($\$X$) and, thus, only two levels in the tree. The system starts in the degenerate case where $\$X = *$. After the first ADD event arrives at the verifier from FD_1 , we fork the tree to separate out the old case and a new case for $\$X = FD_1$. When $\$X$ is FD_1 , the verifier takes the transition ($ET == ADD \wedge p == \$X$) to state $\{S, 1\}$: the current location p is FD_1 , and $\$X$ is also FD_1 . Otherwise if $\$X \neq FD_1$, it takes the self-loop transition to remain in $\{S\}$. For the next event from FD_1 ($REMOVE$), there is no new case to fork, and applying the transition to both cases in the tree leads to both being in state $\{S\}$ once more. Therefore, the states are collapsed together back to $*$. This process continues until the second to last event where a violation is detected for the case where $\$X = FD_2$ due to a duplicate add at FD_1 . The final event (ADD at FD_3) leads to a second violation, where now $\$X = FD_1$, and is subsequently caught by the implementation.

7.3 Fault Tolerance

Failures and message drops/delays can cause *Aragog* to become desynchronized from the ground-truth state of the system. Even so, *Aragog* is able to guarantee both precision and recall of typical network violations under the assumption of ‘partial synchrony’ [15], i.e., that there exists a time, t_s , after which there is some upper bound on message delivery time.

- **Recall:** Under a partial synchrony assumption, *Aragog*’s practice of creating a self loop in the initial state of the SFA means all violations whose trace begins *after* t_s are accurately modelled in the state machine and detected.
- **Precision:** *Aragog*’s precision guarantees are less complete, but still hold in practice. Specifically, we observe that all of the IV specifications we studied contained some property where flow state would eventually be dropped in reaction to a `REMOVE_ENTRY` or `TCP FIN/RST` event; such transitions are common in networked systems and ensure that any desynchronized state machine instances will eventually transition back to the initial state.

In addition to the above, Flink provides guarantees that successfully pulled events are processed by the state machine

Network Function	Invariant Description	LoC	States	Transitions
NAT Gateway	nat_decider_open: After a PW goes into closed state, at least one replica also goes into closed state.	14	4	10
	nat_consensus: All TCP flows are open only after consensus.	5	2	4
	nat_open_to: Open flows are timed out after 4 minutes of inactivity.	5	4	12
	nat_primary_single: There is a single primary per flow.	10	3	7
	nat_primary_to: The NATGW does not start an idle timeout for active flows.	13	6	18
	nat_same_consensus: After TCP flow U is terminated, the next flow for U achieves consensus.	12	5	15
	nat_syn_to: Flows with a TCP handshake in progress timeout after 5 seconds of inactivity.	5	4	12
Firewall [5]	nat_udp_same_consensus: If UDP flow U times out, the next flow for U achieves consensus.	12	6	17
	fw_consistency: <i>all</i> Firewall instances should block suspicious IPs after a block rule is added.	6	4	12
	fw_client_init: Ensure a flow can only be open after a client initiates it.	4	2	4
DHCP	fw_syn_first: Data packets are only allowed after a SYN is sent.	4	2	4
	dhcp_reuse: Leased addresses are not re-used until expiration or release.	6	4	12
	dhcp_overlap: Leases should not overlap between DHCP servers.	6	3	7

Table 1: List of example invariants that *Aragog* can implement for several common network functions and systems.

exactly once. *End-to-end* guarantees of exactly once delivery between Flink and Kafka are also possible, but would incur the overhead of atomic exporting of NF events, transactions, and rollbacks. Instead, *Aragog* chooses to rely on partial synchrony and to alert users after the fact when false positives may have occurred. This can happen when an event arrives with a timestamp earlier than the last processed event, two events arrive from an NF instance with a gap in their sequence numbers, or an NF instance (and its local agent) fail. Upon restarting, the agent can immediately resume exporting events, but the local state machine may be out of sync. In this case, it can temporarily export all events (which is always safe) until it can synchronize with the global verifier to rebuild the local state machines from the global verifier’s state.

8 Implementation

We have implemented *Aragog* with more than 6,500 lines of Java 8 code, packaged with Maven v3.6 and more than 2,000 lines of C++ code. The implementation consists of two major components: the compiler and runtime system. It can be found at: <https://github.com/microsoft/aragog>.

The compiler takes as inputs an event format specification as described in Section 5.1 along with a set of IV specifications in the format of Section 5.2. For each IV specification, it generates the global state machine, the resulting local state machines, information about suppressible events, and a slew of other metadata about variables, filters, and partitioning. The lexer and parser use the ANTLR v4.7 [1] parser generator, and the SFA construction and determinization use the open-source *symbolicautomata* library [6], but with the addition of a custom Z3-based [7] theory of Boolean Algebra designed to support our IV specification language.

We built the runtime system on top of Apache Flink [2] and Kafka [3]. These frameworks are designed for scalable and robust stream processing and provide, intrinsically, fault-tolerant and stateful processing, exactly-once semantics, load balancing, flexible membership, checkpointing, etc. The local agents, implemented in C++, ingest events directly, then filter,

map, and suppress events as necessary before sending them to Kafka. The global verifiers, implemented in Java using Apache Flink, pull from Kafka into a timestamp-based priority queue from which events are dequeued after waiting for a maximum delay; violations are logged to disk. We place the verifiers off of the critical path to avoid any impact on production traffic.

9 Evaluation

We evaluate *Aragog* in CloudLab [37] with a number of network functions and along a number of dimensions.

The deployed NAT gateway (§2). We use two event traces captured from two different builds of the NAT gateway to evaluate *Aragog*. The builds capture the introduction of a set of bugs that arose from the change of an interface between two internal components, with V1 from before the change and V2 from after. The traces are both for 7 flow deciders over a 30 minute interval, but they export a different number of packets (V1: 23.7M; V2: 9.0M) owing to changes in the protocol. The production deployment of NATGW does not yet support fine-grained clock synchronization, but our operators plan to add it in the system’s next version. Instead, we capture the event traces and correct for time drift using a set of known synchronization points within the event stream. In total, there are eight IV specifications for NATGW (see Table 1).

A distributed firewall. We also execute a collection of micro-benchmarks using an open-source, stateful, and distributed firewall implementation built on *iptables*, *conntrackd*, and *keepalived* [5]). On the firewall, we check various invariant violations, some of which were derived from [8]. The list of specific invariant violations we check are listed in Table 1.

We deploy this firewall on a topology with four clients, four internal hosts on a single LAN, and four firewall nodes interposing between the two groups. The firewalls are configured as two high-availability groups with one primary and one hot standby each. Each primary-standby group shares a virtual IP with the VRRP protocol. We base the traffic between external hosts and internal servers on the traces provided in [9].

Invariant Violation	Version 1	Version 2
nat_decider_open	0	0
nat_consensus	0	0
nat_open_to	1	45019
nat_primary_single	0	0
nat_primary_to	1	29964
nat_same_consensus	536	259
nat_syn_to	0	2697
nat_udp_same_consensus	0	0

Table 2: Violations found in traces for NATGW versions. Note that V1’s trace contains more events than V2’s, which may account for the difference in nat_same_consensus violations.

DHCP. To show the flexibility of *Aragog* and its language, we also give examples of DHCP invariant violations in Table 1. With our current implementation, the operator needs to write just 6 lines to express the invariant violations. Each of the state machines uses a small number of states and transitions.

Evaluation metrics. We evaluate *Aragog* along a number of key dimensions: lines of code, throughput, latency, and CPU overhead. In addition, our micro-benchmarks show *Aragog*’s ability to scale as the number of nodes in the NF deployment increase by demonstrating the benefits of our event suppression scheme. Finally, we find *Aragog* is able to identify bugs in production systems. In particular, we were able to identify four bugs in the NAT gateway which were confirmed by our operators. Similarly, in the firewall, *Aragog* was able to find a series of injected configuration errors over real traffic traces.

9.1 Bugs Identified by *Aragog*

NATGW Bugs. Running the traces through *Aragog*, we discovered violations of nat_open_to, nat_primary_to, nat_same_consensus, nat_syn_to, all of which were confirmed as caused by bugs by the NATGW team. Table 2 shows the absolute number of violations observed for each.

nat_open_to was by far the most frequent violator in V2. Discussions with our operators revealed that in V2, this violation (and that of nat_syn_to) were due to related bugs in the code: it had taken operators over an hour to identify the issues while *Aragog* identified it in under a minute. Although nat_open_to also had a violation in V1, further examination revealed that the violation in V1 was due to an expected consequence of eventual consistency—specifically one of the replicas was getting update messages from the packet worker but the primary did not and therefore started a timeout for the flow. This led us to start checking for nat_primary_to.

Also prominent in both systems were violations of nat_same_consensus. This violation occurred because the flow was not closed or removed properly from one of the replicas. The operators suspected this could be an issue, but never had a method to test that hypothesis. *Aragog* confirmed the problem and helped the developers to formulate the test setup to reproduce the issue.

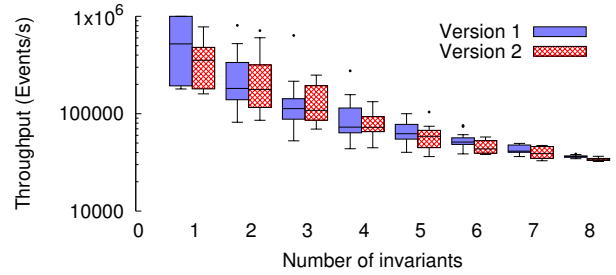

Figure 13: The throughput in events/second for an executor of *Aragog* on the trace.

Bugs in the distributed firewall rules. For the firewall, we manually injected bugs in the firewall configuration to test *Aragog*’s ability to identify this category of errors. The injected issues, for instance, always allowed external traffic from a particular address range into the internal network, violating fw_client_init. *Aragog* found all of them.

9.2 Throughput of *Aragog*

Aragog’s global verifier keeps track of the set of possible states for each IV specification and the possible values for each variable/location. Thus, *Aragog*’s throughput is directly correlated with the number of IVs checked (Figure 13). To evaluate this scaling, we run the V1/2 traces through all the 8 NATGW IV specifications using a single Task Slot on the global verifier (running on an Intel(R) Xeon(R) E5-2450 processor CPU @ 2.10GHz machine). We upload the entire trace on Apache Kafka after local processing to measure the maximum throughput a single task slot of Apache Flink of the global verifier can process. In Figure 13 we randomly select n among the NATGW invariant violations and see the performance. As each type of invariant violation exhibits different resource requirements, we see more variance when the number of type of invariant violations selected is low.

With a single task slot, our optimizations allow *Aragog* to scale and process over 500,000 events per second for a single invariant violation type (over 30,000 for 8). Adding more task slots does not improve the performance as our implementation is parallel in nature and a single task slot is already using multiples core in a single machine.

Aragog scales linearly as we add more machines to the global verifier (Figure 14). Scaling with multiple machines avoids the bottleneck of CPU and I/O.

9.3 Overhead of *Aragog*

To measure the memory and CPU overhead of *Aragog*, we study its behavior while verifying the distributed firewall. In Figures 15, 16 and 17, data is divided into separate groups. ‘Primary’ represents the verifier running at the primary firewall. ‘Backup’ represents the verifier running at the hot-standby firewall. ‘Manager’ and ‘executor’ represent the Apache Flink job manager and executors, respectively. The global verifier runs on the executors.

Process/Location	Resource	Spearman correlation
job manager	CPU	0.14700
job manager	memory	-0.59379
executor	CPU	0.78481
executor	memory	-0.38373
primary	CPU	0.88916
primary	memory	-0.18253
backup	CPU	0.93618
backup	memory	0.24768

Table 3: Spearman Correlation between number of events/s and resource utilization at different locations of verifier while running the firewall.

Figure 14: Throughput of multiple *Aragog* verification server checking all 8 types invariant violations

We see that in Figures 16 and 17, the overhead of the local verifiers is low. This is important as the local components are co-located with the production NF instances. To that end, the CPU utilization of the local verifier increases linearly with the number of flow events per second. We also observe the CPU and memory usage for the local verifier is higher at the primaries as they tend to generate more events. Memory at the local components is much less correlated (Table 3), partly due to *Aragog*’s small memory footprint (Figure 17).

The global verifier has higher CPU (Figure 15) and memory (Figure 17) than local verifiers as the global verifier is implemented in Java using Apache Flink. We have set the maximum memory of job manager to 1 GB and executor to 2 GB. In our graphs, we are plotting active memory in Java’s heap for the global verifier rather than used memory to avoid including memory waiting to be cleaned up by the Java GC.

Figure 18 shows the CDF of *Aragog*’s *time to detection* for violations in the distributed firewall function. The time to detection is low: in the median it takes roughly 70 ms from the time the event was executed (the violation occurred) at the NF instance until *Aragog* raises an alert.

9.4 Efficacy of Suppression

Each optimization in *Aragog* improves scalability by reducing the number of events sent to the global verifier (reducing the network overhead and the number of events processed at the global verifier). Filters remove the need to send events that are not pertinent and reduce the number of events sent to the verifier by up to 61% for the NATGW (Table 4). Suppressible

Figure 15: CPU utilization by *Aragog*’s global component. ‘Manager’ and ‘executor’ refer to the Flink node designations.

Figure 16: CPU utilization by *Aragog*’s local component. The graph shows CPU utilization of the local verifier at both the primary and backup firewall.

events can further reduce this number (by up to an additional 12% in our experiments).

10 Related Work

Runtime verification. Researchers have studied runtime verification extensively, with many papers dedicated to improving its expressiveness and performance. We find that, unfortunately, these existing systems are a poor fit for our setting. For example, D³S [28] is a runtime verifier. Like *Aragog*, it focuses on identifying bugs in distributed systems at runtime, and its usage of C++ implementations to specify general-purpose properties means that it can check a wider range of properties than *Aragog*. On the other hand, *Aragog* is able to leverage its domain-specific IV specification language (based on regular expressions) to reduce overhead (*e.g.*, with event suppression). Similarly, while CrystalBall [39] can proactively steer a distributed system away from bad states, it imposes restrictions on the target system’s architecture that make sense for a distributed system, but not necessarily for a large-scale NF. A third system, Pivot Tracing [31] tracks only causal relationships and not unrelated events at different machines—a property required by some of NATGW’s uniqueness invariants. We emphasize that none of the above implies strict superiority. In particular, as *Aragog* is domain-customized for NFs, it should not be used for more general cases (*e.g.*, it may not be able to verify systems like Chord or Paxos efficiently).

We also note that *Aragog* borrows ideas from two areas within runtime verification. The first is verification of distributed systems, which is broadly separated into two categories based on whether the system assumes a synchronized

Figure 17: Memory utilization of verifier in MBytes.

Figure 18: Latency (alert time – packet time) for detecting a violation in the distributed firewall.

global clock [17]. In this respect, *Aragog* would be considered a *decentralized* [14, 17] runtime verification system. The second is parametric verification, which focuses on checking universally or existentially quantified expressions [13, 20, 30, 36]. The location variables in *Aragog* are examples of parametric variables. The main distinction of *Aragog* from these systems is its combination of parametric and decentralized runtime verification through its support for location variables. Moreover, *Aragog*’s efficient implementation of this combination of features through its use of sharding and local symbolic state machine partitioning is new in this context.

Static verification of NFs and distributed systems. Static verification has as equally rich history, including in the domain of NFs and distributed systems [10, 34, 42, 44]. Static verification approaches may provide exhaustive guarantees of correctness, but often suffer from issues of scalability. For this reason, many static verifiers (*e.g.*, [42, 44]) assume single-machine middleboxes, while others (*e.g.*, [25, 29, 40]) may require checking an exponential number of states/paths. Leveraging hand-written NF models can improve scalability compared to verifying source code, but requires tedious and error-prone manual translation of NF models and divorces the verifier from the behavior of the actual deployed system [10, 34].

Aragog makes a different set of tradeoffs, opting to sacrifice principled exploration for improved scalability and giving up the ability to catch bugs early for the ability to test real implementations running over live data. We argue that these tradeoffs are a better fit for our operators’ requirements.

Related to the above approaches is the use of semi-automated theorem provers such as Dafny [27]. Users can apply these tools to build systems that are provably correct. A good example of this approach is IronFleet [21], which was

Version	Generated	After Filter	After Suppression
V1	189M	92.9M (49.1%)	70.2M (37.1%)
V2	72.2M	36.7M (50.8%)	28.0M (38.8%)

Table 4: Total number of generated events, events processed after filtering, and events processed after filtering and suppression for the NAT gateway with all 8 IV specifications.

used to build a verified, Paxos-based replicated-state-machine library. On the other hand, a drawback of this approach is that it requires significant development effort. IronFleet verification, for example, involved tens of thousands of lines of proof. In contrast, *Aragog* aims to be a lightweight (but sans proof-of-correctness) alternative, requiring little to no developer effort by catching bugs at run time.

Stateless dataplane verification. Dataplane verification tools such as HSA [23] and Anteater [32] verify the correctness of a static snapshot of network forwarding tables. Later tools such as Veriflow [24] perform runtime verification by constantly re-verifying the network state as changes occur. Each of these tools reasons about all packet behaviors—a challenging task—however, their reasoning is limited to verification of *stateless* network forwarding. In contrast, *Aragog* focuses on verifying complex temporal and stateful properties of general-purpose distributed NFs. For example, *Aragog* can ensure a stateful firewall correctly allows traffic only for connections that are established by an internal sender.

11 Discussion and Conclusion

Aragog is a lightweight verification framework for verifying distributed network functions. To scale to large systems with minimal overhead, *Aragog* leverages a two-tiered setup with local monitors at each NF instance sending events to (and hiding events from) a collection of sharded global verifiers. While *Aragog* can verify any distributed system, its scalability will depend on whether the invariant violations of interest can utilize its sharding and suppression optimization effectively.

Finally, as *Aragog* is the first to verify distributed network functions at scale (and at runtime), there are a number of aspects where follow up work may be needed. Included in this set are explorations of other time synchronization protocols, *e.g.*, [18] or some other lightweight and precise event ordering mechanisms. Also for future work are innovations in atomic event export and transactions over streams in *Aragog*.

Acknowledgments

We gratefully acknowledge our shepherd Xi Wang and the anonymous OSDI reviewers for all of their thoughtful reviews, comments, and time. The authors would also like to thank Geoff Outhred for his feedback and support of this work. This work was funded in part by NSF grant CNS-1845749, DARPA contract HR0011-17-C0047, and a Microsoft internship.

A Artifact Appendix

Aragog is available at: <https://github.com/microsoft/aragog>. Instructions for installing and running the artifact can be found in the README of this repository.

A.1 Code Structure

A.1.1 SFA generation

SFA generation has three dependencies: `symbolic automata`, `z3` and `antlr`. The primary classes are:

GenerateSFA.java: This is the main class. It takes the event definition file and the IV specification file, and it outputs the SFA in a form that can be accepted by the runtime verifiers. `Antlr` is used to create the parse tree, which is then used to create the global SFA using the class `InvariantVisitor`, which recursively visits each node of the parse tree while constructing the SFA. A DSFA is generated from this automata and printed to a `.sm.g` file along with a DOT file representation.

GenerateLocalSFA.java: This class is called by `GenerateSFA` to create local versions of the global SFA. Specifically, it takes the SFA and locations as input and outputs the local SFA for each location. The end result of this step is a series of `.sm.[1-9][0-9]*` files, one series for each IV specification.

EventSolver: This class contains the theory of `BooleanAlgebra` logic required to create the SFA. Please refer to Section 6.1 of the paper for details.

A.1.2 Global Verifier

The global verifier has three dependencies: Apache Flink, Apache Kafka, and `antlr`. The primary classes are:

Verifier.java: This is the main class. The program creates state machines according to the provided `.sm.g` files and processes them. The input event messages can come either from a file, a socket, or Kafka. It parses the message, processes it, and raises alerts if required. Everything is done in streams to allow for parallelism.

Creation of the parser uses `ParserFactory.java`, which can parse according to `packetformat.json` or some user-specified custom parser.

GlobalSFAProcessor.java: This class is the runtime DSFA processor. It takes events as input and outputs alerts. Contained in this processor is functionality for reordering events based on their timestamp, tracking stateful variables across events, and advancing all possible instantiations of the DSFA. Critical to the function of the DSFA is an expression tree of binary/boolean operators that assist in evaluating the predicates attached to each transition in the DSFA. See the `expressions` sub-directory for details.

A.1.3 Local Verifier

The local verifier has three dependencies: `cppkafka`, `rapidjson` and `antlr`. The primary files are:

main.cpp: Like `GenerateSFA.java` of the global verifier, the local C++ version is responsible for constructing the state machine from the provided files and processing input events coming from either a file or a socket. The overall flow of the local verifier mirrors that of the global verifier, except that this one is implemented in C++ with none of the Flink support for automatic scaling and fault tolerance: after receiving an event, the event is parsed using the `PacketParser` class and sent to the local SFA processor (described below). The key difference is that the objective of this version is to decide whether the event should be suppressed and output it if not. Events are only suppressed if all state machines agree that they are suppressible.

SFAProcessor.cpp: This is the local, C++ version of `GlobalSFAProcessor.java`. Like other portions of *Aragog*'s local components, the local SFA processor implements a stripped-down, slightly modified version of the global verifier's functionality. In this case, the local node is tracking its view of the global state of the system, given only the locally observed events. As such, it does not need to worry about event reordering or location-variable tracking, which simplifies the implementation and leads to improved performance.

A.2 Firewall Demo

We include in the repository an example experiment involving firewalls and verifiers that emulates a portion of the experimental methodology of Section 9. This experiment expects the user to have a small cluster of machines that can play the

role of each type of node. CloudLab is one viable option and we include configurations to assist in allocating such a cluster. The included code configures the topology of Figure 19.

The setup file, `Setup/setup.sh`, installs the required software on each machine in the user's cluster and also installs IP route rules that create an overlay corresponding to the topology referenced above.

Overall, the experiment consists of four external nodes, four internal nodes on a single LAN, and four firewall nodes interposing between the two groups. The firewalls are configured as two high-availability groups with one primary and one hot standby per group. Each primary-standby group shares a virtual IP with the VRRP protocol. We base the traffic be-

tween external nodes and internal nodes on traffic models from DCTCP [9].

The rules that are installed in the firewall are simple. Internal nodes can communicate with each other and initiate connections to external nodes. External nodes cannot initiate connections to internal nodes.

Alongside the firewall, each firewall node also runs the verifier, which computes filters and suppression. A single global verifier node runs both the Apache Kafka and Apache Flink deployments. Kafka is responsible for receiving and pipelining the events from all of the local verifiers. Flink is responsible for executing the global verifier.

Automated Reasoning and Detection of Specious Configuration in Large Systems with Symbolic Execution

Yigong Hu
Johns Hopkins University

Gongqi Huang

Peng Huang
Johns Hopkins University

Abstract

Misconfiguration is a major cause of system failures. Prior solutions focus on detecting *invalid* settings that are introduced by user mistakes. But another type of misconfiguration that continues to haunt production services is *specious configuration*—settings that are valid but lead to unexpectedly poor performance in production. Such misconfigurations are subtle, so even careful administrators may fail to foresee them.

We propose a tool called Violet to detect specious configuration. We realize the crux of specious configuration is that it causes some slow code path to be executed, but the bad performance effect cannot always be triggered. Violet thus takes a novel approach that uses selective symbolic execution to systematically *reason about* the performance effect of configuration parameters, their combination effect, and the relationship with input. Violet outputs a performance impact model for the automatic detection of poor configuration settings. We applied Violet on four large systems. To evaluate the effectiveness of Violet, we collect 17 *real-world* specious configuration cases. Violet detects 15 of them. Violet also identifies 11 unknown specious configurations.

1 Introduction

Software is increasingly customizable. A mature program typically exposes hundreds of parameters for users to control scheduling, caching, *etc.* With such high customizability, it is difficult to properly configure a system today, even for trained administrators. Indeed, numerous studies and real-world failures have repeatedly shown that misconfiguration is a major cause of production system failures [32, 43, 45, 60].

The severity of the misconfiguration problem has motivated solutions to detect [35, 61, 63], test [37, 57], diagnose [19, 21, 50, 52, 54] and fix [39, 48, 53] misconfiguration. While these efforts help reduce misconfiguration, the problem remains vexing [1–3, 5–10, 17, 18, 31]. They focus on catching *invalid* settings introduced due to user mistakes. But another type of misconfiguration that haunts production systems, yet not well

Figure 1: Value space of a configuration

addressed, is valid but poor configuration. For simplicity, we call them **specious configuration**.

Specious configuration has a broad scope. In this paper, we focus on—and use the term to refer to—valid settings that lead to extremely poor *performance*, which is a common manifestation in production incidents. This scope of focus is different from suboptimal configuration (Figure 1). The latter happens when a setting does not yield the best performance, but the performance is still acceptable. This scope is also complementary to efforts on automated configuration performance tuning [33, 51, 62, 64] to search for the best setting.

Take a real-world specious configuration that caused a service outage as an example. An engineer changed the request tracing code from a hard-coded policy (always tracing) to be configurable with a tracing rate parameter. This rate parameter was initially set to 0.0. To retain the same tracing behavior as before, she decided to change the parameter to 1.0. Based on her understanding, this change will turn on the tracing for all *message* requests that come from *internal* users. But unfortunately, there was a subtle caveat in the code that caused the actual effect to be turning on tracing for *all* requests from *all* users, which quickly overloaded all web servers as well as the backend databases, leading to a catastrophic service outage. Interestingly, before rolling out this specious configuration to production, the change in fact went through a canary phase on a small-scale testing cluster, which unfortunately did not manifest dramatic failure symptoms.

Empirical evidence suggests that specious configuration like the above is prevalent. Yin et al. [60] shows that misconfiguration in the form of legal parameters has similar or higher percentage than illegal parameters. Facebook reports [49] that more than half of the misconfiguration in their high-impact incidents during a three-month period are subtle, “valid” config-

urations. A recent study [51] on performance configurations in distributed systems reports a similar finding.

To reduce specious-configuration-induced incidents, we need to proactively detect it before production. However, what makes specious configuration subtle to detect is that its value is not a unconditionally poor choice. Rather, the setting is only problematic under certain combination with some other parameters, input, and/or environment. Currently, administrators either informally estimate the impact based on their experience, or experimentally measure it by black-box testing the program with configuration. However, neither of the approaches is sufficient to reliably capture the pitfalls.

Through analyzing real-world cases (Section 2), we realize that the crux of specious configuration lies in the fact that some slow code path in the program or library gets executed; but this effect can be only triggered with certain input, other configurations, and environment. Therefore, we argue that analytical approaches are needed to *reason about* the configuration settings' performance implications under a variety of conditions. We propose a novel analytical tool called VIOLET that uses symbolic execution [24, 38] to analyze the performance effect of configuration at the code level.

The basic idea of Violet is to systematically explore the system code paths with symbolic configuration and input, identify the constraints that decide whether a path gets executed or not, and analytically compare different execution paths that are explored. Violet derives a configuration performance impact model as its analysis output. A Violet checker leverages this model to contiguously catch specious configuration in the field. Making this basic idea work for large system software faces several challenges, including the intricate dependency among different parameters, the efficiency of symbolic execution for performance analysis, complex input structure, and path explosion problems. Violet leverages program analysis and selective symbolic execution [26] to address these challenges.

We implement a prototype of the Violet toolchain, with its core tracer built as plugins on the S²E platform [26], the static analyzer built on LLVM [40], and the trace analyzer and checker built as standalone tools. We successfully apply Violet on four large systems, MySQL, PostgreSQL, Apache and Squid. Violet derives performance impact models for 471 parameters. To evaluate the effectiveness of Violet, we collect 17 real-world specious configuration cases. Violet detects 15 cases. In addition, Violet exposes 11 unknown specious configuration, 8 of which are confirmed by developers.

In summary, this paper makes the following contributions:

- An analytical approach to detect specious configuration using symbolic execution and program analysis.
- Design and implementation of an end-to-end toolchain Violet, and scaling it to work on large system software.
- Evaluation of Violet on real-world specious configuration.

The source code of Violet is publicly available at:

<https://github.com/OrderLab/violet>

2 Background and Motivation

In this Section, we show a few cases of real-world specious configuration from MySQL to motivate the problem and make the discussion concrete. We analyze how specious configuration affects system performance at the *source code* level. We choose MySQL because it is representative as a large system with numerous (more than 300) parameters, many of which can be misconfigured by users and lead to bad performance.

2.1 Definition

A program expects its configuration parameters to obey certain rules, *e.g.*, the path exists, the min heap size does not exceed the max size. Invalid configurations violate those rules and usually trigger assertions or errors.

We define specious configuration to be settings that are valid but cause the software to experience bad performance when deployed to production. Admittedly, bad performance is a qualitative criterion. Like prior work, we focus on those issues that cause severe degradation and hurt usability. Ultimately, only users can judge whether the performance slowdown is sub-optimal but tolerable or it is intolerable.

Specious configuration has two classes. One is purely about performance, *e.g.*, buffer size, number of threads. Another class is settings that change the software functionality but the changes also have performance impact. Both classes are important and occur in real-world systems. For the latter class, users might want the enabled functionality and are willing to pay for the performance cost. Thus, whether the setting is specious or not depends on users' preferences. Our solution addresses both forms. Its focus is to analyze and explain the quantitative performance impact of different settings, so that users can make better functionality-performance trade-offs.

2.2 Case Studies

autocommit parameter controls the transaction commit behavior in MySQL. If **autocommit** is enabled, each SQL statement forms a single transaction, so MySQL will automatically perform a commit. If **autocommit** is disabled, transactions need to be explicitly committed with **COMMIT** statements. While **autocommit** offers convenience (no explicit commit required) and durability benefits, it also has a performance penalty since every single query will be run in a transaction. For some users, this performance implication may not be immediately apparent (especially since it is enabled by default). Even if users are aware of the performance trade-off, they might not know the degree of performance loss, only to realize the degradation is too much after deploying it to production. Indeed, there have been user-reported issues due to this setting [13, 15, 60], and the recommended fix is to disable **autocommit**, and manually batch and commit multiple queries in one transaction.

To quantify the performance impact, we use sysbench [16] to measure MySQL throughput with **autocommit** configura-

Figure 2: MySQL throughput for autocommit under two workloads.

```

1 int write_row() {                uintl trx_commit_complete() {
2   if (autocommit) {              if (flush_at_trx_commit==1) {
3     ...                           log_group_write_buf();
4     trx_commit_complete();         fil_flush(); costly operation
5   } else {                        } else if (flush_at_trx_commit==2) {
6     trx_mark_sql_stat_end();       log_group_write_buf();
7   }                               } else {
8 }                               /* do nothing */
9                               }
10                              }

```

Figure 3: Simplified code snippet from MySQL related to autocommit. The elements with orange-colored background represent configuration variables, and the pink ones represent slow operations.

tion set to be ON and OFF. The size of the database is 10 tables and 10K records per table. We run both a normal workload that consists of 70% read, 20% write and 10% other operations, and an insert-intensive workload. Figure 2 shows the result. We can see that in the normal workload (Figure 2a), the performance difference between ON and OFF are small. But in insertion-intensive workload (Figure 2b), enabling autocommit causes dramatically worse (6×) performance.

Figure 3 shows the code relevant to autocommit. We can see that the autocommit setting determines whether function `trx_commit_complete()` will be invoked. In this function, another parameter `flush_at_trx_commit`¹ further determines which path gets executed. When that parameter is set to 1, compared to 2, an additional `fil_flush` operation will be incurred, which has a complex logic but essentially will flush the table writes cached by the OS to disk through the `fsync` system call. The cost of `fsync` is the major contributor to the bad performance of autocommit mode; if `flush_at_trx_commit` is 2 or 0, the performance impact of autocommit mode will be much smaller. In addition, the function in which autocommit is used—`write_row()`—is called when handling write type queries but not select type queries. Therefore, the performance hit only affects insertion/update-intensive workloads.

`query_cache_wlock_invalidate` controls the validation of the query cache in MySQL. Normally, when one client acquires a WRITE lock on a MyISAM table, other clients are *not* blocked from issuing statements that read from the table if the query results are present in the query cache. The effect of setting this parameter to 1 is that upon acquisition of a WRITE lock for a table, MySQL invalidates the query cache that refers to the locked table, which has a performance implication.

As Figure 4 shows, enabling this parameter leads to the `free_query` operation (❶). Different from the autocommit case, this operation itself is not costly. But for other clients that attempt to access the table, they cannot use the associated

¹ Its full name in MySQL is `innodb_flush_log_at_trx_commit`. We abbreviate it and some other parameter names in this paper for readability.

```

void mysql_parse(THD *thd) {
  if (send_result_to_client(thd) <= 0) {
    mysql_execute_command(thd);
  }
  incoming queries not in query cache
  int mysql_execute_command(THD *thd) {
    case SQLCOM_SELECT:
      open_and_lock_tables(thd, all_tables);
      break;
    case SQLCOM_LOCK_TABLES:
      lock_tables_open_and_lock_tables(thd);
      if (query_cache_wlock_invalidate) {
        invalidate_query_block_list();
      }
      void invalidate_query_block_list() {
        free_query(list_root->block());
      }
      ❶ free query cache
  }
}

```

Figure 4: Code affected by `query_cache_wlock_invalidate`.

```

uint64_t log_reserve_and_open(uint len) {
  if (len >= log->buf_size / 2) {
    log_buffer_extend((len + 1) * 2);
  }
  len_upper_limit = LOG_BUF_WRITE_MARGIN + (5 * len) / 4;
  if (log->buf_free + len_upper_limit > log->buf_size) {
    mutex_exit(&(log->mutex));
    log_buffer_flush_to_disk();
    goto loop;
  }
}

```

Figure 5: Code affected by `innodb_log_buffer_size`.

query cache (❷), forcing them to open the table and wait (❸) while the write lock is held. Therefore, the effect is additional synchronization that decreases the system concurrency, which in turn can severely hurt the overall system query throughput.

Similar to autocommit, the performance effect depends on the parameters, execution environment and workloads. Specifically, the bad performance is only manifestable with the combination of MyISAM tables, LOCK TABLES statements and other clients doing select type queries on the locked table.

`innodb_log_buffer_size` determines the size of the buffer for uncommitted transactions. The default value (8M) is usually fine. However if MySQL has transactions with large blob/text fields, the buffer can fill up very quickly and incur performance hit. As shown in Figure 5, the parameter setting has two possible performance impacts: (1) if the length of a new log is larger than half of the `buf_size`, the system will extend the buffer first by calling `log_buffer_extend`, which in normal cases mainly involves memory allocation. But if other threads are also extending the buffer, additional synchronization overhead is incurred. If the buffer has pending writes, they will be flushed to disk first; (2) if the `buf_size` is smaller than the free size plus the length of new log, MySQL will trigger a costly synchronous buffer flush operation.

2.3 Code Patterns

Based on the above and other cases we analyze, we summarize four common patterns on how a specious configuration affects the performance of a system at the source code level:

1. The parameter causes some expensive operation like the `fsync` system call to be executed.
2. The parameter incurs additional synchronization that itself is not expensive but decreases system concurrency.

3. The parameter directs the execution flow towards a slow path, *e.g.*, not using cached result.
4. The parameter triggers frequent crossings of some threshold that leads to costly operations.

The general characteristic among them is that specious configuration controls a system's execution flows—different values cause the program or its libraries to execute different code paths. However, the performance impact is also *context-dependent*—a specious configuration is bad only when its value and other relevant factors together direct the system to execute a path that is significantly slower than others.

2.4 Approaches to Detect Specious Config

To detect specious configuration, operators rely on experience or manuals, which are neither reliable nor comprehensive. A more rigorous practice is to test the system together with configuration and quantitatively measure the end-to-end performance like throughput. However, if the testing does not have appropriate input or related parameters, the performance issue will not be discovered. Also, because the testing is carried out in a black-box fashion, the approach is *experimental*. The results are tied to the testing environment, which may not have the same hardware, dependencies or scale as the production. For example, in the incident described in Section 1, that specious configuration was tested, and the result showed a slight increase of logging traffic to a dependent database. But this increase was deemed small, so it passed the testing.

We argue that while the experimental approach is indispensable, it alone is insufficient to catch specious configuration. We advocate developing *analytical* approaches for *reasoning* about configurations' performance effect from the system code. The outcome from an analytical approach includes not only a conclusion, but also answers to questions “how the parameter affects what operations get executed?”, “what kind of input will perform poorly/fine?”, “does the effect depend on other parameters?”, *etc.* In addition, the analysis should enable *extrapolation* to different contexts, so users can project the outcome with respect to specific workload or environment.

A potential approach is static analysis. Indeed, we can leverage the code patterns in Section 2.3 to detect potential specious configuration. However, mapping them at concrete code construct level requires substantial domain knowledge. Also, the performance effect involves many complex factors that are difficult to be deduced by pure static analysis.

The observations in Section 2.3 lead us to realize that the crux is some slow path being conditionally executed. Thus, we can transform the problem of detecting specious configuration to the problem of finding slow execution flow plus deducing the triggering conditions of the slow execution.

3 Overview of Violet

We propose an analytical approach for detecting specious configuration, and design a tool called VIOLET. Violet aims

to comprehensively reason about the performance effect of system configurations: (1) explore the system without being limited by particular input; (2) analyze the performance effect without being too tied to the execution environment.

Our insight is that the subtle performance effect of a specious parameter is usually reflected in different *code paths* getting executed, depending on *conditions* involving the parameter, input and other parameters, and these paths have significant *relative* performance differences. Based on this insight, Violet uses symbolic execution with assistance of static analysis to thoroughly explore the influence of configuration parameters on program execution paths, identify the conditions leading to each execution, and compare the performance costs along different paths. After these analyses, Violet derives a configuration performance impact model that describes the relationship between the performance effect and related conditions. In this Section, we give an overview of Violet (Figure 6). We describe the design of Violet in Section 4.

3.1 Symbolic Execution to Analyze Performance Effect of Configurations

Background. Symbolic execution [24, 38] is a popular technique that systematically explores a program. Different from testing that exercises a single path of the program with concrete input, symbolic execution explores multiple paths of the program with symbolic input and memorizes the *path constraints* during its exploration. When a path of interest (*e.g.*, with `abort()`) is encountered, the execution engine generates an input that satisfies the constraint, which can be used as a test case. Compared to random testing, symbolic execution systematically explores possible program paths while avoiding redundancy. Consider this snippet:

```
void foo(int n) { if (n > 1000) bar(n); else bazz(n); }
```

Testing may blindly test the program many times with different *n*, *e.g.*, 1, 10, 20, *etc.*, but they all exercise the same path without triggering the call to `bar()`. If we use symbolic execution, we can explore the two paths of `foo` by deriving only two concrete values of *n* to satisfy the path constraints.

Basic Idea. Configuration is essentially one type of input to a program. The basic idea of Violet is simple—make the parameters symbolic, measure the cost along each execution path explored, and comparatively analyze the costs. The path constraints that the symbolic execution engine memorizes characterize the conditions about whether and when a parameter setting is potentially poor. Take Figure 3 as an example. Violet makes variable `autocommit` symbolic. Function `write_row` will fork at line 2. The first path goes into the *if* branch, with a constraint `autocommit == 1`. When `trx_commit_complete` is called in the first path, it encounters another parameter `flush_at_trx_commit`, which is also made symbolic. Two additional paths are forked within that function. While exploring these paths, Violet records a set of performance cost metrics.

Figure 6: Overview of Violet.

Since the subtle performance effect of specious configuration is often only triggered under specific input, besides configuration parameters, Violet can also make the input symbolic. For the example in Figure 3, the input will determine whether the `write_row` function will be called or not. Only insert type queries will invoke `write_row`. This input constraint will be recorded so the analysis later can identify what *class* of input can trigger the specious configuration.

3.2 Violet Workflow

Figure 6 shows the workflow of Violet. The input to Violet is system code and target configuration. We require source code to identify the program variables corresponding to parameters. In addition, as we discuss later (Section 4.3), Violet uses static analysis to assist the discovery of dependent parameters. To symbolically execute the target system, we leverage a state-of-the-art symbolic execution platform S²E [26] and insert hooks into the system code to make parameters and input symbolic. We design the Violet execution tracer as S²E plugins to record the performance results to a trace during state exploration. The Violet trace analyzer conducts comparative cost analysis, differential critical path analysis, *etc.* The output is a configuration performance impact model that describes the relationship among configuration constraints, cost, critical path, and input predicate.

Violet further provides a checker to deploy with the software at user sites. The checker consumes the constructed configuration impact model to continuously detect whether a user-site configuration file or update can potentially lead to poor performance. Upon the detection of potential specious configuration, the Violet checker reports not only the absolute performance result, but also the logical cost and critical path to explain the danger. The checker also outputs a validation test case based on the input predict that provides hints to users about what input can expose the potential performance issue.

4 The Design of Violet

In this Section, we describe the Violet design (Figure 6). We need to address several design challenges. First, configurations have intricate dependencies among themselves and with the input, but making all of them symbolic easily leads to state space explosion. Second, conducting performance analysis in symbolic execution is demanding due to lack of explicit

assertion point, mixed costs, overhead, etc. Third, deriving performance model from code requires balance between being generalizable (not too tailored to specific input or environment) and being realistic (reflects costs in real executions).

4.1 Make Config Variable Symbolic

The starting point for Violet is to make parameters symbolic. A naïve way is to make the entire configuration file a symbolic blob. While this approach is transparent to the target program, it easily leads to path explosion even at the program initialization stage. An improvement could be only making the configuration value string symbolic during parsing. e.g., `make_symbolic(value, 2); buf_size=atoi(value);` But the execution would still spend significant time in the parsing (`atoi`). Also the parameter value range will be limited by the string size, e.g., only explore `buf_size` from 0 to 99.

We should identify the program variables that store configuration parameters and directly make these variables symbolic. Prior works [56,57] observe that the mature software typically uses uniform interfaces such as an array of `struct` to store parameters. Thus they annotate these interfaces to extract variable mappings in static analysis. For Violet, we need to additionally identify the parameter type and value constraints defined by the program (e.g., 1 to 10) to restrict the symbolic value. This is because we are only interested in exploring the performance effect of *valid* values.

Since typically all the config variables are readily accessible after some point during initialization, we take a simple but accurate approach: insert a hook function directly in the source code right after the parsing function and programmatically enumerates these variables and make them symbolic using their type and other info. In this hook function, we read an external environment variable `VI0_SYM_CONFIGS` to decide which target parameter(s) to make symbolic.

Take MySQL as an example. Its configuration parameters are represented by a number of `Sys_var_*` data structures in the code, depending on the parameter’s type. We add a `make_symbolic` API to these data structures, which uses the type, name, value range information to call the Violet library to make the backing store symbolic. Figure 7 shows an example of the added hook API. Then after MySQL finishes parsing its configurations, we iterate through all configuration variables (Figure 8), which are stored in a global linked list called `all_sys_vars`. If the parameter is in the target set, we invoke its new `make_symbolic` API.

```

template <typename T>
class Sys_var_unsigned: public sys_var {
public:
    Sys_var_unsigned(const char *name, T min_val, T max_val, ...) {
        option.min_value= min_val;
        option.max_value= max_val;
        ...
    }
    bool global_update(THD *thd, set_var *var) {
        global_var(T)= var->save_result.ulONGLONG_value;
        return false;
    }
    ...
    bool make_symbolic() {
        violet_make_symbolic(global_var_ptr(), sizeof(T), option.name);
        violet_assume((unsigned)(*global_var_ptr()) <= option.max_value);
        violet_assume((unsigned)(*global_var_ptr()) >= option.min_value);
        return true;
    }
}

```

Figure 7: Add API to one config. data structure in MySQL.

```

static int get_options(int *argc_ptr, char ***argv_ptr)
{
    my_init_dynamic_array(&all_options, sizeof(my_option));
    for (opt= my_long_options; opt < my_options_end; opt++) {
        insert_dynamic(&all_options, (uchar*) opt);
        ...
    }
    violet_parse_config_targets();
    violet_make_mysql_options_symbolic();
    return 0;
}

void violet_make_mysql_options_symbolic()
{
    for (sys_var *var=all_sys_vars.first; var= var->next)
        if (is_config_in_targets(var->name.str))
            var->make_symbolic();
}

```

Figure 8: Call symbolic hooks after config. parsing in MySQL.

4.2 Make Related Config Symbolic

The performance effect of a parameter usually depends on the values of other parameters. Thus, if we only make one parameter symbolic while leaving other parameters concrete, we will only explore incomplete execution paths and potentially miss some problematic combination that leads to bad performance. A straightforward solution is to make all parameters symbolic. Since symbolic execution only forks if a symbolic value is used branch conditions, this approach seems to be feasible. However, the problem with this approach is that most combinations of configuration parameters are unrelated but will be explored during symbolic execution.

Figure 9 illustrates the problem. Suppose we are interested in the performance effect of `opty`. If we simply make all parameters (`optx`, `opty`, `optz`) symbolic in hope of exploring the combination effect, there will be at least 6 execution paths being explored. But `opty` is unrelated to `optx` and `optz`. The performance impact of `opty` is only determined by the cost of its branches. For large programs, the target parameter could be used deep in the code. Including unrelated parameters in the symbolic set can cause the symbolic execution to waste significant time or get stuck before reaching the interesting code place to explore the target parameter. The analysis result can also cause confusions. For example, it might suggest only when `optx>100` && `optz==FILE` && `opty` is true will there be a performance issue and miss detecting specious configuration when `opty` is true but `optx <= 100` or `optz != FILE`.

Therefore, instead of making all parameters symbolic, we carefully choose the set of parameters to symbolically execute

Figure 9: Making unrelated parameters symbolic results in excessive state explorations and confusing conclusions.

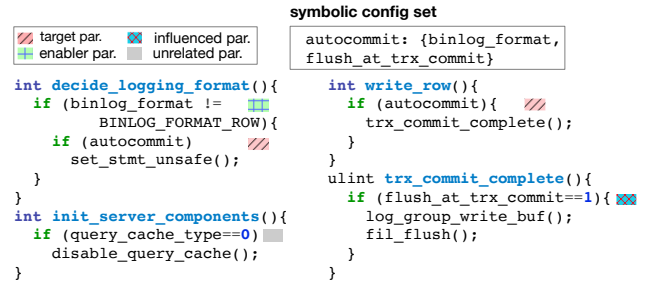

Figure 10: Symbolic config set based on control dependencies.

together. In particular, related parameters are usually control dependent on each other. We discover the parameter control dependency with methods described in the following Section.

4.3 Discover Control Dependent Configs

Violet statically analyzes the control dependency relationship of parameters to determine a reduced symbolic *parameter set*. The static analysis result can significantly help mitigate the path exploration problem during symbolic execution phase.

For a target parameter *C*, Violet identifies two kinds of related parameters to put in its symbolic set. The *enabler parameters* are those that *C* is control dependent on. The *influenced parameters* are those that are control dependent on *C*. Figure 10 shows an example. For target parameter `autocommit`, it is used in `decide_logging_format` and `write_row`, it has an enabler parameter `binlog_format`, which decides if `autocommit` will be activated. `autocommit` itself influences the performance effect of parameter `flush_at_trx_commit`. Thus, for `autocommit`, the set of related parameters to make symbolic together is `{binlog_format, flush_at_trx_commit}`.

Informally, program element *Y* is control dependent on element *X* if whether *Y*'s executed depends on a test at *X*. More formally, control dependency is captured by postdominator relationship in program Control Flow Graph (CFG). Node *b* in the CFG postdominates node *a* if every path from *a* to the exit node contains *b*. *Y* is control dependent on *X* if there is a path $X \rightarrow Z_1 \rightarrow \dots \rightarrow Z_n \rightarrow Y$ such that *Y* postdominates all *Z_i* and *Y* does *not* postdominate *X*. We use postdominator as a building block for our analysis. But our notion of control dependency is broader than the classic definition. For example, `if (X) { if (Z1) { if (Z2) { if (Y) { foo(); } } } }`, the classic definition does *not* regard *X* and *Y* as being control-dependent, because *Y* does *not* postdominate *Z1* or *Z2*;

it regards Z2 and Y as being control-dependent. But for us, all the four parameters are control dependent.

Our analysis is divided into two steps. The first step computes the enabler parameters. Violet builds a call graph of the program. For target parameter p , it locates the usage points of p and extracts the call chains starting from the entry function to the function f that encloses a usage point. If any caller g in the call chain uses some other parameter q , we check if the callsite in g that eventually reaches f is control dependent on the usage point of parameter q in g . If so, q is added to the enabler parameter set of p . Violet identifies enabler parameters within f through intra-procedural control dependency. Our technical report [34] lists the algorithm.

In the second step, Violet calculates the influenced parameters from the computed enabler parameter sets of all parameters. The related config set is a union of the influenced set and enabler set. We also capture control dependency that involves simple data flow. For example,

```
void query_cache_init() {      bool is_disabled() {
    if (query_cache_type == 0) return m_cache_is_disabled;
    m_cache_is_disabled = TRUE; }
}
```

any parameter that is control dependent on the regular variable `m_cache_is_disabled` or return value of `is_disabled()` is also considered to be related to parameter `query_cache_type`.

The static analysis result can be inaccurate due to imprecision in the alias analysis, call graph, infeasible path problem, *etc.* Our general principle is to be conservative and over-approximate the set of related parameters for a target parameter. During symbolic execution, having a few false control dependent parameters does not greatly affect the performance or analysis conclusion and they can manifest through the symbolic execution log if they do cause issues.

4.4 Execute Software Symbolically

After the target software is instrumented with the symbolic execution hooks, Violet symbolically executes the software with a concrete configuration file. The hook function reads the `VIO_SYM_CONFIGS` environment variable and makes symbolic the program variables corresponding to the specified parameter. In addition, the function parses the control dependency analysis (Section 4.3) result file and makes variables in the related parameter set symbolic as well. Other parameters' program variables get the concrete values from the configuration file. Besides parameters, Violet can also make program input symbolic to explore its influence on the configuration's performance impact. This is done through either symbolic arguments (`sym-args`) or identifying the input program variables and inserting `make_symbolic` calls in the code.

4.5 Profile Execution Paths

To measure the symbolic parameters' performance effect, Violet implements a tracer on top of the symbolic execution engine, specifically as a set of plugins on the S²E platform.

Figure 11: Match call/return records.

Measure Function Call Latency. We measure function call latency by capturing the call and return signals emitted by S²E during symbolic execution. To calculate the latency, a straightforward way is to maintain a stack of call record and pops the top element upon receiving a return signal. This algorithm assumes that the call/return signals are paired and the callee's return signal comes before the caller's. But we observe this assumption does not always hold under S²E. We use a safer method based on return addresses to calculate latency. In particular, the Violet tracer records the EIP register value, return address, and timestamp on each call and return signal. The records are stored in two lists. Later, the tracer matches call record list with return record list based on return address fields (Figure 11). The latency for a matched function call is the return record's timestamp minus the call record's timestamp. The total latency of each state (execution path) can be obtained from the latency of the root function call.

For multi-threaded programs, function calls from different threads can get mixed up. To address this issue, the Violet tracer stores the current thread id in each profile record and partitions the call and return lists by thread id.

Re-Construct Call Paths. The tracer records the function call profile to break down total latency and to enable differential critical path analysis (§4.6). To get the call chain relationship, instead of costly stack frame walk, the tracer uses a simple method with little overhead that just assigns each call record a unique incrementing `cid`. Later, the tracer reconstructs the call chain by iterating through all call records in order. If (1) call record A 's `cid` is larger than call record B 's `cid`, (2) the return address of A is larger than B 's EIP (the start address of that function), and (3) the difference of the two addresses is smallest among all other pairs (i.e., B 's start address is closest to the return address in A), then we assign A 's `parentId` to be B 's `cid` and update the current distance.

Measure Logical Costs. Besides absolute latency, we also measure a set of logical cost metrics by a similar method of capturing low-level signals from S²E. In particular, for each execution path, we measure the number of instructions, the number of system calls, the number of file I/O calls, the amount of I/O traffic, the number of synchronization operations, network calls, etc. These logical costs are useful to surface performance issues other than just long latency. They are also crucial for reducing the test environment's biases and enabling extrapolation of the result to different settings. For example, if the tracer finds one execution path has a much higher number of write syscalls compared to other paths whereas

Configuration Constraint	Cost	Workload Predicate
autocommit!=0 && flush_log_at_trx_commit==1	2.6 s, {log_write_buf→fil_flush}, 17K syscalls, 100 I/O insts, ...	sql_command==INSERT
autocommit!=0 && flush_log_at_trx_commit==2	1.7 s, {log_write_buf}, 16.9K syscalls	sql_command==INSERT
autocommit!=0 && flush_log_at_trx_commit!=1 && flush_log_at_trx_commit!=2	1.2 s, {}, 16.9K syscall	sql_command==INSERT
autocommit==0	0.6 s, {trx_mark_sql_stat_end}, 16.8K syscalls	sql_command==SELECT ...

Table 1: Example raw cost table Violet generates for autocommit parameter from symbolic execution of MySQL code in Figure 3.

their latencies are similar. This could be an artifact of the test server having a powerful hard disk or a large buffer cache. But the software might perform poorly in a different environment. The Violet tracer maintains a separate performance profile for each execution path (state) so we can compare the performance effect of different paths. We also need to record the path constraints to identify the parameter combination and the *class* of input that leads to the execution path. The tracer records the final path constraint when an execution path terminates or it exceeds some user-specified cost threshold.

4.6 Analyze State Traces

Once the symbolic execution finishes, the Violet trace analyzer parses the performance traces. It then builds a cost table. Each row represents a state (path) that was explored in symbolic execution. The analyzer does a pair-wise comparison of performance in different rows. If the performance difference ratio exceeds a threshold (default 100%), the analyzer marks that state suspicious. The analyzer compares not only the absolute latency metric but also the collected logical metrics. Even if the latency difference does not exceed the threshold but some logical metric does, the analyzer still marks the state.

Not all pair comparisons are equally meaningful when the symbolic execution explored multiple symbolic variables. To elaborate, assume our target parameter is `autocommit`, which has a related parameter `flush_log`. Since both are made symbolic, one state could represent constraint `autocommit==0 && flush_log==1` and another state could represent constraint `autocommit==1 && flush_log==2`. In this case, comparing the costs of these two states is not very meaningful.

The analyzer tries to compare state pairs that are most “similar” first. Determining the similarity of two paths can be challenging. We use a simple approach: in one state’s constraints formula, for each constraint involving a related parameter, if it also appears in the other state’s formula, the similarity count is incremented by one. This method is imprecise as it merely checks the appearances, not constraint equivalence. For our use cases, the inaccuracies are generally acceptable. Besides, the analyzer can compare all pairs first, surface the bad state-pairs, and then we can decide the meaningfulness of the suspicious pairs.

For each pair that has a significant performance difference, the analyzer computes the *differential* critical path. It first finds the longest common subsequence of the call chain records in the two states. Then it creates a diff trace that stores the common records with performance metrics subtracted, as well as the records that only appear in the slower state. The

analyzer finally locates the call record (excluding entry) with the largest differential cost and constructs the critical call path based on the `cid` and `parentId` of the call records.

When Violet makes the input symbolic, the path constraints in each state will contain constraints about the input. The analyzer separates the input related constraints as input predicate. This is useful to tell what *class* of input can expose the potential performance issue for the combination of parameter values that satisfies the configuration constraint in a state. The final output from the Violet analyzer is the configuration performance impact model that consists of the raw cost table (Table 1) with configuration constraints, cost metrics, and input predicate for each state, the state pairs that have significant performance difference, and the differential critical paths.

4.7 Continuous Specious Config Checker

Violet provides a standalone checker tool to detect specious configuration. It leverages the configuration performance impact model from the analyzer and validates a concrete user configuration file. The checker tool supports three modes:

1. Some config update introduces performance regression.
2. Some default parameter is poor for users’ specific setup.
3. Code upgrade or workload change make old setting poor.

For scenario 1, the checker references the cost table and locates the state(s) that have configuration constraints satisfying the updated parameter’ old value and the parameter’s new value. If the state pair has significant performance difference, the checker alerts the operators and generates a test case based on the input predicate for operators to confirm the performance regression. For scenario 2, the checker validates if the state that the default value lies in appears in some poor state-pair. If so, it means this default value potentially performs significantly worse than another value. For scenario 3, if the system code changes, Violet rebuilds the cost impact table. The checker then identifies if some state in the new table performs much worse compared to the old cost table. If workload changes, the checker validates if cost table rows that previously satisfy the input predicate perform worse compared to rows that satisfy the input predicate now.

5 Scaling Violet to Large Software

In this section, we describe the challenges and our solutions for scaling Violet to large software.

5.1 Choice of Symbolic Execution Engine

We initially build Violet on the KLEE [24] symbolic execution engine because it is widely used and convenient to exper-

iment with. However, while KLEE works well on moderate-sized programs, it cannot handle large programs like MySQL. KLEE models the environment (POSIX runtime and libc) with simplified implementation. Large programs use many libc or system calls that are unimplemented or implemented partially/incorrectly, e.g., `fcntl`, `pread`, and `socket`. KLEE also does not support symbolic execution of multi-threaded programs. We spent several months patching KLEE to fix the environment model and add multi-threading support. When we were finally able to run MySQL with KLEE, it took 40 minutes to just pass initialization even without symbolic data.

We thus decided to switch to the S²E platform [26]. S²E uses real environment with complete OS and libraries. Executing large software would encounter almost no compatibility issues. In addition, S²E uses QEMU and dynamic binary translation to execute a target program. For instructions that access symbolic data, they are interpreted by the embedded KLEE engine; but instructions that access concrete data are directly executed on host CPU. Overall, while the choice of using real environment in symbolic execution in general means slower analysis compared to using simplified models like KLEE, executing concrete instructions on host CPU offsets that slowness and allows S²E to achieve significant speed-up. After migrating Violet to S²E and with some minor adjustments, we can start MySQL server within one minute.

5.2 Handle Complex Input Structure

Since specious configuration is often only triggered by certain input, Violet makes input symbolic besides configuration. For small programs, the input type is typically simple, e.g., an integer, a string, which is easy to be made symbolic. However, large programs' input can have very complex structure. If we make such complex input symbolic, the program may be stuck in the input parsing code for a long time and the majority of the input generated is invalid. For example, we make input variable `char *packet` (32 bytes) in MySQL symbolic and execute it in S²E for 1 hour, which generates several hundred test cases, but none of which is a legal SQL query. Even after adding some additional constraints, the result is similar.

This challenge is not unique to our problem domain. Compiler testing [58] or fuzzing [11] also faces this challenge of how to generate valid input to programs like C compiler or DBMS. We address this problem through a similar practice by introducing workload templates. Instead of having the parser figure out a valid structure, we pre-define a set of input templates that have valid structures. Then we parameterize the templates so that they are not fixed, e.g., the query type, insertion value, the number of queries, etc. In this way, we can make the workload template parameters symbolic.

5.3 Reduce Profiling Overhead

Profiling large programs can incur substantial overhead. We build Violet tracer using low-level signals emitted by S²E rather than intrusive instrumentation. Nevertheless, symbolic

execution is demanding for performance analysis as the program runs much slower compared to native execution. Fortunately, Violet cares about the relative performance between different paths. We can still identify specious configuration if the relative differences roughly match the native execution, which we find is true for most cases. Violet conducts differential analyses to capture performance anomalies. We describe three additional optimizations in Violet tracer.

First, the Violet tracer controls the start and end of its function profiler. This is because if we enable the function profiler at the very beginning, it can be overwhelmed by lots of irrelevant function calls. We add APIs in the tracer and will start the tracer when the target system finishes initialization and stop the tracer when the system enters the shutdown phase.

Second, the tracer avoids guest memory accesses and on-the-fly calculation. Accessing memory in an execution state goes through the emulated MMU in QEMU. Violet tracer only accesses and stores key information (most from registers) about the call/return signals. It defers the record matching, call chain and latency calculation to path termination.

Third, Violet will disable state switching during latency tracking if necessary. Since the function profiler calculates the execution time by subtracting the return signal timestamp from call signal timestamp, if S²E switches to execute another state in between, the recorded latency will include the state switching cost. This in general does not cause serious problems because the costs occur in all states and roughly cancels out with our differential analysis. But in rare cases, the switching costs can distort the results. When this happens, Violet will force S²E to disable state switching.

5.4 Path Explosion and Complex Constraints

A common problem with symbolic execution is path explosion, especially when the symbolic value is used in library or system calls. In addition, some library calls with symbolic data yield complex constraints that make the symbolic execution engine spend a long time in solving the constraints.

Violet leverages a core feature in S²E, *selective symbolic execution* [26], to address this problem. Selective symbolic execution allows transition between concrete and symbolic execution when crossing some execution boundary, e.g., a system call. Violet uses the Strictly-Consistent Unit-Level Execution consistency model, which silently concretizes the symbolic value before entering the boundary and adds the concretized constraint to the symbolic value after exiting the boundary. This consistency model sacrifices completeness but it would not invalidate the analysis result. To improve completeness, we add some relaxation rules in Violet without causing functionality errors: 1) if the library call does not add side effect, such as `strlen`/`strcmp`, we make the return value symbolic and remove the concretized constraint; 2) if the library call has side effect but does not hurt the functionality, such as `printf`, we directly remove the concretized constraint.

Software	Desc.	Arch.	Version	SLOC	Configs	Hook
MySQL	Database	Multi-thd	5.5.59	1.2M	330	197
Postgres	Database	Multi-proc	11.0	843K	294	165
Apache	Web server	Multi-proc-thd	2.4.38	199K	172	158
Squid	Proxy server	Multi-thd	4.1	178K	327	96

Table 2: Evaluated software. Hook: SLOC of core Violet hooks.

One issue we encounter with the S²E silent concretization is that its concretize API will only concretize the symbolic variable. The symbolic variable can taint other variables (make them symbolic) when it is assigned to these variables, but these tainted variables are not concretized during silent concretization. Having these tainted variables remain symbolic can add substantial overhead. We thus add a new API in S²E, `concretizeAll`, that concretizes not only the given symbolic variable but also its tainted variables. We implement this API by recording in each write operation a mapping from the symbolic expression to the target address in the memory object. Later when `concretizeAll` is called, we will look up the memory objects to find addresses that contain the same symbolic expression and also concretize them.

6 Implementation

We implement the major Violet components in C/C++. The Violet checker is implemented in Python. The Violet tracer is written as S²E plugins and leverages S²E’s existing plugin to capture low-level signals. The Violet static analyzer is built on top of LLVM framework [40]. The Violet trace analyzer is implemented as a standalone tool.

In function profiling, for efficiency, the tracer captures the addresses instead of names of invoked functions. This means the analyzer needs to resolve the addresses to names. The problem is that the virtual address of the target program can change in each run. We address this issue by modifying the ELF loader of the S²E Linux kernel to expose the `load_bias`. Then the tracer will record the offset from the `load_bias`. The analyzer can then use the offsets to resolve the names.

7 Evaluation

We evaluate Violet to answer several key questions:

- How effective is Violet in detecting specious configuration?
- Can Violet expose unknown specious configuration?
- How useful is Violet’s checker to the user?
- What is the performance of Violet?

The experiments are conducted on servers with Dual Processor of Intel Xeon E5-2630 (2.20GHz, 10 cores), 64 GB memory, 1 TB HDD running a Ubuntu 16.04. Since S²E engine runs in QEMU, we create a guest image of Debian 9.2.1 x86_64 with 4 GB memory for all the Violet tests.

7.1 Target Systems

We evaluate Violet on four popular and large (up to 1.2M SLOC) open-source software (Table 2): MySQL, PostgreSQL, Apache, and Squid. Violet can successfully analyze large

multi-threaded programs (MySQL and Squid) as well as multi-process (PostgreSQL, Apache) programs.

The manual effort to use Violet on a target system is small, mainly required in two steps: (1) add configuration hooks (Section 4.1); (2) supply input templates (Section 5.2). The other steps in the workflow are automated.

Table 2 shows SLOC of the core hooks we add to the four systems. The hook size varies across systems. MySQL hooks are largest in size mainly because the system defines many (22) configuration types (`Sys_var_*`) so we need to add hook (about 7 SLOC) to each type. But the overall effort for different systems is small. The changes are typically contained in a few places with other codes untouched. In addition, most software rarely modifies the configuration data structure design, so the effort can carry through versions.

For (2), users typically already have some workload profiles. The effort needed is to parameterize and organize them into our format. In our experience with the four evaluated software, this process is straightforward and can be done in a few hours.

7.2 Detecting Known Specious Config

To evaluate the effectiveness of Violet we collect 17 *real-world* specious configuration cases from the four systems. Table 3 lists the case descriptions. We collect them from ServerFault [14], dba [4], blog posts [12], and prior work [19]. A case is marked as detected when Violet explores at least one poor state in its trace *and* the poor states enclose the problematic parameter value(s).

In total, Violet detects 15 of the 17 cases. Table 4 shows the detailed result. For each case, Table 4 lists the total states Violet explored, poor states, related configs, and maximum cost metric differences. The explored states include forks from related configurations and the symbolic workload parameters. In most cases, the specious configuration requires specific related settings to expose the issue. The high success rate of Violet comes from its in-vivo multi-path profiling, dependency analysis, and differential performance analysis.

Another aspect to interpret the high success rate is that the 17 cases we collect admittedly have a selection bias—all cases cause severe performance impact. This is reflected in the max diff column. If a misconfiguration only introduces mild performance issue, Violet may miss it due to the noises in symbolic execution. However, Violet’s goal is to exactly target specious configuration that has severe performance impact, rather than suboptimal configurations.

Violet misses two Apache cases, c14 and c15. Triggering them requires enabling the HTTP KeepAlive feature in the workload. In our Apache workload templates, this feature is not part of the workload parameters and is disabled by default.

We describe two representative cases. MySQL c1 is the running example in the paper. Violet identifies four related parameters for `autocommit` and explores 88 states in total, 4 of which are identified as poor. The configuration constraints

Id.	Application	Configuration Name	Data Type	Description
c1	MySQL	autocommit	Boolean	Determine whether all changes take effect immediately
c2	MySQL	query_cache_wlock_invalidate	Boolean	Disable the query cache when after WRITE lock statement
c3	MySQL	general_log	Boolean	Enable MySQL general log query
c4	MySQL	query_cache_type	Enumeration	Method used for controlling the query cache type
c5	MySQL	sync_binlog	Integer	Controls how often the MySQL server synchronizes binary log to disk
c6	MySQL	innodb_log_buffer_size	Integer	Set the size of the buffer for transactions that have not been committed yet
c7	PostgreSQL	wal_sync_method	Enumeration	Method used for forcing WAL updates out to disk
c8	PostgreSQL	archive_mode	Enumeration	Force the server to switch to a new WAL periodically and archive old WAL segments
c9	PostgreSQL	max_wal_size	Integer	Maximum number of log file segments between automatic WAL checkpoints
c10	PostgreSQL	checkpoint_completion_target	Float	Set a fraction of total time between checkpoints interval
c11	PostgreSQL	bgwriter_lru_multiplier	Float	Set estimate of the number of buffers for the next background writing
c12	Apache	HostNameLookups	Enumeration	Enables DNS lookups to log the host names of clients sending requests
c13	Apache	Deny/Domain	Enum/String	Restrict access to the server based on hostname, IP address, or env variables
c14	Apache	MaxKeepAliveRequests	Integer	Limits the number of requests allowed per connection
c15	Apache	KeepAliveTimeout	Integer	Seconds Apache will wait for a subsequent request before closing the connection
c16	Squid	cache	String	Requests denied by this directive will not be stored in the cache
c17	Squid	Buffered_logs	Integer	Whether to write access_log records ASAP or accumulate them in larger chunks

Table 3: Description of 17 known specious configuration cases we collect in the four evaluated software.

Id.	Detect	Explored States	Poor States	Related Configs	Cost Metrics	Analysis Time	Max Diff*
c1	✓	88	17	4	Latency	6 m25 s	14.5×
c2	✓	24	3	1	Lat.&Sync.	3 m13 s	15.7×

c17	✓	3	1	0	I/O	1 m32 s	2.0×

Table 4: Violet detection result. Poor states are what Violet considers as suspicious. *: relative difference, $\alpha \times$ means $B = (1 + \alpha) * A$.

of the four poor states describe the combination conditions for the 5 parameters to incur significant cost.

In c6, `innodb_log_buffer_size` controls the size of the log buffer. Interestingly, in this case, Violet determines the latency metric difference is not significant, but the I/O logical cost metric is. Specifically, Violet explores almost 100 different queries, and finds that in states with queries involving large row changes and a relatively small buffer size, the I/O metric—`pwrites` operations—is much larger than other states.

7.3 Comparison with Testing

We evaluate the 17 cases with testing as well. We use popular benchmark tools `sysbench` and `ab`. For each case, we set the target parameter and related parameters with concrete values from one of the poor states discovered. We enumerate the standard workloads in the benchmark to test the software with the configurations. Since the absolute performance result are

difficult to judge, we use configurations from the good states and collect performance result with them as a baseline. If the performance difference ratio exceeds 100% (the same threshold used by Violet), we consider the case detected. In total, testing detects 10 cases, with a median time of 25 minutes.

Violet is not meant to replace configuration performance testing. In theory, exhaustive testing can expose all cases, but the cost of it is not affordable in practice. Violet systematically explores program states while avoids the redundancy in exhaustive testing (Section 3.1). Even though in some cases, as shown in Table 4, the Violet analysis time is relatively long, Violet is exploring the performance effects thoroughly, including the combination effect with other parameters and input. Therefore, the performance impact models Violet derives are complete. Once the exploration is done, the outcome can be reused many times while testing needs to be done repeatedly.

Another challenge with testing is to find the baseline for good performance. Our experiment above assumes the existence of good configuration, which users may not have. Violet, in comparison, conducts in-vivo, multi-path analysis, so it naturally has baselines to compare with. The analysis enables Violet to collect deeper logical metrics, which can reveal performance issues that end-to-end metrics may not find.

7.4 Exposing Unknown Specious Config

Besides detecting known specious configuration, we evaluate whether Violet can expose unknown specious configuration. We first apply Violet to derive performance models for all parameters if possible (Section 7.6). We then analyze the results for parameters not in the known case dataset (Section 7.2). We manually check (1) if some parameter’s default or suggested value is in a poor state; (2) if a poor state of a parameter contains related parameters that are undocumented. The manual inspection involves checking the Violet output, the descriptions in the official documentation and tuning guide,

Figure 12: Overall accuracy of judgment in the user study.

Figure 13: Average decision time in the user study.

Figure 14: Violet analysis times for the configs in the four software.

Sys	Configuration	Performance Impact
Postgres	<code>vacuum_cost_delay</code>	Default value 20 ms is significantly worse than low values for write workload.
Postgres	<code>archive_timeout</code>	Small values cause performance penalties.
Postgres	<code>random_page_cost</code>	Values larger than 1.2 (default 4.0) cause bad perf on SSD for join queries.
Postgres	<code>log_statement</code>	Setting <code>mod</code> causes bad perf. for write workload when <code>synchronous_commit</code> is off.
Postgres	<code>parallel_setup_cost</code>	A higher value would avoid unnecessary parallelism when executing join query
Postgres	<code>parallel_leader_participation</code>	Enabling it can cause select join query to be slow if <code>random_page_cost</code> is high.
MySQL	<code>optimizer_search_depth</code>	Default value would cause bad performance for join queries
MySQL	<code>concurrent_insert</code>	Enable <code>concurrent_insert</code> would cause bad performance for read workload
Squid	<code>ipcache_size</code>	The default value is relatively small and may cause performance reduction
Squid	<code>cache_log</code>	Enable <code>cache_log</code> with higher <code>debug_option</code> would cause extra I/O
Squid	<code>store_objects_per_bucket</code>	Higher objects per bucket would enlarge the search time

Table 5: Unknown perf. effect of 11 parameters Violet identifies.

and running tests to confirm, which takes significant time. We only carefully inspect a subset of the results.

The four systems are very mature and maintain high-quality documentations, so it is not easy to find many errors in them. Indeed, a significant portion of the poor states we examined turns out to be already documented. Still we have identified 11 parameters that have potential bad performance effect and the documentation is incomplete or incorrect.

Table 5 lists the cases. For example, our analysis of `vacuum_cost_delay` shows that a higher value can incur large cost for write-intensive workloads, but the default value is 20 ms. Interestingly, we find PostgreSQL 12 (our experiments use v11) changes the default to 2 ms. For `log_statement`, Violet discovers multiple poor states that are not mentioned in the official document. Our analysis reveals that setting it to `mod` causes performance issues for write query when `synchronous_commit` is off. Violet finds some unexpected parameter combination that leads to bad performance, e.g., `parallel_leader_participation` and `random_page_cost`.

We reported our findings to the developers. Eight reports are confirmed. Five lead to documentation or Wiki fixes. For some confirmed cases, developers do not fix them because they assume users should know the performance implications or such performance description should not be put in the reference manual (e.g., “There are a lot of interactions between settings, and mentioning all of them would be impossible”).

7.5 User Study on Violet Checker

To understand whether Violet checker helps users catch specious configuration, we conduct a controlled user study with 20 programmers (no authors are included). Fourteen are undergraduate students who have taken the database class. Six are graduate students. They all have decent experience with databases and Unix tools. We further give a tutorial of MySQL and PostgreSQL, the descriptions of the common configuration, and available benchmark tools they can use.

We use 6 target parameters from MySQL and PostgreSQL. For each parameter, we prepare two versions of configuration files. In one version (bad), the parameter is set with the poor value and the related parameters are also set appropriately that would cause bad performance impact under a workload. In another version (good), we set the target parameter to a good value, or we change the related parameter values, or we tell users the production workloads are limited to certain types (e.g., read-intensive). So in total, we have 12 cases.

Each participant is given 6 configuration files. They need to make a judgment regarding whether the configuration file would cause potential performance issue. Since a configuration file contains many parameters, we explicitly tell users the set of parameters they can focus on, which disadvantages Violet because users in practice do not have this luxury.

The participants are randomly assigned into two groups: *group A* (w/ Violet checker help) and *group B* (w/o checker help). Users in group B can run any tools to help them make the decision. We also tell group A users that they do not have to trust the checker output and are free to run other tools.

Figure 12 shows the accuracy of user study result for each group. Overall, programmers w/o Violet checker’s help have 30% misjudgment rate while programmers with Violet checker’s help only have 5% misjudging rate. Figure 13 shows the time for making a judgment. On average, participants took 20.7% less time (9.6 min. versus 12.1 min.) to make a judgment when they were provided with Violet checker. The reason that time saving is not very large is partly because we explicitly tell users the set of parameters, which creates a biased advantage to group B users; and some of our group A users are extra cautious and spend time running other tools.

7.6 Coverage of Analyzed Configs

We conduct a coverage test of Violet by applying Violet on the four software and try to derive performance models for as many parameters as possible. We manually filter the param-

MySQL	PostgreSQL	Apache	Squid	Total
169 (51.2%)	210 (71.4%)	51 (29.6%)	176 (53.3%)	606 (53.9%)

Table 6: Number of configs Violet derives performance models for. The number in parentheses is the percentage of total configs.

	parA		parB		parC			parD		
	=0	=1	=0	=1	=0	=1	=2	=0	=1	=2
Violet	12.0	23.0	9.81	10.19	9.05	10.92	10.74	4.68	4.77	5.27
S²E	10.8	21.0	7.67	8.94	6.24	7.77	7.92	3.57	3.91	4.59
Native	0.7	1.2	0.55	0.77	0.45	0.63	0.67	0.07	0.07	0.08

Table 7: Absolute latency (ms) for four parameters' different settings w/ Violet, vanilla S²E and native execution. parA: autocommit, parB: synchronous_commit, parC: archive_mode, parD: HostNameLookup.

ters that are not related to performance based on the parameter description (e.g., listen_addresses). Table 6 shows the result. Violet successfully derives models for a total of 606 parameters. The average ratio of analyzed parameters over the total number of parameters for software is 53.9%. The average number of states explored in these generated models is 23. Apache and Squid have a relatively small number of parameters analyzed. This is because the configuration program variables in the two systems are set via complex function pointers and spread in different modules, which make it challenging to write hooks to enumerate all of them (Section 4.1). For parameters that Violet did not generate impact models, one reason is that they are used in code for special environment. Another reason is that the data type of some parameter is too complex (e.g., timezone) to make symbolic.

7.7 Accuracy of Violet Profiling

Since symbolic execution can introduce significant overhead, it seems that the latency traced by the symbolic engine will not be accurate. However, we observe that while the absolute latency under symbolic execution is indeed much larger than native execution, the comparative results between different paths are usually similar. We add a micro-benchmark experiment to test the latency measurement from Violet, vanilla S²E and native mode. Table 7 shows the result from four representative parameters. Take parA as an example. The latency results from Violet and S²E are much later than native result. But the ration of setting 1 to setting 0 is similar: $1.92\times$ for Violet, $1.94\times$ for S²E, and $1.71\times$ for native execution.

7.8 False Positives

The Violet differential performance analysis in general can absorb the performance noises in symbolic execution. But we observe some false positives in the Violet performance analysis output. For example, S²E somehow has a delay in emitting the return signal of some system call functions like gettimeofday, which causes Violet to record inaccurate latency. These false positives are relatively easy to suppress by discounting the cost of the noisy instructions.

We manually inspect the performance models of 10 random parameters that Violet analyzes in the coverage experiment.

Figure 15: Sensitivity of the performance diff threshold (default 100%). For readability, the number of poor states is normalized by values under the default threshold.

We check the accuracy of the reported bad states by verifying them with sysbench. The false positive rate is 6.4%.

7.9 Performance

We measure the Violet analysis time for the 471 parameters in the coverage experiment (Section 7.6). Figure 14 shows the result in boxplots. The median analysis times are 206 s (MySQL), 117 s (PostgreSQL), 1171 s (Apache), and 554 s (Squid). On average, the log analyzer time is 68s. As explained in Section 7.3, even though for some parameters the analysis time is relatively long, the benefit is that Violet derives a thorough performance model for different settings of the target parameter and the combined effect with other parameters and input. The outcome can be re-used many times by the Violet checker. With the performance models, the checker time is fast. On average the checking only takes 15.7 seconds.

7.10 Sensitivity Analysis

Violet uses a differential threshold (default 100%) to detect the suspicious state from the trace log (Section 4.6). We evaluate the sensitivity of this threshold by measuring how many poor state pairs Violet reports when analyzing a parameter under threshold t . For each poor state pair Violet reports, we run benchmarks on the native machine to check whether it is false positive (performance difference is $\geq t\%$).

Figure 15 shows the result for six representative parameters. We can see that if the threshold is set to a relatively lower value, the number of detected specious configuration can dramatically increase, but at cost of higher false positives.

8 Limitations

Violet has several limitations that we plan to address in future work. First, Violet explores the configuration under normal conditions. Some specious configuration may be only used in error handling. Exploring their effect requires specific faults. One solution is to combine symbolic execution with fault injection. Another potential solution is to use under-constrained symbolic execution [46]. Second, our handling of floating point type parameters is imperfect due to limited support in existing symbolic execution engines. We currently explores float parameters by choosing from a set of concrete floating-point values in the valid value range. Third, we use concrete (the host) hardware in the symbolic execution, which may not

capture specious configuration that is only visible in specific hardware. We rely on logical cost metrics to surface such issues. Lastly, Violet does not work on distributed systems.

9 Related Work

Misconfiguration detection and diagnosis. A wide body of work has been done to detect and troubleshoot misconfiguration [20–22, 27, 30, 30, 48, 50, 52, 54, 61, 63]. For example, ConfAid [21] uses dynamic taint tracking to locate configuration errors that lead to failures; Strider [52] and PeerPressure [50] take statistical approaches to identify misconfiguration; EnCore [63] enhances statistical learning with environment information to detect misconfiguration.

These solutions mainly target illegal configuration and have limited effects on specious configuration. X-ray [19] targets performance-related misconfiguration. Our work is inspired by X-ray and is complementary to it. X-ray is a diagnosis tool and uses deterministic record and replay of a specific program execution. Violet focuses on detecting specious configuration beforehand. Violet uses symbolic execution to explore the performance effect in multiple execution paths. Violet is more suitable for performance tuning/bug finding, whereas X-ray is better at diagnosing misconfiguration that has occurred.

LearnConf [41] is recently proposed to detect performance misconfiguration using static analysis. LearnConf summarizes common code patterns of performance configuration and uses simple formulas to approximate the performance effect, *e.g.*, linear relationship. It uses static analysis to identify these patterns and derive parameters to the formulas. The solution is simpler compared to Violet, but its completeness is limited because obtaining comprehensive code patterns is hard. Moreover, the performance effect is often quite complex, which cannot be accurately captured by simple formulas. Static analysis also suffers from well-known inaccuracies for large software. Violet explores a configuration’s influence in the code without requiring or being limited by common patterns; it analyzes the performance effect by executing the code. Additionally, Violet explores the performance impact of input and a large set of related configurations together.

Performance tuning of configuration. There is a wealth of literature on automatic performance tuning, *e.g.*, [33, 44, 51, 55, 59, 62, 64]. They work basically by devising an approximate function between configuration values and the performance metrics measured through testing. While tunable parameters are common specious configuration, performance tuning and detecting specious configuration are two directions. The former searches for settings that yield the best performance, while the latter identifies settings that lead to extremely poor performance. Violet takes an analytical approach to derive configuration performance impact model from the code, instead of exhaustive testing. The result from our in-vivo, multi-path analysis is also less susceptible to noises and enables extrapolation to different contexts.

System resilience to misconfiguration. ConfErr [37] uses a human error model to inject misconfiguration. SPEX [57] uses static analysis to extract configuration constraints and generates misconfiguration by violating these constraints. The injected misconfigurations are illegal values that can trigger explicit errors like crash. Specious configuration typically does not cause explicit errors.

Configuration languages. Better configuration languages can help avoid misconfiguration. Several works make such efforts [23, 25, 28, 29, 35, 42, 47]. PRESTO [29] proposes a template language to generate device-native configuration. ConfValley [35], proposes a declarative validation language for generic software configuration. These new designs do not prevent specious configuration from being introduced.

Symbolic execution in performance analysis. Symbolic execution [24, 38] is typically used for finding functional bugs. S²E [26] is the first to explore performance analysis in symbolic execution as one use case to demonstrate the generality of its platform. The Violet tracer leverages the advances made by S²E, particularly its low-level signals, to build our custom profiling methods (Section 4.5). Our tracer also addresses several unique challenges to reduce the performance analysis overhead (Section 5.3). Bolt [36] extracts performance contracts of Network Function code with symbolic execution. Violet targets general-purpose software and analyzes performance effect of system configuration.

10 Conclusion

Specious configuration is a common and challenging problem for production systems. We propose an analytical approach to tackle this problem and present a toolchain called Violet. Violet uses symbolic execution and program analysis to systematically reason about the performance effect of configuration from code. The derived configuration performance impact model is used for subsequent detections of specious configuration. We successfully apply Violet on four large system software and detect 15 out of 17 real-world specious configuration cases. Violet exposes 11 unknown specious configuration, 8 of which are confirmed by developers.

Acknowledgments

We would like to thank our shepherd, Jason Flinn, and the anonymous OSDI reviewers for their thoughtful comments. We appreciate the discussion and suggestions from Xi Wang. We thank Varun Radhakrishnan and Justin Shafer for their contributions to the Violet tool and study cases. We thank our user-study participants and the open-source developers who responded to our requests. We also thank the S²E authors, especially Vitaly Chipounov for maintaining the S²E platform and answering our questions. We thank Chunqiang Tang for the prior collaboration that provided early motivation for this work. This work is supported by the NSF CRII grant CNS-1755737 and partly by NSF grant CNS-1910133.

Abstract

Large-scale cloud services deploy hundreds of configuration changes to production systems daily. At such velocity, configuration changes have inevitably become prevalent causes of production failures. Existing misconfiguration detection and configuration validation techniques only check configuration values. These techniques cannot detect common types of failure-inducing configuration changes, such as those that cause code to fail or those that violate hidden constraints.

We present ctests, a new type of tests for detecting failure-inducing configuration changes to prevent production failures. The idea behind ctests is simple—connecting production system configurations to software tests so that configuration changes can be tested in the context of code affected by the changes. So, ctests can detect configuration changes that expose dormant software bugs and diverse misconfigurations.

We show how to generate ctests by transforming the many existing tests in mature systems. The key challenge that we address is the automated identification of test logic and oracles that can be reused in ctests. We generated thousands of ctests from the existing tests in five cloud systems.

Our results show that ctests are effective in detecting failure-inducing configuration changes before deployment. We evaluate ctests on real-world failure-inducing configuration changes, injected misconfigurations, and deployed configuration files from public Docker images. Ctests effectively detect real-world failure-inducing configuration changes and misconfigurations in the deployed files.

1 Introduction

1.1 Motivation

Large-scale cloud and Internet services evolve rapidly and deploy hundreds to thousands of configuration changes to production systems daily [35, 38, 53, 55]. For example, at Facebook, thousands of configuration changes are committed daily, outpacing the frequency of code changes [55]. Other cloud services such as Google and Azure also frequently deploy configuration changes [9, 10, 38].

The high velocity of configuration changes has led to prevalent configuration-induced failures. For example, faulty con-

figurations are the second largest cause of service disruptions in a main Google production service [5]. At Facebook, 16% of service-level incidents, including major outages [54], are induced by configuration changes [55]. Similar levels of severity and prevalence of configuration-induced failures occur in other cloud systems [19, 34, 40, 42, 74].

Based on our experience from analyzing hundreds of configuration-induced incidents, failure-inducing configuration changes are rarely caused by trivial mistakes (e.g., typos). This rarity is attributed to the DevOps practices that enforce change review and validation [6, 27, 55]. As a result, the root causes of configuration-induced failures are often non-trivial; they commonly reside in the program and not in the changed configurations. Failures typically occur when *valid* configuration changes expose dormant software bugs [55] and when configuration changes violate undocumented, hidden configuration constraints. The root causes of the former are in the program, while the latter are often due to configuration design or implementation flaws [69]. Review and validation of configuration changes alone can hardly detect failures resulting from these root causes.

Researchers have proposed several configuration validation and misconfiguration detection techniques [70]. These include new languages and frameworks for implementing validators [6, 27, 55], detection techniques that use machine learning and document analysis to infer correctness rules on configuration values [38, 43, 44, 49, 50, 59, 61, 75, 77], and type or constraint checkers [48, 67]. These techniques are successful, but they are limited:

- Existing techniques only check configuration values and cannot detect configuration changes that cause code to fail.
- Very few existing techniques can detect “legal misconfigurations” [71], which have syntactically and semantically valid values but result in unexpected behavior.
- It is costly and hard for human-written or machine-learned rules to check the often subtle, version-specific [78], and inconsistent [69] configuration requirements.

1.2 Contributions

We present ctests, a new type of tests for detecting failure-inducing configuration changes to prevent production failures.

*Co-primary authors

Ctests take a simple and effective approach—connecting software tests with production system configurations. In this way, ctests can test configuration changes in the context of code that is affected by the changes. A ctest is parameterized by a set of system configuration parameters. Running a ctest instantiates each of its input parameters with a configuration value from production or a value to be deployed to production. Like regular software tests, ctests exercise system code and assert that program behavior satisfies certain properties (correctness, performance, security, etc). Ctests can be unit, integration, or system tests.

Existing software testing techniques do not connect tests to *actual* production system configurations. Rather, existing testing techniques sample *possible* configurations through systematic or random exploration of the enormous space of configuration value combinations [37]. Systematic exploration can be prohibitively expensive due to combinatorial explosion [39], while random exploration can have a low probability of covering all offending values that can cause production failures. Ctests have neither the cost of systematic exploration nor the low coverage of random exploration. By connecting tests to production system configurations, ctests can effectively detect failure-inducing configurations.

Ctests can test entire system configurations or incremental configuration changes in the form of configuration file “diffs.” Our ctest infrastructure (see §3) supports *selectively* running only the ctests that are relevant to a configuration change, instead of re-running all ctests. Selectively running ctests saves testing time—most real-world configuration changes modify only a few configuration values [55].

We show how to generate ctests by transforming the existing and abundant tests in mature software projects in an automated fashion that reuses well-engineered test logic and oracles. The main challenge that we address is the automated identification of test logic and oracles that can be transformed into ctests. Existing test logic may assume specific configuration values. Such assumptions can be implicit (assuming default values) or explicit (hardcoding certain values). Thus, naïve parameterization will not always generate valid ctests.

Our transformation identifies and respects the intent of existing tests that assume specific configuration values. First, configuration parameters whose values are explicitly re-assigned in the test code are excluded from the input parameter set of a ctest. Then, the values of the parameters used in candidate ctests are varied to observe the corresponding test output. We exclude parameters whose values are hard-coded in a test because such tests will fail on different but valid values. Our tests-to-ctests transformation is mechanized in a toolchain and we successfully generated 7,974 ctests by transforming the existing test suites in five cloud systems.

Ctests address the following limitations of existing configuration validation and misconfiguration detection techniques:

- Ctests can detect failure-inducing configuration changes where the root cause of the failure is in the code.

- Ctests can detect legal misconfigurations by capturing the resulting unexpected system behavior.
- Ctests can be generated from existing tests, without incurring the high cost of learning or codifying rules.

Our results show that ctests can effectively detect failure-inducing configuration changes before deploying them to production. We evaluated ctests using 64 real-world configuration-induced failures, 1,055 diverse misconfigurations generated by error injection rules, and 92 deployed configuration files from publicly-available Docker images.

Ctests detected the failure-inducing configurations in 96.9% of the real-world failures. The ctests that detected these real-world failures were transformed from the tests in the older version of the systems on which the failures were reported. That is, ctests could have detected these failures earlier. Ctests also detected 10 misconfigurations in 7 deployed files. Additionally, our ctest generation process exposed 14 previously unknown bugs, including a bug that users encountered after we reported it [24]. Developers confirmed 12 of these 14 bugs and fixed 10 of them.

In summary, this paper makes the following contributions:

- Ctests enable a simple and effective approach for detecting failure-inducing configuration changes.
- We present how to generate ctests by transforming the many existing tests in mature systems.
- We show that ctests can effectively detect real-world configuration-induced failures early, during testing.

2 Background and Examples

We describe how ctests address the limitations of existing techniques for validating configuration values [6, 27, 48, 55, 67] and techniques for detecting specific types of misconfigurations [38, 43, 44, 49, 50, 59, 61, 62, 75, 77].

Checking configurations based on program behavior. A key capability of ctests is to check how actual configuration values impact program behavior. This capability is essential for detecting configuration changes that result in code failures or expose dormant bugs. In our experience, checking program behavior can be more effective in capturing failure-inducing configuration changes than checking configuration values against rules (which are usually incomplete).

Figure 1 uses a real-world issue from HBase [21] to illustrate the capability of ctests. There, a ctest detects a misconfiguration that degrades performance (“*too many handlers can be counter-productive* [56]”). The ctest is generated from an existing test in the reported HBase version. It asserts on the computed schedule with the expected behavior that handler counts are not affected by configuration changes. The offending value is “legal” [71] but the reported version had no validation code to check the expected behavior.

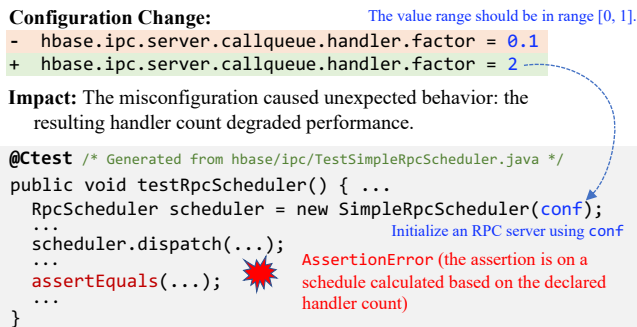

Figure 1: A ctest that detects a real-world misconfiguration in HBase [21] by checking expected system behavior. The ctest is generated from a test available in the reported HBase version.

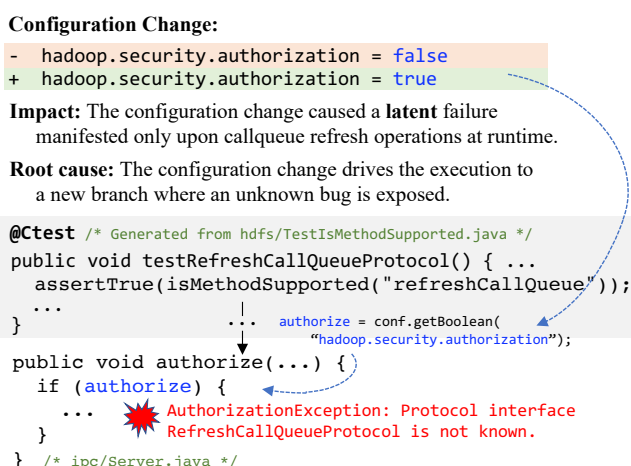

Figure 2: A ctest that detects a dormant bug exposed by a configuration change in Hadoop [20]. The ctest is generated from a test available in the reported Hadoop version.

Detecting dormant bugs exposed by valid configuration changes. Ctests can detect not only misconfigurations but also software bugs exposed by valid configuration changes. Such bugs are common root causes of configuration-related incidents (§1.1). Existing configuration validation and misconfiguration detection techniques only check for erroneous configuration values; they are fundamentally limited to detecting failures with root causes outside the changed configurations. Such software bugs inevitably occur, despite extensive testing and static analysis. Some bugs can only be exposed under specific configurations. Figure 2 shows a real-world failure from Hadoop [20]. A failure-inducing configuration change caused Hadoop to traverse new execution paths and exposed a dormant software bug.

Detecting diverse misconfigurations. Many existing techniques focus on detecting specific kinds of misconfigurations. Ctests are generic. They can detect configuration changes that lead to any kind of unexpected program behavior. So ctests can detect misconfigurations that are hard for state-of-

the-art techniques to detect. Such misconfigurations involve (1) custom regular expressions, user commands, and URIs (statistical analyses and machine learning can detect outliers but cannot deal with custom values [67]), (2) invalid content referred to by path-related configurations (most existing techniques only check metadata), (3) violations of undocumented constraints that cannot be found by text-based document analysis [44, 59, 65], and (4) dependencies among multiple configuration parameters [12]. Figures 8 and 9 show examples of misconfigurations detected by ctests that are hard to detect using existing techniques.

Incremental pre-deployment testing for every configuration change. Ctests can help *prevent* failure-inducing configuration changes from being deployed to production systems. The goal of ctests is to test every configuration change early, during testing. Ctests can be run selectively on configuration file “diffs” to save testing time (§3.2). Ctests do not suffer from limitations of post-deployment configuration checking (e.g., disallowing operations with side effects to avoid corrupting production system states as in PCheck [67]).

3 Ctest Overview

The idea behind ctests is to connect production system configurations to software tests, enabling the checking of configuration changes against program properties in the context of code affected by the configuration changes. Ctests detect *both* misconfigurations caused by assigning invalid values to configuration parameters and bugs in the code that are exposed by changing configuration parameters to new valid values.

3.1 Ctest Definition

A ctest, $\hat{t}(\hat{P})$, is a test \hat{t} that is parameterized by a set of system configuration parameters \hat{P} . Running a ctest instantiates each parameter $p \in \hat{P}$ with a concrete value. In particular, each $p \in \hat{P}$ in a ctest can be instantiated with a value from the production system configuration or a configuration change (in the form of a configuration file “diff”) to be deployed. Note that \hat{P} is typically only a very small subset of all system configuration parameters, denoted as \mathbb{P} . That is, $|\hat{P}| \ll |\mathbb{P}|$.

Ctests can be unit, integration, or system tests. Like regular software tests, a ctest can assert on different kinds of program properties: correctness, performance, security, etc. Ctests can be written from scratch by developers, or they can be generated from existing software tests (see §4). Our generation procedure reuses test logic and assertions in existing tests during transformation to ctests.

3.2 Ctest Usage

Ctests can check an entire system configuration, a configuration change, or a configuration file. So, ctests can be used both as a traditional configuration file checker and as an enabler of configuration checking during continuous integration and

deployment [52]. Ctests are complementary to configuration validation, similar to how software testing complements static analysis for bug detection.

Ctests for checking entire system configurations. We define a system configuration as the values of all configuration parameters in the system denoted as $C = \bigcup_{i=1..|\mathbb{P}|} \{(p_i \mapsto v_i)\}$ (it assigns a value v_i to every parameter p_i in \mathbb{P}). Running a ctest, $\hat{t}(\hat{P})$, instantiates each parameter $p_i \in \hat{P}$ with its value in the system configuration v_i such that $(p_i \mapsto v_i) \in C$. To test the system configuration, C , all available ctests are run. C passes if all ctests pass and fails if any ctest fails.

Ctests for checking configuration changes. In modern continuous integration and deployment, a configuration change has the form of a configuration file “diff”. A diff typically only changes the values of a small set of configuration parameters, P_D [55]. It updates the system configuration from C to C' by changing each $p_d \in P_D$ ’s value from v_d to v'_d . Formally, we define a configuration diff $D = \{(p_d \mapsto v'_d) \mid p_d \in P_D \text{ and } (p_d \mapsto v_d) \in C \text{ and } v_d \neq v'_d\}$.

For a given diff D , a ctest $\hat{t}(\hat{P})$ can be used to test D if at least one configuration parameter in D is in its input parameter set \hat{P} (i.e., if $P_D \cap \hat{P} \neq \emptyset$). We use this *test selection criterion* to re-run only the subset of ctests whose outcome could be altered by D , instead of re-running all ctests after every configuration change.

A selected ctest $\hat{t}(\hat{P})$ can be run before deploying D to production by assigning values in D to the ctest’s parameters that are in D and assigning values in C to the ctest’s parameters that are not in D . Precisely, assign v'_d to each $p_d \in \hat{P} \cap P_D$, where $(p_d \mapsto v'_d) \in D$; then, assign v to each $p \in \hat{P} - P_D$, where $(p \mapsto v) \in C$. Ctests with $\hat{P} \cap P_D = \emptyset$ do not need to be run when testing D . A configuration diff, D , passes if all selected ctests pass and fails if any selected ctest fails.

Ctests for checking configuration files. A configuration file typically only assigns values to a subset of \mathbb{P} . Parameters whose values are not assigned in the configuration file receive their default values. So, ctests treat a configuration file as a diff which updates the default system configuration with the configuration values that are set in the file.

Locating offending configuration values. If a ctest is newly failing on a configuration diff, D , then the offending parameters must be in $\hat{P} \cap P_D$, unless the tests are flaky [8]. Parameters in D are typically very few, e.g., 49.5% of configuration changes have two-line revisions [55]. We discuss our experience on inspecting ctest failures in §7.

3.3 Creating a Ctest Infrastructure

Ctest infrastructure can be built on top of existing software testing frameworks. Specifically, a ctest can be run in the same way as a regular software test by instantiating the test’s input parameters with system configuration values. We built our current ctest infrastructure on top of the Maven build sys-

tem [36]—all the systems that we study use Maven to compile and run their test suites (§5.1). It should be straightforward to extend our infrastructure to support other build systems such as Gradle [16], Bazel [7], and Buck [11].

Ctests should be run in a hermetic test environment (a common software testing practice [41]). Ctests are best run in the same environmental setup as in production because ctests can capture environment-specific, configuration-induced failures (e.g., Figure 8). Our current infrastructure supports running ctests in Linux containers.

Ctest selection. Ctest selection is critical for utilizing ctests during continuous integration and deployment of configuration diffs. Regression test selection, which reruns tests that are affected by code changes [17], does not work for configuration changes. We build our ctest selection mechanism using the test selection criterion described in §3.2; it only runs ctests that are parameterized by parameters in D .

Configuration versioning. We store the latest version of the system configuration C to be updated after a configuration diff passes ctest and is deployed (§3.2). So, our infrastructure can instantiate ctests with updated parameter values in C .

4 Ctest Generation

Ctests can be generated by transforming existing tests in mature software projects with reasonable manual effort. The generated ctests inherit test logic and assertions from the original tests. The inherited assertions hold for *all* correct configuration values.

Ctest generation proceeds in two steps. First, the existing tests are *parameterized* by system configuration parameters, so that they can be run against different system configurations (§3.2). We describe in §4.1 how to parameterize an existing test t to obtain $\hat{t}(\mathbb{P})$ (or \hat{t} in short), where \mathbb{P} represents all the configuration parameters of the target system. Second, the parameterized tests are transformed into ctests.

A parameterized test \hat{t} may not be directly usable as a ctest if the original test t contains test logic or oracles that assume specific configuration values. The resulting parameterized test \hat{t} may fail incorrectly on valid configuration values if the subsequently resulting ctest is run against new values that are not the assumed values. So, if \hat{t} assumes specific values of a configuration parameter $p \in \mathbb{P}$, \hat{t} cannot be a ctest for p . But \hat{t} can still be a ctest for another independent parameter, say $q \in \mathbb{P}$, if \hat{t} does not assume a value for q . In short, if \hat{t} assumes a value for p but not for q , \hat{t} can result in a ctest for q but not for p . We address the challenge of identifying, among all configuration parameters exercised by \hat{t} , those that can be included in the input parameter set \hat{P} of the resulting ctest $\hat{t}(\hat{P})$. In this example, $q \in \hat{P}$ and $p \notin \hat{P}$. We describe in §4.2 how to identify \hat{P} from \mathbb{P} when generating a ctest $\hat{t}(\hat{P})$ from \hat{t} .

One can optionally rewrite generated ctests to allow generated ctests check more configuration parameters or to generate

```

1  static {
2      ...
3      addDefaultResource("core-default.xml");
4      addDefaultResource("core-site.xml");
5 +   addDefaultResource("core-ctest.xml");
6  }
7  /* conf/Configuration.java */

```

Figure 3: Parameterization by intercepting the configuration APIs of Hadoop. After the interception, test code reads configuration values from `core-ctest.xml` which is managed by our ctest infrastructure. In this way, the test code can be instantiated with values in `core-ctest.xml`.

new ctests. §4.3 presents two simple rewriting rules for dealing with hardcoded parameter values and assertions.

In summary, given tests $T = \{t_i \mid i = 1, 2, \dots, Nf\}$, we generate a set of ctests $\hat{T} = \{\hat{t}_i(\hat{P}_i)\}$, where $|\hat{T}| \leq |T|$. For each ctest $\hat{t}_i(\hat{P}_i)$, \hat{t}_i is the parameterized test and \hat{P}_i is the set of configuration parameters that can be tested by the ctest. Each ctest is generated from an existing test and checks one or more parameters. To test to-be-deployed configurations, a ctest instantiates all its input parameters.

Developer effort. To generate ctests from existing tests, developers need to instrument the configuration APIs of the system. We discuss instrumentation in §4.1 and §4.2.1. After instrumentation, ctest generation is mechanized.

4.1 Parameterization

The first step in generating ctests is to parameterize an existing test t into \hat{t} , so that t can be run by instantiating the parameters with actual system configuration values. Parameterization requires changing test code to read configuration values at runtime, as provided by ctest infrastructure (§3.3), instead of from default configuration files or other test files. To generate large numbers of ctests, parameterization is automated.

We find that systematic parameterization can be done by intercepting the configuration APIs that existing tests use for reading configuration values. Figure 3 exemplifies our interception of Hadoop’s configuration API. The idea is to overwrite configuration values as the final step of configuration loading. Thus, when the test code reads configuration values from configuration APIs, the values come from the configurations maintained by the ctest infrastructure (§3.3). Our parameterization approach minimizes the changes needed and avoids changing individual tests. Our approach is applicable to many (if not all) modern cloud systems, but its implementation is project-specific. We implemented parameterization for five cloud systems (§5.1) and validated its applicability to other systems including Spark and OpenStack.

The parameterization step produces a parameterized test, $\hat{t}(\mathbb{P})$, for each test t , where \mathbb{P} is the set of all system configuration parameters. Parameterization is oblivious of the set of configuration parameters exercised by each \hat{t} ; these are automatically identified in §4.2.1.

4.2 Transformation

A parameterized test $\hat{t}(\mathbb{P})$ may not be a valid ctest—a ctest’s parameter set \hat{P} should include only configuration parameters that can be checked by the ctest—the test logic and oracles should not assume specific parameter values.

Transforming a parameterized test into a ctest consists of (1) identifying the set of configuration parameters that are exercised by each test t , denoted as P (§4.2.1), and (2) for each $p \in P$, determining whether the test logic and oracle of t assume any specific value of p ; if so, $p \notin \hat{P}$ (§4.2.2). Figure 4 shows ctest generation process that transforms from t to $\hat{t}(\hat{P})$.

Figure 4: Steps in the ctest generation process.

4.2.1 Identifying Parameters Exercised in Tests

Static or dynamic analysis can be used to identify P for each test t . We implemented and experimented with both. Our static analysis taints the statements that can be reached by t and searches for configuration API usage (§4.1) among the tainted statements. It was straightforward to identify configuration API usages in test code. But, since test code commonly passes configuration values to system code initialization, it is hard to precisely collect the exact configuration API usage in system code that may be reachable from tests. So, static analysis often imprecisely produces a parameter set larger than P .

We chose dynamic analysis under the assumption that most test cases are relatively deterministic [15]. Our dynamic analysis requires developers to instrument configuration GET and SET APIs for reading and writing configuration values in the target system, respectively.¹ Our instrumentation inserts code to log the stack trace of each API invocation and the configuration parameter involved. Figure 5 is an example of our instrumentation for Hadoop. With instrumentation in place, our dynamic analysis runs all existing tests and post-processes the log for each test t to automatically identify (1) the set of configuration parameters P exercised by t , and (2) parameters written (via the SET API) in t (needed in §4.2.2).

Log processing is automated, as our instrumentation produces easily-parsed output. Our dynamic approach is simple,

¹The GET and SET APIs are common configuration abstractions used in cloud systems written in Java and Python [33, 48, 67, 69]. GET APIs are of the form, “<T> get(Class<T> class, String parameter)”; they take a parameter name and return a value. SET APIs are of the form, “void set(Class<T> class, String parameter, <T> value)”; they reset the original value of the given parameter with the input value. Typically, get and set are declared in wrapper classes such as `java.util.Properties` for Java and `configparser` for Python projects.

```

1  public String get(String name) {
2  +   String ctestParam = name;
3     String[] names = handleDeprecation(
4         deprecationContext.get(), name);
5     String value = null;
6     for(String n : names) {
7  +     ctestParam = n;
8         value = substituteVars(
9             getProps().getProperty(n));
10    }
11  +   LOG.warn("[CTEST][GET-API] " + ctestParam);
12  +   CTestUtils.printStackTrace(ctestParam);
13     return value;
14 }
15 /* conf/Configuration.java */

```

Figure 5: Example Instrumentation for a GET API in HCommon. The `get` method is the lowest level API used by high-level GET APIs, e.g., `getInt` and `getBool`. `handleDeprecation` handles deprecated parameters. SET APIs are instrumented similarly.

general, and reliable, requiring modest instrumentation effort (§5.1). Instrumentation of configuration APIs is performed during ctest generation. Instrumentation is neither performed when running ctests nor added to the production system.

For completeness, we consider a test to *exercise* a parameter if the test uses the parameter’s value as it executes. We do not exclude tests based on potential effectiveness for exposing misconfigurations or bugs. In general, such effectiveness is hard to define or model. Our decision is also justified because GET API invocations alone can expose misconfigurations (e.g., those due to type-casting errors [26]) or bugs (e.g., those caused by failing to trim white space [25]).

4.2.2 Generating Parameter Sets for Ctests

For each test $\hat{t}(P)$ that is parameterized after the steps in §4.1 and §4.2.1, our toolchain automatically generates the ctest $\hat{t}(\hat{P})$ by filtering out configuration parameters in $P - \hat{P}$:

Respecting intended configuration resets. If a test explicitly resets a configuration parameter to a specific value, then the test logic or its oracle depends on the new value. So, the test cannot be applied to other valid values of the configuration parameter. Our tool automatically identifies all configuration parameters whose values are reset in a test t . It does so by parsing the logs generated by instrumented SET APIs (§4.2.1) and excluding parameters that are reset from P . Note that we do not exclude configuration parameters from P that are reset in the system (not test) code. System code can reset configuration values in ways that should not impact ctests, e.g., during dynamic configuration tuning.

Detecting implicit assumptions on configuration values. In practice, not all parameter resets are performed using SET APIs. Some tests *implicitly* assume specific parameter values. Most tests with such implicit assumptions expect default parameter values and do not set them explicitly. If the default value is unchanged, then the tests pass. Although such assump-

tions constitute bad software engineering practice (“brittle assertions” in the literature [28]), we observe many such cases in the existing test code. Therefore, we automatically identify and exclude from \hat{P} the parameters on which tests have implicit assumptions.

Our intuition is that, if a test assumes specific values, then it will fail on different but valid values. That is, if $p \in \hat{P}$, then \hat{t} should pass on all valid values of p . So, a configuration parameter on which a test makes an implicit assumption can be identified by assigning a different valid value to the parameter and observing the outcome of the existing test.

Our implementation validates whether \hat{t} makes implicit assumptions on each $p \in P$ by running \hat{t} with p instantiated with a few valid values. If \hat{t} fails on a valid value, then \hat{t} makes an assumption on the value of p , i.e., $p \notin \hat{P}$. In our experience in generating thousands of ctests (§5), using up to three values for validation is sufficient to identify configuration parameters on which tests make implicit assumptions.

We use heuristics to automatically generate values for validation from the default value of each configuration parameter, based on the parameter types. For numeric types, we halve and double the original value. For Boolean values, we use the negation. For environment-related values (e.g., path, address, and port), we generate a similar but different value (e.g., a different port number). We use the regular expression described in [77] to infer parameter value types.

These heuristics are not sound; they do not guarantee the validity of generated values. However, the heuristics are simple and practical—only 1.6% of the generated values were invalid due to hidden constraints (§5.3). Our heuristics could not generate valid values for about 16% of parameters: enum options, class names, and commands. We manually selected valid values in these cases. Our future work includes integrating advanced inference tools [44, 47, 69] to infer valid values for these parameter types.

The validation yields \hat{P} for each parameterized \hat{t} transformed from t . If $\hat{P} \neq \emptyset$, $\hat{t}(\hat{P})$ is a ctest for all $p \in \hat{P}$.

4.3 Rewriting

In addition to the generated ctests, one can optionally manually rewrite an existing test to create a new ctest or rewrite a generated ctest to check more configuration parameters. We find two common patterns for rewriting, exemplified in Figure 6. First, many configuration resets in test code are used for setting up the test environment, e.g., a test file, address, port, etc. Those resets are not needed in ctests which are run with actual environment variables. Figure 6a shows this rewriting pattern. There, by simply removing the reset, the ctest can check `alluxio.master.rpc.port`’s values. Note that removing hardcoded resets may require changing how the test reads the configuration values, if the test code does not use standard APIs (discussed in §5.4). Second, some assertions in the test code assume the default configuration values (§4.2.2) which can be safely removed or rewritten to the actual values

```

1  @Ctest
2  void testStartStopPrimary() {
3  -   conf.set("alluxio.master.rpc.port",
4  -   TEST_PORT);
5     master = new AlluxioMasterProcess(conf);
6     master.start();
7     ...
8  }
9  /* master/AlluxioMasterProcessTest.java */

```

(a) **Removing hardcoded resets.** After removing the `conf.set()` call, the `alluxio.master.rpc.port` parameter's value comes from system configuration. The rewritten ctest can then test `alluxio.master.rpc.port`.

```

1  @Ctest
2  void testNameNodeXFrameOptionsEnabled() {
3      ...
4      header = conn.getHeaderField(
5      "X-FRAME-OPTIONS");
6      ...
7      assertTrue(header.endsWith(
8  -   HttpServer.XFrameOption.SAMEORIGIN));
9  +   conf.getTrimmed("dfs.xframe.value"));
10 }
11 /* namenode/TestNameNodeHttpServerXFrame.java */

```

(b) **Rewriting hardcoded assertions.** The rewritten ctest asserts on the actual value of the `dfs.xframe.value` parameter not its default value (`SAMEORIGIN`).

Figure 6: Two common patterns of test rewrites (§4.3).

being tested, as shown in Figure 6b. For both patterns, test code is rewritten to read values from the system configuration without changing the test logic.

5 Generating Thousands of Ctests

We share our experience in generating over 7900 ctests by transforming existing tests in five mature and widely-used open-source cloud systems: HCommon (Hadoop runtime and core utilities), HDFS, HBase, ZooKeeper, and Alluxio. We chose these projects for our evaluation (§6) because they are widely studied, their configuration APIs represent the state-of-the-art in modern cloud systems, and they expose many configuration parameters (Table 1). We discuss the feasibility of, and opportunities for, generating ctests in practice.

5.1 Evaluated Systems and their Test Suites

Table 1 shows the characteristics of the cloud systems that we studied: tests, configuration parameters, and how much instrumentation we performed.

Instrumentation effort. Our system-specific instrumentation is modest because each system uses a few classes to implement the configuration APIs. In the worst case, we changed only three classes each in ZooKeeper and Alluxio (“# Class” column in Table 1). It takes more lines of instrumentation for ZooKeeper than the others, because the GET and SET APIs

Software	Test Coverage		# Config. Params	Instrum. LoC # Class	
	Stmt Cov.	Meth Cov.		LoC	# Class
HCommon (2.8.5)	73.1%	74.0%	269	24	1
HDFS (2.8.5)	80.3%	79.6%	296	24	2
HBase (2.2.2)	69.5%	80.1%	205	29	2
ZooKeeper (3.5.6)	75.8%	84.3%	32	130	3
Alluxio (2.1.0)	70.8%	72.6%	515	34	3

Table 1: Characteristics of studied systems (test suites, configuration parameters, and instrumentation efforts). The instrumentation includes both parameterization (§4.1) and logging (§4.2.1).

Software	Module	# Tests		# Config. Param.	
		Total	Using Config.	Total	Used in Tests
HCommon	hadoop-common	3268	1923 (58.8%)	269	232 (86.2%)
HDFS	hadoop-hdfs	3957	3293 (83.2%)	296	284 (95.9%)
HBase	hbase-server	2630	2035 (77.4%)	205	169 (82.4%)
ZooKeeper	zookeeper-server	881	180 (20.4%)	32	32 (100.0%)
Alluxio	core	1648	1117 (67.8%)	515	423 (82.1%)

Table 2: Characteristics of configuration parameters exercised in software tests of the studied systems.

are implemented per configuration parameter;² the other four systems implement generic APIs as exemplified in Figure 5.

Test suites. The studied systems all have a good number of tests, mostly at the unit- and integration-test levels. System-level tests are rare, reflecting a common testing practice in modern systems engineering [60]. Further, all five projects enforce rigorous code commit policies that require every code change to be covered by a test. Code coverage is high (“Test Coverage” in Table 1), with at least 70% statement coverage. Proprietary systems report even higher test coverage [29, 51].

We focus on the core modules of the studied systems (“Module” in Table 2), which are likely to be used in production. In the rest of this paper, we only use the tests in the studied modules, even though tests in the other modules can also be leveraged during ctest generation.

Table 2 shows the percentage of existing tests per module that exercise configuration values (“Using Config.”) and the percentage of configuration parameters exercised by tests (“Used in Tests”). We collected these percentages from instrumented configuration API logs (see §4.2.1). Clearly, many tests exercise configuration values and are candidates that can be transformed into ctests. Furthermore, 82.1%–100.0% of configuration parameters across the studied systems are exercised by existing tests. So, most configuration parameters have a chance of being checked by a generated ctest (§5.2).

5.2 Ctest Generation Results

We apply the automated approach in §4.2 to generate ctests from the existing tests in the evaluated systems. We select all 32 configuration parameters in ZooKeeper. For the other

²We are helping ZooKeeper to improve their APIs (e.g., [81]); using ZooKeeper shows applicability of ctests across configuration APIs.

Software	Existing Tests		Generated Ctests	
	# Param.	Tests →	Ctests	#Param. (Cov.)
HCommon	90	1870 →	1846 (98.7%)	90 (100.0%)
HDFS	90	3191 →	3148 (98.7%)	90 (100.0%)
HBase	90	1909 →	1687 (88.4%)	90 (100.0%)
ZooKeeper	32	180 →	176 (97.8%)	32 (100.0%)
Alluxio	90	1117 →	1117 (100.0%)	90 (100.0%)

Table 3: Ctest generation results. The results include only generated ctests (§4.2). The generated ctests have 100% coverage of the configuration parameters.

systems, we randomly select 90 configuration parameters that are exercised by the tests (“Used in Tests” in Table 2). Note that we sampled 90 parameters mainly to bound our manual inspection effort for analyzing effectiveness and false negatives (Tables 8 and 9). The generation process is mostly automated after API instrumentation.

Table 3 shows ctest generation results. Overall, 88.4%–100% of existing tests that exercise the selected configuration parameters were successfully transformed into ctests. Furthermore, the generated ctests cover 100% of the selected parameters, i.e., each parameter is checked by at least one ctest. The small percentage of tests that could not be transformed as ctests were hardcoded to specific values of *all* the parameters that they exercise—a ctest is generated as long as it can check at least one configuration parameter. Section 6 discusses the effectiveness of the generated ctests for detecting failure-inducing configurations in different settings.

5.3 Detecting Bugs and Hidden Constraints

Some *valid* configuration values caused ctests (§4.2.2) to unexpectedly throw runtime exceptions instead of the failed assertions that are typical manifestations of hardcoded tests. We analyze these exceptions and find, surprisingly, that most are caused by (1) previously unknown bugs in the code exposed by configuration changes, or (2) hidden constraints which made seemingly valid configuration values erroneous. We include these ctests which are effective in capturing bugs and misconfigurations in our evaluation.

Dormant bugs exposed by configuration changes. We find 14 previously unknown bugs in the latest versions of the five evaluated systems. 12 of those bugs are confirmed and 10 were fixed by the developers after we reported them; 9 bugs are considered “Major” or “Critical”. Real users encountered a bug after we reported it [24]. 12 of the 14 bugs existed for more than five years in these projects that routinely run static analyses and perform testing. Figure 7 shows one of these bugs, in which changing the value of the parameter to a valid option `TopAuditLogger` will crash the NameNode of HDFS because a default constructor is required but not implemented.

Hidden configuration constraints. We also discovered 11 hidden constraints that cause the generated values to result in errors. We say these constraints are “hidden” because they

Configuration Change

```
- dfs.namenode.audit.loggers = DefaultAuditLogger
+ dfs.namenode.audit.loggers = TopAuditLogger
```

```
@Ctest /* Generated from namenode/TestFSNamesystem.java */
public void testStartupSafemode() {
    ...
    fsn = new FSNamesystem(conf, fsImage);
    ...
}

FSNamesystem(Configuration conf, FSImage fsImage) {...
    className = conf.get("dfs.namenode.audit.loggers");
    logger = Class.forName(className).newInstance();
    ...
} /* namenode/FSNamesystem.java */
```

NoSuchMethodException
BUG: TopAuditLogger has no default constructor

Figure 7: A new bug that was exposed by a valid configuration change and was captured by a ctest [23]. The bug crashes HDFS NameNode due to missing a default constructor. The bug has been fixed after we reported it.

Hidden Constraints

`hbase.http.max.threads`’s value has to be larger than the number of threads *needed* by an external library (which is machine-dependent).

Configuration Change

```
- hbase.http.max.threads = 10
+ hbase.http.max.threads = 5
```

```
@Ctest /* Generated from hbase/TestInfoServer.java */
public void testGetMasterInfoPort() {...}

protected void doStart() {
    if (needed > max)
        throw new IllegalStateException(String.format(
            "Insufficient threads..."));
} /* jetty-server-9.3.27.v20190418.jar */
```

HBase used 5 threads but 6 is needed by jetty.

Figure 8: A hidden constraint exposed by a ctest. The configuration of HBase is constrained by an external library (Jetty).

were not documented and are not intuitive to discover. Figure 8 is an example of a hidden constraint—the configuration parameter of HBase is constrained by an external library, Jetty. Any configuration value that is smaller than the needed variable’s value in Jetty will cause a runtime exception.

5.4 Rewriting Ctests

We further study the intended configuration resets in test code (§4.2.2) to understand the opportunities and challenges of rewriting tests. We focus on environment-related configuration parameters—as discussed in §4.3, tests often reset configuration values to set up test environments, which are not needed by ctests. For this study, we selected 44 configuration parameters with hardcoded environment settings, including all four from ZooKeeper and 10 from the other four systems. There are altogether 263 tests that reset at least one of the 44 parameters; 233 of these tests were transformed to generate ctests but those ctests cannot check the reset parameters. The 233 generated ctests cover all 44 parameters (Table 3).

We manually applied the two test rewriting rules described in Figure 6 to these 263 tests. Removing hardcoded resets alone (Figure 6a) can enhance 86 tests for ctests to cover 8 parameters. Further, by removing or rewriting hardcoded assertions (Figure 6b), we can enhance 16 more tests. In total, the two test rewriting rules can cover 102 (38.8%) tests for 18 out of 44 parameters. The remaining tests either cannot benefit from rewriting, or require significant changes beyond the two simple patterns in Figure 6.

The test rewriting effort was small in HCommon, HDFS, HBase, and Alluxio for which we rewrote 33 tests for 16 parameters using a total of 90 changed lines. Rewriting a test in these four systems takes only two or three lines of test code (Figure 6). The rewriting effort was much larger in ZooKeeper, mainly because ZooKeeper does not utilize similar configuration APIs (§5.1) as other systems—the test code does not use SET APIs to reset the parameter value as in Figure 6a. So, we wrote a new API to load actual configuration values into the tests; our implementation has 14 lines of code. With our new API, we were able to rewrite 69 tests for two parameters, which takes a total of 103 changed lines.

6 Evaluation of Ctest Effectiveness

We used three experimental settings to extensively evaluate ctests’ effectiveness for testing configurations in context:

1. real-world configuration-induced failures documented in issue tracking databases;
2. diverse injected misconfigurations for configuration parameters that have different value types and semantics;
3. non-default configuration files collected from Docker images hosted at DockerHub [14].

6.1 Evaluating Ctests on Real-world Failures

We evaluate the effectiveness of ctests for detecting failure-inducing configurations that caused real-world failures. Our goal is to see how many of these failures ctests could have been detected earlier.

Configuration-induced failures used. We reproduced 64 real-world configuration-induced failures from the issue-tracking database of the five systems (Table 4). Each failure was reported by real system users and was caused by a configuration change (i.e., a value different from the default was used). These 64 failures have diverse root causes, including 51 misconfigurations and 13 software bugs exposed by *valid* configuration changes.³ We collected failures from issue-tracking systems instead of user forums or mailing lists because: (1) failures recorded in issue-tracking databases tend to have had large impact, and (2) issue-tracking databases rigorously record the version of the systems on which the

³For seven failures, misconfigurations triggered bugs in the code. We categorize them as “misconfigurations” in Table 4.

Software	Misconfigs	Bugs (Valid Configs)	Total
HCommon	11 (84.6%)	2 (15.4%)	13
HDFS	21 (95.5%)	1 (4.5%)	22
HBase	8 (61.5%)	5 (38.5%)	13
ZooKeeper	8 (66.7%)	4 (33.3%)	12
Alluxio	3 (75.0%)	1 (25.0%)	4
Total	51 (76.9%)	13 (20.3%)	64

Table 4: Statistics on real-world configuration-induced failures from issue-tracking databases used in ctest evaluation.

Root Cause	# Failures	# (%) Detected by Ctests	
		Gen Only	Gen + Rewrite
Misconfigurations	51	41 (80.4%)	51 (100.0%)
└ Corrupt config files	3	3 (100.0%)	3 (100.0%)
└ Value type errors	3	3 (100.0%)	3 (100.0%)
└ Out-of-range values	12	11 (91.7%)	12 (100.0%)
└ Value semantic errors	22	16 (72.7%)	22 (100.0%)
└ Dependency violations	10	7 (70.0%)	10 (100.0%)
└ Resource violations	1	1 (100.0%)	1 (100.0%)
Bugs exposed by valid config	13	10 (76.9%)	11 (84.6%)
Total	64	51 (79.7%)	62 (96.9%)

Table 5: Ctest effectiveness in detecting real-world configuration-induced failures of various root-cause types. Most types are self-explanatory; value semantic errors refer to misconfigurations that violate the semantics of the configuration parameter, including invalid file paths, URI, IP addresses, permission masks, etc.

failures were reported, which is critical for reproducing failures. Importantly, we only generate ctests from the tests in the reported version, *not* from tests in later versions.

Ctests evaluated. For each failure, we identify each configuration parameter p_i and its value v_i in the failure-inducing configuration change (13 of 64 failures involve more than one configuration parameter). We then generate ctests using the method in §4 for p_i . Further, we apply the two rewriting rules in §5.4 to enhance 11 generated ctests.

6.1.1 Effectiveness

Table 5 shows the effectiveness of ctests in detecting the 64 real-world failures and the root causes of those failures.

The results are promising. 96.9% (62/64) of the failure-inducing configurations are detected by ctests. *All* failures due to misconfigurations are detected. Specifically, 79.7% (51/64) of all failures are detected by using only generated ctests; the other 17.2% (11/64) require rewriting of ctests (§5.4). In 9 of the 11 failures that require rewriting, we only remove unnecessary value resets (like in Figure 6a). In the other two, we also change an assertion (like in Figure 6b). The results show that existing tests contain effective test logic and oracles needed to expose failure-inducing configuration changes. By leveraging those test logic/oracles, ctests can effectively detect failure-inducing configuration changes and prevent them from being deployed to production.

Failure Mode	Count (Pct)
Unexpected runtime exceptions	31 (50.0%)
Exceptions thrown by configuration-checking code	27 (43.5%)
Failing assertions in ctest code	3 (4.8%)
Test timeout (the system hangs)	1 (1.6%)

Table 6: Failure modes of ctests when detecting the failures.

By checking the behavior of code that exercise configuration parameters, ctests have generic ability to detect diverse types of misconfigurations, as well as bugs exposed by valid configuration changes (Table 5). That is, ctests are not designed to detect specific types of misconfigurations or bugs. We exemplified failures detected by ctests in Figures 1 and 2. Table 6 shows the failure modes of ctests on the 62 detected configuration-induced failures. Most failures manifested as unexpected runtime exceptions (division by zero, array index out of bound exceptions, etc.) or exceptions thrown by configuration-checking code. We show examples in Figures 2 and 7. Both types of exceptions would have the same impact on production systems if the failure-inducing changes were deployed. In three failures, test assertions fail because of unexpected behavior. The last failure was a test timeout that occurred because the configuration change caused the system to hang (similar to Figure 9a).

Two of the 64 failures were not detected by ctests [2, 80]. In ALLUXIO-9810 [2], the root cause is a buggy shell script that no test invoked. The root cause of ZOOKEEPER-2299 [80] is a bug in a method that no test in the reported ZooKeeper version exercised. Both bugs can be detected by extending the test suite. In fact, for ZOOKEEPER-2299, the latest ZooKeeper version includes a test from which we have now generated a ctest that detects this bug.

6.1.2 Comparison with State-of-the-Art Techniques

Table 7 compares ctests with two state-of-the-art configuration checking techniques, PCheck [67] and Spellcheck [48]. Both PCheck and Spellcheck are designed for cloud systems and do not require additional training data or rule sets.

None of the 13 failures induced by *valid* configuration changes triggering bugs in code can be detected by existing configuration validation or automatic misconfiguration detection techniques, because those techniques only check whether configuration values are valid.

Ctests detected *all* misconfigurations among the real-world failures, including many that are challenging for state-of-the-art checking and detection techniques to detect. Spellcheck only detects value-type errors. In our real-world configuration-induced failure dataset (Table 5), only three failures were caused by value-type errors.

The following misconfigurations detected by ctests cannot be detected by PCheck: (1) two misconfigurations leading to non-crashing behavior (e.g., Figure 1), (2) five misconfigurations involving operations that have side effects (e.g.,

	# Failures	Spellcheck	PCheck	Ctest	
				Gen Only	Gen+Rewrite
Misconfigs	51	3	41	41	51
Bugs	13	0	0	10	11
Total	64	3	41	51	62

Table 7: A comparison of Ctests, PCheck, and Spellcheck in detecting misconfigurations and bugs exposed by valid configuration changes (Table 5). We assume sound PCheck and Spellcheck static analyses—these are upper bounds for PCheck and Spellcheck.

writing files), and (3) three misconfigurations that require client-side interactions to expose. Note that PCheck performs *post-deployment* configuration validation; PCheck does not run tests but instruments deployed systems. Ctests detect misconfigurations early, during *pre-deployment* testing. PCheck has two limitations that ctests do not have: (1) PCheck cannot have side effects in the production environment, and (2) PCheck cannot deal with external dependencies and events (e.g., client operations) [67]. Moreover, unlike PCheck, ctests can find bugs resulting from valid configuration changes.

6.2 Evaluating Ctests on Diverse Misconfigurations

We ran ctests on injected misconfigurations to (1) systematically evaluate ctests’ effectiveness on many diverse configuration parameters with different value types and semantics, and (2) experimentally evaluate ctests on misconfigurations that were not in the failures from issue-tracking databases.

Injected misconfigurations. We generate up to three erroneous values for each of the 392 configuration parameters in §5. We use the misconfiguration generation rules proposed for misconfiguration injection testing [31, 32, 69]. But we exclude rules such as case alternation and random fuzzing, which lead to many false errors. Note that the misconfiguration generation rules are different from the heuristics for generating *valid* values in §4.2.2. Specifically, we generate misconfigurations based on the types and semantics of each configuration parameter. For Boolean or enum types, we generate invalid options. For numeric types, we generate values containing alphabetic characters, and out-of-range values (smaller/larger than the min/max value). For parameters without explicit data ranges specified in the configuration file, we use the range of their data type, e.g., INT_MAX as the maximum value of integers. For strings, erroneous values are generated based on the semantics of the parameter. We follow the fine-grained rules defined in [32, 69]. For example, for file-path parameters, we generate non-existent files, incorrect file content, and incorrect file types. We reviewed each generated erroneous value to reduce false errors.

Ctests evaluated. We use the generated ctests from §5. For each erroneous value e generated for p , we create a configuration diff $D_e = \{(p \mapsto e)\}$ that sets p ’s value to e . We run all

Software	Complete	Partial	None	N/A
HCommon	43 (48.3%)	22 (24.7%)	24 (27.0%)	1
HDFS	67 (77.9%)	12 (14.0%)	7 (8.1%)	4
HBase	52 (61.9%)	23 (27.4%)	9 (10.7%)	6
ZooKeeper	20 (90.9%)	2 (9.1%)	0 (0.0%)	10
Alluxio	43 (47.8%)	15 (16.7%)	32 (35.6%)	0

Table 8: Ctest effectiveness in detecting injected misconfigurations per parameter. “Complete”, “Partial”, and “None” refer to number of parameters with all, some (but not all), and none of the injected misconfigurations detected, respectively. “N/A” refers to the number of parameters in which all the generated misconfigurations turned out to be valid due to the imprecision of error generation.

Misconfiguration
hadoop.security.random.device.file.path = INVALID_RANDEV

```
@Ctest /* Generated from TestOsSecureRandom.java */
public void testRandomBytes() {
    ...
    OsSecureRandom rand = new OsSecureRandom(conf);
    // checkRandomBytes will timeout if secure random
    // implementation always returns a constant value
    checkRandomBytes(rand, ...);
}
```

The random device is used by the object to get random bytes.

 RuntimeException (not readable file)
 TimeoutException (not rand device)

(a) **Invalid file content.** The ctest detects the misconfigurations by testing the functionality of the random device.

Misconfiguration
hbase.regionserver.hlog.reader.impl = ProtobufLogReader
hbase.regionserver.hlog.writer.impl = SecureProtobufLogWriter

```
@Ctest /* Generated from wal/AbstractTestProtobufLog.java */
public void testWALTrailer() {
    ...
    // Appends entries in the WAL and reads it.
    doRead(...);
}
```

 IOException (the log written by the hlog writer cannot be read by the hlog reader on the region server)

The misconfiguration is latent (causing runtime exception) and undocumented.

(b) **Non-interoperability (undocumented [22]).** The ctest detects the misconfigurations by testing the reader and writer together.

Figure 9: Non-trivial misconfigurations detected by ctests.

the ctests for p on each D_e and check whether any ctest fails on e . Unlike in §6.1, we do not rewrite ctests in this evaluation due to the larger size of experiments. So, our effectiveness results are a lower bound.

6.2.1 Effectiveness on Injected Misconfigurations

Table 8 shows the effectiveness of ctests in detecting the injected misconfigurations. Ctests detect *all* injected errors for 47.8%–90.9% of parameters and *at least one* injected error for 64.4%–100% of the parameters across the five systems.

Figure 9 shows two non-trivial misconfigurations detected by ctests. In Figure 9a, a ctest detects an invalid random device file path in HCommon by using the referred device to generate random bytes. Very few existing misconfiguration detection tools check file content; they mostly just check file paths and metadata. In Figure 9b, most reader and writer

Software	No Observable Symptom		Test Inadequacy	
	Correction	Mask	No Exposure	No Oracle
HCommon	14 (14.0%)	10 (10.0%)	56 (56.0%)	20 (20.0%)
HDFS	4 (11.8%)	8 (23.5%)	9 (26.5%)	13 (38.2%)
HBase	25 (46.3%)	8 (14.8%)	19 (35.2%)	2 (3.7%)
ZooKeeper	2 (100.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)
Alluxio	3 (2.7%)	0 (0.0%)	100 (90.9%)	7 (6.4%)
Total	48 (16.0%)	26 (8.7%)	184 (61.3%)	42 (14.0%)

Table 9: Root causes of false negatives among the injected misconfiguration values.

```
1 if (snapRetainCount < 3) {
2     LOG.warn(
3         "Invalid autopurge.snapRetainCount: "
4         + snapRetainCount + ". Defaulting to 3");
5     snapRetainCount = 3;
6 }
7 /* quorum/QuorumPeerConfig.java */
```

(a) An example of error correcting code in ZooKeeper

```
1 try { ...
2     paths = conf.get("dfs.datanode.shared.file.
3         descriptor.paths")
4     fdFac = FileDescFactory.create(..., paths);
5 } catch (IOException e) {
6     LOG.debug(
7         "Disabling ShortCircuitRegistry", e);
8 }
9 /* datanode/ShortCircuitRegistry.java */
```

(b) An example of partial-failure masking in HDFS

Figure 10: Two patterns that lead to false negatives during misconfiguration injection.

implementations of HBase are interoperable, but a few are not. Ctests checked the interoperability of a specific (reader, writer) pair and detected this non-trivial misconfiguration. The non-interoperability was neither documented nor checked in the system code before we reported it [22]. Using the non-interoperability configurations will fail HBase region servers.

The generated ctests failed to detect 28.4% (300 of 1055) injected misconfigurations, i.e., false negatives. The results are consistent with the evaluation of misconfigurations without rewriting in §6.1. Recall that we do not rewrite tests in this evaluation, which could improve ctest adequacy (§6.1).

We inspected the 300 false negatives. Table 9 shows root causes of false negatives and their distribution. 75.3% of false negatives are due to inadequacy of ctests that either does not expose the effects of the misconfigurations or does not have oracles to check the effects. Many of these effects are non-functional (e.g., performance issues). Moreover, unlike real-world failures (§6.1), many injected misconfigurations are expected to be uncommon in practice. So, the systems have no error-checking logic or test code. For example, in HDFS, negative io.seqfile.compress.blocksize values cause se-

Figure 11: Time-budget analysis results. The results show the effectiveness of detecting misconfigurations if only ctests that finish under each time budget are run. The *inf* budget is equivalent to times from Table 8 where “Complete” and “Partial” are defined. We use the shaded budgets for experiments in §6.3.

vere performance degradation: every append triggers data compression. However, HDFS does not check against negative values nor have a test with performance-based oracles.

The remaining 24.7% of false negatives have no observable effects because of the presence of error-correcting code (e.g., Figure 10a), or because the consequences were masked (e.g., Figure 10b) by the system. Ctests cannot detect misconfigurations that have no observable effects.

6.2.2 Time-Budget Analysis

The per-parameter evaluation enables us to analyze the tradeoff between effectiveness and running time of ctests. To analyze this tradeoff, we performed a time-budget analysis. Our time-budget analysis excludes ctests that do not finish under a specified time budget and measures the effectiveness of the remaining ctests for detecting misconfigurations. We have not yet designed a test prioritization [45, 72] scheme for ctests (§7), so we use per-test budgets (the amount of time *each* ctest is allowed to run) rather than a total-test-time budget (the amount of time *all* ctests are allowed to run). Per-test time budgets are well suited to test-suite parallelization, where each test is run in a separate process. Ctests for time-budget analysis run on an 8-core Intel i7-9700 CPU with 32 GB memory and Ubuntu 18.04.

Figure 11 shows the results of time-budget analysis. We observe that different budget ranges are needed for different systems given their different test characteristics. For example, ZooKeeper does not have many unit tests but relies mostly on integration tests. So, ZooKeeper needs larger per-test time budgets than other systems. Further, all ctests in HCommon finish under two seconds, so there is no decline in effectiveness across the time budgets shown. The key result from Figure 11 is that smaller per-test budgets can still achieve similar levels of effectiveness as running all the ctests for all projects except for Zookeeper. We use the shaded budgets in Figure 11 for evaluating ctests on real-world configuration files in §6.3.2 because they achieve good time-effectiveness

Software	# Files Tested	# Files that Fail Ctests		# False Alarms
		Version/Env.	Misconfig.	
HCommon	20	16	4	0
HDFS	20	15	2	0
HBase	20	12	0	0
ZooKeeper	20	14	0	0
Alluxio	12	3	1	0

Table 10: Results of running ctests on real-world configuration files collected from Docker images.

tradeoff. We use a minimal per-test budget of 4 seconds to leave room for performance variability.

6.3 Evaluating Ctests on Configuration Files

We evaluate the effectiveness of ctests using configuration files collected from public Docker images. The experiments also enable us to measure the false positives and overhead of ctests on real-world configuration files (these are hard to systematically evaluate in §6.1 and §6.2).

Evaluated configuration files. We extract 92 configuration files from Docker images hosted on DockerHub [14] using the method described in [68]. We randomly sample 20 Docker images from the most popular 300 image repositories on DockerHub for the five systems. We only find 12 Alluxio image repositories that use non-default configuration files on DockerHub. We use the most recent image in each repository. The average number of configuration parameters in these files is 5.8 (the minimum is one and the maximum is 29).

Ctests evaluated. We generate ctests using the method in §4. For each configuration file f , we create a diff $D_f = \{(p \mapsto v_f)\}$ for all v_f explicitly set in f and run all the ctests that cover at least one parameter in D_f (see §3.2). We use the selected per-test budget from §6.2.2 to run ctests on each configuration file. We run ctests against the configuration files on our server, rather than deploying the ctest infrastructure in each image’s container to reduce the cost of resolving dependencies and setting up environments (many images are built from old OS distributions with incompatible dependencies).

6.3.1 Ctests Effectiveness on Configuration Files

Table 10 presents the effectiveness of ctests on real-world configuration files. Surprisingly, many configuration files did not pass the ctests. We inspected all failed ctests and found 85 of 537 values to be erroneous. 76 of 85 erroneous values are correct in the container, but fail ctests because (1) certain files, IP addresses and ports in the containers do not exist or are not available on our server, and (2) the ctests are generated from tests from a newer version of the system—the configuration values in the images are no longer correct. We reported one such case, ALLUXIO-3402 [1], where the configuration parameter `alluxio.user.file.metadata.load.type` has the value “Always” in an image, `scality/alluxio`. But, in the latest Alluxio, an all-capitalized parameter value is required.

Software	Ctests with Budget		# All Ctests		
	# Ctests	Runtime	# Ctests	Runtime	Baseline
HCommon	1014.20	1.90	1019.55	3.42	3.84
HDFS	1850.75	37.48	2310.20	126.35	120.43
HBase	842.75	47.70	1053.65	99.47	140.86
ZooKeeper	39.55	6.79	76.95	26.29	19.98
Alluxio	796.5	1.66	796.5	1.66	1.44

Table 11: The number of ctests and their running time (in minutes) per configuration file using all ctests and ctests within time budget (selected in §6.2.2). The numbers are averaged over all evaluated files. “Baseline” is the time for running the corresponding original tests (not ctests).

So a ctest generated for the latest Alluxio fails. These results show that ctests effectively detect misconfigurations caused by version and environment changes [76].

Ctests also detect 9 misconfigurations of various types in seven configuration files (Table 10), including malformed files, value-type errors, and dependency violations, which are misconfigurations in the native container. Based on our inspection on the seven Docker images, we suspect that some of these configuration files may be managed by custom scripts that overwrite those files. Unfortunately, we find no documentation for five of the seven Docker images on DockerHub.

Zero false positives found. We expected a few false positives due to tests that assume some values but were not identified when generating parameter sets for ctests—the heuristics for generating valid values for validation are unsound (§4.2.2). However, we found no false positives (Table 10).

6.3.2 Ctest Running Time on Configuration Files

We measure the ctest-running time per configuration file. Table 11 shows the average total ctest-running time per configuration file when running ctests that finish within the per-test time budgets selected in §6.2.2. HCommon, ZooKeeper and Alluxio take less than ten minutes. HDFS and HBase have longer-running tests and take few tens of minutes.

We run all ctests with the `inf` budget and compare it with running the ctests under the time budget. There is no difference in the effectiveness of ctests, showing that the budgets are sufficient. We also compare total running time of all ctests with a baseline total time for running all the original software tests from which the ctests are generated. The results show that the running times of the ctests are similar to those of the original software tests (“Baseline” in Table 11). The running time for HBase is about 70% of its baseline because many tests in HBase aborted the execution and failed quickly due to the exceptions triggered by misconfigurations.

7 Discussion and Limitations

There is no silver bullet against configuration-induced failures. Ctests offer a simple, effective way to detect failure-inducing configurations, and are complementary to existing techniques.

The effectiveness of generated ctests depends on the adequacy of the original tests. On the evaluated systems, which have abundant tests, ctests outperform state-of-the-art tools. However, ctests cannot be generated if there are no existing tests, which is why no ctest exposed the two bugs in the evaluation (§6.1.1). Mature software systems will likely benefit from ctests because they have comprehensive test suites [29, 51]. For newer projects or projects with less comprehensive test suites, the generation of ctests could be limited. Note that the concept of ctests is not limited by the generation method discussed in §4. Ctests can be implemented by developers, just like they implement regular software tests.

Ctests cannot localize the root causes of configuration-induced failures. Based on our analysis of ctest results (§6.2 and §6.3), root cause localization can usually be done efficiently by analyzing the stack traces. However, a few failures take considerable time to understand, due to (1) complexity of configuration value propagation and transformation, or (2) unexpected, hidden configuration constraints (e.g., Figure 8). Fault localization [64] for configuration-induced failures can be developed to automate root cause analysis.

Ctests can increase the cost of regression testing, which is already expensive. Section 6.3.2 shows that running ctests for the evaluated systems takes reasonable time. On the other hand, we believe that the cost of running ctests can be significantly reduced by developing ctest reduction, prioritization and minimization techniques, as was done for regression testing [72]. One direction is to analyze ctest code and to understand how each ctest exercises configuration changes, towards reducing and prioritizing ctests. Ctests running time can also be further reduced by running ctests in parallel.

The ctest generation described in §4 is neither sound nor complete. First, the heuristics for detecting implicit test assumptions (§4.2.2) are unsound and could lead to false negatives in detecting bugs. Our heuristics minimize false positives. Second, dynamically tracing test executions to identify parameters exercised in tests (§4.2.1) is incomplete, because configuration changes could lead to different execution paths. Like any other form of testing, we do not claim completeness.

Like any other pre-deployment testing, ctests are fundamentally limited by a possible mismatch between the test environment and the production environment. Such a mismatch could lead to both false positives and false negatives.

8 Related Work

The severity and prevalence of configuration-induced failures [18, 19, 34, 35, 40, 42, 55, 74] has resulted in novel techniques for misconfiguration troubleshooting and debugging [3, 4, 46, 61–63, 73]. Advanced techniques have also been developed for diagnosing production failures [10, 13, 30, 79]. Ctests proactively detect failure-inducing configuration changes to *prevent* production failures in the first place.

Ctests is complementary to our prior work, PCheck [67]. We compared ctests with PCheck [67] in §6.1.2, despite

PCheck being a *post-deployment* technique. Note that PCheck can only detect misconfigurations, because it considers only statements on the data-flow path of each configuration value. Differently, ctests can detect valid configuration changes that expose bugs in the code, a common type of failure-inducing configuration changes [55]. Techniques designed for pre- and post-deployment have fundamentally different opportunities and challenges. In our experience, it is difficult (if not impossible) for auto-generated checking code to deal with many sophisticated real-world misconfigurations. This was the main motivation behind ctests which can exercise code and configurations together. But post-deployment techniques such as PCheck do not have problems caused by the mismatches between the test and the production environments.

We mentioned in §3.2 that ctests are complementary to configuration validation and misconfiguration detection [6, 27, 38, 43, 44, 49, 50, 55, 59, 61, 62, 66, 67, 75, 77], similar to how software testing complements static bug detection tools. Ctests can detect failure-inducing configuration changes that are challenging for existing techniques to detect, e.g., valid configuration changes that expose bugs. Most automated detection techniques only focus on specific types of misconfigurations. For example, Rex [38] detects dependency violations between source-code files and configuration files which should be updated together. Ctests are not specific to any type of misconfigurations or software bugs—they detect failure-inducing configuration changes based on the resulting program behavior. A common class of existing validation/detection techniques requires validation rules or training data that either do not exist (e.g., for systems that we evaluate) or are not available (we found no rule sets or training data online). In contrast, ctests do not rely on external rule sets or training data—they leverage existing abundant test cases.

Ctests complement software and system testing. In essence, ctests enhance existing testing techniques to focus on the actual configurations in production or configurations to be deployed, given that testing all possible configurations is infeasible. A ctest is a parameterized test. But ctests differ from traditional parameterized unit tests (PUTs) [57, 58] in goal, parameter source, and generation method. The goal of PUTs is to allow developers rerun the same test against different inputs, to cover more program paths. The goal of ctests is to connect production system configurations to software tests, to find failure-inducing configuration changes. The inputs to PUTs are either specified by developers or automatically generated by symbolic execution, but the inputs to ctests are read from the system configuration files or diffs.

9 Conclusion

This paper proposes ctests to connect software testing with production system configurations to enable detecting failure-inducing configurations during testing. We present how to generate ctests from existing software tests that are abundant in mature cloud systems. We show that ctests are ef-

fective in detecting real-world failure-inducing configurations, including both misconfigurations and dormant software bugs exposed by valid configuration changes. Our goal of ctests is to make testing of configuration changes a key component of configuration management and fill the missing piece in the practice of treating configuration as code. We have made all the code and datasets available at: <https://github.com/xlab-uiuc/opencctest>.

Abstract

Cloud providers rent the resources they do not allocate as evictable virtual machines (VMs), like spot instances. In this paper, we first characterize the unallocated resources in Microsoft Azure, and show that they are plenty but may vary widely over time and across servers. Based on the characterization, we propose a new class of VM, called Harvest VM, to harvest and monetize the unallocated resources. A Harvest VM is more flexible and efficient than a spot instance, because it grows and shrinks according to the amount of unallocated resources at its underlying server; it is only evicted/killed when the provider needs its minimum set of resources. Next, we create models that predict the availability of the unallocated resources for Harvest VM deployments. Based on these predictions, we provide Service Level Objectives (SLOs) for the survival rate (*e.g.*, 65% of the Harvest VMs will survive more than a week) and the average number of cores that can be harvested. Our short-term predictions have an average error under 2% and less than 6% for longer terms. We also extend a popular cluster scheduling framework to leverage the harvested resources. Using our SLOs and framework, we can offset the rare evictions with extra harvested cores and achieve the same computational power as regular-priority VMs, but at 91% lower cost. Finally, we outline lessons and results from running Harvest VMs and our framework in production.

1 Introduction

Motivation. Cloud providers usually rent their resources to customers as Infrastructure as a Service (IaaS) VMs. When deployed, each VM consumes a fixed amount of resources from the server where it lands. Customers can keep their VMs for seconds or years [16] and may request more VMs over time. Thus, providers need to provide the illusion of perfectly elastic resources (*e.g.*, by reserving demand growth buffers) while operating the infrastructure with high availability (*e.g.*, by transparently handling hardware failures). For these reasons, they need to leave unallocated capacity.

* Ambati is affiliated with the Univ. of Massachusetts Amherst, but was at Microsoft Research during this work. Gun and Wang are now with Google.

To monetize this unallocated capacity, providers offer VMs with relaxed SLOs at discounted prices. Specifically, they offer low-priority evictable VMs, often called spot VMs [1, 8, 14]. These VMs are evicted if their resources are needed by regular-priority (or simply regular) on-demand VMs. Thus, evictable VMs are ideal for customers to run batch jobs or other workloads that can tolerate evictions, at very low cost.

Unfortunately, an evictable VM cannot consume all the unallocated resources of a server unless it fits perfectly in it. Even if it does, a large evictable VM will be promptly evicted whenever even a single resource is needed by a newly arriving regular VM. Multiple small evictable VMs can allocate the same amount of resources but will add overhead to operate more VMs. In addition, their larger number of evictions introduce VM re-creation and application re-initialization overheads that may even cause unavailability.

Given these limitations of existing evictable VMs, we argue that there should be a new class of evictable VMs able to *dynamically* and *flexibly* harvest all the unallocated resources of any server on which they land.

Our work. We first characterize the unallocated resources in Microsoft Azure. The characterization shows that there is potential for harvesting these resources, but they fluctuate over time and their availability is heterogeneous across servers and clusters. The characterization unearths the dynamics of the unallocated resources over multiple time durations.

Next, we propose a new class of evictable VM, called Harvest VM, as a novel way to monetize unallocated resources. A Harvest VM has a minimum size in terms of its physical resources, but it dynamically receives more or fewer physical resources beyond this minimum, depending on the amount of unallocated resources at its underlying server. A Harvest VM is only evicted if its minimum size is needed for a regular VM. In this paper, we focus on harvesting CPU cores.

Provisioning applications to run on harvested resources is challenging. However, we can predict the availability and amount of the unallocated resources in the datacenter. We use these predictions to provide SLOs for Harvest VM deployments. The SLO specifies the probability for a Harvest VM to survive for a certain period and how many resources it will get on average. For example, if a customer wants to create 100 VMs, the SLO may indicate that 90% of them

will survive for more than 1 day, with an average of 10 cores. The provider does not monitor or actively seek to meet each individual SLO; instead, we retrain our prediction models frequently and provide our SLO as a statistical estimate [12]. As such, our SLOs can be considered predictions or estimates over large numbers of Harvest VMs, rather than guarantees.

Renting unallocated resources is cheap, but requires applications to manage the evictions. In addition, with Harvest VMs, the amount of resources backing each VM can vary. Harvest VMs are most useful when the applications they run can adapt to the number of available resources. For example, many applications use thread pools and can naturally adapt their parallelism. Others can schedule more load on larger VMs. The provider can hide these complexities by using Harvest VMs to create cheap SaaS (Software-as-a-Service), PaaS (Platform-as-a-Service), and FaaS (Function-as-a-Service) offerings. In fact, Harvest VMs are ideal for cluster scheduling (e.g., Apache YARN [37], Kubernetes [22]) and serverless (e.g., AWS Lambda [32], Azure Functions [4]) frameworks. These frameworks can schedule more tasks/functions on a Harvest VM that has grown to use more physical cores, and stop scheduling tasks/functions on one that has lost physical cores. To demonstrate how to adapt these frameworks, we build Harvest Hadoop to schedule computation (e.g., data-processing, machine learning training) on harvested resources.

Our evaluation shows that we accurately predict the unallocated resources and provide SLOs. We predict the survival rate of a VM for 1 hour with an average error under 2% and lower than 6% for longer terms. We also predict the additional cores that can be harvested within a fraction of a core on average. Our SLOs and framework allow us to run Hadoop workloads on Harvest VMs at 91% lower cost to the customer than regular VMs, by offsetting the rare evictions with additional harvested cores. Compared to standard evictable VMs, the cost savings can reach 47%. Finally, we discuss lessons and results from deploying Harvest VMs and Harvest Hadoop in production to run internal workloads in Azure.

Summary. Our contributions are:

- We characterize the unallocated resources of a large cloud.
- We propose Harvest VMs to harvest unallocated resources.
- We build predictors for the availability of unallocated resources and provide a new SLO for these resources.
- We build Harvest Hadoop, a cluster scheduling framework to leverage Harvest VMs.
- We discuss lessons and results from our production deployment of Harvest VMs and Harvest Hadoop.

2 Background and related work

Deploying VMs. Each VM deployment targets a geographical region, which is partitioned into clusters of servers that have the same hardware. Each region may have a different number of clusters and hardware mix. A region-level scheduler decides which VMs go to which clusters based on several

factors (e.g., hardware required, maintenance tasks, available capacity) [19]. These factors can cause clusters to have different VM loads, even in the same region. Then, a cluster-level scheduler decides which server in the cluster will run each VM. When a VM is assigned to a server, a server-level agent creates the VM and manages its lifecycle.

Evictable VMs. Providers sell their excess capacity at discounted prices as evictable VMs [1, 8, 14]. These VMs are evicted/killed when the provider needs the capacity (e.g., due to a spike in the number of on-demand VMs). Providers notify the VMs before they evict them: GCP and Azure provide a 30-second warning, whereas AWS gives 2 minutes.

Variable-resource VMs. Sharma *et al.* [33] recently proposed Deflatable VMs, which change *virtual* resources dynamically (via hot-plugging/unplugging), and a multi-level resource reclamation approach for explicitly adapting applications, operating systems, and hypervisors to the available resources. They also combined reclamation with deflation-aware VM scheduling. We believe that expecting the whole stack to adapt is unrealistic in practice. Instead, we favor simplicity and maintainability for *production deployment*: (1) we minimize the changes to the cloud platform, so deploying Harvest VMs is no different than deploying any other VM, and the VM scheduler is unaware that Harvest VMs grow and shrink; (2) we do not change the number of virtual cores, and instead transparently vary the number of physical cores.

A more aggressive VM design could harvest the unallocated cores *and* any allocated cores that are temporarily idle. This is out of the scope of this paper. Instead, we focus on the usability of core-harvesting VMs (aggressive or otherwise) in practice with SLOs and software for them. Our SLOs can be extended for aggressive harvesting, whereas Harvest Hadoop can be used directly.

Like a Harvest VM, a burstable VM [7, 13] has a fixed number of virtual cores and receives a minimum number of physical cores. However, it is only allowed to burst (*i.e.*, receive additional physical cores) up to its maximum size, after accumulating enough “credits” by staying below a predefined core utilization. A Harvest VM differs in that (1) it harvests as many cores as are unallocated for as long as they remain so, *i.e.* there is no concept of credit; and (2) it is evictable. These characteristics mean that providing SLOs for Harvest VMs is also quite different than for burstable VMs.

Resource harvesting. Other approaches to resource harvesting have either focused on running batch workloads on idle machines (e.g. [25, 26]) or co-locating batch workloads with latency-sensitive services on bare-metal servers (e.g. [23, 27, 38, 39, 46, 47]). In contrast, we focus on a virtualized infrastructure where physical resources are reserved for the VMs that allocate them (as is the norm in the public cloud), and predict the availability and dynamics of the unallocated resources to produce SLOs.

Characterization and SLOs. To indirectly characterize the unallocated resources at cloud providers, prior work [2, 9, 31,

Figure 1: Allocation of VMs on a server, including hypothetical VMs (dashed) that consume unallocated resources.

[34] has analyzed publicly available traces of EC2 spot prices. Using the traces, they tried to model the availability of spot instances. In contrast, we use actual resource allocation data from the entire Azure server fleet to characterize the resources more accurately and comprehensively.

From the perspective of the provider, Carvalho *et al.* [12] characterized the reclaimable resources in 6 Google clusters. They aggregated the cluster-wide resources and predicted their availability for long-term (6-month) SLOs. They did not consider VM evictions or how the reclaimable resources vary at each server. However, the majority of VMs live less than 1 day and get deployed in relatively small groups [16]. Hence, we quantify the unallocated resources *per server* at a *fine time granularity*. Moreover, our SLOs quantify VM survival rates and average numbers of cores over horizons as short as 1 hour.

3 Characterizing unallocated resources

In this section, we characterize the potential for resource harvesting and the dynamics of the unallocated capacity in Azure. The characterization is affected by the Azure VM scheduler [19]. However, the scheduler behaves similarly to those of other providers [38] by tightly packing VMs while ensuring that it can find big enough holes for large VMs.

Methodology. We analyze the resource allocation in Azure from February to October 2019. The data we present does not include confidential metrics, such as number of servers or percentage of unallocated resources. However, the trends we illustrate are enough for the purposes of this paper.

We compute the allocated resources in each server based on the regular VMs running over time, *i.e.* we exclude resources that have been allocated to existing evictable VMs. We account for the main resources (*i.e.*, cores, memory, storage, and network bandwidth) for both the VMs and the servers. We then check if we could allocate in each server a hypothetical evictable VM of a minimum size, for how long, and how many unallocated resources it could potentially get.

In more than 80% of cases where we could not allocate the hypothetical VM, the scarcest resource (*i.e.*, the one that prevents the allocation) is cores. This is not surprising as Azure matches its hardware and VM sizes to have a single dominant resource and simplify capacity management. In the

Figure 2: VM allocations on two servers in our characterization (left) and when the VM scheduler is aware of VMs consuming unallocated capacity (right).

vast majority of remaining cases, disk space is the constraint. Thus, if we can find unallocated cores at a server, the other resources will most likely be unallocated as well.

Figure 1 shows an example server that runs 3 VMs over six months with the allocation of cores on the Y-axis. In early February, there are no VMs allocated to the server so we can run a 1-core hypothetical VM (dashed box) during that time. In late February, VM 1 starts and takes the full server so we cannot run any other VM. Once VM 1 finishes, the server becomes empty so we can run another hypothetical VM. VM 2 starts in late March but it only takes half of the server, so we can keep running the hypothetical VM until VM3 starts. In this period, we could place 3 hypothetical VMs with an average lifetime of almost one month.

This figure shows the hypothetical VMs with a fixed size but there are plenty of additional unallocated cores still left in the server. For example, when the hypothetical VM can run, at least half of the cores are unallocated.

Our characterization is *pessimistic* in that the unallocated resources are actually *more stable* in practice. For example, our characterization may find the scenario on the left side of Figure 2, which shows two servers with real VMs and hypothetical VMs. However, if the VM scheduler were to actually allocate VMs to consume the unallocated resources, it could allocate the real VMs differently to avoid evicting the hypothetical VMs as on the right side of the figure.

Temporal patterns. A key aspect to quantify is how long we could run a hypothetical evictable VM to consume unallocated resources in each server. Figure 3 shows how many servers could host a 1-core VM with 16GB of memory and 200GB of disk for a given time (*e.g.*, 1 hour, 1 day) in a popular region. We do not list the actual numbers of servers on the Y-axis for confidentiality reasons. Considering 1 hour into the future, we can see a daily pattern where there are more unallocated resources at night. For 1 day, we can see a weekly pattern and how weekends have substantially more unallocated resources. Once we consider the next week, the temporal pattern is not as clear. Overall, the longer horizon numbers show a decrease in unallocated resources over time. These data show that it is important to account for the time of day and day of the week (at least implicitly) when predicting the unallocated resources, especially for shorter periods.

Figure 3: #servers with 1 unallocated core in a region.

Figure 4: Survival rate with 1 unallocated core in a region.

From these numbers, we can compute the survival rate, *i.e.* the percentage of these evictable VMs that would survive for a given time (*e.g.*, dividing the “1-hour” values by the corresponding “Current” values computes the percentage of VMs that would survive for 1 hour). Figure 4 shows this survival rate over time. For example, it shows that in April, an average of roughly 60% of the 1-core evictable VMs (at most one per server) would survive for one week.

Cluster behaviors. As we discuss in Section 2, clusters may behave differently even within a region. Figure 5 shows how many servers could host a 1-core evictable VM in one specific cluster in the same region as Figure 3. In both late May and early June, the number of allocated VMs increased substantially, each time leaving less unallocated capacity. This shows that the amount of unallocated resources can change drastically over time. There are multiple reasons for such an effect, but in this case it was due to a shift in load across clusters, driven by the higher level across-clusters scheduler. These results show that we must consider each cluster individually when predicting the available unallocated resources.

Aggregating across all regions. So far, we have discussed servers in 1 region. Now, we discuss aggregate data over all regions. First, we consider the average durations over which at least 1 core is unallocated at each server. Over all regions, most servers can host a 1-core evictable VM for at least 1 hour on average. This number drops by 40% for 1 day and by another 40% for 1 month. As expected, fewer servers have at least 1 unallocated core for long periods (*e.g.*, 1 month) than short ones (*e.g.*, 1 hour). Moreover, even when servers have the same overall amount of unallocated capacity over time

Figure 5: #servers with 1 unallocated core in a cluster.

Figure 6: Survival rate of deployable evictable VMs as a function of lifetime and minimum size.

(measured in core×hours), they may be able to host widely different numbers of evictable VMs: servers that tend to have short periods with unallocated cores can host many (short-lived) evictable VMs, whereas those that tend to have long periods with unallocated cores host fewer (long-lived) VMs.

Next, we consider the average survival rate of the deployable 1-core VMs (at most one per server), again aggregating across all regions. The purple bars in Figure 6 plot the average survival rate for all deployable 1-core VMs for 1 hour, 1 day, 1 week, and 1 month. These four bars compute the average of the curves in Figure 4 but for all regions. Almost 100% of the VMs would survive for 1 hour, but only 80% of them would survive for 1 day and 32% would survive for 1 month.

Minimum unallocated cores. These results quantify the survival rate of 1-core evictable VMs. However, many servers have more unallocated cores than 1. For example, only 55% of the servers have 4 unallocated cores (*i.e.*, capable of hosting a 4-core evictable VM) for at least 1 hour on average.

Figure 6 also plots the average survival rate of other minimum sizes (at most one VM per server). Larger deployed evictable VMs tend to survive longer than smaller ones, even though they are less likely to find a server where to run. For example, 88% of the 16-core VMs survive for 1 day or longer, but only 80% of the 2-core VMs survive for that long. This effect is due to the cluster-level scheduler trying to pack new VMs tightly in servers that are already closer to being full.

Additional unallocated cores. The results above consider evictable VMs that consume a minimum number of unallocated cores. However, as shown in Figure 1, there are many

Figure 7: Percentage of deployable evictable VMs that could have received more cores, for each minimum size.

periods when there are additional unallocated resources in the server. Figure 7 shows the percentage of evictable VMs of each minimum size that could potentially have been as large as 1, 2, 4, 8, 16, and 20 cores. For example, 78% of 1-core VMs could have gotten 4 or more cores, and 85% of the 4-core evictable VMs could have gotten 8 or more cores. These results illustrate that (1) a large percentage of the (more numerous) small VMs could have been much larger; and (2) a large percentage of the (less numerous) large VMs could have been even larger. However, allocating a larger evictable VM on a server increases the chance that it will be evicted when the additional cores are needed for higher priority VMs.

Another important consideration is how stable the set of additional cores is, *i.e.* how quickly the set changes due to core allocations/deallocations. We find that 94% of these state changes last for more than 1 second, 90% of them last for more than 5 seconds, 50% of them last for more than 10 minutes, and 10% of them last more than 3 hours. Clearly, the set of additional cores is stable enough that they could be effectively harvested and used by applications.

Multiple VMs per server. So far, we have discussed deploying at most one evictable VM in each server. However, the results above show that there are often enough unallocated resources for more VMs and the amount of these resources varies over time. Under these conditions, the provider can maximize the amount of unallocated resources it monetizes via evictable VMs with as many 1-core VMs as will fit in each server at each point in time. Unfortunately, a larger number of VMs per server increases management (more evictions) and resource (more copies of the guest OS) overheads. The key problem is that *standard evictable VMs are not the ideal abstraction to maximize the use of unallocated resources while keeping overheads down.*

High-level takeaways. Our characterization shows that:

1. There are many unallocated resources that can be harvested. However, they fluctuate significantly over time. There are plenty of unallocated resources for a short time but many fewer for longer periods.
2. These resources are not evenly distributed across clusters. A cluster's allocation may also change drastically over time.
3. The available unallocated resources vary substantially de-

pending on amount (minimum size) and duration. Smaller minimum sizes are more widely available but they do not survive as long as larger minimum sizes.

4. There are many additional unallocated resources in each server beyond this minimum size that can be harvested. The additional resources vary over time at a fairly coarse granularity, but trying to harvest them with standard evictable VMs could cause many evictions and waste resources.

4 Harvest Virtual Machines

Section 3 shows that there are plenty of unallocated resources that can be harvested, while takeaway #4 suggests that doing so with standard evictable VMs is not ideal. Thus, we propose a new class of evictable VM, called *Harvest VM*, that dynamically grows and shrinks to harvest as many unallocated resources as available on the server where it runs. With Harvest VMs, we maximize the resource harvesting at each server, while keeping evictions and overheads down.

Overview. Users select a minimum size for each Harvest VM. A Harvest VM starts with as many unallocated physical resources as are available in its host server, but grows and shrinks dynamically after that. For example, a Harvest VM may have 4 physical cores as its minimum size. At server selection time, this VM is assigned to a server that has at least 4 unallocated cores. Say this server has 20 cores. At creation time, the Harvest VM would be created with 20 *virtual* cores and would receive an initial number of *physical* cores equal to the number of unallocated cores in the server (at least 4 cores, of course). During its lifetime, the Harvest VM will grow (*i.e.*, receive more physical resources) when a co-located regular VM terminates and shrink (*i.e.*, lose physical resources) when a new regular VM lands on the same server. Since the Harvest VM changes size only when other VMs arrive/terminate, these changes occur fairly infrequently (Section 3). As a Harvest VM has lower priority, it is evicted/killed if the cloud platform needs its minimum size for a regular VM.

As an example, Figure 8 shows a server with 8 physical cores that hosts 2 regular VMs with 2 cores each. At t_0 , a Harvest VM with a minimum size of 2 cores lands on the server. As there are unallocated cores, the Harvest VM grows to 4 cores. At t_1 , VM 2 finishes and the Harvest VM grows to 6 cores. At t_2 , VM 3 with 4 cores lands on the server and the Harvest VM shrinks to 2 cores (its minimum size). At t_4 , VM 4 with 2 cores lands on the server, causing the Harvest VM to be evicted as it would have to shrink below its minimum size.

Production implementation in Azure. We create a new family of hyperthreaded Harvest VMs that users can select from. The family defines VM types with a minimum size of 1, 2, or 4 cores (*i.e.*, 2, 4, and 8 hyperthreads, respectively). The smallest Harvest VM has a minimum of 1 core, 16GB of memory, 200GB of disk with 3k IOPS, and 1Gbps of network bandwidth. The resources for the larger sizes scale proportionally to the number of minimum physical cores.

Figure 8: Harvest VM dynamically changing sizes over time.

Our current implementation only harvests physical cores; the other resources stay fixed during the Harvest VMs’ lifetimes. The Harvest VMs can grow to use all physical cores of the server, as this fits nicely our current production uses (Section 6), which can consume as many cores as are available. For simplicity, the implementation does not allow more than one Harvest VM per server. We discuss upcoming changes to this design in Section 8.

Users can deploy many Harvest VMs to a region at the same time. The provider deploys the Harvest VMs in the same way that it deploys any other VM. Ultimately, each Harvest VM is scheduled onto a server by a cluster-level VM scheduler. On each server, Azure runs the Hyper-V hypervisor [29] and an agent responsible for managing VMs locally, including VM creation, termination, and physical core reassignment across VMs. The agent uses hypercalls for assigning a Harvest VM to a group of cores and capping the amount of CPU time the group receives. To prevent cache interference between a Harvest VM and the co-located regular VMs, the agent constrains the Harvest VM to a subset of cache ways of the last-level cache, using cache allocation technology [15].

The changes in the number of physical cores are not directly visible by the Harvest VM, as its number of virtual cores does not change. However, the application or scheduling framework running on a Harvest VM may want to take advantage of any harvested cores. Thus, we expose the number of currently assigned physical cores to the Harvest VM via the KVP mechanism of Hyper-V [30]. Applications or frameworks can use this information to adapt their behaviors. For example, a scheduling framework can assign more tasks to a Harvest VM that has just received more cores.

The scheduler may evict a Harvest VM (1) when it needs the minimum resources for a regular VM, or (2) proactively to avoid the eviction latency when it expects that its minimum resources will be needed soon. In either case, the scheduler informs the Harvest VM about the upcoming eviction, and gives it 30 seconds to shutdown cleanly. At deployment time, users can specify whether they want another Harvest VM to be created (on a different server) to replace an evicted one.

Comparison to standard evictable VMs. Unlike evictable (e.g., spot) VMs, Harvest VMs are only evicted when the provider needs their minimum resources for higher priority VMs. In addition, Harvest VMs harvest additional unallocated

cores from the servers that host them. In Figure 8, using evictable VMs to harvest those additional cores would have caused them all to be killed at t_2 , whereas the Harvest VM shrinks and avoids the high eviction overhead. Due to the additional harvested cores, it takes many more evictable VMs to harvest as many cores as Harvest VMs, implying higher management and resource overheads. In Section 7.5, we show that evictable VMs also imply higher costs to users.

Using Harvest VMs. Harvest VMs are most useful when workloads can gracefully adapt to evictions and a time-varying number of physical cores. First, workloads must be able to continue operating correctly after VM evictions. An eviction is similar to a server failure, so all practical distributed applications are already capable of handling them. Embarrassingly parallel applications handle these failures even more easily. Regardless of application type, users often want new (evictable) VMs to be created to replace evicted VMs, and cloud platforms already provide this functionality. However, as VM re-creation and application re-configuration are expensive, users can make informed decisions about their Harvest VM deployments using our SLOs.

Second, applications must be able to leverage additional cores and degrade gracefully when cores are removed. To do so, applications can check the number of currently assigned physical cores and adapt accordingly. Core re-assignments are much cheaper than VM re-creation and re-configuration, so applications can more easily handle them. For example, the application may create (destroy) software threads when more (fewer) cores are available or have a thread pool where work can wait for cores. Despite their lower overhead, users can use our SLOs to know how many cores to expect per Harvest VM, so they can provision enough threads and VMs.

Still, providers may decide that Harvest VMs are not ideal as an IaaS offering. Instead, they can use them to implement cheaper SaaS, PaaS, or FaaS offerings. In fact, our current Azure deployment uses Harvest VMs to implement a core-harvesting version of Hadoop.

Privacy/confidentiality. On individual servers, Harvest VMs reveal the VM arrival and departure events. However, they do not threaten the confidentiality of the cloud platform’s resource utilization, as long as determined (and well-funded) users are not allowed to deploy Harvest VMs to most servers. To avoid this, the provider can simply establish an overall quota of Harvest VMs in each region. The privacy of the workloads is also protected, as Harvest VMs do not reveal any info about (1) co-located regular VMs to the users of Harvest VMs, or (2) their workloads to the provider or co-located regular VM users. In addition, using Harvest VMs for SaaS, PaaS, or FaaS adds an extra software layer that further reduces the chance of leaking sensitive information.

Pricing and deployment cost. A detailed pricing discussion is beyond our scope. Instead, we assume that users pay (in $\$/(\text{core} \times \text{hours})$) the same for their Harvest VM minimum size as a standard evictable VM of equal size (evictable VMs

are already heavily discounted compared to regular VMs), and get a further discount on any additional cores beyond the minimum (billing for these cores can be per-use or per-allocation to the Harvest VM). This pricing scheme is beneficial for both users, who can rent resources cheaply, and the provider, who can aggressively monetize its unallocated capacity.

To compute the cost to the user of a deployment of multiple Harvest VMs, we need to consider evictions. An eviction forces the re-creation of the VM at another server, which takes the time to instantiate the VM and restore the application. This results in a loss in useful compute power (measured in $\text{core} \times \text{hours}$). Thus, the average cost per useful core hour (in $\$/(\text{core} \times \text{hours})$) of a deployment is:

$$\frac{\text{minsize core hrs} \times \text{price} + \text{additional core hrs} \times \alpha \times \text{price}}{\text{minsize core hrs} + \text{additional core hrs} - \text{recovery core hrs}}$$

where *minsize core hrs* is the total core hours for the VMs' minimum size, *additional core hrs* is the total number of cores hours harvested beyond the minimum size, α is the extra discount the provider offers on the additional cores ($\alpha = 0$ means those cores are free and $\alpha = 1$ means they cost the same as the minimum size cores), and *recovery core hrs* is the total amount of core hours spent recovering from evictions.

Harvesting other unallocated resources. Our current implementation only harvests cores. Many workloads can use additional cores (e.g., ML training and most data analytics) with stable needs for other resources. Yet, harvesting other resources would make Harvest VMs more broadly beneficial, so we are building prototypes for harvesting some of them.

Harvesting network and disk bandwidth are similar to core harvesting (they are all compressible resources). Current hypervisors manage bandwidth limits and set them up when starting each VM. To harvest these resources, the server agent can dynamically change the limits. For applications or frameworks to be aware of changes, we expose these values to the Harvest VM using our existing mechanisms.

Harvesting memory is more challenging. Current hypervisors support dynamically changing the memory assigned to a VM. When adding new memory, this shows as hot-plugged memory in the VM. When removing memory, the guest OS uses memory ballooning to make some part of it unavailable. This may trigger swapping in the Harvest VM and the applications/frameworks should be aware. If the VM cannot free up memory, the operation may crash (or ungracefully evict) the VM. Other works discuss similar approaches [33].

For disk space, VMs usually mount a virtual disk (VHD) for data. A naive option would be to extend and shrink the VHD. Extending a VHD can be done while it is mounted, but shrinking it requires unmounting and compressing. Another option would be to add and remove full VHDs depending on the disk space available in the server. Both approaches are intrusive and require applications/frameworks to be aware.

5 Providing SLOs for Harvest VMs

Our characterization showed that the amount of unallocated resources to run Harvest VMs varies over time, in terms of temporal patterns (e.g., daily and weekly) and across-cluster behavior changes (e.g., shift in load across clusters). Moreover, the VM scheduling dynamics produce numerous smaller sets of unallocated resources that survive shorter times, and fewer larger sets that survive longer. These factors make it difficult for users to provision the right minimum size and number of Harvest VMs.

To ease this task, we predict the survival rate of the Harvest VMs and the amount of resources they are likely to receive on average, and provide these predictions to users in the form of an SLO. The SLO is a best-effort statistical estimate as in prior work [12], so the provider should retrain the prediction models frequently (e.g., every day). The provider need not monitor or actively try to enforce each SLO individually, which would be impractical. Nevertheless, the SLO enables applications beyond just batch workloads to use Harvest VMs, as long as they can tolerate the occasional eviction and the core reassignments (Section 6).

Our predictions leverage machine learning (ML) models and features we can collect in production.

User input and SLO definition. The user must first inform her desired number of Harvest VMs (e.g., 100), minimum size (e.g., 2 physical cores), and region. Based on these requirements, we provide an SLO for the survival rate and the number of additional cores for a set of predefined time horizons: 1 hour, 1 day, 1 week, and 1 month. For example, the survival rate SLO for each horizon can be: 60% of the Harvest VMs will likely survive at least 1 hour, 40% will likely survive at least 1 day, 25% will likely survive at least 1 week, and 15% will likely survive at least 1 month. We also provide confidence intervals (e.g., between 55% and 70% will last 1 hour with 95% confidence).

For each horizon, our SLO also estimates the average number of additional cores. For example, the Harvest VMs will likely receive an average of 5-7 cores with 95% confidence for the first hour, 8-11 cores over the first day, etc.

If the SLO is not acceptable, users can change the number and/or minimum size of the Harvest VMs they request. If no SLO is acceptable after multiple tries, users may opt for a mix of regular and Harvest VMs or select a different region. Once the Harvest VMs are running, users can check for updated SLOs, which become more accurate over time. Based on this updated information, they can adapt their deployments.

ML models and features. To provide the SLO, we use ML models to predict the survival rates and average sizes for each time horizon. After experimenting with multiple modeling approaches, we settled on Random Forest regressors [10].

The features we use in our models are as follows.

Cluster characteristics: This includes (1) number of servers, (2) number of racks, (3) generation of the hardware (including

their sizes), and (4) total resources (*e.g.*, cores and memory) in the cluster. Clusters with similar characteristics (*e.g.*, same type of servers) are likely to have similar behaviors. This is useful for new clusters without much historical data or clusters that have not seen particular conditions (*e.g.*, high allocation). *Cluster name*: The identifier for the cluster helps improve the prediction accuracy for a specific cluster. This complements the cluster characteristics and still allows learning from the historical data from similar clusters.

Total resources allocated: This includes the total number of cores and memory (*e.g.*, in GBs) currently allocated to regular VMs in the cluster. Together with the cluster characteristics, we can compute the allocation percentage.

Number of VMs: This is the total number of VMs currently running in the cluster. The ratio between resources allocated and the number of VMs gives insights on how large the VMs in the cluster are. This is particularly useful to estimate the sets of unallocated resources in the cluster for Harvest VMs.

Auto Regressive: These are previous time series values of the outputs we want to forecast. This feature is especially useful because, as our characterization shows, past values are a reasonable indicator of the current values. Each output will use values for different past periods. For example, if we are predicting the survival rate for Harvest VMs in 1 day, this would include the evictions we actually saw in the last day.

Moving Average: This is similar to the Auto Regressive feature, but it smooths the past values using averages. We use multiple periods for the averages (*e.g.*, 1 hour, 1 day). This feature is useful to filter out peaks and reduce noise.

ML training and inference. We can *train* our models using data from Harvest VMs that ran in production in the past. This data includes the aspects that we want to predict (*e.g.*, how long the VM lasted for), the characteristics of the Harvest VM (*e.g.*, a minimum of 2 cores), and the state of the cluster at each point in time. However, as Harvest VMs have not run in production long enough, we use traces from production as our training data in this paper (Section 7.1).

At model *inference* time (*i.e.*, an SLO needs to be shown to a user), we first check which cluster in the desired region would potentially host the Harvest VMs that are being requested, and use the cluster characteristics and name for the cluster as input features for the inference. If the Harvest VM deployment is to be split across multiple clusters, we then predict for each one independently.

Discarded features. Other features' impact on prediction quality was small or even detrimental. Some of them are:

Number of VMs of each type: A VM type defines the number of cores, memory size, if it has GPUs, etc. There are hundreds of types and the model cannot make sense of them. Some features we use (*e.g.*, total number of VMs and cores allocated) are proxies and enable our models to infer this data concisely.

Date/time: These features were used in [36]. We do not include them, as features like the total number of VMs already carry implicit temporal patterns (*e.g.*, weekdays vs weekends).

Predicting standard evictable VM survivability. Our survival rate predictions can be directly applied to standard evictable VMs. In fact, we are working on a simpler version of our model to provide survival rate predictions for evictable VMs in production. The uses for these predictions are similar to the ones for Harvest VMs.

6 Harvest Hadoop

Cluster scheduling frameworks, such as Apache YARN [37] or Kubernetes [22], are good targets for Harvest VMs. A large number of applications already run on them, and they can be adapted to use Harvest VMs transparently to applications. These frameworks are built to handle server/VM failures, so they can be easily extended to manage evictions. Applications built for these frameworks, like Spark [44], also manage the straggler tasks that might result from an eviction. Moreover, these frameworks can be modified to schedule more tasks on a Harvest VM that has grown to use more cores, and stop scheduling new tasks on a Harvest VM that has lost cores. To demonstrate how to adapt these frameworks, we build *Harvest Hadoop* to schedule computation on harvested resources.

Harvest Hadoop architecture. Harvest Hadoop is an extension to the Hadoop [3] ecosystem. Hadoop includes the YARN cluster scheduler [37], which enables running many applications (*e.g.*, Spark [44], Flink [11]) to leverage harvested resources. It also includes the Hadoop Distributed File System (HDFS), which is optimized for large data files.

A key goal for Harvest Hadoop was to minimize the number of intrusive changes to YARN and HDFS, so that our system would be simple and practical, and our changes could be more easily contributed to open-source Hadoop. With this in mind, we design Harvest Hadoop with the following main features:

- It executes the YARN and HDFS master processes (called Resource Manager and Name Node, respectively) on regular VMs, as it is expensive to manage the failure of the masters;
- It executes the YARN and HDFS worker processes (called Node Manager and Data Node, respectively) on Harvest VMs;
- It uses storage within each Harvest VM simply as a cache of remote data (from the provider's highly available storage service), as evictions do not leave enough time for fully decommissioning a storage server; and
- It introduces a Harvest VM Manager (HVM Manager) that monitors the number of resources currently available to its Harvest VM and the informs the master processes. The master processes act accordingly at the next heartbeat.

We have contributed all the needed code changes to open-source Hadoop 3.3.0 [40,41]. Figure 9 illustrates the architecture, showing a server that has two regular VMs and a Harvest VM consuming all the resources not used by the regular VMs.

Managing evictions. We leverage the decommissioning feature in YARN [42]. When the provider notifies the Harvest VM that it will be evicted, the HVM Manager notifies the YARN Resource Manager (RM) to kill the containers in that

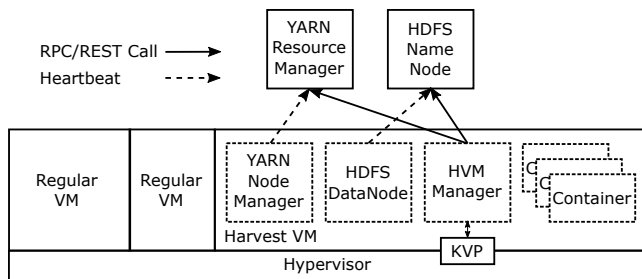

Figure 9: Architecture of Harvest Hadoop.

VM. If the worker gets evicted before killing all the containers, the RM will handle this as a failure and re-schedule the containers. Otherwise, the applications can decide whether they want to re-schedule any of their killed containers.

Evictions are more intrusive for data storage. We leverage the decommissioning mechanisms available in HDFS [20]. The HVM manager catches the eviction notification from the provider and tells the HDFS Name Node to start decommissioning the corresponding Data Node. As the advance notice to evict a VM is usually short (e.g., 30 seconds), there is little time to decommission a full data node. This is the reason why we only cache remote replicas in Harvest VMs, as we mention above. HDFS replicates the cached files in other Harvest VMs, and uses a write-back policy for them [21].

At Harvest Hadoop deployment time, the user specifies (as an auto-scaler option) whether she wants her Harvest VM deployment to be replenished by the cloud platform to its original number of Harvest VMs when an eviction occurs.

Managing core reassignments. To adapt the scheduling, we leverage the resource updates in the existing heartbeats to the YARN RM. Zhang *et al.* took a similar approach in the bare-metal scenario [47]. The HVM manager periodically checks the number of cores assigned to its Harvest VM, and it notifies the RM if the number has changed.

If the Harvest VM gets more cores, the RM can now assign more containers to the VM. If the VM shrinks, the scheduler can: (1) kill some containers and let the application handle it as a failure, (2) run the containers in a deprived mode and wait until the application terminates them, or (3) notify the application to free up some containers.

Our current implementation uses a combination of the three options. The RM first selects the containers that should be killed based on their priorities and whether they are opportunistic [43]. Then, it notifies the applications in case they can terminate the containers. After a grace period (30 seconds), if the cores are still not enough, it will terminate the containers. This period allows graceful termination and can correct for the number of cores increasing again.

Harvesting other resources. We also modify Hadoop to be aware of the VMs' memory allocation, so it will work out-of-the-box when Harvest VMs become capable of harvesting memory. When the Harvest VM gets more memory, Harvest Hadoop can just deploy more containers to it. However, when

the Harvest VM shrinks, we cannot run in deprived mode, unless the VM allows swapping to disk. For this reason, we keep a buffer of unused unallocated memory. The HVM manager notifies the Harvest VM when memory from this buffer is allocated, so that it can free up some of its own memory. The HVM manager kills the Harvest VM if the buffer is exhausted, i.e. the Harvest VM cannot release memory fast enough.

Hadoop does not need changes to benefit from harvested network and disk bandwidth, as applications can automatically use any additional bandwidth that becomes available.

7 Evaluation

7.1 Methodology

Our evaluation focuses on two sets of results. First, we assess the benefits of Harvest VMs and the accuracy of our SLOs. Ideally, we would do this assessment based on real production data. However, our SLOs are not in production yet. Moreover, the set of conditions under which we can evaluate our SLOs is limited with the production deployments of Harvest VMs. For these reasons, we use a *validated* simulator and production VM data for 25 clusters for our SLO evaluation.

Second, we explore the *real implementation of Harvest VMs and Harvest Hadoop in the provider's production infrastructure*. We use two large clusters: one running internal production VM workloads, and another running VM workloads that stress the cluster.

Simulator. We use Azure's own cluster simulator, which executes the real VM scheduler [19] code in assigning VMs to physical servers. Thus, the simulator closely mimics the constraints and preferences in the real scheduler. We feed the simulator with production VM arrival traces, and add Harvest VMs continuously to fill the cluster (i.e., no new Harvest VMs can be allocated). We run the simulations in real Harvest VMs, i.e. each harvested core allows us to run one more (single-threaded) simulation in parallel.

We validate the simulator by comparing the number of Harvest VMs that can be created in a real cluster (based on logs of VM assignments to servers) and in simulation (replaying the corresponding VM arrival trace). Figure 10 shows this validation for Harvest VMs of 3 minimum sizes over 1 week, where dashed lines represent the real executions and solid lines represent simulated executions. The curves match closely because the simulator mimics the packing per server accurately. We also validate using longer periods and other clusters, and find an absolute average error of just 3%.

As inputs for our simulations, we use VM arrival data from 25 randomly selected clusters across 14 regions, including relatively small satellite regions. The data was collected from December 1st 2019 to March 1st 2020. We process the VM arrival data to generate the allocation state of each server every 10 minutes. The clusters exhibit a wide range of behaviors in terms of how highly allocated they are on average and how

Figure 10: Simulation validation over 1 week. Solid curves are actual data; dashed curves are simulated.

stable the total allocated resources are over time. The number of servers per cluster ranges from several hundred to several thousand. There is no correlation between cluster size and allocation percentage or stability. When training our models, we use data from December 1st 2019 to January 15th 2020. We use the other 45 days for evaluating predictions.

Real experiments. For our real experiments, we use the Harvest Hadoop implementation we describe in Section 6. We configure the provider’s deployment system to replace any Harvest VMs that get evicted, so that the overall number of Harvest VMs stays fixed during our experiments.

We use two large clusters, which we call *private* and *canary*. The private cluster has over 1700 servers and runs VMs that implement a production key-value store. The VM load is fairly stable over time. We create Harvest VMs in this cluster and attach them to a Harvest-Hadoop-based production data analytics and ML training system. We have deployed Harvest VMs to other private clusters as well, but selected this one for our results because it has been the most extensively used.

The canary cluster has around 650 servers and runs a synthetic VM load that stresses the provider’s production infrastructure. This cluster is in the top percentile in terms of VM creations and terminations, and produces many resource allocation changes and evictions. For our experiments with this cluster, we create full Hadoop clusters. Each cluster consists of 3 Name Nodes and 2 Resource Managers (which run on regular VMs) and Harvest VMs that we scale on demand. For coordination, we also deploy a 5-node ZooKeeper 3.6.0 stamp in the same regular VMs. We run synthetic jobs, including MapReduce (e.g., TeraGen and TeraSort) and Spark.

7.2 Benefits of Harvest VMs

We start the evaluation by assessing the benefits of Harvest VMs over standard evictable VMs in terms of numbers of VMs and evictions. Our comparison simulates the 25 production clusters in two scenarios: one in which we consume all the clusters’ unallocated resources using evictable VMs, and another where we consume them using Harvest VMs. We place as many evictable 1-core VMs as will fit; larger sizes would not consume many unallocated resources. In the Har-

Figure 11: Number of VMs required to consume the unallocated resources of 25 production clusters.

vest VMs scenario, 1 core is the minimum size and we only place one Harvest VM per server. In both scenarios, each VM has 16GB of memory and 200GB of disk.

Figure 11 shows the number of VMs required to consume the unallocated resources with evictable and Harvest VMs for each cluster. Across all clusters, we need between 8% and $10.7\times$ ($3.7\times$ on average) more evictable VMs than Harvest VMs. The number of evictions of evictable VMs is also much higher by $\sim 3.6\times$ on average. These results quantify our earlier observation that standard evictable VMs incur higher management and resource overheads than Harvest VMs.

7.3 Accuracy of SLOs for Harvest VMs

The accuracy of our SLOs hinges on our ability to accurately predict survival rates and average numbers of harvested cores. We start our evaluation with a detailed analysis of prediction accuracy for a few sample clusters, and then offer a global view of all clusters. The last part of the section evaluates our ML model and studies its sensitivity to multiple parameters.

Detailed analysis. Let us first consider the accuracy of our survival rate SLOs. For a cluster with fairly stable load, the graphs on the left of Figure 12 show the number of Harvest VMs with a minimum size of 4 cores that can be created (top), those that would survive 1 day (middle), and their survival rate after 1 day (bottom) over time. Each graph shows the actual and predicted values (with 95% confidence intervals), as well as the corresponding absolute errors. We plot predictions and errors every 10 minutes, given the actual cluster state at those times. For example, if the actual value is 100 and the prediction is between 90 and 120 with 95% confidence, the absolute error is 0%. Instead, if the actual value is 60, the error is -33% (i.e., $(60-90)/90$) and the absolute error is 33%. The vertical line at January 15th marks the split between the training and test datasets. The graph on the right shows the CDF of the errors comparing the actual survival rates to our predictions with and without 95% confidence intervals, during the test period. These would be the error distributions of our 1-day survival rate SLO.

The top graph shows that our predictions for the number of VMs that can be created are very accurate, even though the training data is almost a flat line and there are substantial variations after January 15th. Our model recognizes that these behaviors are unknown and leverages the data from other

Figure 12: Predictions for Harvest VMs with 4-core minimum size and their survival rates after 1 day for a stable cluster.

Figure 13: Predictions for Harvest VMs with 4-core minimum size and their survival rates after 1 day for the worst cluster.

clusters to provide a prediction that is not as precise. So, when those variations occur, the confidence intervals widen. The middle graph also shows very good accuracy when predicting the number of VMs that would survive after 1 day. Most importantly, the bottom graph and the CDFs to the right show that 80% of the absolute errors are very close to 0%, and 95% of them are lower than 15%, when compared to the predictions with confidence intervals. Errors are larger when comparing to exact predictions, but 90% of them are still lower than 20%. These results show very good accuracy for our SLO.

For comparison, we now study the cluster with the largest 99th-percentile errors in our dataset in Figure 13. Again, we assume 4-core Harvest VMs and 1 day survival. The top graph shows very low absolute errors, despite the significant change in behavior after January 15th. In contrast, the middle and bottom graphs show significant errors at times, despite the wider confidence intervals. The CDFs show the distribution of the errors in our SLO prediction. In this case, 85% of the predictions are within 10% and 95% within 20%. Thus, even in the worst cluster, our SLO would still provide valuable guidelines (e.g., an actual survival rate of 85% while we predicted 65%).

We now study the accuracy of our predictions of average number of harvested cores. Figure 14 shows these predictions for Harvest VMs with 1 (top), 2 (middle), and 4 (bottom) minimum cores in another cluster with significant unallocated capacity. The horizontal lines show the minimum and maximum numbers of cores for each VM. The figure shows that a Harvest VM with a minimum size of 1 core gets between 6 and 14 cores in the cluster. During the test phase, the prediction accuracy is very good, showing that our average cores SLO would be accurate for this cluster. In addition, we can see

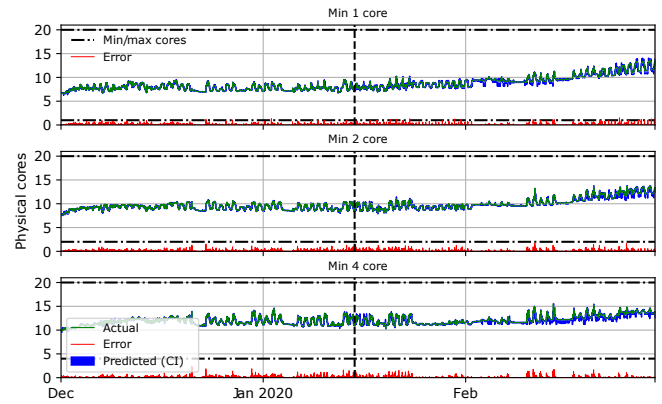

Figure 14: Prediction of unallocated cores in one cluster.

Figure 15: Prediction errors for the 1-day survival rate, as a function of minimum size and cluster.

that the larger Harvest VMs get slightly more cores overall.

Results for all clusters. The results above illustrate the accuracy of our predictions for individual clusters. We now turn to results for all clusters. Figure 15 plots the errors (in boxplot format) when predicting 1-day survival rate with 95% confidence, for each minimum size and cluster. Each box ranges between the first and third error quartiles, with the line representing the mean error, whereas the whiskers extend out to the 2.5th and 97.5th percentiles. The clusters marked C1, C2, and C3 are those from Figures 12, 13, and 14, respectively. The vast majority of mean errors are around 0% and the bulk of the errors are lower than 20% for most clusters.

Figure 16 plots the error distribution of the survival rate without confidence intervals, for each horizon and minimum size, aggregated across all clusters. As expected, short-term predictions (i.e., current, 1-hour) have the lowest errors. The short-term results show that >90% of the predictions have no errors and the worst predictions have an error under 15%. Interestingly, long-term predictions (i.e., 1-month) tend to be more accurate than medium-term ones (i.e., 1-day, 1-week). The reason is that small load changes have a larger impact when predicting medium-term survival, whereas they often get smoothed out in the long term.

The figure also shows that errors are balanced and there

Figure 16: Prediction errors for time horizon and min size.

are not many more overpredictions than underpredictions (or vice-versa). When we average all the absolute errors, both current and 1-hour survival predictions exhibit errors lower than 2%. The 1-day and 1-week average absolute errors are roughly 6%, whereas the 1-month average absolute error is just under 4%.

Our predictions of the average number of cores available to Harvest VMs are even more accurate: the average error is smaller than 2.3% (<0.9% considering the confidence interval). When predicting the median and the 75th percentile numbers of cores, the errors are below 4.1% (<1.5% considering the confidence interval). Even though our current Harvest VM implementation does not harvest memory, targeting our model to predict the memory available for harvesting also produces accurate results: the average absolute error is smaller than 1.5% (<0.5% considering the confidence interval).

Prediction adaptability. During this work, our model has been exposed to three versions of the VM scheduler that changed the allocation behaviors over time. We periodically re-train our model to capture these new behaviors. In addition, the auto-regressive features are especially good at adjusting to such changes. We have also evaluated our predictions with multiple hardware generations (our results are for the two most popular ones) and the model is able to adjust to them.

In summary, our predictions for both survival rate and average number of cores are *accurate and robust* for a wide range of cluster characteristics and behaviors.

Impact of the ML model. For comparison against our Random Forest model [24], we evaluated a Multi-Layer Perceptron (MLP) [35], Gradient Boosting [17], Exponential Smoothing (ETS) [18], and ARIMA [45]. MLP is a type of neural network. It achieves the closest results to our model, but we had to explore multiple combinations in the numbers of layers and neurons per layer. Figure 17 shows a comparison between the prediction errors of the two models' survival rates (left) and number of cores (right). The predictions are slightly worse using MLP and it does not provide confidence intervals. Training times are not a concern for large cloud providers. For context, one Random Forest training session typically takes around 16 hours on one Harvest VM, using 45 days of data from all 25 clusters. A similar MLP training session takes much longer, but we did not try using GPUs for

Figure 17: Avg absolute errors for Random Forest and MLP.

Figure 18: Avg absolute errors using two model types.

it. Prediction times are negligible in both cases.

The other models do not compare as well. Random Forests outperformed Gradient Boosting in both accuracy and performance. ETS and ARIMA are well-behaved for certain clusters and provide confidence intervals. However, they cannot incorporate other features (*e.g.*, cluster characteristics) that improve predictions in unseen situations. In contrast, Random Forests can easily use data from other clusters when the cluster starts to behave differently from its past (*e.g.*, the load increase in Figure 13). Nevertheless, our approach does incorporate the auto-regressive and moving average aspects of ARIMA.

Impact of the features. Our model uses 31 features. Both SHAP analysis [28] and a feature importance algorithm indicate that the auto-regressive features are the most relevant. However, the other features do improve prediction quality, especially when the cluster starts to behave differently. The features that we discarded do not improve our predictions.

Impact of global modeling. We can see the benefit of using data from other clusters by comparing prediction errors from 25 per-cluster models vs a single model trained with data from all 25 clusters. Figure 18 shows this comparison for survival rates. The top graph shows the errors of the independent models and the bottom one the errors for the single model. The bottom graph shows lower errors in every case.

7.4 Harvest VMs and Harvest Hadoop

As we mention in Section 7.1, we experiment with Harvest VMs and Harvest Hadoop in the Azure's production infrastructure, using two clusters called private and canary.

Private cluster. We have been running Harvest VMs and Harvest Hadoop in this cluster in production for more than 6 months. The organic regular-VM workload is a key-value

Figure 19: Time to evict Harvest VMs in the two clusters.

store that uses full-server VMs but leaves many other servers empty. Our Harvest VMs (minimum 2 cores) run on these servers and execute Hadoop-based ML and data analytics jobs. As the Harvest VMs run alone, they grow to consume all the cores on their host servers. The left side of Figure 19 shows their survival statistics over 3 months. The “Not Evicted” VMs are those that terminated, instead of being evicted. Roughly 95% of the Harvest VMs that are evicted survive one hour or more, and roughly 40% survive for one month. These durations match the production jobs nicely: this cluster ran 105k tasks in a month, 90% of them ran for less than 10 minutes, 95% less than 1 hour, and only 1% longer than 6 hours. Interestingly, roughly 90% of the not evicted Harvest VMs last for more than a month. Over time, the organic load has increased and we now have capacity for around 450 Harvest VMs.

Canary cluster. To stress Harvest Hadoop, we create full deployments in the canary cluster, whose organic workload also seeks to stress the platform and varies significantly. Each deployment includes 100 workers in Harvest VMs of minimum size 2, and executes various Hadoop benchmarks. The results over 3 months appear on the right side of Figure 19. The constantly varying organic load and our stress-benchmarking result in only roughly 30% of the Harvest VMs that are evicted surviving one hour or longer. Even the ones that are not evicted are very short, and terminate before they are evicted.

To see these behaviors in more detail, we let a 100-VM setup run for over a week, continuously executing the TeraGen and Terasort benchmarks with 1000 map tasks. From these experiments, Figure 20 shows the minimum, maximum, and average number of cores the Harvest VMs got over the week. Most of the time, the Harvest VMs got over 18 cores on average. On March 29th there was a surge in load and the average dropped to 15 cores. During this time, there was at least one Harvest VM with only 2 cores. The figure also shows the number of evictions per hour. During the load surge, there were 19 evictions but in 30% of the hours there were no evictions and in 75% there were 2 or fewer. After every eviction, the auto-scaler replaced the evicted Harvest VM with a new one trying to keep 100 workers at all times. For most of the VM re-creations, accesses to the remote storage service were not needed to re-hydrate the cache, because the data could come from other cached replicas; the exceptions

Figure 20: Minimum, maximum, and average number of harvested cores and evictions over one week.

were the 19 evictions during the load surge, which actually lost all cached replicas of certain files.

7.5 Cost comparisons

To compute the cost savings that Harvest VMs can accrue, compared to standard evictable and regular VMs, we can use the formula from Section 4. To use it, we need to instantiate the time to recover from evictions in $\text{core} \times \text{hours}$ (*recovery core hrs*), the prices per $\text{core} \times \text{hour}$ (*price* and α), and the number of minimum (*minsize core hrs*) and additional (*additional core hrs*) Harvest VM $\text{core} \times \text{hours}$. The number of cores used by regular and standard evictable VMs as equivalent to the minimum size of Harvest VMs.

We compute the recovery time for each evicted VM from the experiments with the canary cluster. Specifically, an eviction forces the re-creation of the VM at another server, which takes roughly 30 seconds. In addition, Harvest Hadoop needs to re-create its workers, which takes a minimum of 2 minutes and 5 minutes at the 90th percentile. The breakdown for the common case is 1 minute to get all the binaries (e.g., Java, Hadoop, Docker, libraries), 30 seconds to setup and install dependencies, around 10 seconds to setup the environment (including security packages, compliance, and firewall setup), and around 10 seconds to start the services (DataNode and NodeManager) and heartbeat. Some stages are prone to long tails, which usually occur when creating a few hundred Harvest VMs at the same time. For this analysis, we assume that each eviction causes 5.5 minutes of recovery time.

To instantiate the prices, we use the amounts that Azure charges for the VMs from which we derive the Harvest VM resource quantities. Specifically, we instantiate the prices as \$0.126/(core×hour) for a regular VM and \$0.019/(core×hour) for a standard evictable VM [5, 6]. We use the latter price for the minimum size of the Harvest VMs as well. By default, we assume that the discount for additional Harvest VM cores (beyond the minimum size) over the evictable core price is 50%, i.e. $\alpha = 0.5$. Below, we discuss other values as well. As Harvest Hadoop can use as many cores as Harvest VMs give it, it is immaterial whether the provider charges for additional cores per-use or per-allocation.

Figure 21: Costs when consuming the unallocated resources of 25 production clusters.

Using data from the simulations in Section 7.2 (where we consume as much of the unallocated resources as possible), we combine the recovery time above with the average survival rates for the 25 clusters and compute an average per-VM recovery overhead of only 0.13%. Again for the 25 clusters, we find that Harvest VMs receive an average of 7.2 additional cores beyond the 1-core minimum.

With these parameters instantiated, we compute the cost per useful core of Harvest VMs in the 25 clusters to range from 34% to 47% cheaper than standard evictable VMs. On average, Harvest VMs are 42% cheaper at \$0.011/(core×hour). Figure 21 illustrates these costs. The fact that evictable VMs suffer many more evictions is a minor factor in these savings, since survival times are much larger than recovery times for both VM classes. Instead, the key reason for the large savings is the additional cores that can be harvested at discounted prices. When those cores are priced the same as the minimum size ($\alpha = 1$), there are almost no savings. When they are free ($\alpha = 0$), Harvest VMs cost \$0.003/(core×hour) on average across the clusters, *i.e.* a savings of 84%.

Compared to filling the unallocated capacity of the 25 clusters with 1-core regular VMs, Harvest VMs are 91% cheaper on average for $\alpha = 0.5$. Here, the heavily discounted nature of evictable cores dominates. Lower prices for the additional cores increase these savings, whereas charging the same price as for evictable/minimum cores lowers the savings to 85%.

8 Lessons from production deployment

Adapting applications and fast adoption. We initially thought that the main users of Harvest VMs would be those who could deploy lots of evictable VMs. However, after discussing with internal teams, we soon realized that their workloads could not benefit from additional cores without modification. This made adoption harder, despite the much lower price of Harvest VMs. Fortunately, many large users at the provider rely on the Hadoop stack, so we devised Harvest Hadoop. These users then immediately and transparently adopted Harvest VMs. We are now starting to adapt a FaaS platform and Kubernetes for Harvest VMs.

Harvesting without evictions. Other potential users were concerned about experiencing frequent evictions. They were the motivation for our SLOs. Still, some would prefer not to have any evictions. For them, we are considering regular-

priority Harvest VMs, which still have a (non-evictable) minimum size but can grow. For these VMs, the discount will apply only to the cores used beyond the minimum size.

Unbalanced Harvest VMs. Our current implementation only harvests cores, which may lead to VMs that cannot use some cores because their memory becomes too small. For example, some production VMs harvest 20 cores with only a fixed 16GB of memory. This imbalance is fine for some workloads but not others. Based on this, we started prototyping harvesting of unallocated memory. Another option is to define Harvest VM types with larger (fixed) memories, but that would make it harder to place them. The other resources have not posed imbalance problems so far.

Multiple Harvest VMs per server. Our implementation allows one Harvest VM per server because this works well for our initial (Hadoop) customers. However, to address the imbalance above and enable workloads that have less parallelism per VM, we are implementing the ability for users to specify a maximum size for each Harvest VM, and the fair sharing of a server’s unallocated cores across multiple Harvest VMs. Our models easily extrapolate to having multiple of them per server. We need to add the maximum size of each Harvest VM and the number of Harvest VMs in the cluster as features.

New VM family. We initially limited Harvest VMs to a few pre-defined sizes (Section 4). However, some users needed VMs with faster disks or a different hardware generation. So, we had to create new types. For this reason, we plan to make harvesting a feature that can be enabled for most VM types, instead of being a separate family.

Impact on regular VM creation times. Our initial implementation of core reassignments had the unexpected side-effect that regular VM creation could be slowed down significantly on servers that were already hosting many VMs. The problem only became noticeable when we started testing in the canary cluster. Fixing it involved using a different API to the hypervisor and made the overhead negligible.

9 Conclusion

In this paper, we first characterized the unallocated resources of a large cloud provider. We then proposed to dynamically harvest the unallocated resources using Harvest VMs. To provide SLOs for these resources, we built an accurate ML-based predictor for VM survival rates and average number of cores. To demonstrate the use of Harvest VMs, we built a cluster scheduling framework called Harvest Hadoop. Finally, we discussed the lessons and results from our production deployment of Harvest VMs and Harvest Hadoop in Azure.

Abstract

Web services rely on caching at nearly every layer of the system architecture. Commonly, each cache is implemented and maintained independently by a distinct team and is highly specialized to its function. For example, an application-data cache would be independent from a CDN cache. However, this approach ignores the difficult challenges that different caching systems have in common, greatly increasing the overall effort required to deploy, maintain, and scale each cache.

This paper presents a different approach to cache development, successfully employed at Facebook, which extracts a core set of common requirements and functionality from otherwise disjoint caching systems. *CacheLib* is a general-purpose caching engine, designed based on experiences with a range of caching use cases at Facebook, that facilitates the easy development and maintenance of caches. *CacheLib* was first deployed at Facebook in 2017 and today powers over 70 services including CDN, storage, and application-data caches.

This paper describes our experiences during the transition from independent, specialized caches to the widespread adoption of *CacheLib*. We explain how the characteristics of production workloads and use cases at Facebook drove important design decisions. We describe how caches at Facebook have evolved over time, including the significant benefits seen from deploying *CacheLib*. We also discuss the implications our experiences have for future caching design and research.

1. Introduction

Large web services rely on caching systems to achieve high performance and efficiency. For example, at Facebook, CDN caches serve 70% of web requests, reducing latency by an order of magnitude. A single caching server can replace tens of backend database servers by achieving 20× higher throughput and hit ratios exceeding 80%.

At Facebook, a wide variety of caching systems form an integral part of the system architecture. Facebook’s architecture includes CDN caches, key-value application caches, social-graph caches, and media caches (Figure 1). Caching plays a similar role at Amazon [26], Twitter [42, 92], Reddit [33, 89], and many other large web services.

Caching systems at Facebook. Historically, each caching system at Facebook was implemented separately. For example, Facebook separately designed CDN caches [86], key-value caches [72], social-graph caches [17], storage caches [71],

Figure 1: Large web services rely on caching in many subsystems to improve system performance and efficiency.

database caches [2], and many others. The belief was that each of these highly specialized systems required a highly specialized cache in order to implement complex consistency protocols, leverage custom data structures, and optimize for a desired hardware platform.

Although these caching systems serve different workloads and require different features, they share many important engineering and deployment challenges (Section 2). All of these systems process millions of queries per second, cache working sets large enough to require using both flash and DRAM for caching, and must tolerate frequent restarts due to application updates, which are common in the Facebook production environment. As the number of caching systems at Facebook increased, maintaining separate cache implementations for each system became untenable. By repeatedly solving the same hard engineering challenges, teams repeated each other’s efforts and produced redundant code. Additionally, maintaining separate caching systems prevented the sharing of efficiency gains from performance optimizations between systems.

Hence, Facebook was faced with a tradeoff between generality and specialization. A more general-purpose caching solution might lose some domain-specific optimizations for individual systems, but it could reduce development overhead and increase synergistic efficiency between systems. The desire to balance this tradeoff gave rise to *CacheLib*, the general-purpose caching engine.

This paper describes Facebook’s solution for scalable cache deployment: *CacheLib*. *CacheLib* is a C++ library that provides a common core of cache functionality, including efficient implementations of cache indexes, eviction policies, and stability optimizations for both DRAM and flash caches. *CacheLib* exposes its features via a simple, thread-safe API that allows programmers to easily build and customize scal-

Figure 2: The number of Facebook services built using CacheLib over time. For example, one service is Facebook’s key-value caching system. Initial growth was due to migration of existing systems, but more recently, many new systems are built using CacheLib.

able, highly concurrent caches. CacheLib is used both to build standalone caching systems and to add in-process caches to applications. Facebook’s CDN, social-graph cache, application look-aside cache, and block-storage system all use caches built and customized using CacheLib.

CacheLib has been deployed in production since 2017 and today powers over 70 different services. Figure 2 shows CacheLib’s growth during this period. Initially, CacheLib replaced existing caches, but since mid-2018 it has facilitated an explosive growth in caches throughout Facebook, leading to a significant reduction in backend load.

1.1. Lessons Learned from CacheLib

Developing an effective general-purpose caching framework has required not only understanding common caching use cases within Facebook, but also understanding more general trends in how caches will be deployed in the future. This section describes instances where the conventional wisdom about caching does not match our experience with Facebook’s production environment.

Specialized caching systems can and should be built using a general-purpose caching engine. At Facebook, CacheLib has replaced existing specialized caches in several major services and has spurred the adoption of caches in many new applications. CacheLib offers a broader feature set than any single specialized caching system. Having a common core of features saves tens of thousands of lines of redundant code, improves system stability, and makes it easy for developers to deploy and tune new caches. Moreover, CacheLib serves as an aggregation point for optimizations and best practices. As a result, systems built on CacheLib achieve peak throughputs of a million requests per second on a single production server and hit ratios between 60 and 90%. To achieve this performance, each caching system customizes its cache to use their desired subset of CacheLib’s features. To accommodate as many systems as possible, CacheLib’s feature set has grown over time. As a result, features that once justified the construction of a specialized caching system are now available to any CacheLib-based system.

Production workloads require caching at massive scale. Prior workload studies of production systems [4,5] have not shared the popularity distribution of keys. Consequently, pop-

ular benchmarking tools [24, 59] and academic papers [19, 36, 41, 49, 53, 65, 66, 68, 74, 90, 94] assume a Zipf popularity model with shape parameter $\alpha \approx .9$. This leads to the conclusion that DRAM-based caches are sufficient in most situations. We provide strong evidence that prior models have been too optimistic about the cacheability of production workloads.

Because workloads at Facebook are less cacheable than is generally assumed, caches at Facebook require massive capacities to achieve acceptable hit ratios. Caching systems at Facebook often comprise large distributed systems where each node has hundreds of gigabytes of cache capacity. This makes the use of flash for caching attractive. However, most caching systems have historically targeted DRAM and do not achieve acceptable performance using flash.

Caching is not a solved problem. CacheLib has continuously added features since its initial deployment in 2017 as new use cases and feature requests have come to light. These new features have seen rapid, widespread adoption from both existing CacheLib users and new systems developed using CacheLib, so that the common core of CacheLib features has grown with applications over time.

1.2. Bridging the Gap between Research and Production Caching Systems

Just as developers at Facebook had historically developed specialized caching systems, we note that the caching literature has often targeted specialized caching systems. This presents an obstacle to the uptake of ideas from the research community by industry, since the assumptions made by a specialized research system rarely align perfectly with the realities of a production environment. Our hope is that CacheLib can reduce these obstacles by providing a platform for the exploration of new ideas developed outside of Facebook. CacheLib and a selection of Facebook workloads will be open-sourced ¹.

2. Motivation: Caching Use Cases

Large web services rely on hundreds of specialized services, which contain diverse use cases for caching. This section describes the caching needs of a sample of six production systems at Facebook.

Hierarchical and geo-distributed caches. Facebook’s CDN focuses on serving HTTP requests for static media objects such as photos, audio, and video chunks from servers in user proximity. Specifically, a goal of CDN servers deployed outside of Facebook’s network is to reduce the number of bytes sent over the wide-area network (byte miss rate). There are also CDN servers within Facebook’s data centers; their goal is to reduce the number of backend and storage queries (object miss rate). Each CDN server uses a local cache, spanning both DRAM and flash.

Application look-aside caches. Web applications have a wide range of caching needs. For example, applications must cache database queries, user data, and usage statistics. Provid-

¹For more information, visit www.cachelib.org

ing a specialized caching service for each application would be inefficient and hard to maintain. Thus, applications use RPCs to access a set of shared caching services. Each caching service consists of a large distributed system of caches.

In-process caches. Many applications cannot tolerate the RPC overhead of a remote cache. CacheLib makes it easy for these applications to include high-performance, in-process caches that are decoupled from the application logic.

For example, some backend applications use a CacheLib cache to store client session information which is used to rate-limit clients. Specifically, these applications cache flow counters that see very high bursts in request rates but can be evicted once a flow slows down. In this case, the latency and bandwidth requirements of the cache make remote caches infeasible. Instead, applications instantiate a CacheLib cache which provides zero-copy access to cached flow counters.

Machine-learning-model serving systems. User-facing machine-learning applications benefit from caching in multiple places. First, models often use inputs based on how users interact with content (e.g., liking a piece of content). Content interaction counters are thus cached so applications can quickly access the inputs required to generate a prediction (e.g., ranking content). Second, because repeatedly generating predictions based on the same inputs is computationally expensive, model predictions are also cached.

Storage-backend cache. Facebook uses large clusters of servers with spinning disks to store blocks of persistent data. Even with several caching layers in front of the block storage servers, some blocks remain popular enough to exceed the target IOPS of the disks. Storage servers use flash drives to cache popular blocks and shield the spinning disks from load. To support byte-range requests and append operations, these flash caches are tightly integrated in the storage-system stack.

Database page buffer. Data structures and small objects are stored in a variety of database systems. Database systems use page caches to increase their throughput and decrease access latencies. To support consistency and transactional operations, page caches are tightly integrated with database logic.

Across Facebook, we find hundreds of different services which implement a cache or whose efficiency could benefit from a caching layer. These use cases span all layers of the data-center stack and administrative domains. Research on caching spans operating systems [16, 52], storage systems [20, 58], distributed systems [8, 22, 66], network systems [9, 65], databases [30], and computer architecture [7, 56, 91].

CacheLib handles these diverse use cases by providing a *library* of components that makes it easy to rapidly build performant caches. In many cases, CacheLib caches have replaced highly specialized caching systems at Facebook. CacheLib is currently used in dozens of production systems, spanning five of the six examples described above. Notably, CacheLib is not currently used as a database page buffer (see Section 6). Hence, while CacheLib will not replace every special-

Figure 3: Many services are hard to cache. Each graph plots the number of requests per object as a function of object popularity rank (log-log) for four production caching systems at Facebook. The green dashed line shows the best-fit Zipf distribution for each workload. Lower values of α indicate that a workload is harder to cache, hence *SocialGraph* and *CDN* are harder to cache. *Storage* is not Zipfian. Each sample consists of requests taken over 24 hours. The black dashed vertical lines along the x-axis show the cumulative size of the popular objects to the left of the line.

ized caching system, we have seen significant adoption of a general-purpose caching engine at Facebook.

3. Shared Challenges Across Caching Systems at Facebook

Despite the diversity of use cases for caching, our experience scaling and maintaining caching systems has revealed a set of core challenges that frequently overlap between use cases. This section describes the common challenges at Facebook.

The data in this section was gathered between December 2019 and May 2020 from 4 important workloads from a variety of caching use cases (Section 2). The *Lookaside* and *SocialGraph* systems are both from application-data caches. *Lookaside* is a service which provides on-demand caching to a variety of applications. *SocialGraph* is specifically used to cache information from the Facebook social graph. The *Storage* system is a storage backend cache, and *CDN* is a cache in Facebook’s CDN. Each workload represents the traffic to one machine within its respective service.

3.1. Massive Working Sets

One central challenge at Facebook is massive *working sets*. A working set describes the set of objects in a workload which are popular enough to benefit from caching. A workload with a larger working set requires a larger cache to produce the same hit ratio as a workload with a smaller working set.

To measure working sets, one must account for both the amount of popular data seen over time and the rate of change in the popularity of data over time. Therefore, we present both popularity distributions and churn rates at Facebook.

Popularity. The popularity distribution of a workload measures the frequency of each key over some time horizon

Figure 4: Object popularity changes rapidly over time. Each graph plots the probability that the top 10%-most-requested objects remain popular after x hours. Across all workloads, there is a significant drop off in popularity after even a single hour.

in a sampled trace. These frequencies indicate the relative popularity of different objects in the system. Prior measurements of CDN and web workloads indicate that highly-skewed Zipf distributions are a common popularity distribution [5, 14, 24, 38, 41, 48, 83, 85]. Informally, in a Zipf distribution “the most popular 20% of objects account for 80% of requests”. Formally, in a Zipf distribution the i -th most popular object has a relative frequency of $1/i^\alpha$. While some studies indicate α as low as 0.56 [38, 40], most prior measurements indicate $0.9 < \alpha \leq 1$ [5, 14, 24, 41, 48, 85]. This parameter range has become the standard evaluation assumption in many recent system papers [19, 36, 41, 49, 53, 65, 66, 68, 74, 90, 94].

Figure 3 shows the popularity distributions on log-log scale for four workloads at Facebook. At this scale, a Zipf distribution would be a straight line with negative slope ($-\alpha$). *Lookaside* is the only system of the four whose popularity distribution is Zipfian with α close to 1. *Storage*’s distribution is much flatter at the head of the distribution, even though the tail follows a Zipf distribution. Furthermore, although Zipfian, *SocialGraph* and *CDN*’s distributions exhibit $\alpha = 0.55$ and $\alpha = 0.7$, respectively. Lower α means that a significantly higher proportion of requests go to the tail of the popularity distribution, which leads to a larger working set.

Churn. *Churn* refers to the change in the working set due to the introduction of new keys and changes in popularity of existing keys over time. The popular YCSB [24] workload generator assumes that there is no churn, i.e., each key will remain equally popular throughout the benchmark. This benchmark and the no-churn assumption is used widely in the evaluation of system papers [19, 36, 49, 53, 65, 66, 68, 74, 90, 94].

In Facebook production workloads, we find a high degree of churn. We define an object to be *popular* if it is among the 10% of objects that receive the most requests. Figure 4 shows how the set of popular objects changes over time. For example, the blue bar at $x = 3$ shows the probability that an object which was popular 3 hours ago is still in the top 10%-most-requested objects. Across all workloads, over two-thirds of popular objects in a given hour fall out of the top 10% after

Figure 5: Object sizes vary widely and small objects are common. Distribution of value sizes for all four workloads. Object size is shown on the X-axis on a log scale. The Y-axis shows a complementary CDF – the fraction of requests for objects which are less than a given size. Object sizes are small in the *Lookaside* and *SocialGraph* workloads. *Storage* and *CDN* split objects greater than 64 KB and 128 KB, respectively, across multiple keys.

just one hour. Such high churn applies independent of which hour we use as the baseline, for different percentiles (e.g., top 25%), and with different time granularities (e.g., after 10 minutes, 50% of popular objects are no longer popular). This high churn rate increases the importance of temporal locality and makes it harder for caching policies to estimate object popularity based on past access patterns.

3.2. Size Variability

In addition to popularity and churn, object sizes play a key role in cache performance. Figure 5 shows the object size distribution for four large use case. For *Storage* and *CDN*, we find that 64KB and 128KB chunks, respectively, are very common, which result from dividing large objects into chunks. For *Lookaside* and *SocialGraph*, we find object sizes spanning more than seven orders of magnitude. Note the preponderance of small objects, which arise from graph edges/nodes, RPC computation results, and negative caching (see Section 4.3).

These findings restrict the design space for a general caching system. For example, many existing caching systems [3, 32, 35, 37, 70, 75, 79, 87] store at most a single object per cache line (64B). For a system such as *SocialGraph*, where a significant fraction of objects are between 10B and 20B, this approach wastes space. Another challenge is in-memory data structures which are used as an index for objects on flash. The per-object overhead differs across existing systems between 8B and 100B [32, 37, 70, 79, 86, 87]. For a system with a median object size of 100B, such as *Lookaside*, this means that 80GB - 1TB of DRAM is needed to index objects on a 1TB flash drive. It is imperative to handle highly variable object sizes while limiting memory and storage overhead.

3.3. Bursty Traffic

Another common theme is that Facebook’s traffic is quite bursty. Figure 6 shows the actual request arrival rate compared to a Poisson arrival sequence, which is often assumed in system evaluations [53, 66, 73, 74, 84]. Figure 6 shows that the actual arrival rate varies much more than Poisson suggests.

Figure 6: Requests are very bursty. Number of requests (blue) for every two minutes over the 2 hour horizon compared to a Poisson arrival sequence (orange) with the same mean number of arrivals. The two hour window covers the peak traffic time within a day for each service. CDN has particularly high short-term bursts.

This is particularly apparent for *CDN*, which has sharp bursts of traffic on top of a fairly steady request rate. Variable arrival rates make it hard to provision caching systems with sufficient resources to maintain low latencies during a load spike.

3.4. Resource Management

To be efficient, caches should make use of all available resources without exceeding them. This is particularly important for DRAM. A common deployment scenario includes CacheLib as well as application processes, and the kernel, all of which consume DRAM. As the workload composition or intensity changes, the memory available for caching can vary widely. For example, caches which handle variable-sized objects often have unpredictable levels of memory usage. Attempting to provision all available memory for caching can therefore lead to memory over-commitment, a well known challenge for in-process caches [78]. Specifically, a memory spike in the application might lead to the cache being dropped due to the kernel's out-of-memory (OOM) killer. Many open-source caching systems are not OOM-aware [87], leading to significant operational challenges [77]. CacheLib dynamically allocates and frees memory used by the cache to avoid these crashes without leaving too much unused memory.

3.5. Computationally Costly Query for Empty Results

Caching systems typically focus on tracking and storing results for valid backend queries. However, some use cases frequently send queries that have empty results, indicating that the requested object does not exist. This occurs often in database systems that track associations between users, where a user might query for the set of acquaintances they have in common with another user. Such queries are typically computationally costly for the backend database. For example, when querying the social graph, users frequently ask to see the set of associations they share with another user, and find that these associations do not exist. Hence, in *SocialGraph*'s workload, we measure that 55.6% of requests are for keys that do not exist. The remaining 44.4% of requests ask for valid objects, and the corresponding cache hit ratio among these

requests is 86.5%. Failure to cache empty results would thus lower the cache hit ratio significantly.

3.6. Updating Cached Data Structures

Caches should efficiently support structured data. This is particularly important for in-process caches that directly interact with application data structures. For instance, the rate limiter described in Section 2 stores multiple fields in a single cache object. Applications often want the ability to update specific fields in a cached data structure without deserializing, updating, and re-serializing the object.

3.7. Frequent Restarts

Finally, production caches frequently restart in order to pick up code fixes and updates. This happens because engineering teams require the ability not only to roll out new code quickly, but to roll back changes quickly as well. For example, 75% of *Lookaside* caches and 95% of *CDN* caches have an uptime less than 7 days. Even systems such as *Storage* and *SocialGraph* which have longer uptimes on average follow a regular monthly maintenance schedule which requires restarting cache processes. Most caching systems are transient, meaning that their content is lost upon application restart [37,55]. Transience is problematic because large caches take a long time to warm up. It would take hours or even days for cache hit ratios to stabilize following the restart of a transient cache at Facebook. Prior work has suggested the alternative of warming a cache after restart, but this requires an explicit warm-up phase as part of routing [33,72] or requires slow deployments [42].

3.8. Summary

While not every caching use case exhibits every challenge above, each use case does exhibit multiple of these challenges. We describe how CacheLib addresses these issues next in Section 4. The power of using a general-purpose caching engine to address these challenges is that all applications which use CacheLib have access to every CacheLib feature if and when it is needed.

4. Design and Implementation

CacheLib enables the construction of fast, stable caches for a broad set of use cases. To address common challenges across these use cases as described in Sections 2 and 3, we identify the following features as necessary requirements for a general-purpose caching engine.

Thread-safe cache primitives: To simplify programming for applications that handle highly bursty traffic, CacheLib provides a thread-safe API for reads, writes, and deletes. In addition, thread-safety simplifies the implementation of consistency and invalidation protocols. Concurrent calls to the CacheLib API leave the cache in a valid state, respect linearizability [47] if referencing a common key, and incur minimal resource contention.

Transparent hybrid caching: To achieve high hit ratios while caching large working sets, CacheLib supports caches composed of both DRAM and flash, known as *hybrid caches*.

Hybrid caches enable large-scale deployment of caches with terabytes of cache capacity per node. CacheLib hides the intricacies of the flash caching system from application programmers by providing the same byte-addressable interface (Section 4.1) regardless of the underlying storage media. This transparency allows application programmers to ignore when and where objects get written across different storage media. It also increases the portability of caching applications, allowing applications to easily run on a new hardware configurations as they become available.

Low resource overhead: CacheLib achieves high throughput and low memory and CPU usage for a broad range of workloads (Section 2). This makes CacheLib suitable for in-process use cases where the cache must share resources with an application. Low resource overheads allow CacheLib to support use cases with many small objects.

Structured items: CacheLib provides a native implementation of arrays and hashmaps that can be cached and mutated efficiently without incurring any serialization overhead. Caching structured data makes it easy for programmers to efficiently integrate a cache with application logic.

Dynamic resource monitoring, allocation, and OOM protection: To prevent crashes from temporary spikes in system memory usage, CacheLib monitors total system memory usage. CacheLib dynamically allocates and frees memory used by the cache to control the overall system memory usage.

Warm restarts: To handle code updates seamlessly, CacheLib can perform *warm restarts* that retain the state of the cache. This overcomes the need to warm up caches every time they are restarted.

4.1. CacheLib API

The CacheLib API is designed to be simple enough to allow application programmers to quickly build in-process caching layers with little need for cache tuning and configuration. At the same time, CacheLib must scale to support complex application-level consistency protocols, as well as zero-copy access to data for high performance. Choosing an API which is both simple and powerful was an important concern in the design of CacheLib.

The API centers around the concept of an *Item*, an abstract representation of a cached object. The *Item* enables byte-addressable access to an underlying object, independent of whether the object is stored in DRAM or flash. Access to cached *Items* is controlled via an *ItemHandle* which enables reference counting for cached *Items*. When an *ItemHandle* object is constructed or destroyed, a reference counter for the corresponding *Item* is incremented or decremented, respectively. An *Item* cannot be evicted from the cache unless its reference count is 0. If an *Item* with a non-zero reference count expires or is deleted, existing *ItemHandles* will remain valid, but no new *ItemHandles* will be issued for the *Item*.

Figure 7 shows the basic CacheLib API. To insert a new object into the cache, `allocate` may first evict another *Item*

```
ItemHandle allocate(PoolId id, Key key,
    uint32_t size, uint32_t ttlSecs = 0)
bool insertOrReplace(const ItemHandle& handle)
ItemHandle find(Key key)
void* Item::getMemory()
void* Item::markNvmUnclean()
bool remove(Key key)
```

Figure 7: The CacheLib API uses an *Item* to represent a cached object, independent of whether it is cached in DRAM or on flash.

(according to an eviction policy) as long as there are no outstanding *ItemHandles* that reference it. The new *Item* can be configured with an expiration time (TTL). It is created within the given memory “pool” (see below), which can be individually configured to provide strong isolation guarantees. Any new *Items* only become visible after an `insertOrReplace` operation completes on a corresponding *ItemHandle*.

To access cached *Items*, `find` creates an *ItemHandle* from a key, after which `getMemory` allows unsynchronized, zero-copy access to the memory associated with an *Item*. To atomically update an *Item*, one would allocate a new *ItemHandle* for the key they wish to update, perform the update using `getMemory`, and then make the update visible calling `insertOrReplace` with the new *ItemHandle*. Because CacheLib clients access raw memory for performance, CacheLib trusts users to faithfully indicate any mutations using the method `markNvmUnclean`. Finally, `remove` deletes the *Item* identified by a key, indicating invalidation or deletion of the underlying object.

```
struct MyType {int foo; char bar[10];}
TypedHandleImpl<Item, MyType> typedHandle{
    cache->find(..);}
```

Figure 8: Typed *ItemHandles* allow CacheLib to natively store structured objects. In addition to statically sized *Items*, CacheLib also supports variably sized *Items*. For example, CacheLib implements a hashmap that can dynamically grow, offer zero-copy access to its entries, and is treated as an evictable cache *Item*.

Figure 8 shows a simple example of CacheLib’s native support for structured data. Structured *Items* are accessed through a *TypedHandle*, which offers the same methods as an *ItemHandle*. *TypedHandles* enable low-overhead access to user-defined data structures which can be cached and evicted just like normal *Items*. In addition to statically sized data structures, CacheLib also supports variably-sized data structures; for example, CacheLib implements a simple hashmap that supports range queries, arrays, and iterable buffers.

CacheLib implements these APIs in C++, with binding to other languages such as Rust.

4.2. Architecture Overview

CacheLib is designed to be scalable enough to accommodate massive working sets (Section 3.1) with highly variable sizes (Section 3.2). To achieve low per-object overhead, a single

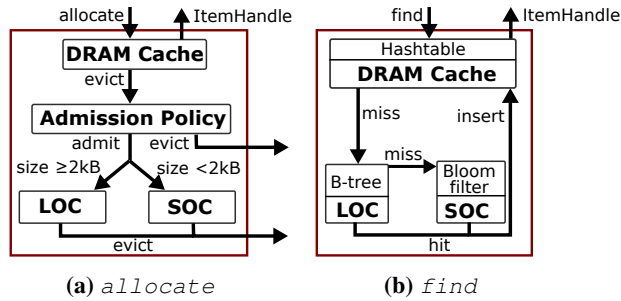

Figure 9: The *find* and *allocate* paths for a hybrid cache constructed using CacheLib.

CacheLib cache is composed of several subsystems, each of which is tailored to a particular storage medium and object size. Specifically, CacheLib consists of a DRAM cache and a flash cache. The flash cache is composed of two caches: the Large Object Cache (LOC) for items $\geq 2\text{KB}$ in size and Small Object Cache (SOC) for items $< 2\text{KB}$ in size.

An *allocate* request is fulfilled by allocating space in DRAM, evicting items from DRAM if necessary. Evicted items are either admitted to a flash cache (potentially causing another eviction) or discarded. A *find* request successfully checks for an object in DRAM, then LOC, then SOC. This lookup order minimizes the average memory access time [46] of the cache (see Appendix A). A *find* call returns an *ItemHandle* immediately. If the requested object is located on DRAM, this *ItemHandle* is ready to use. If the requested object is located on flash, it is fetched asynchronously and the *ItemHandle* becomes ready to use once the object is in DRAM. An empty *ItemHandle* is returned to signify a cache miss. These data paths are summarized in Figure 9.

We now describe CacheLib’s subsystems in more detail.

DRAM cache. CacheLib’s DRAM cache uses a chained hash table to perform lookups. The DRAM cache can be partitioned into separate *pools*, each with its own eviction policy. Programmers select a particular *PoolId* when calling *allocate* (see Figure 7), allowing the isolation of different types of traffic within a single cache instance.

For performance, cache memory is allocated using slab classes [6, 22, 37] which store objects of similar sizes. CacheLib uses 4MB slabs and implements a custom slab allocator. Each slab requires 7B of DRAM (3B of internal metadata + 4B to identify the size of objects in the slab). Because CacheLib workloads often include many objects of a specific size (e.g., 80B), the sizes corresponding to each slab class are configured on a per-workload basis to minimize fragmentation. Further optimizations for objects smaller than 64B or larger than 4MB are described in Section 4.3.

Each slab class maintains its own eviction policy state. CacheLib is designed to support the continual development of new eviction policies, and currently supports LRU, LRU with multiple insertion points, 2Q [54, 93], and TinyLFU [31]. These eviction policies differ in their overheads and their

Item Metadata	DRAM Overhead	Data Type
Eviction policy state	12B	1x4B timestamp, 2x4B pointers
Item creation timestamp	4B	4B timestamp
Expiration time (for TTLs)	4B	4B timestamp
Key size + object size	4B	4B <i>size_t</i>
Reference counting	2B	13b public ref count, 3b internal ref count
Hash table chaining	4B	4B pointer
Flags	1B	8 binary flags

Table 1: CacheLib’s DRAM cache uses 31B of metadata per item.

biases towards either recency or frequency, and are thus configured on a per-workload basis as well. To approximate a global eviction policy, memory is rebalanced between slab classes using known rebalancing algorithms [72]. To support these policies, among other features, CacheLib dedicates 31B of DRAM overhead per item. Table 1 describes the metadata which comprises this DRAM overhead.

To guarantee atomic metadata operations, CacheLib relies on a variety of known optimization techniques [35, 62, 64], including fine-grained locking, user-space mutexes, and C++ atomics. This is particularly important for eviction policies, where naive implementations lead to lock contention and limit throughput [6, 9, 10, 61]. For example, under LRU, popular items frequently compete to be reset to the most-recently-used (MRU) position. This is particularly common at Facebook due to our high request rates (see Figure 6). CacheLib adopts a simple solution to reduce contention: items that were recently reset to the MRU position are not reset again for some time T [9, 87]. As long as T is much shorter than the time it takes an object to percolate through the LRU list (i.e., eviction age), this simplification does not affect hit ratios in practice. CacheLib also uses advanced locking mechanisms such as flat combining [45] to reduce resource contention.

Flash cache. When items are evicted from the DRAM cache, they can optionally be written to a flash cache. Due to high popularity churn (Section 3), the content cached on flash changes continually. Hence, in addition to maintaining low per-object overhead, CacheLib must contend with the limited write endurance of flash cells.

To reduce the rate of writes to flash, CacheLib selectively writes objects to the flash cache. If an object exists on flash and was not changed while in DRAM, it is not written back to flash. Otherwise, CacheLib admits objects to flash according to a configurable admission policy. CacheLib’s default admission policy is to admit objects to the flash cache with a fixed probability p [57]. Adjusting the probability p allows fine-grained control over write rate to flash. Section 5 describes our experience with more complex admission policies.

Another consideration for flash endurance is *write amplification* which happens when the number of bytes written to the device is larger than the number of bytes inserted into the cache. For instance, CacheLib performs extra writes to

store metadata and is forced to write at block granularities. We distinguish between *application-level* write amplification, which occurs when CacheLib itself writes more bytes to flash than the size of the inserted object, and *device-level* write amplification, which is caused by the flash device firmware. CacheLib’s flash caches are carefully designed to balance both sources of write amplification and DRAM overhead.

The *Large Object Cache* (LOC) is used to store objects larger than 2KB on flash. Because LOC objects are larger than 2KB, the number of unique objects in a LOC will only number in the millions. It is therefore feasible to keep an in-memory index of the LOC. The LOC uses segmented B+ trees [23, 34, 63] in DRAM to store the flash locations of Items. Items are aligned to 4KB flash pages, so the flash location is a 4B, 4KB-aligned address. This allows the LOC to index up to 16TB of flash storage space.

The LOC uses flash to further limit the size of the DRAM index. Keys are hashed to 8B. The first 4B identify the B+ tree segment, and the second 4B are used as a key within in a tree segment to lookup a flash location. A hash collision in the DRAM index will cause CacheLib to believe it has found an object’s flash location. Hence, LOC stores a copy of each object’s full key on flash as part of the object metadata and validates the key after the object is fetched off flash. Each flash device is partitioned into regions which each store objects of a different size range. Hence, the object size can be inferred from where it is located on flash, without explicitly storing object sizes in DRAM. CacheLib can then retrieve the object via a single flash read for the correct number of bytes. To reduce the size of addresses stored in DRAM, every 4KB flash page stores at most a single object and its metadata. This is space-efficient because LOC only stores objects larger than 2KB. Objects larger than 4KB can span multiple pages. Because the LOC reads and writes at the page level, any fragmentation also causes application-level write amplification.

To amortize the computational cost of flash erasures, the LOC’s caching policy evicts entire regions rather than individual objects. (Region size is configurable, e.g., 16MB.) By default, FIFO is used so that regions are erased in strictly sequential order [60]. Writing sequentially improves the performance of the flash translation layer and greatly reduces device-level write amplification (see Section 5.2). If FIFO eviction evicts a popular object, it may be readmitted to the cache [86]. Alternatively, LOC supports a pseudo-LRU policy which tracks recency at region granularity. A request for any object in a region logically resets the region to the MRU position. Evictions erase the entire region at the LRU position.

The *Small Object Cache* (SOC) is used to store objects smaller than 2KB on flash. Because billions of small objects can fit on a single 1TB flash device, an exact lookup index (with associated per-object metadata) would use an unreasonably large amount of DRAM [32]. Hence, SOC uses an approximate index that scales with the number of flash pages.

SOC hashes keys into sets. Each set identifies a 4KB flash

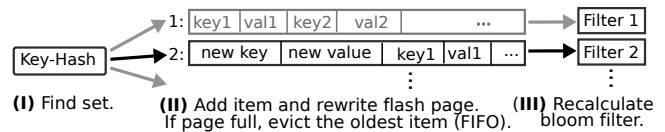

Figure 10: SOC *alloc* proceeds by hashing into sets (I). CacheLib then rewrites the page (II), possibly evicting an object (following FIFO order). Finally, CacheLib recalculates the bloom filter with the Items currently stored in this set’s 4KB page (III).

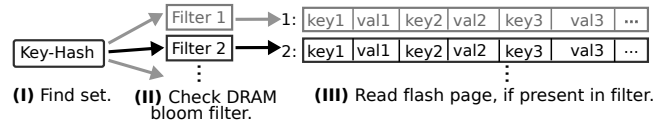

Figure 11: SOC *find* proceeds by hashing into sets (I) and then checking a bloom filter, which indicates whether an object is likely to be stored on flash (II). If the bloom filter does not contain the key, the object is definitely not present on flash. Otherwise, CacheLib reads the 4KB flash cache and searches for the key (III).

page which is used to store multiple objects. Objects are evicted from sets in FIFO order. A naive implementation of this design would always read a set’s page off flash to determine whether it contains a particular object. As an optimization, CacheLib maintains an 8B Bloom filter in DRAM for each set, each with 4 probes. This filter contains the keys stored on the set’s flash page and prevents unnecessary reads more than 90% of the time [11, 12]. Figure 10 shows the *alloc* path, and Figure 11 shows the *find* path.

Controlling write amplification in the SOC is particularly challenging. Admitting an object to the SOC requires writing an entire 4KB flash page, and is thus a significant source of application-level write amplification. This also applies to the *remove* operation, which removes an object from flash. Similarly, because keys are hashed to sets, admitting a stream of objects to the SOC causes random writes that result in higher device-level write amplification. Furthermore, the SOC only supports eviction policies that do not require state updates on hits, such as FIFO, since updating a set on a hit would require a 4KB page write. These challenges highlight the importance of advanced admission policies (see Section 5.2).

4.3. Implementation of Advanced Features

CacheLib supports many applications with demanding requirements. To support these applications efficiently, CacheLib implements several advanced features, making them available to all CacheLib-based services under the same, general-purpose CacheLib API. We describe the implementation of four important features: structured items, caching large and small objects, warm restarts, and resource monitoring, corresponding to challenges already discussed in Section 3.

Structured items. Because CacheLib provides raw access to cached memory, flat data structures can be easily cached using the CacheLib API. In addition, CacheLib natively supports arrays and maps. CacheLib supports an `Array` type for fixed-size objects at no additional overhead for each entry in the array. The `Map` type supports variable object sizes, and comes

in ordered and unordered variants. The overhead for each Map entry is 4B to store its size.

Caching large and small objects in DRAM. To store objects larger than 4MB in size, CacheLib chains multiple DRAM Items together into one logical large item. This chaining requires an additional 4B next pointer per object in the chain. The most common use case for large objects is the storage of structured items. While it is uncommon for a single, logical object to be larger than 4MB, we frequently see Arrays or Maps that comprise more than 4MB in aggregate.

CacheLib also features *compact caches*, DRAM caches designed to cache objects smaller than a cache line (typically 64B or 128B). Compact caches store objects with the same key size and object size in a single cache line [18, 29, 46, 80]. Compact caches are set-associative caches, where each cache line is a set which is indexed by a key’s hash. LRU eviction is done within each set by repositioning objects within a cache line. Compact caches have no per-object overhead.

One prominent example of using compact caches is CacheLib’s support for *negative caching*. Negative cache objects indicate that a backend query has previously returned an empty result. Negative cache objects are small, fixed-size objects which only require storing a key to identify the empty query. As discussed in Section 3.5, negative caching improves hit ratios drastically in *SocialGraph*. Negative caching is not used by *Lookaside*, *Storage*, or *CDN*, but it is employed by 4 of the 10 largest CacheLib-based systems.

Both of these features reinforce CacheLib’s overarching design, which is to provide specialized solutions for objects of different sizes in order to keep per-object overheads low.

Dynamic resource usage and monitoring. CacheLib monitors the total system memory usage and continuously adapts the DRAM cache size to stay below a specified bound. CacheLib exposes several parameters to control the memory usage mechanism. If the system free memory drops below `lowerLimitGB` bytes, CacheLib will iteratively free `percentPerIteration` percent of the difference between `upperLimitGB` and `lowerLimitGB` until system free memory rises above `upperLimitGB`. A maximum of `maxLimitPercent` of total cache size can be freed by this process, preventing the cache from becoming too small. Although freeing memory may cause evictions, this feature is designed to prevent outright crashes which are far worse for cache hit ratios (see Figure 15). As system free memory increases, CacheLib reclaims memory by an analogous process.

Warm restarts. CacheLib implements warm restarts by allocating DRAM cache space using POSIX shared memory [76]. This allows a cache to shut down while leaving its cache state in shared memory. A new cache can then take ownership of the cache state on start up. The DRAM cache keeps its index permanently in shared memory by default. All other DRAM cache state is serialized into shared memory during shutdown. The LOC B-tree index and SOC Bloom filters are serialized and written in a dedicated section on flash during shutdown.

Figure 12: A comparison of CacheLib to Memcached for a range of cache sizes. CacheLib and Memcached achieve similar hit ratios, but CacheLib achieves much higher throughput.

5. Evaluation

In evaluating CacheLib, we aim to show that CacheLib’s API and feature set is flexible enough to implement common use cases both inside and outside Facebook. Specifically, we show that CacheLib-based systems can easily achieve performance that is competitive with specialized solutions without requiring any specialization of the core caching engine. We also show how CacheLib’s widespread adoption has had a significant impact on the Facebook production environment.

5.1. System Comparisons

We drive our experiments using *CacheBench*, the cache benchmarking tool that ships with CacheLib. For the sake of comparison, we extend CacheBench to target an in-process version of Memcached [37], as well as HTTP proxy (CDN) caches.

CacheBench provides a modular request generator by sampling from configurable popularity, key size, and object size distributions. To emulate churn, CacheBench continuously introduces new keys at a configurable rate. We instantiate these parameters from the measurements for the application look-aside and CDN use cases presented in Section 3.

Application look-aside cache. Before CacheLib was developed, several teams at Facebook used an internal variant of Memcached as a look-aside cache. However, applications now use a CacheLib-based look-aside cache. We therefore compare CacheLib to a minimally changed Memcached v1.6.6, which is the latest version and incorporates many recent optimizations. For fairness, we configure CacheLib and Memcached to both use their implementations of LRU eviction. To implement the look-aside pattern, CacheBench configures CacheLib to implement a “set” as an `allocate` followed by `insertOrReplace` and a “get” by `find` and a subsequent access to the `ItemHandle`’s `getMemory` method.

We evaluate CacheLib and Memcached on a range of cache sizes using 32 threads each. When the cache is small, the hit ratio is low, which stresses the eviction code paths (set operations). When the cache is large, the hit ratio is high, which stresses the LRU-head update code paths (get operations).

Figure 12 shows the hit ratios and throughputs for cache sizes between 8 and 144GB and a typical working set of 100 million objects. Memcached and CacheLib achieve similar hit

Figure 13: Comparison of CacheLib to ATS and NGINX HTTP flash caching systems for different object sizes. CacheLib significantly improves throughput for most object sizes.

ratios, with Memcached slightly higher at small cache sizes and slightly lower at large cache sizes. Across all cache sizes, CacheLib achieves higher throughputs than Memcached, processing up to 60% more requests per second than Memcached.

CacheLib’s higher throughput is largely due to optimizations that reduce lock contention. For example, CacheLib uses flat combining (see Section 4.2) to reduce contention on the LRU list head. Also, CacheLib uses $T = 60$ seconds (see Section 4.2) in this experiment. For $T = 10$ seconds, CacheLib consistently outperforms Memcached’s hit ratio, at the cost of lower throughput. In production, most deployments use the default $T = 60$ seconds.

HTTP server cache. Hybrid DRAM-flash caches are prevalent at Facebook. For example, hybrid caches are used as CDN proxy caches. We compare a CacheLib-based HTTP server cache to NGINX and Apache Traffic Server (ATS), which are widely used to build flash-based CDNs [1, 44, 69, 82]. The CacheLib implementation is a FastCGI server with an NGINX frontend. Each system uses its default configuration for a 512GB flash cache. The systems fetch misses from a high-performance origin backend that is never the bottleneck.

To illustrate the effect of object size on flash cache performance, we configured all object sizes to be equal and then repeated the experiment for a range of object sizes. To keep hit ratios constant across trials, we adjusted the number of unique objects to maintain a constant working set size.

Figure 13 shows that CacheLib’s explicit handling of small objects for flash caching provides a sizable advantage over NGINX and ATS. As the object size becomes larger, this advantage wanes. Eventually object sizes become large enough that all three systems become network-bound and their throughputs drop precipitously.

We observe that NGINX performs particularly well when object sizes are between 4KB and 16KB, outperforming CacheLib slightly when objects sizes are 8KB. We were unable to pinpoint the cause of this trend. Nonetheless, CacheLib compares favorably to both NGINX and ATS across a wide range of object sizes.

LSM tree-based stores. It is natural to ask whether existing storage systems that target flash devices could be used as flash caching systems. In particular, Facebook’s RocksDB [13] key-value store provides hybrid DRAM and flash storage by using

a Log-Structured Merge-Tree (LSM Tree). We investigated whether RocksDB could be used as a hybrid look-aside cache for application data by deploying RocksDB in production to cache data from the *SocialGraph* workload.

RocksDB trades off higher space usage in favor of lower write and delete latencies, using tombstones to defer deletes operations until compaction time [13]. However, most compaction methods are computationally expensive and must be done sparingly. It is therefore infeasible to use RocksDB’s Delete method to perform targeted evictions of objects, since compaction does not happen frequently enough for deletes to control the flash footprint of the cache. If RocksDB fills a flash device, it begins failing write and delete operations. This is particularly problematic in the *SocialGraph* system, which relies on deletes to maintain cache consistency. If a *SocialGraph* cache fails a certain number of deletes, the policy is to perform a cold restart (see Figure 15) to restore consistency.

As an alternative, we tested RocksDB using FIFO compaction, which simply evicts the oldest data when the size of the store exceeds its desired size. This compaction method is lightweight enough to run constantly and effectively limit RocksDB’s flash usage. Evicting the oldest data will tend to evict the least recently *updated* objects, but these are generally not the same as the least recently *used* objects. RocksDB does not provide facilities for tracking which blocks contain recently used objects. Due to its simple eviction policy, RocksDB achieved only a 53% hit ratio compared to CacheLib’s 76% hit ratio when tested with a production *SocialGraph* workload. Additionally, RocksDB under FIFO compaction suffers from severe read amplification and thus required 50% higher CPU utilization than CacheLib in order to meet production throughput levels. Hence, although some of the principles of LSM tree-based solutions can be carried over to the design of flash caches, we conclude that RocksDB itself is not suitable for caching at Facebook.

5.2. Characterizing CacheLib in Production

We quantify the impact that CacheLib has had on the Facebook production environment by considering the notable caching improvements that CacheLib has introduced.

DRAM overhead. By design, the DRAM overheads of the LOC and SOC are small; in production we measure less than 0.1% and 0.2%, respectively. The DRAM Cache has generally low ($< 7\%$) overhead. There are two main sources of DRAM overhead: slab class fragmentation and metadata overhead (Section 4.2). Tuning CacheLib’s slab classes is crucial to limit fragmentation. Tuning currently happens manually. Without tuning, fragmentation overhead would more than double in many clusters. Unfortunately, we are not aware of automated tuning algorithms for slab-class boundaries². A detailed analysis of DRAM overhead appears in Appendix B.

²Prior work has considered how to partition cache space between fixed slab classes [22] but not how to optimally define boundaries in the first place. Conceptually, this problem resembles the facility placement problem on a line [15], but we are not aware of optimal algorithms.

Flash endurance. CacheLib is designed to limit the rate of writes to flash in order to prolong flash device lifetimes (see Section 4.2). We now evaluate the effectiveness of this design.

The LOC incurs application-level write amplification due to fragmentation from the use of 4KB pages and size classes. Fragmentation is generally small, but *Storage* and *CDN* caches have 4.9% and 7% fragmentation overhead, respectively. To further reduce write amplification, CacheLib has recently introduced a new feature which buffers all writes to a region before flushing it to disk. This allows the application to write in sizes aligned to as low as 512 bytes, reducing fragmentation in *CDN* caches from 7% to 2%.

The LOC’s use of FIFO eviction instead of LRU allows CacheLib to write to flash sequentially. Writing sequentially reduced device-level write amplification from $1.5\times$ to $1.05\times$ at the expense of slight increase in application-level write amplification. The net effect was a 15% reduction in the number of NAND writes to the flash device per second.

The SOC incurs application-level write amplification due to always writing 4KB (even as object sizes $< 2\text{KB}$). On average, we measure this to be around $6.5\times$ the number of inserted bytes. The SOC also incurs significant device-level write amplification from writing random 4KB pages [43]. We measure this overhead to be between $1.1\times$ (for *Lookaside*) and $1.4\times$ (for *Storage*) depending on the workload.

To achieve these levels of device-level write amplification, flash is typically overprovisioned by 50%. This overprovisioning is offset by the space efficiency of the SOC and the low cost of flash relative to DRAM, but reducing flash overprovisioning while maintaining the current level of performance is an open challenge at Facebook.

To further limit the number of bytes written to a flash device, CacheLib uses admission policies for flash caches. The default CacheLib admission policy, which admits objects with a fixed probability, prolongs flash device lifetimes, but also decreases hit ratios by rejecting objects at random. CacheLib also includes *reject first* admission policies, which reject objects the first n times they are evicted from DRAM.

Recently, CacheLib was updated to include a more advanced admission policy, similar to the *Flashshield* policy proposed in [32], which makes flash admission decisions by trying to predict an object’s future popularity. Flashshield’s predictions are based on how many hits an object receives while in DRAM. At Facebook, however, many objects do not stay in DRAM long enough to get multiple hits. Thus, CacheLib implements efficient tracking of object request frequencies beyond their DRAM-cache lifetimes. These frequencies are then used to predict how many hits an object would receive if admitted to flash. Our experience with this advanced admission policy is described in detail in Appendix C. The advanced admission policy reduced the rate of writes to flash by 44% in *SocialGraph* without decreasing hit ratios.

Hit ratios. CacheLib’s DRAM cache initially used a variant of the LRU eviction policy. A notable improvement in hit

Figure 14: Distribution of hit ratios for servers in the top four CacheLib users during a typical day.

Figure 15: *SocialGraph* L1 cache (left) and L2 cache (right) hit ratios during a cache restart. Hit ratios suffer when warm restarts are disabled.

ratios across systems occurred when we deployed a 2Q-based eviction policy [54]. For example, the hit ratio for *SocialGraph* caches increased by 5 percentage points and the hit ratio for *CDN* caches increased by 9 percentage points.

An even larger improvement in hit ratios resulted from the deployment of high-capacity hybrid DRAM-flash caches. Services requiring massive cache capacities generally consist of a two-layer hierarchy where “L1” DRAM-only cache forward misses to “L2” hybrid DRAM-flash caches. To see the improvement due to hybrid caches, we compare *SocialGraph*’s L2 caches from a deployment which uses hybrid caches to *SocialGraph*’s L2 caches from a deployment which still uses DRAM-only caches. The DRAM-only L2 caches for *SocialGraph* currently achieve a 25% hit ratio. The hybrid-cache L2 offers $20\times$ more cache capacity, achieves a 60% hit ratio, and costs 25% less than the DRAM-only deployment.

Figure 14 shows hit ratio distributions for L1 and L2 caches for *Lookaside*, *SocialGraph*, and *CDN* clusters, some of the largest CacheLib deployments. L1 caches achieve much higher hit ratios than L2 caches, with median hit ratios ranging from 75% (*CDN*) to 92% (*SocialGraph*) while median L2 cache hit ratios range from 67% (*CDN*) to 75% (*SocialGraph*). The combined hit ratios of these systems are very high: ranging between 95-99%.

Impact of warm restarts. Figure 15 shows the hit ratios of L1 and L2 *SocialGraph* caches restarting without performing a warm restart. Without this feature enabled, a cache restart causes a dip in hit ratio, which slowly returns to normal. This is particularly damaging in L2 hybrid caches where large-capacity caches can take several days to “warm-up”. Such a hit ratio dip can translate into temporary overload on backend systems, which assume a relatively stable arrival rate.

6. Experience and Discussion

Facebook's experience with CacheLib reveals a great deal about the trajectory of modern caching systems.

New features are adopted by many systems. One might expect that many CacheLib features end up being suitable for only a small number of services. However, our experience shows a trend in the opposite direction: *features developed for one particular service are frequently adopted by many other CacheLib-based services*. For example, hybrid caches and efficient object expirations (TTLs), were both added after the initial deployment of CacheLib. Today, hybrid caches are used by five large CacheLib use cases. Object expirations were originally added to enforce fair sharing in look-aside caches, but were later adopted by CDN caches, which need to refresh static content periodically. Nevertheless, not every feature is used by every system. Using a general-purpose caching engine is not equivalent to developing a single, one-size-fits-all approach to caching. Instead, we aim to benefit from extracting common caching functionality while still allowing a high degree of flexibility for cache customization.

Performance improvements help many systems. Even small performance improvements in CacheLib (see Section 5.2) have an outsized impact due to the broad deployment of CacheLib-based systems at Facebook. Deploying new features typically involves a simple code update or configuration change. The ability to make centralized improvements motivates a continuous effort to optimize the CacheLib code base. For example, while writing this paper, the LOC index implementation (see Section 4) changed to use a new sparse hashmap implementation, lowering CPU utilization by 0.5% with no change in memory overhead. While a 0.5% CPU decrease in a single system may not be worth the development cost, a 0.5% decrease across all of Facebook's hybrid caches amounts to a massive resource savings. This highlights the advantage of a common engine over specialization.

Improved stability. Another benefit of a common caching engine is improved stability due to the reduction of previously disjoint implementations to a single mature, well-tested platform. As new systems are built, using CacheLib greatly reduces the number of new lines of code that must be introduced into the production environment. This reduces the potential for production incidents and outages. CacheLib also provides explicit mechanisms for stability informed by years of experience deploying caches in the production environment.

No single caching system dominates. One can ask whether it might be sufficient to focus CacheLib engineering efforts on accommodating a small set of use cases instead of deploying CacheLib widely. To answer this question, we compare the total amounts of DRAM cache used by each system³. Figure 16 shows that the top ten users account for 89% of all DRAM cache usage, but no single service dominates. For example, the top two services account for only 25% and

20% of DRAM usage, respectively. Hence, unless CacheLib can accommodate many diverse use cases, the overall gains from optimizing CacheLib would be limited.

Figure 16: A wide range of Facebook services are built using CacheLib. We measure a service's deployment size in terms of its total DRAM cache size. No service has more than 25% of the total cache space across Facebook services.

Flash caching signals a paradigm shift. One might think that cache hit ratios are generally high, and hence expect little benefit from the additional cache capacity afforded by flash. While this is true in some cases, high hit ratios do not always imply that additional cache capacity is futile. Specifically, engineers provision caches to equalize the marginal cost of the next byte of DRAM with the marginal benefit of the ensuing increase in hit ratio. Flash caches alter this cost calculation, lowering the marginal cost of additional cache capacity by an order of magnitude. This makes it worthwhile to not only increase cache capacities dramatically, but to deploy new hybrid caches that did not make sense with DRAM alone.

Additionally, the benefit of a cache hit is no longer strictly a latency proposition for most systems. While a classical view of caching suggests that caching is only worthwhile if it reduces average memory access time [46], this ignores the knock-on effects of a cache miss such as increased network congestion, backend load, and backend power usage. From this perspective, a cache hit in flash is as valuable as a DRAM hit, even though flash is several orders-of-magnitude slower than DRAM. This again tips the scales of the marginal cost calculation in favor of deploying flash caches.

CacheLib does not always lead to performance gains. CacheLib-based systems have not always outperformed the specialized systems they replaced from the outset. For example, the first CacheLib-based implementation of the CDN system was not able to match the performance of the original CDN system, which optimized for flash caching by implementing advanced eviction policies with low flash write rates. The first CacheLib-based implementation of CDN achieved a 10% lower hit ratio and 20% higher flash write rate than the specialized system in testing.

Before the CacheLib-based implementation of CDN was deployed, optimizations were added to CacheLib to improve the hybrid caching mechanism. The LOC eviction policy was expanded from pure FIFO eviction to include a readmission policy which can readmit frequently requested objects when they are evicted. Write buffers were also added between the DRAM and flash caches. These buffers reduce application-level write amplification by reducing the internal fragmentation due to 4KB aligned writes. The write buffers also allow CacheLib to issue fewer, larger writes to flash, which reduces device-level write amplification.

³Not all services use hybrid caches, especially throughput-focused L1 caches.

The improved LOC eviction policy achieved a hit ratio close to that of the specialized system while performing 10% fewer writes to flash than the specialized system. Both of these optimizations add almost no overhead if turned off, and ended up improving the performance of other CacheLib-based systems as well. *Lookaside*, for example, saw a 25% reduction in P99 flash read latency, and a 2% reduction in flash write rate after these changes.

The CDN example illustrates the common case in balancing the generalization-versus-specialization tradeoff: CacheLib does not always address the needs of every use case from the outset. However, the features needed by specialized systems are often not fundamentally incompatible with the design of CacheLib. If one is willing to invest time into building the necessary features into CacheLib, they will gain access to CacheLib's full feature set while exporting new optimizations to the rest of the Facebook's caching systems.

CacheLib does not work for every use case. Although CacheLib handles many use cases, we are aware of limitations that have prevented some from adopting CacheLib. For instance, some ad-serving systems rely on caching *nested* data structures. In order to control its memory usage and quickly serialize *Items* from DRAM into flash, CacheLib only supports data structures that map into a flat address space. These ad-serving systems were thus unable to adopt CacheLib.

Another example is RocksDB, which wanted to use CacheLib to implement its internal page buffer. CacheLib's C++ API leverages object constructors and destructors to perform reference counting for *ItemHandle* objects. This ultimately prevented programmers from integrating CacheLib with RocksDB's C-style code base. However, the ease of automatic reference counting has led to widespread adoption of CacheLib for C++- and Rust-based use cases.

7. Related Work

There is vast body of research on caching systems including in-depth descriptions of individual production caches. We review prior work from industry and academia relevant in the context of web and data center caches.

Production caching systems. Caching systems are found within many major web services. Akamai's geo-distributed CDN [9, 28, 39, 67, 81, 85], Microsoft's web caching systems [8], Amazon's use of aggregation caches [26], and Facebook's many individual caching systems [5, 48, 71, 72, 86] are all documented in the literature. Similarly, Twitter [42, 92] and Reddit [33, 89] frequently talk about their DRAM caches based on open-source caching systems. CacheLib addresses a superset of the challenges faced by these individual systems, providing a single, general-purpose caching engine.

Research caching systems. Academic research has considered optimizing many different aspects of caching systems. These include building highly concurrent systems [6, 9, 35, 62, 64] and improving hit ratios [6, 9, 10, 21, 50, 51, 61, 88]. Facebook's goal is to use CacheLib as a platform to more

easily evaluate and deploy systems based on this research.

While the literature mainly focuses on DRAM caching, there is some prior work on flash caching [32, 57, 60, 86]. CacheLib incorporates ideas from [86] and [60] to reduce write amplification by doing FIFO eviction on flash. Likewise, CacheLib includes the admission policy of [57] and a variant of the admission policy from [32] (see Appendix C).

Although dynamic cache partitioning is possible in CacheLib, the impact of existing research on cache partitioning policies is limited at Facebook. Partitioning can be used to eliminate performance cliffs in a cache's hit ratio as a function of size [7, 22, 88], but performance cliffs are not a major issue at Facebook. As the authors of RobinHood [8] note in their work, the RobinHood partitioning scheme is limited when infrastructure is shared between different backend systems, which is the case at Facebook. Additionally, the computational overhead of retrieving the size of objects stored on flash is too high to use size-aware sharding [27] in practice.

8. Conclusions

Caching is an important component of modern data-center applications, and this paper has only scratched the surface of its many challenges and opportunities. CacheLib shows that it is feasible to build a general-purpose caching engine to address a wide variety of caching use cases. In sharing our experience of building and deploying CacheLib, we hope to solicit ideas and feedback from the growing community of caching researchers and to encourage other production systems to share their architectures and workloads. We hope that CacheLib will serve as an aggregation point for best practices in industry and academia, enabling a continual improvement in performance and facilitating the deployment of caches in many new applications. There are many exciting directions to explore in future caching systems, including (i) better resource-management policies (e.g., eviction/admission policies, memory management); (ii) emerging hardware platforms (e.g., FPGA acceleration, non-volatile memories, zoned-namespace SSDs); and (iii) novel application features (e.g., as seen in negative caching). We look forward to growing CacheLib to address these challenges and many others.

Appendix

A. Cache Lookup Order and Latency

CacheLib uses the lookup sequence 1) DRAM cache, 2) LOC, 3) SOC. Note that an object's size is not known in advance. So, after a DRAM cache miss, CacheLib does not know whether the object is stored in the LOC or the SOC. Thus, it has to query one of them first, and on a miss, query the other.

The order for CacheLib's lookup order is motivated by the following analysis of average lookup penalties (also known as average memory access time, AMAT [46]). We consider the lookup penalty for each cache component as the time to determine that an object is not cached in this component. Our key assumption is that reading from DRAM is orders of magnitude faster than flash reads (e.g., 100ns compared to

16us [25]). Thus, the lookup penalty for the DRAM cache is a few memory references (say 500ns).

To calculate the penalty for the LOC, recall that the LOC stores neither an object’s key nor the object’s exact size in memory to reduce DRAM metadata overhead. The LOC is indexed via 4-byte hash-partitioned B-trees, which each use 4-byte hashes to identify an object’s offset. If the overall 8-byte-hash does not have a hash collision, then the LOC’s lookup penalty constitutes a few memory references (say 1us, due to hash operations). If there is a hash collision, the LOC requires a flash read (16us) to compare the object key and determine the miss status. Assuming the smallest LOC object size (2KB) and 1TB of flash, at most 536 million objects are stored in the LOC. Thus, the probability of an 8-byte-hash collision can be calculated to be less than one in a million and the LOC’s average lookup penalty is slightly more than 1us.

To calculate the penalty for the SOC, recall that the SOC does not use an in-memory index. The SOC uses a per-page Bloom filter (say 1us) to opportunistically determine the miss status. However, as these Bloom filters are small, their error rate is 10%. In case of a Bloom filter error, the SOC requires a flash read (16us) to compare the object key. The SOC’s average lookup penalty is thus 2.6us.

The average latency (AMAT) of CacheLib with the default order (1) DRAM cache, (2) LOC, (3) SOC is as follows, where L denotes lookup latency and H hit ratio: $L(\text{DRAM}) + (1 - H(\text{DRAM})) \times (L(\text{LOC}) + (1 - H(\text{LOC})) \times L(\text{SOC}))$. With the order of SOC and LOC inverted, the average latency would increase by several microseconds, depending on the LOC and SOC hit ratios. Thus CacheLib queries the SOC last.

B. Details on DRAM Overheads

DRAM Cache. We measure CacheLib’s DRAM cache overhead as the ratio between its total memory footprint and the sum of cached key and value sizes. We further break up overheads into slab-class fragmentation and metadata. Across *Lookaside*, *Storage*, and *SocialGraph*, we find that overall overheads are between 2.6 and 7% and evenly divided between fragmentation and metadata.

	<i>Lookaside</i>	<i>Storage</i>	<i>SocialGraph</i>
Fragmentation	3.9%	3%	1.6%
Metadata	3%	4%	1%
Overall overhead	6.9%	7%	2.6%

Large Object Cache. Recall that, while the LOC uses an 8-byte hash, 4-bytes are used to partition B-tree and thus do not need to be counted. So, the LOC stores 4-bytes for key hashes, 4-bytes for flash offsets, and an average of 2.5-bytes per item for B-tree pointers. For the small LOC object, this is 0.61%. In production systems, this overhead is low and ranges from to 0.01% (*Storage*) to 0.1% (*Lookaside*).

C. Advanced Admission Policies for Flash

One significant challenge in using flash for caching is respecting the limited write endurance of flash devices. If all DRAM evictions in a hybrid cache were admitted to flash, we would observe write rates 50% above the rate which allows flash devices to achieve their target life span. A flash admission policy thus plays an important role in CacheLib’s performance.

Flashield [32] is a recently proposed flash admission policy. Flashield relies on observing an object as it traverses the DRAM portion of a hybrid cache. When an object is evicted from DRAM, Flashield makes a flash admission decision based on how often the object was accessed while in DRAM.

Unfortunately, DRAM lifetimes at Facebook are too short for Flashield to be effective. A significant number of objects are popular enough to produce hits if stored on flash, but do not receive DRAM cache hits. In fact, for an L2 *Lookaside* cache, only 14% of objects being considered for flash admission have received either a read or a write while in DRAM.

To adapt the main idea behind Flashield to Facebook’s environment, CacheLib explicitly gathers features about objects beyond their DRAM-cache lifetime. We use Bloom filters to record the past six hours of accesses⁴. Additionally, we change the admission policy’s prediction metrics from the abstract notion of “flashiness” to instead directly predict the number of reads an object is expected to receive in the future.

Our advanced admission policy was trained and deployed in production for *SocialGraph*. The default admission policy for CacheLib flash caches is to admit objects with a fixed probability that keeps flash write rates below a target rate in expectation. Compared to this default admission policy, the advanced admission policy wrote 44% fewer bytes to the flash device without decreasing the cache hit ratio. Hence, while training the models required for the advanced admission policy can be cumbersome, this policy gain significantly extend the lifetime of flash devices in production.

We also thank the members and companies of the PDL Consortium (Alibaba, Amazon, Datrium, Facebook, Google, HPE, Hitachi, IBM, Intel, Microsoft, NetApp, Oracle, Pure Storage, Salesforce, Samsung, Seagate, Two Sigma and Western Digital) and VMware for their interest, insights, feedback, and support.

⁴Specifically, we are using 6 Bloom filters, each set to hold 1 hour of accesses. Each hour, the oldest Bloom filter is reset and used to track the upcoming hour. These Bloom filters are configured for 0.02% false positives at maximum observed query rate. The space efficiency of Bloom filters is necessary to avoid using up too much DRAM - using 8 bytes per stored key to store history would be too much space overhead.

Facebook Inc.

Abstract

We present *Twine*, Facebook’s cluster management system which has been running in production for the past decade. Twine has helped convert our infrastructure from a collection of siloed pools of customized machines dedicated to individual workloads, into a large-scale shared infrastructure with fungible hardware.

Our goal of ubiquitous shared infrastructure leads us to some decisions counter to common practices. For instance, rather than deploying an isolated control plane per cluster, Twine scales a single control plane to manage one million machines across all data centers in a geographic region and transparently move jobs across clusters.

Twine accommodates workload-specific customization in shared infrastructure, and this approach further departs from common practices. The *TaskControl* API allows an application to collaborate with Twine to handle container lifecycle events, e.g., restarting a ZooKeeper deployment’s followers first and its leader last during a rolling upgrade. *Host profiles* capture hardware and OS settings that workloads can tune to improve performance and reliability; Twine dynamically allocates machines to workloads and switches host profiles accordingly.

Finally, going against the conventional wisdom of prioritizing stacking workloads on big machines to increase utilization, we universally deploy power-efficient small machines outfit with a single CPU and 64GB RAM to achieve higher performance per watt, and we leverage autoscaling to improve machine utilization.

We describe the design of Twine and share our experience in migrating Facebook’s workloads onto shared infrastructure.

1 Introduction

The advent of computation as a utility has led organizations to consolidate their workloads onto *shared infrastructure*, a common pool of resources to run any workload. Cluster management systems help organizations utilize shared infrastructure effectively through automation, standardization, and

economies of scale. Cluster management systems have made large progress in the past decade, from Mesos [17], Borg [39], to Kubernetes [23]. Existing systems, however, still have limitations in supporting large-scale shared infrastructure:

1. They usually focus on isolated clusters, with limited support for cross-cluster management as an afterthought. These silos may strand unused capacity in clusters.
2. They rarely consult an application about its lifecycle management operations, making it more difficult for the application to uphold its availability. For example, they may unknowingly restart an application before it has built another data replica, rendering the data unavailable.
3. They rarely allow an application to provide its preferred custom hardware and OS settings to shared machines. Lack of customization may negatively impact application performance on shared infrastructure.
4. They usually prefer big machines with more CPUs and memory in order to stack workloads and increase utilization. If not managed well, underutilized big machines waste power, often a constrained resource in data centers.

These limitations can lead to underdelivery of the promise of shared infrastructure: (1) artificially caps the sharing scope to one cluster; (2) & (3) highlight the tension between shared infrastructure’s preference for standardization and applications’ needs for customization; (4) calls for a shift of focus from single-machine utilization to global optimization.

In this paper, we describe how we address the above limitations in *Twine*, Facebook’s cluster management system. Our two insights are 1) we scale a single Twine control plane to manage one million machines across data centers in a geographic region while providing high reliability and performance guarantees, and 2) we support workload-specific customization, which allows applications to run on shared infrastructure without sacrificing performance or capabilities.

Twine packages applications into Linux containers and manages the lifecycle of machines, containers, and applications. A *task* is one instance of an application deployed in a container, and a *job* is a group of tasks of the same application.

A single control plane to manage one million machines.

A region consists of multiple data centers, and a data center is usually divided into *clusters* of tens of thousands of machines connected by a high-bandwidth network. As with Borg [39] and Kubernetes [23], an isolated control plane per cluster results in stranded capacity and operational burden because workloads cannot easily move across clusters. For example, power-hungry jobs colocated in a cluster can trigger power capping [26, 41], affecting service throughput until humans move the problematic jobs to other clusters.

Similarly, large-scale hardware refresh in a cluster may result in idle machines and operational overhead. Our current hardware refresh granularity is 25% of a data center. Figure 1 shows the duration for all owners of thousands of jobs to migrate jobs out of a cluster prior to a hardware refresh in 2016. The P50 is at 7.5 days and the P100 is at 87 days. A large portion of the cluster sat idle in these ≈ 80 days while waiting for all jobs to migrate.

Figure 1: CDF of time to close job-migration work tickets.

To address the problems above, we scaled a single Twine control plane to manage one million machines across all data centers in a region. Unlike Kubernetes Federation [25], Twine scales out natively without an additional federation layer.

Collaborative lifecycle management. Cluster management systems generally lack visibility into how an application manages its internal state, leading to suboptimal handling of hardware and software lifecycle events that impact application availability. Figure 2 provides a stateful service example.

Figure 2: Replicas of data shards A–D are distributed across tasks 1–7. Tasks 1 and 3 should not be restarted concurrently for a software upgrade, as shard A would lose two replicas and become unavailable. If the machine hosting task 4 were to fail or be restarted for a kernel or firmware upgrade, the cluster management system would need to ensure that neither task 1 nor 7 is restarted concurrently in order to keep shard C available.

Twine provides a novel *TaskControl* API to allow applications to collaborate with Twine in handling task lifecycle events that impact availability. For example, an application may postpone a task restart and rebuild a lost data replica first.

Host-level customization. Hardware and OS settings may significantly impact application performance. For example,

our web tier achieves 11% higher throughput by tuning OS settings. Twine leverages *entitlements*, our quota system, to handle hardware and OS tuning. For example, an entitlement for a business unit may allow it to use up to 30,000 machines. We associate each entitlement with a *host profile*, a set of host customizations that the entitlement owner can tune. Out of a shared machine pool, Twine dynamically allocates machines to entitlements and switches host profiles accordingly.

Power-efficient machines. Facebook’s workloads have grown faster than our data center buildup. Power scarcity motivated us to maximize performance per watt, either by employing universal stacking on big machines or deploying power-efficient small machines. We found it challenging to stack large workloads on big machines effectively. Further, unlike a public cloud that needs to support diverse customer requirements, we only need to optimize for our internal workloads. These factors led to us to adopt small machines with a single CPU and 64GB RAM [32].

Shared infrastructure. As we evolved Twine to support large-scale shared infrastructure, we have been migrating our workloads onto a single shared compute pool, *twshared*, and a single shared storage pool. Twine supports both pools, but we focus on *twshared* in this paper. *twshared* hosts thousands of systems, including frontend, backend, ML, stream processing, and stateful services. While *twshared* does not host durable storage systems, it provides TBs of local flash to support stateful services that store state derived from durable storage systems. Figure 3 shows *twshared*’s growth.

Figure 3: Growth of *twshared*. *twshared* was created in 2013, but adoption was limited in its first six years. We enhanced Twine and rebooted the adoption effort in 2018. *twshared* hosts 56% of our fleet as of October 2020, in contrast to 15% in January 2019. We expect that all compute services, $\approx 85\%$ of our fleet, will run on *twshared* by early 2022, while the remaining 15% will run in a separate shared storage pool.

twshared has become our ubiquitous compute pool, as all new compute capacity lands only in *twshared*. We had broad conversations with colleagues in industry and are unaware of any large company that has achieved near 100% shared infrastructure consolidation.

The rest of the paper is organized as follow. §2 presents the design and implementation of Twine. §3 and §4 describe how we scale Twine to manage one million machines and do so reliably. §5 evaluates Twine. §6 shares our experience with driving *twshared* adoption. §7 describes lessons learned. §8 summarizes related work. Finally, §9 concludes the paper.

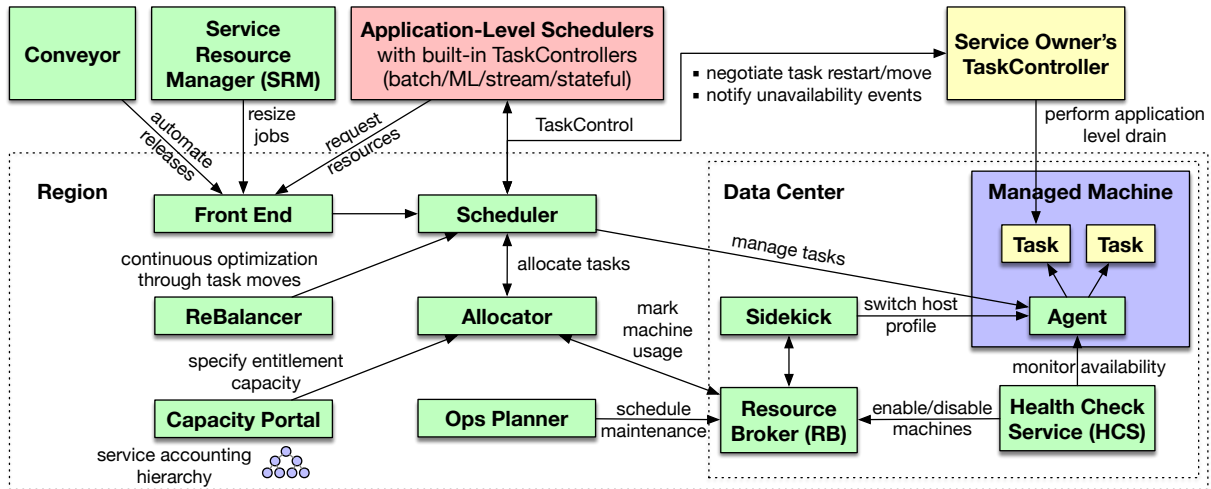

Figure 4: The Twine Ecosystem. Note a potential terminology confusion. The Twine *scheduler* corresponds to the Kubernetes [23] controllers, whereas the Twine *allocator* corresponds to the Kubernetes scheduler.

2 Twine Design and Implementation

Facebook currently operates out of 12 geo-distributed *regions*, with several more under construction. Each region consists of multiple *data center* (DC) buildings. A *main switchboard* (MSB) [41] is the largest fault domain in a DC with sufficient power and network isolation to fail independently. A DC consists of tens of MSBs each powering tens of rows that feed tens of racks of servers as shown in Figure 5.

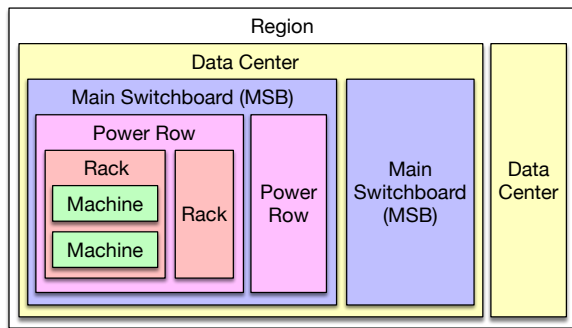

Figure 5: Data center topology.

Historically, a *cluster* was a subunit within a DC consisting of about ten thousand machines connected by a high-bandwidth network and managed by an isolated Twine control plane. Over time, our network transitioned to a fabric architecture [2, 14] that provides high bandwidth both within a DC and across DCs in a region, empowering a single Twine control plane to manage jobs across DCs.

2.1 Twine Ecosystem

Figure 4 shows an overview of Twine. The *Capacity Portal* allows users to request or modify *entitlements*, which associate capacity quotas with business units defined in the *service*

accounting hierarchy. With a granted entitlement, a user deploys jobs through the *front end*. The *scheduler* manages job and task lifecycle, e.g., orchestrating a job’s software release. If a job has a *TaskController*, the scheduler coordinates with the TaskController to make decisions, e.g., delaying a task restart to rebuild a lost data replica first. The *allocator* assigns machines to entitlements and assigns tasks to machines. *ReBalancer* runs asynchronously and continuously to improve the allocator’s decisions, e.g., better balancing the utilization of CPU, power, and network. *Resource Broker* (RB) stores machine information and *unavailability events* that track hardware failures and planned maintenance. DC operators schedule planned maintenance through *Ops Planner*. The *Health Check Service* (HCS) monitors machines and updates their status in RB. The *agent* runs on every machine to manage tasks. *Sidekick* switches host profiles as needed. *Service Resource Manager* (SRM) autoscales jobs in response to load changes. *Conveyor* is our continuous delivery system.

2.2 Entitlements

Conceptually, an *entitlement* is a pseudo cluster that uses a set of dynamically allocated machines to host jobs. An entitlement grants a business unit a quota expressed as a count of machines of certain types (e.g., 2,000 Skylake machines) or as Relative Resource Units (RRU) akin to ECU in AWS.

A machine is either free or assigned to an entitlement, and it can be dynamically reassigned from one entitlement to another. An entitlement can consist of machines from different DCs in a region. Existing cluster management systems bind a job to a physical cluster. In contrast, Twine binds a job to an entitlement. Jobs in an entitlement stack with one another on machines assigned to the entitlement.

By default, Twine spreads tasks of the same job across DCs and MSBs as shown in Figure 6. This reduces buffer capacity

needed for fault tolerance [29]. Suppose a job’s tasks are spread across 12 MSBs in one DC. We need $\frac{1}{12} \approx 8.3\%$ of buffer capacity to guard against the failure of one MSB. If the job’s tasks are spread across five DCs’ 60 MSBs, the needed buffer reduces to $\frac{1}{60} \approx 1.7\%$. For workloads that require better locality for compute and storage, Twine allows an entitlement to override the default spread policy and pin its machines and jobs to a specific DC. These workloads are in the minority.

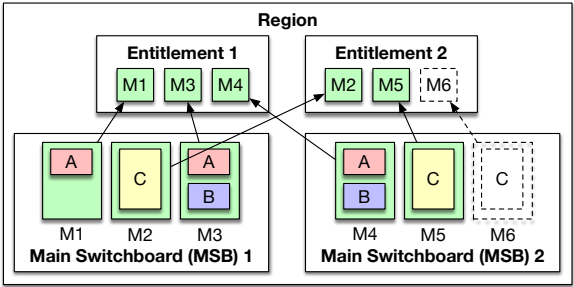

Figure 6: Entitlement example. Entitlement 1 consists of machines M1, M3, and M4 from different MSBs. Jobs A and B are bound to Entitlement 1, and job C is bound to Entitlement 2. Jobs A and B stack their tasks on machine M3. As job C grows, Twine adds machine M6 to Entitlement 2.

The allocator assigns machines to entitlements, and it also assigns tasks to machines in an entitlement. For an entitlement with a quota of N machines, the number of machines actually assigned to the entitlement may vary between 0 and N , depending on the actual needs of jobs running in the entitlement. Figure 7 depicts an example of how an entitlement changes over time.

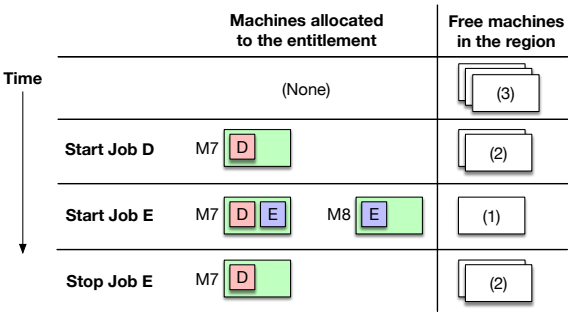

Figure 7: Allocation of machines and tasks. Initially, no machine is assigned to the entitlement. When job D starts, the allocator assigns machine M7 to the entitlement. When job E starts, the allocator stacks one task on M7 and adds machine M8 to the entitlement to run E’s other task. When job E stops, the allocator returns M8 to the free machine pool for use by other entitlements.

We optimized the allocator to make quick decisions when starting tasks; this optimization limits computation time and leads to best-effort outcomes. The addition or removal of machines and workload evolution may result in hotspots in CPU, power, or network. ReBalancer runs asynchronously and continuously to improve upon the allocator’s allocation decisions by swapping machines across entitlements or moving tasks across machines. ReBalancer uses a constraint solver to perform these time-consuming global optimizations.

Entitlements help automate job movements across clusters. Consider a cluster-wide hardware refresh. We first add new machines from other clusters into the regional free machine pool (see the right side of Figure 7). Then the allocator moves tasks from machines undergoing hardware refresh to new machines acquired from the free machine pool, requiring no actions from the job owner. To migrate a task, Twine stops the task on the old machine and restarts it on the new machine. We do not use live container migration.

2.3 Allocator

One instance of Resource Broker (RB) is deployed to each DC. RB records whether a machine in the DC is free or assigned to an entitlement. A regional allocator fetches this information from all RBs in the same region, maintains an in-memory write-through cache, and subscribes to future changes.

The scheduler calls the allocator to perform a job allocation when a new job starts, an existing job changes size, or a machine fails. The allocation request contains an entitlement ID, an allocation policy, and a per-task map of which tasks need to be allocated or freed. The allocation policy includes hard requirements (e.g., using Skylake machines only) and soft preferences (e.g., spreading tasks across fault domains).

The allocator maintains an in-memory index of all machines and their properties to support hard requirement queries, such as “all Skylake machines with available CPU $\geq 2RRU$ and available memory $\geq 5GB$.” It needs to search machines beyond the ones already assigned to the entitlement because it may need to add more machines to the entitlement to host the job. After applying hard requirements, it applies soft preferences to sort the remaining machines.

A soft preference is expressed as a combination of 1) a machine property to partition machines into different bins with the same property value, and 2) a strategy to allocate tasks to these machine bins. For example, the allocator spreads tasks across fault domains by using a soft preference with `fault domain` as the machine property, and the strategy that assigns tasks evenly to the machine bins that represent fault domains.

The allocator uses multiple threads to perform concurrent allocations for different jobs, and relies on optimistic concurrency control to resolve conflicts. Before committing an allocation, a thread verifies that all impacted machines still have sufficient resources left for the allocation. If the verification fails, it retries a different allocation.

To avoid repeating the costly machine selection process, the allocator caches the allocation results at the job level. The allocator invalidates a cache entry if the job allocation request changes or the properties of the machines hosting the tasks change. The cache hit ratio is typically above 99%.

2.4 Scheduler

The scheduler manages the lifecycle of jobs and tasks. As the central orchestrator, the scheduler drives changes across

Twine components in response to different lifecycle events, including hardware failures, maintenance operations, power capping [41], kernel upgrades, job software releases, job resizing, task canary, and ReBalancer moving tasks.

The scheduler handles a machine failure as follows. When the Health Check Service detects a machine failure, it creates an unavailability event in Resource Broker, which notifies the allocator and scheduler. The scheduler disables the affected tasks in the service discovery system so that clients stop sending traffic to these tasks. A job is impacted by the machine failure if it has tasks running on the machine. If an impacted job has a TaskController, the scheduler informs the TaskController of the affected tasks. After the TaskController acknowledges that these tasks can be moved, the scheduler requests the allocator to deallocate the tasks and allocate new instances of the tasks on other machines. The scheduler instructs agents to start the new tasks accordingly. Finally, the scheduler enables the tasks in the service discovery system so that clients can send traffic to the newly started tasks.

The scheduler paces changes to a job's tasks to avoid application downtime. For example, regardless of reasons (e.g., hardware failure or software upgrade), if a job's total unavailable tasks exceed a user-configured threshold, no more tasks can be restarted for a software release. The scheduler has built-in support for commonly used lifecycle policies and offers the TaskControl API to implement more complex policies.

2.5 TaskControl

An application often knows best how to safely handle hardware or software lifecycle events that affect its availability, but it cannot inform the cluster management system how to orchestrate these actions. Figure 2 depicts one example. Another example is a ZooKeeper deployment that wishes to apply a software release to its followers first and its leader last [8]. Otherwise, an n -member ZooKeeper ensemble in the worst case experiences n leader failovers during a release. We designed the *TaskControl* API to allow applications to collaborate with Twine when deciding which task operations to proceed and which to postpone, as depicted in Figure 8.

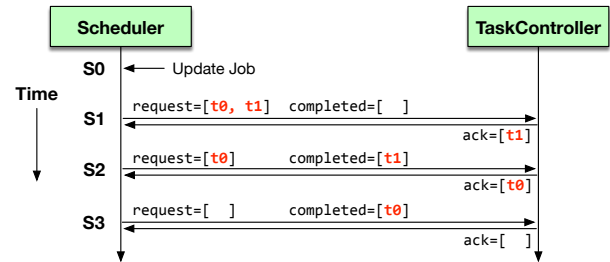

Unlike software releases, maintenance events like a power device replacement cannot be blocked indefinitely by a TaskController; the scheduler gives the TaskController advance notices with a deadline to react. Upon reaching the deadline, the scheduler stops the remaining tasks on the affected machines, allowing maintenance to proceed. Before the deadline, a TaskController has multiple options: 1) move the tasks to other machines, 2) stop the tasks on the current machine and restart them after the maintenance completes, or 3) do nothing and keep the tasks running. For example, a top-of-rack switch maintenance typically incurs only a few minutes of network downtime, and a stateful service may prefer option 3 because rebuilding a data replica elsewhere takes longer than the maintenance itself.

```
service TaskController {
    TaskControlResponse process(TaskControlRequest request);
}

struct TaskControlRequest {
    string jobHandle;
    list<> request; // Pending task operations to be approved.
    list<> completed; // Completed task operations.
    list<> advanceNotices; // Upcoming planned maintenance.
    list<> allUnhealthyTasks; // Tasks unhealthy due to any reason.
    int sequenceNumber; // Increase after each call.
}

struct TaskControlResponse {
    list<> ack; // Approved task operations.
}
```

(a) TaskControl API.

(b) Calling sequence of the TaskControl API when handling a job update. The job has two tasks: t_0 and t_1 . At time S_0 , the user initiates a job update. At time S_1 , the scheduler requests the approval of updates on tasks t_0 and t_1 , with $\text{request}=[t_0, t_1]$. The application's TaskController can selectively approve updates for any subset of tasks in any order. It approves the update on task t_1 by replying $\text{ack}=[t_1]$, but delays the update on task t_0 to keep one task available. At time S_2 , the scheduler completes the update on task t_1 with $\text{completed}=[t_1]$, and requests an update on the remaining task t_0 . This time, the TaskController approves the request.

Figure 8: TaskControl API and an example of the calling sequence.

2.6 Host Profiles

Our fleet runs thousands of different services, and Figure 9 shows that the 50 largest services consume $\approx 70\%$ of all capacity. Similar capacity skew exists in Borg as well [36].

Figure 9: CDF of machines used by services. A small number of services dominate the capacity consumption. Note that the x-axis is in log scale.

Our efficiency effort focuses on these large services, and we find that host-level customization is important for maximizing their performance. For example, customizations help our large web tier achieve 11% higher throughput. However, some custom settings may be beneficial for one service but detrimental to another. As an example, a combination of explicit 2MB and 1GB hugepages improves the web tier's throughput by 4%; however, most services are incapable of utilizing explicit hugepages and enabling this setting globally would lead to unusable memory.

We resolved the conflict between host-level customization and sharing machines in a common pool via *host profiles*, a framework to control host-level customizations on entitlements. An entitlement is associated with one host profile; all machines in the entitlement share the same host profile. When a machine is reassigned from one entitlement to another, *Sidekick* automatically applies the target entitlement's host profile. By fully automating the process of machine allocation and host customization in our shared infrastructure, we can perform fleet-wide optimizations (e.g., swapping machines across entitlements to eliminate hotspots in network or power) without sacrificing workload performance. Supported host profile settings include kernel versions, sysctls (e.g., hugepages and kernel scheduler settings), cgroupv2 (e.g., CPU controller), storage (e.g., XFS or btrfs), NIC settings, CPU Turbo Boost, and hardware prefetch.

2.7 Application-Level Schedulers

As shown at the top of Figure 4, multiple application-level schedulers are built atop Twine to better support vertical workloads such as stateful [16], batch [21], machine learning [13], stream processing [28], and video processing [18]. Twine provides containers as resources for these application-level schedulers to manage and delegates task lifecycle management to them through TaskControl.

Shard Manager (SM) [16] is an example of an application-level scheduler. It is widely used at Facebook to build sharded services like the one in Figure 2. It has two major components: the SM client library and the SM scheduler. The library is linked into a sharded service and provides two APIs for the service to implement: `add_shard()` and `drop_shard()`. The SM scheduler decides the shards each Twine task will host and calls the service's `add_shard()` implementation to prepare the task to serve requests for those shards. To balance load, SM may migrate a shard from task T_1 to task T_2 by informing T_1 to `drop_shard()` and T_2 to `add_shard()`.

The SM scheduler integrates with Twine through TaskControl and can handle the complex situations depicted in Figure 2. In another example, Twine gives SM advance notice about an upcoming maintenance on a machine. If the maintenance duration is short and the shards hosted by the machine have replicas elsewhere, SM may do nothing; otherwise, SM may migrate the impacted shards out of the machine.

2.8 Small Machines and Autoscaling

To achieve higher performance per watt, our server fleet uses millions of small machines [32], each with one 18-core CPU and 64GB RAM. We have worked with Intel to define low-power processors optimized for our environment, e.g., removing unneeded NUMA components. Four small machines are tightly packed into one sled, sharing one multi-host NIC. They are replacing our big machines, each with dual CPUs,

256GB RAM, and a dedicated NIC. Under the same rack-level power budget, a rack holds either 92 small machines or 30 big machines. A small-machine rack delivers 57% higher total compute capacity measured in RRU. Averaged across all our services, using small machines led to 18% savings in power and 17% savings in total cost of ownership (\$5.4).

We are consolidating all our compute services onto small machines, as opposed to offering a variety of high-memory or high-CPU machine types. This unification simplifies downstream supply chain and fleet management. It also improves machine fungibility across services, as we can easily reuse a machine across all compute services. Our consolidation journey has been challenging (\$7.4), as some services initially did not fit the limited 64GB in our small machines. To address this, we used several common software architectural changes:

- Shard a service so that each instance consumes less memory. Our Shard Manager platform (\$2.7) helps developers easily build sharded services running on Twine.
- Exploit data locality to move in-memory data to an external database and use the smaller memory as a cache.
- Exploit data locality to provide tiered memory on top of 64GB RAM and TBs of local flash. For example, when migrating TAO [7], our social graph cache, from big machines to small machines, CacheLib [5] transparently provided tiered memory to improve cache hit ratio and reduce load on the external database by $\approx 30\%$.

Our largest services fully utilize small machines without stacking. We rely on Autoscaling to free up underutilized machines. Active Last Minute (ALM) is the number of people who use our online products within a one-minute interval. The load of many services correlates with ALM. *Service Resource Manager* (SRM) uses historical data and realtime measurements to continuously adjust task count for ALM-tracking services and frees up underutilized machines in their entirety for other workloads to use. This work has allowed us to successfully build a large-scale shared infrastructure that consists primarily of small machines.

3 Scaling to One Million Machines

We designed Twine to manage all machines that can fit in a region's 150MW power budget. Although none of our regions host one million machines yet, we are close and anticipate reaching that scale in the near future. Two principles help Twine scale to one million machines and beyond: 1) sharding as opposed to federation, and 2) separation of concerns.

3.1 Scale Out via Sharding

To scale out, we shard Twine schedulers by entitlements, as depicted in Figure 10. We assign newly-created entitlements to shards with the least load. Entitlements can change size and can migrate across shards. If a shard becomes overloaded,

Twine can transparently move an entitlement in the shard to another shard without restarting tasks in the entitlement. Twine can also migrate an individual job from one entitlement to another. To do this, Twine performs a rolling update of the job until all tasks restart on machines belonging to the new entitlement. We automate the execution of these migrations, but humans still decide when and what to migrate. Since migrations happen rarely, we do not automate these further.

Figure 10: Sharding a scheduler by entitlements. Each scheduler shard manages a different subset of entitlements for the region. Scheduler Shard 1 manages entitlements E1, E2, and E3. The front end maintains an entitlement-to-shard map and forwards requests to the responsible shards. Each data center has a Resource Broker (RB) managing the machines in that data center. Conceptually, all RBs in a region jointly maintain a free machine pool shared by all entitlements in the region. We also shard the allocator by entitlements and there is a 1:1 mapping between a scheduler shard and an allocator shard. We do not show allocator sharding in the figure as it currently manages a small fraction of our fleet and is still in the process of broader production deployment.

With sharding, the scheduler can easily scale to one million machines. Each data point in Figure 11 plots the P99 CPU utilization of a scheduler shard. The largest shard manages $\approx 170K$ machines, using up to 40 cores and 80GB memory. We are moving towards smaller shards to reduce the impact of a shard failure. Assuming each shard manages 50K machines in the future, a single Twine deployment can manage 1M machines with 20 shards. We believe Twine can easily scale beyond 1M machines by adding more shards.

Figure 11: P99 CPU usage of production scheduler shards over one week.

The simplicity of scheduler sharding comes with a theoretical limitation: a single job must fit in a single scheduler shard. This is not a practical limitation. Currently, the largest scheduler shard manages $\approx 170K$ machines; the largest entitlement uses $\approx 60K$ machines; and the largest job has $\approx 15K$ tasks.

Figure 12: P99 CPU usage of production allocators over one week.

Each data point in Figure 12 plots the P99 CPU utilization of a production allocator. At its peak, a large allocator performs $\approx 1,000$ job allocations per second, with an average job size of 36 tasks. We run a few deployments of the scheduler and allocator at the global level to manage machines and jobs across multiple regions (§7.3). Our largest global allocator currently manages more than one million machines across regions. The allocator is scalable because it has a high cache hit ratio (§2.3), does not handle allocations for short-lived batch jobs (§3.2), and does not perform time-consuming optimizations (§3.2).

3.2 Scale Out via Separation of Concerns

We avoid Kubernetes' centralized architecture where all components interact through one central API server and share one persistent store. These centralized components become bottlenecks and limit Kubernetes' scalability to 5K machines. We shard all Twine components and scale them out independently. Sharded components include the front end, scheduler, allocator, Resource Broker, Health Check Service, and Sidekick. Further, each stateful Twine component (front end, scheduler, allocator, and RB) has its own separate persistent store for metadata. Like Kubernetes [23] and unlike Borg [39], we use external persistent stores for components, as opposed to building the stores directly into components. This allows us to independently shard and scale out persistent stores as needed.

Separation of allocation and optimization responsibilities helps the allocator scale. The allocator makes quick decisions when starting tasks, whereas ReBalancer asynchronously runs a constraint solver to perform time-consuming global optimizations such as balancing CPU, network, and power.

Separation of responsibilities between Twine and application-level schedulers helps Twine scale further. Application-level schedulers handle many fine-grained resource allocation and lifecycle operations without involving Twine. For example, the Twine scheduler and allocator do not directly manage batch jobs, whose lifetime might last just a few seconds and cause high scheduling loads. The application-level batch scheduler acquires resources from Twine in the form of Twine tasks. It reuses these tasks over a long period of time to host different batch jobs, avoiding frequent host profile changes. The batch scheduler can create nested containers inside the tasks, similar to that in Mesos [17].

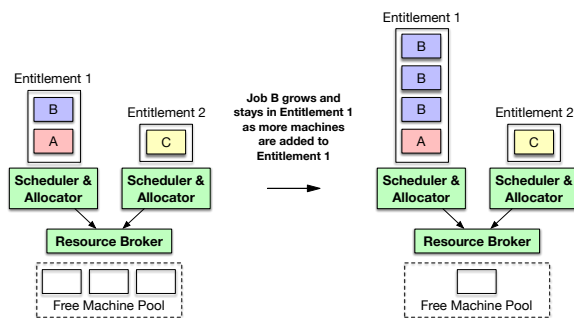

3.3 Comparison of Sharding and Federation

We acknowledge that Twine’s scale of managing millions of machines is not unique, as Borg [39] and several public clouds likely manage infrastructure of that scale as well; however, we believe that Twine’s approach is unique. Other cluster management systems scale out by deploying one isolated control plane per cluster and operate many siloed clusters. They pre-allocate machines to a cluster; once a job starts in a cluster, it stays with the cluster. This lack of mobility results in stranded capacity when some clusters are overloaded while others are idle. It also causes operational burden during cluster-wide maintenance such as hardware refresh, as shown in Figure 1.

To avoid stranded capacity, we can introduce mobility by moving either jobs or machines. To that end, the federation approach (e.g., Kubernetes Federation [25]) allows a job to be split across multiple static clusters, whereas Twine dynamically moves machines in and out of entitlements. Figure 13 compares these two approaches.

(a) Federation approach. This approach uses a Cluster Manager per cluster and introduces an additional Federation Manager layer. Each cluster has a set of statically configured machines. As job B in Cluster 1 keeps growing, it overflows into Cluster 2.

(b) Twine’s sharding approach. As job B grows, Twine adds more machines to Entitlement 1, and job B stays with the same entitlement and scheduler shard.

Figure 13: The two figures above contrast how federation and sharding support a job growing over time without stranding capacity in isolated clusters.

The federation approach can support complex multi-region, hybrid-cloud, or multi-cloud deployments, but it adds complexity as a scale-out solution. In order to provide a seamless user experience, the Federation Manager in Figure 13a has to perform complex coordination for a job whose metadata and management operations are split among multiple distributed Cluster Managers. In contrast, Twine is simpler for scaling

out because a job is exclusively managed by one scheduler shard, and Resource Broker provides a simple interface to manage the shared regional pool of machines.

4 Availability and Reliability

Compared with the traditional approach of deploying one control plane per cluster, Twine’s regional control plane incurs additional risks: 1) a control plane failure may impact all jobs in a region as opposed to just a cluster, and 2) network partitions may result in a regional Twine scheduler unable to manage an isolated DC.

Design principles. We observe several design principles to mitigate the risks listed above.

- **All components are sharded:** Each shard manages a small fraction of machines and jobs in a region, limiting the impact of a shard failure. Assuming Twine uses 20 scheduler shards to manage a 150MW region, each scheduler shard manages 7.5MW worth of machines, which is no bigger than a traditional cluster.
